Glucoprivation. Acute glucoprivation by peripheral administration of insulin or 2-deoxyglucose (2DG) results in rapid counterregulatory HPA axis and feeding responses. Destruction of medullary Eergic and NEergic neurons via retrograde transport of selective neurotoxins delivered to PVN profoundly blunts counterregulatory responses, but has no effect on HPA responses to psychogenic stress or circadian variations in GCs, thus validating a systemic/psychogenic distinction.

Pain. Nociceptive stimuli (e.g., sharp pinch, thermal, or visceral pain) stimulate the HPA axis through systemic and psychogenic networks. Spinohypothalamic pathways transmit pain stimuli to the lateral hypothalamus (LH), which projects ipsilaterally to PVN CRF neurons. The spinothalamic pathway projects from spine to ventral posterolateral thalamus, then to sensory cortical areas. The spinoreticulothalamic pathway projects from spinal cord to reticular formation, then to midline and intralaminar thalamic nuclei, and on to limbic cortical areas (cingulate, piriform, and entorhinal cortices). Vagal and glossopharyngeal nerves convey visceral pain to the NTS, then to the parabrachial nucleus, thalamus, and visceromotor prefrontal cortex. A2 and C2 cell groups also project to A1 and C1 neurons in the ventrolateral medulla, locus coeruleus, amygdala, and PVN, which shows strong bilateral activation of CRF parvicellular neurons in response to many noxious stimuli. VNAB hemisections reduce PVN activation primarily on the hemisected side. Noncatecholaminergic neurons in the NTS, terminating in the PVN, also express fos after nociceptive stimuli. (Cognitive control of the HPA axis is discussed later.)

Proinflammatory stimuli. Systemic inflammatory responses to immune challenges are powerful stimuli to autonomic outflow and HPA axis activation, which inhibits proinflammatory processes. Proinflammatory molecules include tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), and interleukin-6 (IL-6). Brain vasculature expresses receptors for TNF-α, IL-1β, and IL-6 under basal conditions; further induction occurs following immune challenge when plasma cytokine concentrations increase. Activation of cytokine receptors in the blood–brain barrier results in the transcription of various substances, including prostaglandins (PGs) following signaling cascades involving cyclooxygenase-2 (COX-2) and nuclear factor-kappa B (NF-κB). The brain vasculature and irrigation systems are thought to be the primary source of central PGs following systemic cytokine treatment, as COX-2 expression is highly co-expressed in areas staining for von Willebrand factor, a marker for cerebral endothelium. Activation is particularly striking in blood vessels, choroid plexus, and the CVOs.

Prostaglandin E_2 (PGE_2) is involved in neuronal responses to systemic immune challenge. Injection of IL-1 results in PGE2 expression in CVOs, preoptic nuclei, PVN, dorsal hippocampus, and lateral ventricles. Central administration of PGE_2 increases HPA axis and autonomic outflows. Febrile responses may originate in the MPO, whereas HPA axis activation may originate in the PVN, as prostaglandins (PGs) induce CRF mRNA and type 1 receptors in the PVN. Immune challenge activates specific receptors for PGE_2 (subtypes EP1–EP4) in brain regions controlling HPA axis and autonomic outflows. Neurons expressing EP1–EP4 particularly show c-fos activation after systemic IL-1β administration in CVOs and central stress networks, with highest expression in PVN CRF neurons. Central HPA axis and autonomic outflows following systemic immune challenge appear to be coordinated by classic central stress response networks, in part by activation of brain endothelial and leptomeningeal tissues, resulting in signal transduction to neuronal tissues.

Immune signaling may also originate in liver, as hepatic vagotomy eliminates febrile responses, and blunts brain stem c-fos responses, PVN noradrenergic levels, and ACTH responses to endotoxin. Endotoxin-clearing Kupffer cells also release PGE_2 in response to immune challenge stimulating excitatory vagal afferents, relaying signals to regions involved in febrile (MPO) and HPA axis (PVN) responses. Rapid febrile responses to immune challenges occurring prior to cytokine elevations utilize this pathway. Whether the argument holds for rapid HPA axis activation has not been thoroughly tested. Hepatic vagotomy has reduced HPA axis output by about half in response to endotoxin, but had a much smaller effect on responses to IL-6. Unfortunately, HPA axis responses were not measured until 2 h after injections, and not all studies agree on the effects of vagotomy. Inactivating the Kupffer cell phagocytotic activity using gadolinium chloride failed to reduce HPA axis responses to lipopolysaccharide (LPS), but again, ACTH and corticosterone were measured many hours later, long after cytokines were produced and acted in brain.

The Hypothalamic Visceromotor Pattern Generator

Recent anatomical evidence suggests the existence of a hypothalamic visceromotor pattern generator (HVPG)

located between hypothalamic neuroendocrine, preautonomic, and behavioral motorneuron pools, involving a DMH 'hub' and five preoptic nuclei. Figure 3 shows a schematic of connections between the HVPG and the PVN. Core nodes of the HPVG are massively interconnected, with each node idiosyncratically projecting to neuroendocrine and preautonomic cell groups. Notable among the few extrahypothalamic targets are the BNST, lateral septum (LS), periaqueductal gray (PAG), subfornical organ (SFO), and the PVT. The coordination of visceromotor outflow likely includes not only sympathetic, but also parasympathetic, outflow via strong connections between the DMH and parasubthalamic nucleus, which projects heavily to the dorsal vagal complex.

Figure 3 The hypothalamic visceromotor pattern generator. This schematic is based on Thompson's and Swanson's hodological analysis of relations among various hypothalamic nuclei with respect to neuroendocrine and autonomic divisions of the paraventricular hypothalamus. The hypothalamic visceromotor pattern generator consists of the dorsomedial hypothalamus (DMH), its major hub, and five preoptic nuclei, including the anteroventral preoptic (AVP), anterodorsal preoptic (ADP), anteroventral periventricular preoptic (AVPV), parastrial nucleus (PS), and medial preoptic nucleus (MPO). Magnocellular oxytocinergic (OXY) and vasopressinergic (AVP) neurons are shown in the upper left. Parvicellular corticotropin-releasing factor (CRF)-containing neurons are shown in the upper right. The descending division of the paraventricular hypothalamus includes preautonomic neurons in the dorsal cap (d. cap), the caudolateral perifornical (lpf) paraventricular hypothalamus, and the medial parvicellular (mpv) neurons residing between neuroendocrine cell groups. Heavier projections are indicated by heavier lines. Note the massive interconnectivity between the DMH and preoptic nuclei, and their more idiosyncratic relations to neuroendocrine and autonomic divisions of the paraventricular hypothalamus.

Inputs to the DMH include top-down inputs from cortico-striato-pallidal circuits, including visceromotor cortex (infralimbic), ventral subiculum, LS, MeA, as well as BNST; medial hypothalamic nuclei involved in basic behavioral functions such as reproduction, feeding, and defense; sensory nuclei, such as the parabrachial nucleus, relaying viscerosensory information, and the SFO, relaying humorosensory information; and substantial input from SCN and the subparaventricular zone. Hodological analysis strongly suggests that the HVPG integrates cognitive, systemic, and circadian inputs to coordinate neuroendocrine, autonomic, and some behavioral outflows.

The specific coordinating functions are uncharacterized, but good evidence indicates that the DMH drives the HPA axis and autonomic outflows. Disinhibiting the DMH using $GABA_A$ antagonists (or stimulating the DMH, using excitatory amino acids) increases sympathetic outflow and plasma catecholamines, heart rate, blood pressure, and blood flow to skeletal muscle while reducing blood flow to viscera. Blood pressure increases resulting from DMH stimulation can be blocked by inactivating the rostral ventrolateral medulla (RVLM), whereas tachycardia is likely relayed through descending projections to PAG or raphe pallidus. Lower doses of excitatory amino acids are required to obtain visceromotor outflow in the DMH compared to the PVN. Likewise, the blunting of autonomic and HPA axis outflows to psychogenic stress is greater after DMH than after PVN inactivation by muscimol. Neurons in the DMH expressing c-fos following footshock have been retrogradely labeled from the PVN and are glutamatergic. Muscimol microinfusion into the DMH reduces PVN activation to air-puff stress, but not to hemorrhage, although this should not be interpreted to mean that the DMH plays no role in systemic threats, as hemorrhage is a powerful stimulus.

Psychogenic Networks Driving the HPA Axis

Psychogenic stress is distinct from systemic stress; knife cuts of the ascending VNAB reduce PVN activity after nociception, but not after restraint stress. Top-down pathways to the PVN and surrounding networks consist of excitatory cortical, inhibitory striatal, and disinhibitory pallidal inputs operating both serially and in parallel. Medial prefrontal cortices (mPFCs) are the highest level of motor control over visceromotor outflow. Violations of cortical predictions or changes in the valence of experience alter prefrontal activity

and downstream HPA axis and autonomic outflows. Cognitive networks are sensitive to feedback from the visceromotor processes they control, and exhibit stress-dependent plasticity. Hypofunctional cortical states are associated with HPA axis dysregulation.

The mPFC shows substantial immediate early gene activation following stressors, high levels of GR staining, and ADX-reversible glutamate release following a stressor. Inputs to prefrontal cortex include ascending dopaminergic, noradrenergic, and serotonergic inputs, all of which are modulated by HPA axis function. Both dorsal and ventral regions of the mPFC may be involved in HPA axis outflow, but the ventral regions, including infralimbic (IL) cortex and ventral prelimbic cortex, contribute to HPA axis activation and project directly to brain stem preautonomic centers.

After receiving highly processed cortical input, the largely ipsilateral projections of the IL cortex to cerebral nuclei include the CeA, MeA, and LS in the striatum, BNST, and substantia innominata in the pallidum. In hypothalamic brain stem, the IL cortex projects to key nodes of the HVPG, including MPO, lateral preoptic (LPO), DMH, and perifornical LH, all areas projecting to the PVN, but the IL has negligible direct projections to the PVN. In lower brain stem there are moderate to light projections to autonomic areas, such as the parabrachial nucleus (PBN) and PAG, Barrington's nucleus, the DMV, NTS, nucleus ambiguous, and the RVLM. Like nearly every driver of the HPA axis, this also projects substantially to the PVT in the dorsal brain stem. Although some projections to brain stem visceromotor centers may be light, subcortical targets of the IL cortex also project to these centers. Thus, the IL cortex drives a cascade of direct excitatory projections, inhibitory striatal projections, and disinhibitory pallidal projections, layers of stimulation aimed at visceromotor processes.

Chemical, electrical, and lesioning manipulations of mPFC alter HPA axis and autonomic outflows. Corticosterone implants into dorsal mPFC inhibit HPA axis output. Infusions of GABA agonists and *N*-methyl-D-aspartate (NMDA) antagonists into mPFC exaggerate adrenocortical responses to cage-change stress. In contrast, electrical stimulation of IL cortex results in stimulation of the HPA axis, whereas lesions inhibit stress-induced HPA axis activation. It appears that dorsal mPFC tends to inhibit the HPA axis, whereas ventral activation stimulates. Issues of laterality exist, insofar as right hemispheric lesions blunt stress responses, whereas those in the left do not. Unfortunately, large lesions involving dorsal and ventral regions were used.

Subcortically, stimulation of LS or BNST, a pallidal gate of the CeA, also stimulates HPA axis outflow. The BNST also gates input from MeA, as MeA stimulation in anesthetized rats stimulates the HPA axis in intact animals, but not those bearing BNST lesions. The same lesions do not prevent ether-induced HPA responses. BNST and CeA CRF-containing neurons both converge on the PVT, which is involved in changed HPA axis output following chronic stress.

GCs in Central Motive States and Central Plasticity

HPA axis control cannot be viewed without regard for GC effects on brain outside of classical inhibitory feedback mechanisms. GCs also feed forward in brain, facilitating HPA axis outflow, and affect aversive and appetitive motive states, learning and memory, and gross neuronal remodeling, ultimately affecting HPA axis functioning.

Corticotropin-Releasing Factor

Central CRF systems are critical to aversive responding. Although ADX upregulates CRF in the PVN in a GC-reversible fashion, GC pellets implanted in dorsal CeA increase anxiety, stress-induced elevations in CRF mRNA, ACTH and GC secretion, colonic motility, and visceromotor responses to colorectal distension. Chronic stress or GC treatment also increases CRF mRNA in BNST. Chronic intracerebroventricular (icv) infusions of GCs enhance basal and stress-induced HPA outflow. Chronic elevations of GCs in brain upregulate central stress networks and increase HPA, autonomic, and behavioral outflows.

Depolarization of sheep PVN CRF neurons through stress, chemical, or electrical means increases venous cortisol and extracellular amygdalar CRF. Amygdalar CRF response to psychogenic stress exhibits a bimodal pattern: one immediate stressor-related peak, and a second peak resulting from GCs entering the brain. GCs infused intravenously causes one rise in amygdalar CRF following the venous cortisol signal. Repeated activation of amygdalar CRF by GCs causes potentiated acute CRF responses to novel stressors. Exposing sheep once daily to predator stress increases amygdalar CRF upon each exposure. When a novel forelimb shock is later applied, animals show facilitated amygdalar CRF responses, unless daily predator exposures were accompanied by cortisol synthesis inhibition, which prevents GC-mediated facilitation. GC exposure recruits both acute and chronic central stress networks.

Norepinephrine

The ascending dorsal NE system is sensitive to stress and central CRF. Cognitive stressors virtually always activate locus coeruleus (LC) NE neurons, in association

with increased NE release in LC targets, such as mPFC and BNST, arousal and anxiety, and HPA axis outflow. Depletion of LC NE blunts HPA axis outflow. CeA and BNST CRF neurons target LC dendrites, and CRF infusions into LC increase LC discharge rates, alter cortical electroencephalogram (EEG), and behavioral, autonomic, and HPA axis responses. CRF effects on LC are dose dependent and are blocked by CRF antagonists. Although tyrosine hydroxylase-immunopositive neurons in LC stain for GRs, the role of GCs in LC is unclear. ADX increases LC discharge rats in a GC-reversible fashion, but also causes metabolic disturbances that disinhibit brain stem TH networks. It is unclear if GC inhibition of LC is due to direct action or to peripheral metabolic corrections.

Dopamine

GCs and CRF target mesocorticolimbic DA systems are associated with multiple appetitive, aversive, and reinforcement mechanisms. GCs stimulate dopamine (DA) efflux in DAergic terminal fields, including nucleus accumbens, prefrontal cortex, BNST, and amygdala. Adrenalectomized rats given low levels of GCs show greatly reduced DA efflux compared to intact rats after tail pinch, cocaine, or morphine treatments. Rapid DA efflux occurs if sufficient GC concentrations are achieved. GR co-localize with D1 receptors in prefrontal pyramidal neurons, substantia nigra, and the ventral tegmental area (VTA). Stress or GCs enhances VTA discharge rates stimulated by excitatory ligands, a GR antagonist-reversible effect. GCs given alone have no effect, suggesting enhanced glutamatergic transmission is required. GC antagonists also block plastic processes in the VTA. Stress-related interactions between prefrontal glutamatergic neurons and VTA DAergic neurons play important roles in stress-related pathologies, including drug abuse. Central CRF systems also target the VTA, and CRF receptors co-localize with DAergic neurons. Like GCs, CRF potentiates excitatory signaling in VTA DAergic neurons, and contributes to neuronal sensitization. Footshock increases CRF and glutamate efflux in the VTA and DA efflux in terminal fields, and promotes reinstatement to drug seeking, a CRF antagonist-reversible effect.

Endogenous Opioid Peptides

Endogenous opioid peptides (EOPs) affect central stress networks state dependently. CRF and AVP both stimulate EOP secretion, and enkephalinergic neurons in the RVLM project to PVN and LC dendrites, overlapping with CRF-containing fibers. The PVN also receives enkephalinergic (ENK) innervation from the MPO and DMH. Stress increases ENK mRNA in the PVN, but downregulates it in the RVLM. Administration of opioid agonists and antagonists can cause both activation and inhibition of the HPA axis. In resting sheep, β-endorphin causes a naloxone-reversible increase in ACTH, whereas in chronically stressed animals it causes a naloxone-reversible inhibition of HPA output. Opioid-induced increases in ACTH are abolished by pretreatment with CRF antiserum. Thus, in a state of stress, opioids may act as a counterregulatory limb of the central stress response, whereas under basal conditions they are stimulatory, as if CRF and EOPs exist as opponent processes, a contention supported by the fact that opioids inhibit LC discharge rates. The effect is again state dependent, as opioid antagonists have no effect on basal LC discharge, but do increase LC discharge under stress, suggesting stress-induced recruitment of opioid signaling. Likewise, excess opioid signaling recruits CRF/NE systems, and dramatic increases in LC discharge rates occur when opioid-dependent animals are given opiate antagonists. Complex sequelae unfold in the HPA axis following intermittent opioid treatment and withdrawal, indicating initial recruitment of HPA axis facilitators leading to HPA axis hyperresponsiveness to stress, followed by recruitment of some mechanism that makes the HPA axis hyporesponsive to stress.

Memory

GCs influence memories of aversive and appetitive events, but the direction of the effect is a structure- and task-dependent event. In the hippocampus, correlates of learning exhibit an inverted-U-shaped dependency on GC concentrations, such that moderate levels promote correlates of learning, whereas absence of or excess GCs degrade them. On the other hand, ADX, GC synthesis inhibition, or selective blockade of GRs all impair memory for aversive tasks, such as inhibitory avoidance. ADX-induced deficits are reversible by GC administration. GCs are most constructive memorially when given immediately posttraining, whereas they impair retrieval when given prior to testing. One locus of positive GC effects is the basolateral amygdala (BLA). GC microinfusions into the BLA, but not its striatal target, the CeA, improve memory consolidation, whereas BLA lesions abolish facilitating effects of high levels of systemic steroid. Improved consolidation is partly mediated by NE, as blockade of β-adrenoreceptors within the BLA prevents the facilitating effects of high steroid levels. The source of NE may be medullary, as GR agonists-infused into NTS improve memory which is blocked by β-adrenoreceptor blockade in BLA. Posttraining CRF infused into the BLA also improves memory. As the BLA contains CRF receptors, but few CRF-immunopositive fibers, CRF probably diffuses into

the BLA from the CeA. Dopamine agonists given simultaneously into the BLA and the accumbens shell region also enhance memory for conditioned fear.

GC-mediated conditioned responses feed back on HPA axis and autonomic outflows. The CeA is essential for expressing behavioral and neuroendocrine measures of conditioned fear, whereas lesions of the LH prevent autonomic but not behavioral components, and lesions of the PAG interfere with behavioral but not autonomic responses. For the HPA axis, lesions of the CeA disrupt conditioned responses to both discrete (e.g., light, tone) and contextual (e.g., room cues) stimuli, whereas lesions of the BNST only disrupt responses to contextual, but not discrete, stimuli, suggesting alternative routes to the HPA axis output, depending on the modality of association.

Neuronal Remodeling

GCs remodel gross brain structure. Acute GC elevations rapidly induce spinogenesis in hippocampal slices in the absence of protein synthesis. Chronic stress, GCs, and ADX inhibit neurogenesis in the dentate gyrus, suggesting that moderate steroid level is permissive to normal structure. Chronic stress reduces dendritic arborization in CA3 fields and total hippocampal volume, effects reversed by stress-free periods. Similar events occur in the mPFC. In contrast, a regimen of repeated immobilization stress increases dendritic length and spinogenesis in the BLA. Acute stress only increases spinogenesis, which increases, rather than decreases, during stress-free periods. The BNST shows some similar effects. Structure-dependent effects of stress on neuronal remodeling are consistent with the direction of correlates of learning in these structures. GCs favor memorial and structural modifications related to emotional processing at the expense of cognitive executive processing.

Conclusion

Although the HPA axis is a relatively simple final common output pathway, its complexity increases when properly viewed in terms of its integration of diverse central drivers and its feedback and feedforward effects on the brain. Diverse central drivers include two distinct circadian oscillators controlling daily cycles of energy balance, bottom-up inputs controlling systemic homeostatic pressures, such as the melanocortin system and the ascending catecholaminergic system, and top-down cortico-striato-pallido-hypothalamic circuits controlling psychogenic responses, and a putative intrahypothalamic pattern generator that coordinates HPA axis outflow with behavioral and autonomic outflows. In addition, a system of circumventricular organs and perhaps signals from the hepatic vagus allow signaling between the immune system and the HPA axis. GCs enter the brain to have both immediate, membrane-mediated effects on various transmitter and neuromodulatory systems and more delayed, genomically mediated effects. The net effect of GC feedback in brain depends on the parameters of stimulation, such as whether a stressor is acute or chronic, with some effects being time or state dependent. GC actions in brain can lead to both inhibition and facilitation of further HPA axis outflow, affecting other motor outflows and influencing mood, incentive, memorial, and structural systems relevant to adaptation. The HPA axis defends the body against systemic derangements, while sculpting and mounting brain networks to anticipate and avoid further challenge.

Introduction

The maintenance of thyroid function is dependent on a complex interplay between the hypothalamus, anterior pituitary, and thyroid gland, as well as other factors that influence the function of these organ systems. This function is critical to achieve a constant level of free thyroid hormone in the bloodstream to support peripheral tissues by affecting protein synthesis and/or altering the metabolic activity of cells, as well as for brain development during fetal growth and early infancy. The hypothalamic peptide primarily responsible for this action by stimulating the biosynthesis and release of thyrotropin (TSH) from the anterior pituitary gland is thyrotropin-releasing hormone (TRH). TSH then stimulates the release, from the thyroid gland into the circulation, of the thyroid hormones, thyroxine (T4) and tri-iodothyronine (T3), which feed back on the hypothalamic TRH neurons and anterior pituitary thyrotropes, completing what is recognized as a classic example of a negative feedback loop system (Figure 1).

Biosynthesis and Processing of TRH

TRH (pyroGlu–His–ProNH2, MW 362) arises by a messenger RNA (mRNA)-directed ribosomal mechanism and posttranslational processing of a larger precursor prohormone. The complete sequence of the TRH precursor, deduced from its complementary DNA, has been elucidated for frog, rat, mouse, and human and is illustrated schematically in Figure 2. Common to each prohormone are multiple copies of a progenitor sequence for TRH, Gln–His–Pro–Gly, flanked on either side by paired basic amino acids, Lys–Arg or Arg–Arg, that are processing signals for carboxypeptidase B-like enzymes. The C-terminal glycine functions as a substrate for α-amidating enzymes that convert TRH-Gly to TRH, and the N-terminal glutaminyl is modified by glutaminyl cyclase to result in the fully mature and biologically active TRH. Presumably, the repeating progenitor sequences of TRH in the prohormone are of importance to magnify the response to signals that trigger TRH secretion. Pre-proTRH$_{141–149}$ (referred to as human thyrotropin-releasing hormone-associated peptide 3 (hTAP-3)) is also present in human serum and corresponds in position to the intervening sequence preproTRH$_{160–169}$ in the rat prohormone.

In addition to the sequences that give rise to TRH, the TRH precursor contains several cryptic peptides between the TRH progenitor sequences, and N- and C-terminal flanking peptides that may be biologically active. At least one peptide, preproTRH$_{160–169}$, a decapeptide that follows the third TRH sequence in the rat prohormone, has little activity on anterior pituitary secretion by itself, but in the presence of TRH, it potentiates the secretion of TSH by increasing TSHβ mRNA in thyrotropes. As receptors for preproTRH$_{160–169}$ have been identified only in folliculostellate cells, specialized glial cells of anterior pituitary origin, the effect of preproTRH$_{160–169}$ to potentiate the action of TRH on TSH secretion is presumed to be indirect via paracrine interactions between the processes of folliculostellate cells and anterior pituitary thyrotropes.

PreproTRH$_{178–199}$ separates the fourth and fifth progenitor TRH sequences and is also released from the rat median eminence, but as yet, no receptors for this peptide have been identified. Claims for biologic activity of preproTRH$_{178–199}$ were based on its ability to act as a corticotropin-inhibiting factor, blocking both the release of adrenocorticotropic hormone and the transcription of POMC mRNA, but the data are controversial. PreproTRH$_{178–199}$ may also exert other pituitary actions, including inhibition of growth hormone and prolactin secretion.

In the hypothalamus, preproTRH is fully processed to yield all five copies of TRH. Two enzymes that are critical for the processing of proTRH and present in most TRH neurons in the hypothalamus are the proconvertase enzymes, PC1/3 and PC2. Processing begins in the trans-Golgi network and continues in secretory granules. Both PC1/3 and PC2 are inversely regulated by thyroid hormone in hypophysiotropic TRH neurons, thereby contributing to thyroid hormone action on the regulation of TRH.

TRH Gene and Promoter Regulation

The murine, rat, and human TRH genomic structures are identical, each containing three exons and two introns (Figure 3(a)); exon 1 encodes the 5′ untranslated region, whereas exons 2 and 3 contain the

Figure 1 Neuroregulatory control systems involved in the secretion of thyroid hormone. Bold lines denote the negative feedback loop of thyroid hormone on thyrotropin-releasing hormone (TRH) secretion from the hypothalamus and thyroid-stimulating hormone (TSH) secretion from the anterior pituitary. Both the hypothalamic TRH neurons and anterior pituitary thyrotrops are impinged on by numerous other potential regulatory influences that are activated under specific physiological or pathological conditions. CART, cocaine- and amphetamine-regulated transcript; α-MSH, α-melanocortin-stimulating hormone; VIP, vasoactive intestinal polypeptide; AGRP, agouti-related peptide; GABA, γ-aminobutyric acid; 5-HT, 5-hydroxytryptamine; NPY, neuropeptide Y; PVN, paraventricular nucleus; ARC, arcuate nucleus; ME, median eminence; T4, thyroxine; T3, tri-iodothyronine.

sequence that encodes the preproTRH message. The promoter region of the TRH gene is located immediately 5′ to exon 1 and is presumably the major locus where regulation of the gene takes place. *In vivo* studies in transgenic mice using TRH promoter fragments linked to a luciferase reporter gene suggest that sequences within the proximal promoter, as well as the first exon, are critical for TRH expression in the hypothalamus. It remains unclear, however, which regions of the TRH gene allow for its expression in individual hypothalamic nuclei or other tissues, such as the pituitary, pancreas, or heart.

The TRH promoter region is heralded by the presence of a conserved TATAA box, allowing for transcriptional initiation by RNA polymerase II. Just proximal to the TATAA box is an important regulatory

Figure 2 Schematic representation of rat, mouse, human, and frog prepro thyrotropin-releasing hormone (TRH). Each sequence contains multiple copies of a TRH progenitor sequence (Gln–His–Pro–Gly) flanked by paired basic residues. The cryptic peptides, preproTRH$_{160–169}$ and preproTRH$_{178–199}$, are located between the third and fourth progenitor TRH sequence, and the fourth and fifth progenitor TRH sequence in rat preproTRH, respectively. aa, amino acid.

Figure 3 (a) Genomic and promoter structure of thyrotropin-releasing hormone (TRH). The murine, rat, and human TRH genes are composed of three exons and two introns. The coding sequence for the precursor protein is present on exons II and III. As depicted, the TRH promoter region precedes the transcription start site in exon I. The proximal 250-bp sequences of the human (H), mouse (M), and rat (R) promoters are similar and share the indicated transcription factor binding sites. The locations of the cyclic adenosine monophosphate-responsive element binding protein (CREB) binding site (Site 4) across animal species are indicated. The locations of the signal transducer of activated transcription (STAT) element and glucocorticoid receptor (GR) response element are also shown. (b, c) Hypothesized schematic representation of the interaction between phosphorylated CREB (PCREB) and the thyroid hormone receptor at Site 4. (b) In the presence of abundant PCREB, there may be less availability for binding of the thyroid hormone receptor/tri-iodothyronine (T3) complex; hence, an increase in TRH gene transcription. When PCREB concentrations fall as shown in (c), increased binding of the thyroid hormone receptor/T3 complex reduces TRH gene transcription as illustrated by the thicker arrow. RXR, retinoic acid X receptor; TR, thyroid hormone receptor. element termed Site 4 (TGACCTCA) that is conserved in the mouse, rat, and human promoters (**Figure 3(a)**). This sequence is important for basal expression of the TRH promoter in many different mammalian cell lines when they are assessed by means of transfection studies. In addition, Site 4 serves as a multifunctional binding site for the transcription factor cyclic adenosine monophosphate (cAMP) regulatory response element binding protein (CREB) and for thyroid hormone receptors (TRs), including TR homodimers, as well as heterodimers of TR and the retinoic acid X receptor (RXR). It appears that Site 4 cooperates with a second, weak TR binding site, 11 bp 3′ to Site 4, that binds both TR homodimers and TR/RXR heterodimers. Altogether Site 4 appears to be a critical sequence within the TRH promoter, is preserved across species, and controls both basal and regulated expression of the TRH gene.

The importance of Site 4 in the regulation of TRH expression was first demonstrated in functional studies in mammalian cell lines. These studies showed that it was required for downregulation of TRH promoter constructs by T3 in the presence of the TR. T3 mediates its effects on gene expression via the three TR isoforms (TRα_1, TRβ_1, and TRβ_2). TRα_1 is expressed in many tissues but plays little role in negative regulation by T3. The TRβ isoforms are products of a single gene and differ only in their N-terminal regions. TRβ_1 mediates the effect of T3 in the inner ear, liver, and kidney, and recent genetic studies have confirmed that TRβ_2 is critical for negative regulation of the TRH and the TSHα and β subunit genes by T3.

The molecular mechanism governing negative regulation of the TRH by T3 has not been firmly established. Site 4 and its surrounding region can bind TRβ_2, which appears to be necessary for negative regulation. However, it is not clear which cofactors are involved. On genes positively regulated by T3, the TR isoforms are bound constitutively to thyroid hormone response elements. In the absence of T3, they recruit nuclear corepressors that repress transcription of target genes. The presence of T3 causes the release of corepressors and the recruitment of coactivators such as SRC-1, which lead to transcriptional activation. The role of corepressors and coactivators in the negative regulation of the TRH gene remains less clear, given that the recruitment of coactivators by TRβ_2 in the presence of T3 would be expected to activate rather than repress TRH expression. Surprisingly though, they also appear to be important as mutations in TRs in knock-in mice that prevent binding of coactivators without altering DNA binding are unable to mediate negative regulation *in vivo*. Furthermore, mice that lack SRC-1 are also unable to downregulate TSH subunit gene regulation. Thus, coactivators play a role in negative regulation *in vivo*, though the exact mechanism remains to be determined.

Site 4 can also be bound by CREB. CREB is bound constitutively to target promoters, usually as a homodimer or as a heterodimer with other members of the ATF-1 family. When phosphorylated by protein kinase A after activation of the cAMP signaling cascade by activators such as forskolin, PCREB recruits the coactivator CREB binding protein, thereby allowing for transcriptional activation of the TRH gene via modifications of the histone structure surrounding the gene. Mutation or deletion of Site 4 prevents activation of TRH promoter constructs by cAMP. The phosphorylation of CREB, therefore, is likely a key mechanism for positive regulation of TRH gene expression and, by competing with PCREB for Site 4, TRβ_2, could prevent activation of the TRH promoter (**Figures 3 and 3(c)**). Binding of PCREB to Site 4 also has an important role in mediating the effects of melanocortin signaling on the TRH gene (see the section titled 'Regulation of hypophysiotropic TRH by fasting and infection (nonthyroidal illness syndrome)').

Activation of the TRH gene also occurs via a canonical signal transducer of activated transcription (STAT) binding site in the murine and rat promoter 5′ to Site 4. A similar site in the human promoter located between −150 and −125 has also been identified, suggesting the importance of this sequence across animal species (**Figure 3(a)**). Tyrosine phosphorylation allows phospho-STAT to dimerize and enter the nucleus to bind to its target regulatory elements, such as the one found in the TRH promoter. STAT activates transcription by recruiting coactivators such as CREB binding protein. The leptin receptor activates transcription via the JAK-STAT signaling pathway and is able to significantly enhance TRH promoter activity in transfection experiments in mammalian cells. Furthermore, the TRH promoter is able to recruit STAT3 *in vivo* in chromatin immunoprecipitation experiments. The presence of such a STAT site also suggests that the TRH promoter is poised to respond to other cytokine signaling pathways that could engage TRH neurons in the PVH or elsewhere.

The TRH promoter also contains binding sites for the glucocorticoid receptor and SP-1. The glucocorticoid receptor response element is located just upstream of the STAT element and appears to be functional in the pituitary, where glucocorticoids enhance TRH gene expression (**Figure3(a)**). However, glucocorticoids appear to be inhibitory to TRH gene expression in the paraventricular nucleus (PVN). There are multiple potential SP-1 sites within the promoter, but one located adjacent to the STAT site is required for full induction by leptin.

Anatomical Organization and Central Mediators of the Hypothalamic TRH Tuberoinfundibular System

The origin of TRH-containing neurons that regulate anterior pituitary TSH secretion is the hypothalamic PVN, a triangular, midline nuclear group symmetrically located on either side of the dorsal portion of the third ventricle (Figures 4(a)–4(c)). The PVN is composed of two major parts: magnocellular neurons, located in more lateral portions of the nucleus, and parvocellular neurons, located in more medial portions of the nucleus. The magnocellular component gives rise to the hypothalamic neurohypophysial tract that carries vasopressin and oxytocin to the posterior pituitary. The parvocellular component has a number of subcompartments, including anterior, medial, periventricular, ventral, dorsal, and lateral parvocellular subdivisions. TRH-synthesizing neurons are found primarily in the anterior, medial, and periventricular parvocellular subdivisions and to a lesser extent in the dorsal and lateral subnuclei (Figures 4(d) and 4(e)). However, only TRH neurons in medial and periventricular parvocellular subdivisions project to the median eminence (and are often referred to as hypophysiotropic neurons as they are involved in regulation of the anterior pituitary), and thereby they are functionally distinct from the TRH neurons in the anterior parvocellular subdivision. Functional heterogeneity between the two major groups of TRH neurons in the PVN is further indicated by the co-expression of cocaine- and amphetamine-regulated transcript (CART) in medial/periventricular parvocellular TRH neurons but not in anterior parvocellular TRH neurons.

Axons from hypophysiotropic TRH neurons in the PVN project to the median eminence, one of several so-called 'circumventricular organs' in the mammalian brain that lie outside the blood–brain barrier. Here, they terminate in the external zone of the median eminence (Figure 4(f)), where they have access to the fenestrated capillaries of the portal system. Some fibers also descend in the pituitary stalk to terminate in the posterior pituitary and may provide an alternative pathway by which TRH can regulate anterior pituitary secretion through the vascular channels (short portal veins) that connect the posterior pituitary to the anterior pituitary.

By residing in the PVN, TRH-producing neurons are situated in a region highly enriched by afferent inputs from other regions in the brain. These inputs are important to establish the set point for feedback regulation of hypophysiotropic TRH by thyroid

Figure 4 (a–c) Location of the major subdivisions in the rat paraventricular nucleus (PVN). AP, anterior parvocellular subdivision; DP, dorsal parvocellular subdivision; LT, lateral parvocellular subdivision; MN, magnocellular division; MP, medial parvocellular subdivision; P, periventricular parvocellular subdivision; VP, ventral parvocellular subdivision. Thyrotropin-releasing hormone (TRH) neurons are located in the anterior (d), medial, and periventricular (e) parvocellular subdivisions of the PVN, but only those in the medial and periventricular parvocellular subdivisions terminate in (f) the external zone of the median eminence (ME). Note close contact of TRH-containing axon terminals with capillaries of the portal vascular system (arrows). III, third ventricle. (a–c) Adapted from Sarkar S, Wittmann G, Fekete C, and Lechan RM (2004) Central administration of cocaine- and amphetamine-regulated transcript increases phosphorylation of cAMP response element binding protein in corticotropin-releasing hormone-producing neurons but not in prothyrotropin-releasing hormone-producing neurons in the hypothalamic paraventricular nucleus. *Brain Research* 999: 181–192.

hormone under basal conditions and during times when it is necessary to increase or decrease circulating levels of thyroid hormone (described in the section titled 'Feedback regulation of hypophysiotropic TRH by thyroid hormone'). Central modulation of hypophysiotropic TRH neurons through afferent projections may also occur in the external zone of the median eminence that could influence tuberoinfundibular TRH release by axo-axonal associations, but true axo-axonic synapses have only rarely been recognized in the mammalian median eminence.

While several regions of the brain project to the PVN, at least three regions provide the major input to hypophysiotropic TRH neurons, A1,2/C1–3 catecholamine neurons in the medulla of the brain stem, the hypothalamic arcuate nucleus, and the hypothalamic dorsomedial nucleus (Figure 5(a)). Axon terminals containing catecholamines give one of the most conspicuous innervations to TRH neurons in the PVN (Figure 5(c)) arising from catecholamine cell groups in the medulla. These axons establish mostly asymmetric synapses with both perikarya and dendrites of TRH neurons, suggesting an excitatory function. Noradrenergic axon terminals have also been identified in close apposition to TRH axons in the external layer of the rat median eminence, indicating that catecholamine inputs may influence TRH hypophysiotropic neurons, not only through direct effects on their perikarya and dendrites, but also on their axon terminals. The trajectory of catecholamine-containing axons from the brain stem is to course rostrally in the dorsal and ventral noradrenergic bundles, ultimately to enter the median forebrain bundle in the hypothalamus before terminating in the PVN (Figure 5(b)). Transection of the noradrenergic bundle at the level of the midbrain results in marked depletion of the catecholamine input to the PVN, in keeping with its origin from the brain stem. Approximately

Figure 5 (a) Sagittal drawing of the rat brain showing three major sources of innervation of thyrotropin-releasing hormone (TRH) neurons in the hypothalamic paraventricular nucleus (PVN): the brain stem A1,2/C1–3 cell groups that carry the catecholamines NE and E, as well as neuropeptide Y (NPY) and cocaine- and amphetamine-regulated transcript (CART), to the PVN; the hypothalamic arcuate nucleus (ARC) that carries the neuropeptides NPY, agouti-related peptide (AGRP), α-melanocortin-stimulating hormone (α-MSH), and CART to the PVN; and the dorsomedial nucleus (DMN), for which the neurotransmitter mediators are unknown. (b) Neurons arising in each of the three regions innervate the PVN by traversing or joining fibers in the medial forebrain bundle (arrow). (c) Arrows denote catecholamine-containing fibers (green) innervating TRH neurons (blue) in the PVN. (d) CART-containing fibers (red) also innervate TRH neurons in the PVN. Some of these fibers co-contain catecholamines and CART and appear yellow due to color mixing. Note co-expression of CART immunoreactivity in the cytoplasm of one of the TRH neurons (arrowhead). Modified from Lechan RM and Fekete C (2006) The TRH neuron: A hypothalamic integrator of energy metabolism. *Progress in Brain Research* 153: 209–235.

20% of the neuropeptide Y (NPY) and more than 60% of the CART input to TRH neurons (Figure 5(d)) in the PVN also derive from catecholamine-producing brain stem neurons.

At least four different peptides of arcuate nucleus origin, α-melanocortin-stimulating hormone (α-MSH), CART, NPY, and agouti-related peptide (AGRP), are contained in axon terminals in synaptic contact with TRH hypophysiotropic neurons (Figure 5(a)). Neurons of the arcuato-PVN pathway project their axons primarily ipsilateral to the PVN and, like the catecholamine axon trajectory from the brain stem, course in the medial forebrain bundle prior to entering the PVN. In the rat, α-MSH and CART arise from the same neurons located in lateral portions of the arcuate nucleus, whereas NPY and AGRP are co-contained in a distinct population located in more medial portions of the nucleus, although both neuronal populations can have similar terminal fields on TRH neurons in the PVN. A similar organization is also present in the human brain, suggesting the evolutionary importance of this neuroregulatory control system. Indeed, in the rat and mouse, pharmacologic ablation of the arcuate nucleus not only results in profound reduction in the number of axons contacting TRH neurons in the PVN that contain these neuropeptides but also reduces circulating levels of TSH and thyroid hormone. Similar to the catecholamine innervation, asymmetric specializations between axons containing α-MSH/CART and TRH neurons in the PVN are observed, suggesting an excitatory function, while axon terminals containing NPY and AGRP establish primarily symmetric synaptic specializations, suggesting an inhibitory function. The latter associations are sometimes so dense as to completely envelop the perikarya and first-order dendrites of TRH neurons.

While the arcuate nucleus contributes 100% of the AGRP and α-MSH innervation to hypophysiotropic TRH neurons and approximately 80% of the NPY innervation, it contributes only less than 34% of the CART innervation. Brain stem catecholaminergic neurons provide the remaining 20% of the NPY innervation, particularly to the distal dendrites of TRH neurons, and approximately 66% of the remaining CART innervation originates from the brain stem, primarily adrenergic C1–3 neurons in the medulla.

The hypothalamic dorsomedial nucleus also gives rise to a major projection pathway to the PVN, coursing in the medial forebrain bundle before entering the caudal pole of the PVN. Practically all TRH neurons in the PVN are innervated by the dorsomedial nucleus arising from neurons in the dorsal and ventral subdivisions. While the chemical mediators remain unknown, evidence that the dorsomedial nucleus gives rise to a prominent galaninergic innervation of the PVN and that galanin-containing axon terminals densely innervate TRH neurons in the PVN provides circumstantial evidence for a role of this neuropeptide in mediating the actions of the dorsomedial nucleus on hypophysiotropic TRH. The dorsomedial nucleus may also contribute to the γ-aminobutyric acid and glutamate innervation of hypophysiotropic TRH neurons. As retrogradely transported marker substances injected into the PVN concentrate in neurons in the dorsomedial nucleus that are densely innervated by axon terminals containing α-MSH, it is conceivable that the arcuate nucleus regulates TRH neurons in the PVN by both direct and indirect pathways, using the dorsomedial nucleus as a relay center ultimately to affect hypophysiotropic TRH neurons in the PVN.

Feedback Regulation of Hypophysiotropic TRH by Thyroid Hormone

The anatomical specificity of the TRH neuronal population in the medial and periventricular parvocellular subdivisions of the PVN is associated with a functional specificity of these cells with respect to feedback regulation by thyroid hormone. When circulating levels of thyroid hormone fall below normal values (hypothyroidism), perikaryal size and the content of proTRH and proTRH mRNA increase in these neurons but remain unchanged in other TRH neurons in the forebrain. This increase is accompanied by a decline in the content of TRH in the median eminence due to an increase in the secretion of TRH into the portal blood for conveyance to the anterior pituitary. Conversely, increased circulating levels of T4 cause marked suppression of proTRH mRNA in the PVN and a reduction in the secretion of TRH into the portal plexus, establishing an inverse relationship between thyroid hormone and the biosynthesis and secretion of hypophysiotropic TRH.

The increase or decrease in the amount of hypophysiotropic TRH secreted into the portal system for conveyance to the anterior pituitary as dictated by variations in circulating levels of thyroid hormones, is important to establish the set point for feedback regulation by thyroid hormone on anterior pituitary TSH secretion. When portal blood TRH concentrations are low, TSH can be suppressed by less T4 circulating in the bloodstream (reduced set point), whereas high portal blood TRH concentrations raise the set point for feedback regulation by thyroid hormone. Thus, thyroidectomized animals with lesions of the hypothalamus that include the PVN can suppress TSH with smaller doses of T4 than can animals

with an intact hypothalamus, whereas chronic intrathecal infusion of TRH can elevate TSH and circulating free and total thyroid hormones.

The selectivity of TRH neurons in the medial and periventricular parvocellular subdivisions of the PVN to negative feedback regulation by thyroid hormone is an intrinsic property of these cells, mediated by the presence of thyroid hormone receptors in these neurons and the high vascular flow to the PVN. Stereotaxic implantation of microcrystals of T3 adjacent to one side of the PVN in hypothyroid animals, therefore, leads to marked inhibition of proTRH mRNA only on that side, but not on the opposite side.

The source of nuclear T3 responsible for feedback regulation of TRH neurons in the PVN differs from the source of T3 in other regions of the CNS, such as the cerebral cortex and anterior pituitary, where the majority of T3 arises from the intracellular monodeiodination of T4 to T3 by type 2 iodothyronine 5′-monodeiodinase (D2). This is because the PVN contains little, if any, D2 activity or D2 mRNA, indicating that cells in this region are not capable of intracellular conversion of T4 to biologically active T3. Thus, hypophysiotropic TRH neurons in the PVN must receive T3 from an exogenous source, either directly from the bloodstream, the cerebrospinal fluid (CSF), or adjacent glia or by transneuronal transport. The possibility that feedback regulation by thyroid hormone on TRH neurons in the PVN is mediated exclusively by circulating levels of T3 alone is unlikely since the systemic infusion of graded doses of T3 to hypothyroid animals that restore plasma levels of T3 to normal does not suppress proTRH mRNA levels in the PVN to euthyroid levels in the absence of T4. Only by increasing plasma T3 into the supranormal range (approximately 1.6 times euthyroid levels) is there an apparent reduction in hybridization signal for proTRH mRNA to euthyroid levels, suggesting that like other regions of the brain, feedback regulation of thyroid hormone on TRH neurons in the PVN is partially dependent on circulating T4.

One potential source of conversion of T4 to T3 is the base of the third ventricle, where among the ependymal cells are specialized glial cells, tanycytes, that contain one of the highest concentrations of D2 mRNA in any region of the brain (**Figure 6**). These cells also express the monocarboxylate transporter 8, recently demonstrated to be an important thyroid hormone transporter and necessary for normal feedback regulation of hypophysiotropic TRH. Tanycytes extend apical villus-like projections into the CSF and cytoplasmic extensions into the neuropil that envelop the portal capillaries in the median eminence and blood vessels in the hypothalamic arcuate nucleus. Thus, tanycytes may provide a cytoplasmic conduit between the bloodstream and the CSF, allowing bidirectional movement of substances between the vascular and CSF compartments. 'D2 tanycytes,' therefore, may have an important role in the conversion of T4 to T3, either by the uptake of T4 from the CSF or from vascular compartments in the median eminence/arcuate nucleus, and then in the delivery of T3 to the CSF. By volume transmission, T3 would have access to extracellular spaces in the brain, such as the hypothalamic PVN, where it could mediate actions directly on hypophysiotropic TRH neurons. Alternatively, tanycytes may release T3 into the median eminence, where it can be taken up by axon terminals of hypophysiotropic TRH neurons and transported retrogradely or released into the arcuate

Figure 6 Rostral–caudal distribution of type 2 iodothyronine deiodinase (D2) messenger RNA in the mediobasal hypothalamus (darkfield illumination). In the most rostral section (a), hybridization is present in the external zone of the median eminence (ME) but is absent from walls of the third ventricle (III). In more caudal sections (b–d), intense hybridization is seen over cells lining the floor and infralateral walls of the third ventricle and in the arcuate nucleus (ARC) and ME. Hybridization is absent in the dorsal portions and roof of third ventricular wall in (b–d) (arrows). Adapted from Tu HM, Kim SW, Sulvatore D, et al. (1997) Regional distribution of type 2 thyroxine deiodinase messenger ribonucleic acid in rat hypothalamus and pituitary and its regulation by thyroid hormone. *Endocrinology* 138: 3359–3368.

nucleus through tanycyte–neuronal interactions, where it could influence the activity of arcuate nucleus neurons that have known projections to TRH neurons in the PVN.

Regulation of Hypophysiotropic TRH by Cold Exposure and Suckling

Thyroid hormone levels and TSH are acutely elevated by cold exposure in several animal species because of the increased secretion of TRH in the median eminence. This response is accompanied by a rapid increase in the transcription of TRH in the PVN, resulting in increased secretion of TRH into the portal capillaries from axon terminals in the median eminence, and it can be abolished with TRH antiserum or ablation of the PVN. Particularly intriguing is that proTRH mRNA is increased at a time when circulating levels of thyroid hormone are high. This is contrary to the mechanism of inverse feedback regulation by thyroid hormone, discussed in the section titled 'Feedback regulation of hypophysiotropic TRH by thyroid hormone,' in which proTRH mRNA would be expected to be inhibited. Thus, cold exposure may override the normal mechanism for feedback regulation by altering the set point for inhibition of TRH gene expression by T3.

There is strong evidence to suggest a role of catecholamines in altering the set point for feedback inhibition by thyroid hormone during cold exposure. Norepinephrine stimulates the release of TRH from hypothalamic preparations in culture, and depletion of catecholamines with inhibitors of catecholamine biosynthesis such as α-methyl-paratyrosine or selective catecholamine neurotoxins such as 6-hydroxydopamine abolishes the response of the hypothalamic–pituitary–thyroid (HPT) axis to cold exposure. In addition, the TSH response to acute cold exposure does not occur within the first 10 days after birth in the rat, when the hypothalamic norepinephrine innervation is still immature. Because CART is co-contained in greater than 50% of catecholamine axons in contact with TRH neurons in the PVN and increases TRH gene expression and monoamine accumulation in several regions of the brain, CART may also participate in activation of the HPT axis during cold exposure, either through direct effects on hypophysiotropic TRH neurons or by potentiating catecholamine secretion.

The molecular mechanisms that explain the ability of catecholamines to override the feedback effects of thyroid hormone on TRH gene expression may involve the increased availability of PCREB for binding to Site 4 in the TRH promoter as a result of the binding of catecholamines to G-protein-coupled α receptors on TRH neurons. Presumably, the inhibitory feedback of thyroid hormone bound to its receptor on the TRH promoter may be reduced under these conditions due to increased competition by elevated intranuclear concentrations of PCREB.

Suckling also increases proTRH mRNA in the PVN within 30 to 60 min of the response but for the primary purpose of increasing prolactin secretion from the anterior pituitary. TSH and thyroid hormone levels do not increase, perhaps due to the simultaneous release of CART co-expressed with TRH in hypophysiotropic neurons that can attenuate TRH-induced TSH secretion. While serotonergic afferents from the midbrain raphe may mediate this response, the mechanism for the suckling-induced increase in TRH gene expression remains elusive.

Regulation of Hypophysiotropic TRH by Fasting and Infection (Nonthyroidal Illness Syndrome)

Fasting and infection also alter the normal mechanisms of feedback regulation by circulating levels of thyroid hormone on hypophysiotropic TRH. Under these circumstances, there is a fall in thyroid hormone levels yet a reduction in TRH gene expression in the PVN rather than the anticipated increase that would occur in primary hypothyroidism. Presumably, these conditions override the normal feedback mechanism described earlier by reducing the set point for feedback inhibition by circulating thyroid hormone and thus inducing a state of central hypothyroidism, commonly referred to as 'nonthyroidal illness' or the 'sick euthyroid syndrome' in humans. By reducing thyroid thermogenesis and preserving nitrogen stores, this mechanism is an important adaptive response to reduce energy expenditure until the adverse stimulus has been removed.

The state of central hypothyroidism induced by fasting is orchestrated by a circulating cytokine of white adipose tissue origin, leptin, which declines with fasting and is restored to normal levels by refeeding. If leptin is administered systemically or intracerebroventricularly (icv) to fasting animals, the reduction in circulating levels of thyroid hormone, TSH, and hypophysiotropic proTRH mRNA in the PVN is prevented (Figure 7). Two actions of leptin on hypophysiotropic TRH have been proposed, a direct action as a result of leptin receptor-induced phosphorylation of STAT3 within the hypophysiotropic TRH neurons and an indirect action mediated by neurons in the hypothalamic arcuate nucleus. If the arcuate nucleus is destroyed, not only is the response of the thyroid axis to fasting abolished, but the response of the thyroid axis to the exogenous administration of leptin is lost as well. The arcuate

nucleus, therefore, would appear to serve as a critical locus to mediate the effects of leptin on the HPT axis and in so doing, presumably establishes the set point for feedback sensitivity of proTRH-producing neurons in the PVN to thyroid hormone, lowering the set point at which TRH levels are suppressed during fasting.

At least two anatomically distinct populations of neurons present in the arcuate nucleus with opposing functions, α-MSH-producing neurons that co-express CART and NPY-producing neurons that co-express AGRP, are responsible for the actions of leptin on hypophysiotropic TRH. Both α-MSH and CART have activating effects on hypophysiotropic TRH neurons, and when administered intracerebroventricularly, they have potent effects to restore the fasting-induced suppression of proTRH mRNA in hypophysiotropic neurons to levels in *ad lib* feeding animals (Figures 8(a) and 8(c)). The activating mechanism for α-MSH on the TRH promoter is likely mediated by the phosphorylation of CREB, and

Figure 7 *In situ* hybridization autoradiographs of prothyrotropin-releasing hormone (proTRH) messenger RNA (mRNA) in the rat paraventricular nucleus (PVN; arrow) of (a) normal fed and (b) fasting animals. Note the marked reduction in hybridization signal for the fasting animal. (c) ProTRH mRNA levels are restored to normal in fasting animals administered leptin. From Legradi G, Emerson CH, Ahima RS, Flier JS, and Lechan RM (1997) Leptin prevents fasting-induced suppression of prothyrotropin-releasing hormone messenger ribonucleic acid in neurons of the hypothalamic paraventricular nucleus. *Endocrinology* 138: 2569–2576.

Figure 8 (a–c) *In situ* hybridization autoradiograms of prothyrotropin-releasing hormone (proTRH) messenger RNA (mRNA) in the medial and periventricular parvocellular subdivisions of the rat paraventricular nucleus (PVN) of (a) fed, (b) fasted, and (c) fasted animals receiving α-melanocortin-stimulating hormone (α-MSH) icv. Fasted animals receiving α-MSH show a marked increase in proTRH mRNA that is similar to that of the fed control. (d)–(f) Effect of icv α-MSH on cyclic adenosine monophosphate-responsive element binding protein (CREB) phosphorylation (PCREB) in the PVN of fasted animals. (d) Fasted animals show little PCREB in the medial and periventricular parvocellular subdivisions but (e) a marked increase following α-MSH administration. (f) Double-labeling immunocytochemistry shows that following α-MSH administration, the majority of TRH neurons (brown cytoplasm) contain PCREB (black nucleus). III, third ventricle. (a–c) Modified from Fekete C, Legradi G, Mihaly E, et al. (2000) Alpha-melanocyte-stimulating hormone is contained in nerve terminals innervating thyrotropin-releasing hormone-synthesizing neurons in the hypothalamic paraventricular nucleus and prevents fasting-induced suppression of prothyrotropin-releasing hormone gene expression. *Journal of Neuroscience* 20: 1550–1558. (d–f) From Sarkar S, Legradi G, and Lechan RM (2002) Intracerebroventricular administration of alpha-melanocyte stimulating hormone increases phosphorylation of CREB in TRH- and CRH-producing neurons of the hypothalamic paraventricular nucleus. *Brain Research* 945: 50–59.

Figure 9 Darkfield illumination photomicrographs of prothyrotropin-releasing hormone (proTRH) messenger RNA (mRNA) in the medial parvocellular subdivision of the hypothalamic paraventricular nucleus (PVN; denoted by arrow) in (a) artificial CSF-treated control *ad lib*-fed animals, (b) *ad lib*-fed animals treated with neuropeptide Y (NPY) intracerebroventricularly (icv), and (c) *ad lib*-fed animals treated with agouti-related peptide (AGRP) icv. Note marked reduction in silver grains over neurons of the PVN in the AGRP- and NPY-treated groups that are selective for the PVN. No effects of NPY or AGRP are seen on proTRH mRNA expression in the lateral hypothalamus (LH). III, third ventricle. Modified from Fekete C, Sarkar S, Rand WM, et al. (2002) Agouti-related protein (AGRP) has a central inhibitory action on the hypothalamic–pituitary–thyroid (HPT) axis *Endocrinology* 143: 3846–3853.

following intracerebroventricular administration, α-MSH markedly increases the number of TRH neurons in the PVN that contain PCREB in their nucleus (Figures 8(d)–8(f)). In addition, mutation of Site 4 in the TRH promoter or introduction of a dominant negative inhibitor of CREB that cannot be phosphorylated in an *in vitro* expression system prevents activation of the TRH promoter by α-MSH. The mechanism by which CART activates TRH neurons in the PVN remains unknown.

Conversely, both NPY and AGRP, when administered icv to *ad lib* feeding animals (Figure 9), have profound inhibitory effects on TRH gene expression in hypophysiotropic neurons, creating a state of central hypothyroidism that closely compares with that observed in fasting animals. Presumably, AGRP produces its inhibitory effects on TRH gene expression by antagonizing the activating effects of α-MSH at the melanocortin 4 receptor and/or by suppressing constitutively active melanocortin receptors by functioning as an inverse agonist. The inhibitory effect of NPY is mediated through both Y1 and Y5 receptors and is likely due to inhibition of cAMP and hence a reduction in the accumulation of PCREB in the nucleus of TRH neurons.

Thus, during fasting when circulating leptin levels decline, there is simultaneous inhibition of α-MSH and CART production and increase in AGRP and NPY production in arcuate nucleus neurons. Under these circumstances, the end result for hypophysiotropic TRH neurons in the PVN would be a decline in CREB phosphorylation, reducing the availability of PCREB for binding to Site 4 in the TRH promoter. Therefore, the inhibitory feedback effects of thyroid hormone bound to its receptor on the TRH promoter may become enhanced due to reduced competition by lower intranuclear concentrations of PCREB, essentially lowering the set point for feedback inhibition of the TRH gene by thyroid hormone. Activation of D2 in tanycytes may also contribute to fasting-induced inhibition of hypophysiotropic TRH that may be dependent on leptin and glucocorticoid signaling.

Paradoxically, suppression of the HPT axis following endotoxin administration is associated with increased circulating leptin levels, increased melanocortin signaling, and increased CART gene expression in the arcuate nucleus that would predict activation of hypophysiotropic TRH gene expression. Nevertheless, endotoxin suppresses TRH gene expression in the PVN, resulting in central hypothyroidism similar to that observed with fasting. Presumably, therefore, a set of regulatory controls different from that observed during fasting must come into play under these conditions, superseding all other regulatory effects on hypophysiotropic TRH. The observation that endotoxin markedly increases D2 gene expression and enzymatic activity in tanycytes has raised the possibility that central hypothyroidism associated with infection may be secondary to an endotoxin-induced increase in local tissue levels of T3 in the mediobasal hypothalamus. This could have the result of suppressing hypophysiotropic TRH by inhibitory feedback effects on TRH gene expression, as schematically shown in Figure 10. The mechanism for endotoxin-induced increase of D2 activity in tanycytes is unknown but is unlikely related to the fall in circulating levels of thyroid hormone. Thyroid hormone replacement to thyroidectomized animals treated with endotoxin still shows an increase in tanycyte D2 activity, whereas the T4 clamp blocks the endotoxin-induced increase of D2 activity in the anterior pituitary and cerebral cortex. In addition, elevated levels of corticosterone probably have little role because corticosterone-clamped adrenalectomized animals still show a D2 response to lipopolysaccharide. Rather, the effects of endotoxin on tanycyte D2 activity may be mediated by endotoxin itself or by endotoxin-induced cytokines via the activation of nuclear factor-kappa B. This hypothesis is based on the observation that the

Figure 10 Proposed mechanism for type 2 iodothyronine deiodinase (D2) regulation of the hypothalamic–pituitary–thyroid axis following the administration of lipopolysaccharide (LPS). LPS increases D2 activity in tanycytes, resulting in increased thyroxine (T4) to tri-iodothyronine (T3) conversion. (1) T3 is released from tanycyte apical processes into the cerebrospinal fluid (CSF) for conveyance to the paraventricular nucleus (PVN) or (2) taken up from hypophysiotropic thyrotropin-releasing hormone (TRH) axonal processes in the median eminence and transported retrogradely to its cell body in the PVN. (3) T3 may also be released into the portal capillary system and directly inhibit the secretion of thyroid-stimulating hormone. Local tissue hyperthyroidism inhibits TRH in the PVN. D2 promoter contains nuclear factor-kappa B binding sites that can cause profound activation of the human D2 promoter in several cell lines. Inhibitory effects of endotoxin on the HPT axis may also be mediated directly on hypophysiotropic TRH neurons by cytokines such as interleukin-1, interleukin-6, tumor necrosis factor, and interferon, which rise dramatically following endotoxin administration and abolish both the normal circadian variation and pulsatile secretion of TSH.

Ideal Observer Theory

D Kersten, University of Minnesota, Minneapolis, MN, USA

© 2009 Published by Elsevier Ltd.

Introduction

An ideal observer is ideal in the sense that it achieves statistically optimal performance for a specified task. It makes the best decisions or estimates given uncertain sensory information and prior knowledge. What is best is specified in terms of costs and benefits. Ideal observer models can be used to study different types of real test observers, such as in the psychophysical analysis of the input/output behavior of humans and spike-train analysis of information carried by single neurons. If human perceptual performance approaches that of an ideal observer, this can, in principle, rule out a large class of candidate neural mechanisms that are suboptimal relative to the ideal. Although the ideal observer concept can be traced to earlier work, the modern notion of an ideal observer was developed in the 1950s by Peterson, Birdsall, Fox, Tanner, Swets, and others in the context of a general theory of signal detectability. The theory and its initial applications to human auditory and then visual sensitivity are described in a classic 1966 book by Green and Swets. In the late 1970s, Horace Barlow applied ideal observer analysis to higher-level perceptual tasks, such as the perception of symmetric patterns. By the 1990s, comparisons of human and ideal performance were extended to an increasingly wider set of problems, including object and motion perception, perceptual organization, reading, and motor control. Ideal observer analysis has shown, for example, that the way in which human observers integrate depth or motion information takes into account uncertainty in the input image cues, as we might expect from an ideal observer doing the same task.

Defining the Ideal Observer

The key ingredients in defining an ideal observer are (1) the generative model; (2) the task requirements, including a measure of performance; and (3) an observer model that specifies the optimal action rule for the given task requirement. The ideal observer can be defined in terms of four classes of random variables on a directed graph (i.e., one with arrows) that represents how the variables influence one another (see Figure 1). These variables represent states of the world s, observations (data) x that result, actions a (e.g., decision or estimate) on the data, and the losses (costs) $L(a, s)$ of action a, given the true state s. The spaces can be discrete or continuous. For example, a state of the world could mean one of two positions of a light switch or the distance of an object. An action may be only indirectly related to the state, for example, when a person throws a ball, the speed of release of the ball aimed at a distant target versus an estimate of the state itself (distance). We now go over the elements in greater detail.

The Generative Model

The generative model specifies how the states of the world s determine the observed data x, that is, sensory input (e.g., the pattern of image intensities). The state space can be discrete or continuous. In general, states and data are multidimensional, $s = (s_1, s_2, s_3, \ldots)$ and $x = (x_1, x_2, x_3, \ldots)$, and the relationship between states and data can have complex dependencies (a simplified example is shown in Figure 1(b)). The generative model consists of the prior probability of the state s, $p(S = s)$ and the probability of the observation x given s, $p(X = x|s)$. The prior probability can be simple, representing the probability of a hypothesis with just two values, such as a light switch being set to high $S = s_{\mathrm{H}}$ rather than low $S = s_{\mathrm{L}}$. But the prior probability on s can also be used to model complex pattern regularities that take into account covariation among elements of s, such as the probability of a surface tending to have smoothly varying, rather than rapidly changing, depths. In this case, validating the model for the prior from real-world data can be a significant problem by itself; however, in the lab, an experimenter can specify the prior. The probability of an observation x given s describes how the signal s is encrypted in the data and is the likelihood of the hypothesis (the state s) given the data. The description could be as simple as $x = s + n$, where x is light intensity, s is the average level of one of two fixed light intensities, and n is a sample of Gaussian noise. Then $p(X = x|s) = p(x - s)$. Or $p(X = x|s)$ could be derived from a more complicated function $x = \phi(s, n)$, where x is a vector representing an image, and ϕ is a function that describes how a shape s together with a confounding variable n, such as viewpoint (or slant angle in the next example), determines the image observation. In the context of a psychophysical experiment, the generative model can be thought of as a probabilistic description of how the stimuli are generated.

Figure 1 State and observation spaces in an ideal observer model: (a) components of the model; (b) an example in which state variables S_1 and S_2 both influence observation X_1 but only S_2 directly influences X_2. In (a), the nodes represent random variables, and the arrows indicate how they influence one another. The arrows in the graph (formally, a directed acyclic graph) can be interpreted as describing the dependencies among variables. The graph structure determines how to factor the joint distribution for the task, $p(s, x, l, a) = p(l|a, s)p(a|x)p(x|s)p(s)$. From this, we can formalize the problem of estimating components, such as the probability of a loss value $p(L = \mathrm{l})$ (i.e., probability of error $L = 1$) and other performance measures, such as the hit rate $p(L = 0|s_{\mathrm{H}})$, or false positive rate $p(L = 0|s_L)$ for signal state s_{H} and noise state s_{L}. As shown in (b), the state and observation spaces can have complex dependencies. Solid lines indicate the generative model, and the dashed lines the directions of (inverse) inference for two tasks. Suppose the goal is to estimate S_2; then both observations determine the optimal estimate (blue dashed lines). This is an example of cue integration, in which the two observations are conditionally independent of S_2. If the goal is to estimate S_1, both observations again determine the estimate, but X_2 indirectly affects beliefs about S_1 through S_2 (red dashed lines). This is an example of explaining away. The graph structure is equivalent to the factorization $p(s_1, s_2, x_1, x_2) = p(x_1|s_1, s_2)p(x_2|s_2)p(s_2)p(s_1)$.

The Task Requirements

The task requirements are twofold: (1) decide what is to be done with the data, for example, detect the presence or absence of the signal (e.g., high vs. low contrast? or animal present or not?), identify the signal (e.g., which letter, A, B, or C?), and estimate a continuous value (e.g., what is the depth of the object?); and (2) determine the value of achieving or not achieving the goal. Not all elements of the state variable, $s = (s_1, s_2, s_3, \ldots)$, are equally important and need to be determined accurately. In classic signal detection theory, state variables are divided into two types – the relevant variables to be inferred accurately (signals) and those to be discounted (noise) – with associated losses for right and wrong answers. Generally, the value of accuracy can be expressed in terms of a loss function (or, alternatively, a gain function, equal to one minus the loss function). For example, different degrees of relevance can be placed on the state variables by specifying a loss function $L(a_1, a_2; s_1, s_2)$, which puts a cost on choosing actions a_1, a_2 when the true states are s_1 and s_2. If the action is an estimate of s, $a = \hat{s}$, loss may be expressed in terms of differences, $L(\hat{s} - s)$.

Optimal Action or Decision Rule

Of the many possible observer models, the ideal observer is defined as one that uses an action rule $a(x)$ that minimizes the risk for the task. The expected risk is defined as the loss averaged over both state and observation variables: $R(a|x) = \sum_{s,x} L(s, a(x))p(s, x)$. For a given observation x, the decision rule is to choose action a so as to minimize $R(a|x) = \sum_{s,x} L(s, a(x))p(s|x)$. Often the action space has a simple relationship with the signal state space. For example, in a detection or discrimination task, the state space is discrete and binary, and the action is to decide whether the signal was sent or not (answer yes or no to questions such as 'Is Thomas there?' or 'Is Thomas bigger than Simon?'). For identification, the state space is discrete with multiple values ($S = \{Thomas, Simon, Hermann, Jacob\}$), and the actions are decisions based on x ('Is it Thomas? Simon? Hermann? Jacob?'). For estimation, the action is an estimate of the state variable, $a = \hat{s}$ from observation x (e.g., 'How tall is she?'). If the loss is uniformly high for all wrong decisions and low for the correct decision, then the optimal action is to pick the most probable state s given the data x. This is the maximum *a posteriori* (MAP)

observer: $a(x) = \text{argmax}_s p(s|x)$. This rule yields the smallest average error. If the loss is the squared error between the state and estimated state variables, then the optimal action is to choose the mean of the posterior. Next, we illustrate task requirements with examples for detection and estimation tasks.

Applications of Ideal Observer Theory

We can distinguish two types of applications of ideal observer theory. For the purposes of this article, we refer to the first as ideal observer analysis; in this application, the test observer (humans or neural system) competes against the ideal observer in the same well-defined laboratory task. Because the experimenter controls the conditions for the stimuli and task, no observer can do better (on average) for the specified task. In this case, the performance of an ideal observer can be thought of as a benchmark against which to measure human performance. The emphasis is on departures from ideal performance, which provides clues to the underlying, generally subideal mechanisms. Ideal observer analysis is a useful addition to the experimenter's toolbox alongside linear and nonlinear systems analysis. Ideal observer analysis has been used to show that humans perform some tasks with strikingly high efficiency relative to the ideal observer but perform others quite poorly. One of the historic success stories was to show that the human ability to discriminate light intensity under nighttime viewing conditions can be extremely high. Following on the work of Hecht, Schlaer, and Pirenne in the 1940s, Horace Barlow showed in the early 1960s that human quantum efficiencies were sufficiently high as to rule out any explanation that required the retinal transduction of more than a few photons.

The second application of ideal observer theory is as an approximate theory or model of performance. The primary distinction between the two applications is that the second typically makes simplifying assumptions about the generative model (see the section titled 'Estimation'), including the nature of the input representation (e.g., the ideal observer may have geometrical features as input, whereas the human observer receives image intensities as input, from which geometrical information is derived) or how the data are caused by the states of the world (e.g., Gaussian noise is added, whereas the actual noise may be non-Gaussian). In other words, the ideal observer is optimal with respect to a generative model that may differ in detail from the true generative model, either as defined in a particular laboratory study or in a real-world task. The primary reason for these simplifying assumptions is practical – the true ideal observer is too hard to calculate. Even though humans are in general suboptimal, an ideal observer model may nonetheless go a long way in explaining the observed behavior. In this second type of application, ideal observer theories are equivalent to Bayesian theories of perceptual performance. As a modeling tool, a general advantage of the Bayesian ideal observer approach is that it avoids a commitment to untestable mechanistic details, such as a particular neural architecture, while still providing quantitative predictions of behavior (Table 1).

Table 1 Ideal observer model equations

Terms	*Equations*
Conditioning	$p(x\|y) = p(x,y)/p(y)$
Marginalization	$p(x) = \int p(x,y)\mathrm{d}y$
Bayes's rule	$p(s\|x) = p(x\|s)p(s)/p(x)$
Signal-to-noise ratio for equal variance Gaussian case	$d'_{\text{snr}} = (\mu_{\text{s}} - \mu_{\text{n}})/\sigma$
Relation of z and P	$z(P) : p = (1/\sqrt{2\pi}) \int_x^\infty e^{-x^2/2}\mathrm{dx}$
Sensitivity from false alarm and hit rates	$d'_{\text{perf}} = z(P_{\text{FA}}) - z(P_{\text{H}})$
ROC in terms of z values for unequal variance case	$z(P_H) = (\sigma_n/\sigma_s)z(P_{FA}) - [(\mu_s - \mu_n)/\sigma_s]$
d' for 2AFC from proportion correct	$d'_{\text{2afc}} = -\sqrt{2}z(P_{\text{c}})$
Efficiency	$E = (d'_{\text{snr}_{\text{I}}}/d'_{\text{snr}_{\text{T}}})^2$

2AFC, two-alternative forced-choice task; ROC, receiver operating characteristic; snr, signal-to-notice ratio.

Examples of Ideal Observer Analysis

Signal Detection

Figure 2 illustrates a classic task in signal detection theory in which a switch is set to high or low and the observer has to guess the setting based on an observation, in this case a measurement of light intensity.

The generative model The switch setting is the state variable. If the two switch settings are equally likely, independent of the data, then the prior is constant and equal to one-half, $p(S = s) = 1/2$. The second part of the generative model, the likelihood, specifies how the observations depend on the state. Suppose that when the switch is set to high the average light intensity is higher than when the switch is set to low. However, because of trial-to-trial fluctuations (noise), the measured or observed light intensity varies. So sometimes the measured light intensity is higher for the low setting than for the high switch setting. Note that in ideal observer analysis, we may be able to test the validity of the generative model, apart from questions of optimal inference. Thus, for example, the

Figure 2 Example of a simple ideal observer for a binary task, signal detection: (a) schematic of the physical model in which a light source produces an observation x, of light intensity; (b) graph showing causal dependencies corresponding to factorization in terms of the components of the generative model: $p(x, s, n) = p(x|s, n)p(s)p(n)$ (the direction of the inference for the detection task is shown by the dashed arrow); (c) Gaussian probability densities of the observation under the two hypotheses (switch states), also known as the likelihood functions corresponding to different means, μ_L, μ_H (top) and graphs of the posterior probabilities (bottom). In (c, top), the standard deviations are the same, σ. In (c, bottom), when the switch probabilities are not equal, choosing the highest likelihood no longer produces the lower error rate. The ideal observer guesses the state with highest posterior probability.

light switch model assumes additive Gaussian noise (although at low intensities at which fluctuations in photon emission and absorption may dominate; a Poisson model is a better choice). Figure 2(c) (top) shows the Gaussian distributions of observations under the two possible state conditions. The noise is additive because the high switch setting produces the same distribution as that of the lower setting, except that the mean is shifted by an added amount. The standard deviation remains the same.

The task Suppose that given an observation the observer has to decide whether it was due to a high or a low switch setting. Further, suppose that the task requires that the probability of error $p(L=1)$ be as small as possible. Loss is represented by $1-\delta_{s,\hat{s}}$ (the Kronecker delta function, $\delta_{s,\hat{s}}=1$ if $s=\hat{s}$, and $\delta_{s,\hat{s}}=0$ otherwise). Another common task in psychophysics is the two-alternative, forced-choice task (2AFC). The test observer (e.g., a human subject) and ideal observer share the same state, observation, and action space, as well as loss function (scoring system). In general, they differ in their mappings of observations to actions, that is, their decision rules.

The optimal decision rule Intuitively, we guess that the best strategy might be to choose s_H if $p(x|s_H) > p(x|s_L)$, and, in fact, this is the optimal rule for the constant prior case if we want to have the smallest error rate. In our example, this rule is equivalent to choosing s_H if $x > x_c$, where x_c is the point where the two curves in Figure 2(c) (top) cross one another. However, the general rule for minimizing error is the MAP rule, which takes into account the prior probability and picks the state with the higher posterior probability; that is, it chooses s_H if $p(s_H|x) > p(s_L|x)$. The posterior $p(s|x)$ is determined by the prior and likelihood through Bayes's rule: $p(s|x) = p(x|s)p(s)/p(x)$. If, for example, the prior probability of the switch setting high is bigger than the probability of low, this is equivalent to moving the criterion to x_m (i.e., choosing s_H if $x > x_m$; compare the upper and lower panels of Figure 2(c)). But there are other rules depending on the loss function we choose. The loss function is a 2×2 payoff matrix with loss values for hit (true positive), false alarm (false positive), correct rejection (true negative), and miss (false negative). We can assign distinct losses to each of these outcomes, in which, for example, false

alarms are more or less costly. In general, this results in a different rule r based on minimizing the risk – choose s_H if $r(s_H|x) > r(s_L|x)$. Standard results in signal detection theory show that for this problem the optimal rule is equivalent to: choose s_H if $x > x_m$, where the value of x_m (the criterion) depends on the loss matrix.

How to compare test and ideal observers? The test observer can perform no better than the ideal and in general does worse because of suboptimal action rules, such as systematically failing to use all the relevant information in the input stimulus. In this specific example, an observer can be suboptimal by putting the criterion x_m at the wrong place – a response bias. As the criterion shifts, the values of the hit and false alarm rates also shift. A graph of hit versus false alarm rates is known as the 'receiver operating characteristic' (ROC). A key contribution of signal detection theory was to show that underlying human sensitivity to a sensory signal (d') could be teased apart from the value of the criterion.

In theory, the ideal and test observers can be compared in terms of their scores (average loss, i.e., proportion of errors) or d'_{perf}, given the same states and resulting observations. However, it is often not practical to directly compare error rates (when the ideal is making a modest number of mistakes, the test observer may be near chance and would thus require too many measurements to estimate d'_{perf_T}); alternatively, we can compare state parameters in the generative model that produce identical performances (e.g., sensitivities d'_{perf_T}, d'_{perf_I} for test and ideal in an equal-variance Gaussian noise-detection task are determined by the signal-to-noise ratios d'_{snr_T} and d'_{snr_I}). Suppose, for example, that a human and ideal observer both have the same proportion correct in a 2AFC task; then, the ideal observer can be used as a benchmark, where a standard measure of comparison is statistical efficiency $E =$ (Number of samples required by the ideal observer/Number of samples required by test observer). In the case of additive Gaussian noise, this is equivalent to $E = (d'_{\text{snr}_I}/d'_{\text{snr}_T})^2$. If the noise is the same, efficiency takes on the simple form of the ratio of the squared threshold values of the ideal observer to the human observer. In the case of detecting an image pattern in additive Gaussian noise, an observer can be suboptimal by failing to use all the image samples (pixels) or by performing as if there were additional noise. These two sources of suboptimality have been teased apart in psychophysical experiments, measured in terms of calculation (or central) efficiency or transduction efficiency. Efficiency provides a unit-free measure of performance that allows for the stimulus complexity and task constraints.

Estimation

Perception is critical to a wide range of tasks, of which signal detection is just one. Consider the problem of determining the dimensions of a three-dimensional object from a two-dimensional projected image. In this case, a major source of uncertainty results from the loss of information due to projection. Figure 3 illustrates a Bayesian ideal observer model for a simple task to estimate the height and slant of a class of elliptical disks. Given an elliptical shape on the retina, what object could have produced it? It could be an elliptical disk, but a flat circular disk could also produce an elliptical image.

The generative model For simplicity, assume that the world consists of elliptical disks of width equal to 1 but with various heights h. These disks can have various slants, α, with respect to a viewer. The states are continuous and can be represented by $s = (s_1, s_2) = (h, \alpha)$. We can hypothesize a prior, $p(s) = p(h, \alpha)$ on these values. Figure 3 shows the graph of a bivariate Gaussian prior that assumes that the average slant is $\pi/4$ and the average height is 1. If viewed from a far distance, the width of the projection of any disk from this state space is a constant value (say, 1); but the height of the projection depends on both the true height of the disk and the slant. An observation of the height x of the retinal image provides data that constrains but, without additional information, does not uniquely determine the possible states. In the signal-detection example, uncertainty resulted from added Gaussian noise; here, although we assume some additional measurement noise, the critical uncertainty results from the property that the surface could be slanted away from the viewer by various unknown degrees. For a distant view, the image observation x can be approximated as $x \sim h\cos(\alpha) + n$. Assuming Gaussian noise, this determines the likelihood function, $p(x - h\cos(\alpha))$, where $p(n) = e^{-n^2/2\sigma^2}/(\sigma\sqrt{2\pi})$ is the standard formula for a Gaussian distribution with 0 mean.

The task Given an observation, say $x = 1/2$, the ideal observer needs to determine the height and slant with the least risk. Figure 3 illustrates the steps. It first computes the likelihood of the observation for all possible values of the state variables. The likelihood has a high ridge of constant height, meaning that there are infinitely many pairs of height and slant values that are equally likely. Thus, for example, a height of 4 inclined at 83° is no less likely than a head-on slant of 0 together with a height of 1/2.

Figure 3 Example of ideal observer theory applied to object perception; a Bayesian ideal observer model for estimating the height and slant of a class of elliptical disks.

This ambiguity can be resolved by multiplying the likelihood by the prior distribution to obtain the posterior distribution, $p(h, \alpha|x)$. At this point, we could stop and pick off the peak values of the posterior as the most probable values of height and slant. This corresponds to the decision rule for the MAP observer. However, suppose the task is more complex, requiring greater precision, say, in estimating the slant than the height.

The optimal decision rule In this more general case, we use a rule that minimizes risk. A simple model of risk is to define loss in terms of the absolute values of the errors, that is, the difference between the true and estimated state variables. We then assign a uniformly low loss to errors of height that fall within a wide range, but penalize slant errors more narrowly, as shown by the loss function in Figure 3. The risk is then a convolution of the loss function with the posterior, $R(h, \alpha|x) = \int p(h', \alpha'|x) L(h - h', \alpha - \alpha') \mathrm{d}h' \mathrm{d}\alpha'$, and the decision rule is to pick the pair of state variables corresponding to the lowest values of R. It is straightforward to show that if the tolerance to errors in height and slant are infinitely wide and narrow, respectively, then height effectively drops out of the risk, and minimizing risk corresponds to the MAP estimation on the marginal posterior, $p(\alpha|x)$.

How to compare test and ideal observers? Even if human observer estimates differ in detail from an ideal observer model, we can still test the degree to which information is optimally combined. Consider the posterior term, which is proportional to the product of the likelihood and prior terms. The ideal observer combines the image cues and the prior information in such a way as to take into account the reliability of each of the sources. Thus, smaller variances on the prior bias the final estimate toward the prior means, and, conversely, highly reliable (e.g., noise-free) image data move the estimates of slant

and/or height toward values consistent with the data. Task differences also affect shifts in the optimal estimates of the state variables. Although this example illustrates the balance between the prior and likelihood, there is a similar trade-off in the case of cue integration. For example, if there is additional information for the slant of the surface (e.g., a texture gradient), then the ideal observer combines and weights the cues according to their reliabilities. For the case of conditional independence and Gaussian noise, the optimal cue weighting is given by $s_{\text{opt}} = [(s_1 r_1)/(r_1 + r_2)] + [(s_2 r_2)/(r_1 + r_2)]$, where s_i is the estimate of the state variable from cue i, and r_i is the reciprocal of the variance for that cue.

Related Areas

Ideal observer theory has close connections to several other areas of neuroscience and cognitive science. Optimal control theory has a similar structure to that illustrated in Figure 1(a). In applications to motor control, the state variables change continuously in time and correspond to internal physical parameters that influence a movement. The Bayes's risk function is replaced by a cost function (e.g., physical energy of a movement), and the action rule is replaced by a control law.

Ideal observer analysis can be naturally extended to optimal learning. Bayes's optimal learning corresponds to updating the parameters (e.g., mean and variance) of the posterior distribution as new data come in. Rather than using the data to infer the causes or states of the generative model, we use Bayes' rule to learn the values of the parameters that determine the posterior.

Computational techniques such as expectation maximization (EM) and Bayesian belief propagation, have provided the means to deal with more complicated and non-Gaussian generative models, with applications to inference and learning. Future work should produce a growing number of applications to the experimental study of cognitive and neural processes.

Comparisons of ideal and human perceptual behavior inevitably lead to the question of the nature of the underlying neural mechanisms that might support ideal-like computation. One of the central issues is how information about uncertainty may be represented and processed in the nervous system.

Imaging Studies Using Reporter-Gene Transgenic Rats

A Kimura and E Kobayashi, Jichi Medical University School of Medicine, Tochigi, Japan

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In recent efforts to create specifically designed models for imaging experiments, mouse and rat have been essential. Mouse is an excellent experimental model that has well-developed genetic tools, but rat models also show greater benefit in surgical interventions due to their larger body size. Indeed, surgical manipulation of rats has provided excellent experimental models of neurological disorders, including brain infarction, Parkinson's disease, and spinal cord injury. These rat models have been valuable not only in elucidating disease processes but also in evaluating experimental therapies. We have created genetically engineered rats and tested their application in imaging experiments. Here, we outline the use of reporter gene-transgenic rats in imaging studies for neurological research.

Reporter Genes

There are a number of different methods for labeling cells of interest so that they can be tracked *in vivo*. Labeling with fluorescent dyes is an easy method; however, there is a drawback in that the signal intensity decreases during cell division and/or by photobleaching. In this regard, reporter genes that can be stably integrated into the genome have a distinct advantage over conventional methods, especially in long-term studies.

LacZ (β-Galactosidase)

For over two decades, lacZ has been the reporter gene of choice for a variety of biological experiments. LacZ is a bacterial gene that encodes hydrolase enzyme β-galactosidase, which breaks down the colorless substrate X-gal (5-bromo-4-chloro-3-indolyl-β-D-galactoside) into galactose and a blue insoluble product. LacZ is useful for labeling distinct populations of cells in chimeras or for reporting the activity of specific promoters; however, this reporter has a major disadvantage in that it requires tissue fixation and chemical staining for visualization. Other histochemical marker genes, such as alkaline phosphatase (AP) and β-glucuronidase (GUS), have a similar pitfall.

Green Fluorescent Protein and Spectral Variants

Green fluorescent protein (GFP), a novel fluorescent genetic reporter derived from the bioluminescent jellyfish *Aequorea victoria*, currently represents a unique alternative to other conventional reporter genes. Because wild-type GFP has unsatisfactory properties with regard to fluorescent intensity, folding properties, and biphasic excitation spectrum, many efforts were undertaken to optimize the properties of this protein by introducing point mutations, which finally led to the generation of enhanced green fluorescent protein (EGFP), with brighter fluorescence and a single excitation peak at 488 nm. The direct visualization of EGFP under excitation light has great advantage over conventional markers such as β-galactosidase (LacZ) and alkaline phosphatase, which require tissue fixation and chemical staining for visualization.

The improved properties of EGFP have brought innovations in a variety of biological experiments over the past decade. In principle, application of EGFP can be broadly categorized into two approaches. First, it can be used as a tag in a fusion protein to visualize its localization in time-lapse imaging of living cells. EGFP is usually much less harmful when illuminated in living cells than most small fluorescent molecules such as fluorescein isothiocyanate (FITC), which induces strong phototoxicity caused by the generation of free radicals. Imaging studies using EGFP-tagged proteins have provided valuable information about complex cellular processes that had been analyzed with fixed specimens in the past. Second, it can be used as a genetically encoded reporter gene to identify cells of interest *in vivo*. This latter application has become increasingly popular in imaging studies with the emergence of transgenic animals, in which EGFP is genetically encoded under the control of various promoters. EGFP-transgenic animals can be a source of EGFP-labeled cells or organs that can be transplanted into experimental disease models and be directly visualized under fluorescent light.

Spectral variants of EGFP have been developed by genetic manipulation of the EGFP gene; these include blue fluorescent protein (BFP), cyan fluorescent protein (CFP), and the yellow fluorescent protein (YFP), emitting blue, cyan, and yellow fluorescence, respectively. Furthermore, a red fluorescent protein was obtained by cloning a coral fluorescent protein (*Discosoma* sp.), and this was named DsRed. These spectral variants allowed the tracking of two, three, or even more distinct targets simultaneously.

Luciferase

Luciferases comprise a group of enzymes that emit light in the presence of oxygen and a substrate (luciferin). Such a luciferin–luciferase system is found in

nature, for example, in bacteria (*Vibrio harveyi*), dinoflagellates (*Gonycaulax*), and the firefly (*Photinus pyralis*). These luciferases, in particular the eukaryotic firefly luciferase (Luc), have been commonly used as a light probe in a number of biological experiments, including promoter activity assays. Furthermore, thanks to recent advances in high-sensitivity photon-counting video cameras, a number of studies have employed Luc as a reporter gene in real-time noninvasive *in vivo* imaging. This *in vivo* imaging allows the visualization of the spatial and temporal behavior of Luc-expressing cells in living animals; for example, growth of tumor cells, trafficking of immune cells, and migration of transplanted cells. These imaging studies using Luc-labeled cells have offered new insights that could not have been gained using conventional histological approaches.

Transgenic Animals Carrying a Reporter Gene

Establishment of Transgenic Animals

Transgenic animals are generally established by traditional zygote-injection-based technology or embryonic stem (ES) cell-mediated technology. However, transgenic rat models are established only by the former technology because of a lack of rat ES cell lines. Interestingly, in both technologies, established transgenic animals show variable intensity of reporter expression, depending on the animal lines, organs, phenotypes of cells, and developmental stages. Because the reporter-encoding DNA is randomly integrated into the genomes, the expression of a reporter gene is largely influenced by the integration site. Therefore, careful selection of lines is required to obtain animals with sufficient and stable reporter expression. The variability in gene expression caused by the positional effect of integrated DNA is a weak point of conventional transgenic technology; however, once an animal line with preferential reporter expression is established, the phenotype is stably inherited by the progeny. In addition, the intensity and specificity of reporter expression depends largely on the type of promoter that drives a reporter gene. The promoters are broadly divided into two categories: (1) tissue-specific promoters and (2) ubiquitous promoters.

Tissue-Specific Promoters

In neurological disease research, specifically labeled neurons, glial cells, and immune cells are extremely valuable in elucidating disease processes and in evaluating experimental therapies. Transgenic animals with tissue-specific promoters enable the selective labeling of cells or tissues *in vivo*. In particular, fluorescent proteins driven by the Thy1 promoter specifically label neurons and even individual organelles in neurons; that is, the cytoplasm, membranes, mitochondria, and axon tracts can all be selectively labeled. Specifically labeled transgenic mouse models are further advanced than similar rat models. Thy1-driven fluorescent protein transgenic mice have been used to explore the formation of synapses and the regeneration processes of severed axons. Other cellular elements of the central nervous system, including astrocytes, oligodendrocytes, and microglia, can be selectively labeled with fluorescent proteins under the control of the specific promoters, such as glial fibrillary acidic protein (GFAP) promoter, proteolipid protein (PLP) promoter, and CX_3CR1-locus S100 promoter, respectively. These transgenic mice, combined with emerging optical imaging technologies including multiphoton microscopy, have the potential to elucidate the complicated biological processes occurring in neuroinflammatory lesions.

Ubiquitous Promoters

Housekeeping-type promoters, such as cytomegalovirus (CMV) enhancer/chikin β-actin (CAG), thymidine kinase (TK), Simian virus 40 (SV40), and ROSA26, drive general expression of reporter genes. There are a variety of transgenic lines that express a reporter gene extensively in their organs, driven by ubiquitous promoters. This type of transgenic animal model has been developed not only in mice but also in animals with a larger body size, such as rats, rabbits, and pigs. The mouse represents the premier mammalian model organism; however, its use for biomedical research involving surgical manipulation may be restricted due to limitations imposed by its body size. In contrast, rats are suitable for surgical manipulation because of their larger body size, which also makes it easy to produce disease models and to test various therapeutic interventions in clinical medicine. Therefore, we have focused on establishing transgenic rats with generalized reporter gene expression driven by a ubiquitous promoter. These rats were designed for the use of imaging experiments, especially to trace the fate of cells involved in transplantation therapy. Here, we describe some examples of the use of transgenic rat lines in investigating stem cell-based therapy.

Tracking of Green Fluorescent Protein-Labeled Neural Stem/Progenitor Cells

Transplantation of neural stem/progenitor cells (NSPCs) has emerged as a potential therapeutic strategy for various disorders of the central nervous

Figure 1 Differential GFP-expression pattern between CAG/GFP-Wistar, CAG/GFP-LEW Tg rats, and wild-type LEW rats: (a–d) small intestine; (e–h) liver; (i–n) brain. Representative organs were removed from CAG/GFP-LEW (panels (a), (b), (e), (f), (i), and (j)) and CAG/GFP-Wistar Tg rats (panels (c), (d), (g), (h), (k), and (l)) and examined under visible (panels (a), (c), (e), (g), (i), (k), and (m)) or 489 nm excitation light (panels (b), (d), (f), (h), (j), (l), and (n)). Panels (m) and (n) are from wild-type LEW rats (as a negative control). CAG, CMV enhancer/chikin β-actin; GFP, green fluorescent protein; LEW, Lewis; Tg, transgenic.

Figure 2 Migration of neural progenitor-derived cells to the cerebral infarction area: (a) neural progenitor cells from CAG/GFP-LEW Tg rats expressing substantial levels of GFP, as seen under 489 nm excitation light 40× magnification); (b) nestin (red color) expressed in neural progenitor cells from CAG/GFP-LEW Tg rats (40× magnification); (c) representative scheme of stereotactic microinjection into the cerebral ventricle; (d) accumulation of GFP^+ neural progenitor-derived cells in the area of the cerebral infarction. CAG, CMV enhancer/chikin β-actin; CC, corpus callosum; Ctx, cortex; GFP, green fluorescent protein; LEW, Lewis; LV, left ventricle; Scp, superior cerebellar peduncle; Str, striatum; Tg, trangenic.

system. Following the fate of transplanted cells (e.g., survival, proliferation, migration, and differentiation) with appropriate markers is indispensable for elucidating uncharacterized regeneration processes involved in stem cell-based therapies. Transgenic animals carrying a fluorescent protein can be an ideal source of genetically labeled NSPCs. Recently, our group established a new GFP-Lewis rat

Figure 3 Establishment of Luc-Tg rats: (a) representative scheme of transgene composition; (b) representative luminescent images of Luc-Tg rats (hemizygote, homozygote, and wild-type (WT) littermate); (c) luciferase expression profile in various tissues from the Luc-Tg rats; (d) luciferase activity in Luc-Tg embryos in the pregnant rat; (e) isolated rat embryos emitting luminescent light in the presence of D-luciferin (upper photos: appearance of rat embryos; lower photos: luminescent imaging). As shown in (a), the transgene consists of the ROSA26 promoter and a firefly luciferase gene. In (b), luciferase activity in the Luc-Tg homozygote rat was almost twice that in the hemizygote rat. The values in the right lower corners represent total photons per animal (in photons per second). As shown in (c), luciferase expression is ubiquitous and is particularly strong in the liver, lung, brain, skin, thymus, and eye. The red dotted line represents the background level (WT rat skin). In (d), the WT LEW female rat was mated with the Luc-Tg male rat, and embryos obtained at 14.5 embryonic days were safely visualized using luminescent imaging. Arrows indicate the location of Luc-Tg embryos in a pregnant rat. BM, bone marrow; LEW, Lewis; Luc, luciferase; Tg, trangenic.

Figure 4 *In vivo* imaging using dual-reporter transgenic rats: (a) BMCs obtained from the (Luc × GFP) F1 rat transplanted into lethally irradiated wild-type Lewis rats; (b) hepatocytes obtained from the (Luc × LacZ) F1 rat transplanted into the portal vein of hepatectonized wild-type Lewis rats. Shown in (a) are a representative scheme of luminescent *in vivo* imaging (left) and flow cytometry analyses of GFP-positive cells in peripheral blood 30 days after transplantation (right). Shown in (b) are a representative scheme of luminescent *in vivo* imaging (left) and X-gal staining of the recipient liver (right). BMCs, bone marrow cells; GFP, green fluorescent protein.

(CAG/EGFP-Lewis rat) that expresses GFP strongly and ubiquitously in most organs, including the central nervous system, compared with the previously established GFP-Wistar rat (CAG/EGFP-Wistar rat) (Figure 1). NSPCs derived from fetal brains of GFP-Lewis rats also expressed high levels of GFP (Figure 2(a)). Most of the GFP^+ NSPCs were positive for the neural stem cell marker Nestin (Figure 2(b)), and they differentiated into neurons, astrocytes, and oligodendrocytes after the removal of growth factor and addition of serum. To investigate the potential of GFP^+ NSPCs to be tracked *in vivo* after cell transplantation, we employed a rat cerebral infarction model. Briefly, a rat with a cerebral infarction received a stereotactic injection of $EGFP^+$ NSPCs into the cerebral ventricle. Four weeks later, the accumulation of $EGFP^+$ NSPCs around the cerebral infarction area was examined (Figure 2(c)). The GFP fluorescence was sufficient to allow visualization of cells without the need for immunohistochemical amplification.

In Vivo Tracking of Luciferase-Labeled Cells

A growing number of studies have employed Luc as a biological light probe for real-time *in vivo* imaging. Luc-labeled cells can be visualized externally in living animals using a luminescent imaging device because luminescence from the Luc–luciferin reaction has significantly greater signal-to-noise ratios in mammalian tissues. *In vivo* imaging was applied to some experimental models of neurological diseases in relation to NSPCs. Previous studies have visualized the recruitment of Luc-labeled NSPCs toward sites of brain infarction and brain tumors in living animals. Accumulation of transplanted Luc-labeled NSPCs in the injured spinal cord was also visualized using time-lapse *in vivo* imaging studies, in which Luc was genetically encoded by a virus-mediated approach.

Recently, our group established a Luc-transgenic rat (ROSA/Luc-Lewis rat) that expresses Luc in

almost all organs, including the central nervous system (Figure 3). NSPCs were cultured from fetal brains of Luc-transgenic rats, and their expression of Luc was verified *in vitro* (data not shown). Therefore, this transgenic rat model, combined with *in vivo* imaging technologies, may be useful for research of neural stem cell-based therapies.

Imaging Studies Using Dual-Reporter Genes

Real-time *in vivo* imaging using the Luc–luciferin system is an attractive tool for a variety of biomedical research, but it has some pitfalls. First, the luminescence signal emitted from a small number of cells cannot be detected externally in living animals, even under highly sensitive imaging devices, whereas the minimum number of cells required for detection is influenced by the intensity of Luc expression. Second, Luc-labeled cells are portrayed as poorly marginated areas in *in vivo* imaging systems. Histological examinations after *in vivo* imaging experiments may partially resolve these problems; however, the enzymatic activity of Luc is lost in fixed specimens. Third, Luc-labeled cells are not appropriate for flow cytometry analysis, in contrast to GFP-labeled cells.

To address these problems, we developed dual-reporter gene transgenic rats. Our transgenic rats, which express single reporter genes such as Luc, LacZ, and GFP, are inbred Lewis rat lines. Thus, we can obtain dual-labeled rats by mating these lines with one another. When Luc-transgenic Lewis rats were mated with GFP-transgenic Lewis rats, the hybrid progeny ((Luc × GFP) F1 rat) represented a source of Luc-GFP-dual-labeled cells. These dual-labeled cells can be applied not only to *in vivo* imaging but also to flow cytometry analysis (Figure 4(a)). In the same way, (Luc × LacZ) hybrid rats provide Luc-LacZ-dual-labeled cells that can be visualized by X-gal staining after the period of *in vivo* imaging (Figure 4(b)).

Immune Function During Sleep and Sleep Deprivation

J M Mullington, Harvard Medical School, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Context and Questions

Physicians through the ages have recommended rest and sleep to assist in the healing and recovery process. Most of us have experienced a time when we were overcome by sleepiness due to an illness and were unable to function, leaving little alternative but sleep. Once infection is established, it seems that sleep aids in the healing process, but does it actually help to clear the body of pathogens and, if so, how? It is also common experience that when we do not get adequate sleep for a prolonged period, we become 'worn down' and feel susceptible to common colds and other ailments. It is clear that sleep responds to challenges to the host defense system (the body's immune protective and defensive systems), but does sleep actually serve a function in defending against microbial invasion? Are host defenses bolstered in some way by sleep? Do adequate quantity and quality of sleep assist in building defenses against future attacks? Does poor sleep, or going without sufficient sleep for a period, compromise the early host defense system or the development of immunological memory? Does sleep support good health in a more general way, such as supporting homeostatic endocrine and metabolic systems that facilitate a balanced and measured host defense? Host defense mechanisms are highly integrated in physiology, and so the answers to these questions will not be simple. Controlled studies designed to test these intuitive assumptions have been sparse. An overview of the major findings is provided in this article.

Sleep Responds to Experimental Immune Challenge

Animal Models

Studies carried out in many species have shown that animals need sleep in order to survive. If deprived of sleep, rats will die within approximately 3 weeks. In studies in which infectious agents were administered to rabbits, the probability of survival was increased in animals that slept more and whose sleep following challenge showed enhanced slow-wave activity. The animals that were able to increase their slow-wave sleep were not only more likely to survive but also had higher increases over baseline in their white blood cell count (immune participating) and a lower triglyceride response to challenge (a marker of the acute phase response or early immune response to infection or trauma) compared to the animals that died. Sleep, it seems, does help the recovery process.

There are specialized receptors for the outer membrane lipopolysaccharide (LPS) fragment of gram-negative bacteria, called CD14 receptors, that work through a JAK-STAT (Janus kinase and signal transducers and activators of transcription) pathway to activate the production of inflammatory protein mediators such as interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α), interleukin-6 (IL-6), and others within immune-competent cells such as the monocyte, macrophage, and endothelial cell in the periphery and glial cells in the brain. In animals, levels of IL-1β and TNF-α in the brain vary with the sleep–wake cycle and are increased following host challenge.

Several studies in animal models have shown that IL-1β and TNF-α are key stimulators of the central nervous system (CNS) production of sleep and enhanced slow-wave activity, and they are therefore thought to be important for physiological sleep regulation. If the production of these proinflammatory cytokines is inhibited, the sleep-inducing and -enhancing effects are also inhibited. In fact, blocking TNF-α and IL-1β inhibits normal increases in non-rapid eye movement (NREM) sleep that occur after sleep deprivation. Anti-inflammatory factors such as glucocorticoids or counterinflammatory cytokines such as IL-10 also reduce the normal NREM rebound following sleep deprivation.

The CNS response to immune challenge is not linear. Sleep may aid in recovery in animals experimentally challenged with pathogens, but there are clear dose-dependent effects in the response to challenge. Rabbits and rats show increased NREM sleep despite moderate fever. Beyond a certain level of inflammatory system activation and fever, sleep onset is delayed and/or fragmented. The NREM slow-wave enhancing properties of this CNS response to the acute phase reaction is not simply a by-product of fever because studies that have blocked the fever response to challenge have shown that sleep is nonetheless enhanced. Further evidence comes from species-specific differences – for example, the human sleep response to LPS.

Human Models

As a species, we are exquisitely sensitive to gram-negative LPS and achieve fevers after being challenged with very small amounts of endotoxin. The preparations used for research in humans and those used in animal research are very different. When prepared for human use, endotoxin is stripped

of protein so that real infection does not develop. It is the outer membrane component of the gram-negative bacteria, the LPS fragments, that cause the pyrogenic response. Approximately 1 h after injection, TNF-α is already elevated and temperature begins to increase. Unlike the typical NREM sleep response in rabbits and rats that occurs in the context of moderate fever, humans show increased NREM slow-wave sleep only when the dose of LPS is subpyrogenic and when it is too low to increase cortisol. This subpyrogenic dose of LPS is nonetheless able to cause manyfold increases in key cytokines such as TNF-α and its receptors, p55 and p75. IL-1β is generally not measured in peripherally sampled plasma due to insufficient assay sensitivity. Based on animal studies, TNF effects on sleep appear to be mediated through the TNF type 1 receptor (p55) and not its type 2 receptor (p75).

Effects of Sleep Deprivation on Host Defense

Animal Models

The role of sleep in host defense mechanisms is complex. Although there is ample evidence that sleep is necessary for survival, there is also apparently contrary evidence suggesting it is not so important for adequate host defense. For example, although the likelihood of survival is increased by slow-wave sleep following lethal challenge in rabbits, sleep deprivation in rabbits for 4 h by gentle handling, prior to an endotoxin challenge, leads to higher fevers than found in animals that were permitted to sleep prior to challenge. If animals were similarly deprived after challenge, there were no differences in fever response. In fact, except for the fever response, sleep deprivation did not alter the severity of clinical parameters in response to infection. Blood cells, triglycerides, and stress hormones (cortisol and corticosterone) were not negatively impacted by sleep deprivation. The deprivation used may not have been severe enough to cause the expected changes in host response, and the time window with which to see the changes may not have been ideally placed. However, another study using an influenza challenge also failed to demonstrate a sleep advantage compared with sleep deprivation that preceded and/or followed inoculation. Taking yet another approach, tumors implanted in rats that are subsequently sleep deprived shrink in size, counter to what would be expected if sleep loss was compromising host defense. Furthermore, one study in rats failed to find any positive effects of sleep versus 72 h of sleep deprivation on wound healing. Thus, it seems that sleep deprivation, for at least variations of relatively plausible duration, do little to compromise the host defense response to various forms of challenge. This does not mean that sleep is not involved in supporting host response systems, but it does indicate that the systems function very well and hold up for reasonably long deprivation periods. This is perhaps not surprising, given the central importance of the host defense system for survival and the evolutionary necessity to have the ability to maintain wakefulness for prolonged periods in order to flee danger.

As noted previously, sleep deprivation in animal models does lead to death, usually within 2 or 3 weeks of total sleep deprivation and up to 6 weeks when REM sleep is selectively deprived. Although the ability of animals to withstand the deprivation varies greatly, the pattern of physiological changes is quite consistent. Norepinephrine levels increase early in both total and REM sleep deprivation. Body temperature is increased during the first half of the survival period during total sleep deprivation, but the second half of REM and total sleep deprivation periods are marked by decreases in temperature. Animals undergoing sleep deprivation lose weight despite increased food consumption. This increased energy expenditure and thereby negative energy balance are accompanied by changes in metabolic markers, including decreases in total and free thyroxine and triiodothyronine and reductions in growth hormone, insulin-like growth factor 1, prolactin, and leptin. Fur becomes dull and unkempt in appearance, although grooming time is maintained; tail and paw lesions form.

Leukocytes and some mediators of the immune system (innate and cellular) have been reported to increase under conditions of total sleep deprivation in rats. In addition, consistent with a model of sepsis, bacterial pathogens have been found in organs and tissues of sleep-deprived animals, and these findings have been interpreted by some as evidence of failure of host defense systems. This interpretation is not without opposition, however, because antibiotic treatment is quite successful at controlling aerobic bacteria during deprivation but the animals proceed to accumulate a negative energy balance and die within the same time frame as untreated animals. However, human sepsis, once begun, is often treatment resistant in spite of antibacterial intervention.

In interpreting the findings, it is important to remember that host defense systems are complex and broad in terms of systems mobilized. Sleep supports very complex homeostatic systems, and therefore short-term deprivation and a long-term sleep deficit may have different effects. Very few data are available to enable comparison of the effects of experimental chronic partial sleep deprivation, in which

sleep is reduced to a percentage of normal sleep diet for a prolonged period, and total sleep deprivation, in which no sleep is permitted.

Normal Rhythms of Immune-Active Cells and Modulating Hormones in Humans

A diurnal rhythm in human circulating blood cells has long been established. In Figure 1, the diurnal pattern of white blood cells and cortisol is illustrated for 25 healthy male and female volunteers between the ages of 25 and 53 years. Participants slept between 11:00 p.m. and 7:00 a.m. before and during the blood sampling period. Blood was sampled every 4 h through an indwelling forearm catheter and results are shown for a 36 h period. The clearly established rhythm of cortisol can be seen. The time of day of lowest circulating levels is morning to early afternoon for lymphocytes, monocytes, and eosinophils, and through the sleep period for neutrophils. Several hormones that show diurnal variation have been reported to modulate immune activity, most notably cortisol, growth hormone, and prolactin. Studies have reported a diurnal rhythm in several circulating cytokines as well, with IL-6 consistently showing an early morning nadir and a nocturnal peak. TNF-α and its receptors have also been reported to have diurnal rhythms, but the peaks and troughs of these rhythms are less consistent across studies.

Cortisol is a clear modulator of immune response. It is used at pharmacological doses to suppress immune function, and at physiological levels it participates in the modulation of the early host response to endotoxin challenge in humans.

Sleep Deprivation in Humans

An interplay of balance between cellular and humoral immune system responding has been described in which type 1 responses are predominantly cellular and type 2 predominantly humoral. The hormonal and cytokine milieu associated with healthy sleep supports growth, probably including development of immunological memory because monocyte production of IL-12, a key cytokine involved in the development of cellular (type 1) memory, is increased during sleep in humans.

Total and partial sleep deprivation studies have been carried out investigating levels of circulating white blood cells and inflammatory mediators. In humans, total sleep deprivation studies have found monocytes and neutrophils to be increased and lymphocytes decreased. Studies of prolonged partial sleep deprivation have also found increased white blood cells due to deprivation. Both total and partial sleep deprivation studies have found that circulating levels of IL-6 and C-reactive protein (RCP) are increased in healthy volunteers. The soluble TNF receptor 1 has been shown to increase during acute total sleep deprivation. These changes may indeed be related to autonomic changes because some studies have shown norepinephrine to be increased in sleep deprivation,

Figure 1 Diurnal rhythm in cortisol and white blood cells. Twenty-five healthy men and women slept between 11:00 p.m. and 7:00 a.m., and blood was drawn through intravenous forearm catheter at 4 h intervals for 36 h. The shaded bar illustrates the time of the sleep period, and the 4 h measurements are shown with standard error bars.

Figure 2 Effects of acute sleep deprivation on C-reactive protein (CRP) and systolic blood pressure (SBP). The average data are shown for the baseline (bl) day, days 1–3 of wakefulness (d1–d3; 88 h total), and the recovery day (r1). Data from Meier-Ewert HK, Ridker PM, Rifai N, et al. (2004) Effect of sleep loss on C-reactive protein, an inflammatory marker of cardiovascular risk. *Journal of the American College of Cardiology* 43: 678–683.

and several studies have shown blood pressure to be increased during sleep deprivation. As can be seen in Figure 2, systolic blood pressure has been found to increase with a time course similar to that of CRP. Although the IL-6 and CRP elevations are small, they may be very important in long-term health.

IL-6 and CRP are important acute phase markers of the innate immune system (the type of immunity that humans have without requiring exposure and development of immunological memory) known to be elevated in overweight individuals and which have been linked to development of future cardiovascular disease and diabetes, even independent of their relationship with adiposity. It is important to understand that even very small subclinical elevations in inflammatory mediators have been linked with future risk for the development of disease. It has only been possible to detect these small basal shifts with improvements in assay technology that were made about a decade ago. For this reason, epidemiological studies have only recently been uncovering important predictive relationships that not long ago were undetectable. What used to be thought of as subclinical from the perspective of the acute phase response is now understood to be meaningful from the perspective of understanding risk and disease vulnerability. Do these shifts in inflammatory mediators seen during sleep deprivation translate into increased risk for future disease development? It is too early to know. However, epidemiological studies show that there are risks associated with habitual short sleep duration.

Epidemiological studies show that individuals who sleep less than 6 h per night are at increased risk for developing future cardiovascular disease and diabetes, independent of other known risk factors such as body mass index. Individuals with sleep-disordered breathing have higher levels of inflammatory mediators, including IL-6 and CRP. Of particular importance in this regard, healthy asymptomatic individuals with very low-level basal increases in CRP have a higher likelihood of developing future cardiovascular disease. This association has also been described for other proinflammatory cytokines such as IL-6, but CRP is particularly useful to examine in population-based studies because it is quite stable and has a long half-life (between 15 and 19 h) and has been shown not to have a diurnal rhythm.

Individuals with disturbed sleep due to disorders such as sleep apnea have been reported to show elevated basal levels of proinflammatory cytokines. It is less clear whether treatment of these disorders resolves the elevated basal inflammatory mediators and to what extent these changes are related to metabolic changes. However, sleep deprivation alters basal metabolic function, which in itself is likely to contribute to changes in immunological homeostasis. Sleep plays a key role in maintaining homeostasis of physiological systems – most important, metabolic and endocrine systems. It is reassuring that host defense mechanisms are intact in the face of acute short-lasting deprivation, but in the long term, sleep is essential for life and both chronic partial sleep deprivation and severe acute sleep deprivation are associated with increased inflammation. Elevations in inflammatory mediators are associated with the development of many diseases, and further investigations are needed to determine the contribution of insufficient sleep to their etiology.

Immune System–Neuroendocrine Interactions

Introduction

Inflammation is a general name for reactions occurring after most kinds of tissue injuries or infections or immunologic stimulations as a host defense against foreign or altered endogenous substances. The local inflammatory reaction is characterized by an initial increase in blood flow to the site of injury, enhanced vascular permeability, and selective accumulation of different effector cells from the peripheral blood to injured regions. These cells, mostly circulating neutrophils and monocytes and locally resident macrophages, together mount a rapid inflammatory response that is characterized by the secretion of cytokines, among other features (Figure 1). Their secretion into the bloodstream is a key step in triggering the neuronal activity and subsequent neurophysiological responses that take place during systemic and localized tissue insults. Cytokines influence many neuroendocrine systems, the most prominent of which is the hypothalamic–pituitary–adrenal (HPA) axis, activation of which results in the release of adrenocorticotrophic hormone (ACTH) and glucocorticoids. Once present in the bloodstream, these cytokines also have the ability to increase body temperature (fever) and cause symptoms of sickness. The proinflammatory cytokine interleukin-1 (IL-1), especially its β form (IL-1β), is probably the most important molecule capable of modulating cerebral functions during systemic and localized inflammation. Systemic IL-β injection activates the neurons involved in the control of autonomic functions, and neutralizing antibodies or IL-1 receptor antagonists are capable of preventing numerous responses to inflammatory stimuli. Studies in IL-1β-deficient mice have provided solid and compelling evidence supporting the critical role played by this cytokine in neural–immune interaction.

Other cytokines implicated in neuroendocrine and febrile responses include tumor necrosis factor-α (TNF-α) and IL-6. Like IL-1β, intravenous TNF-α injection has a profound influence on the brain, on fever, and on hormones of the HPA axis. In contrast, the role of IL-6 in neuroendocrine and febrile responses is quite controversial. From the observation that IL-6-deficient mice were unable to develop normal fever in response to lipopolysaccharide (LPS) and IL-1β, IL-6 has been defined as one of the principle endogenous pyrogens. It has also been demonstrated that prostaglandins (PGs) mediate IL-6-induced fever and activation of the HPA axis, but IL-6 is unable to stimulate PG formation in the brain. However, a specific antiserum to IL-6, IL-6AS, was able to prevent LPS-induced febrile response, and cyclooxygenase 2 (COX-2)-deficient mice do not develop fever in response to icv IL-6 injection. The mechanisms by which IL-1β and IL-6 activate the autonomic functions are likely to be quite different, and IL-1β is clearly more potent than IL-6 in triggering PGE_2 synthesis in the central nervous system (CNS).

Possible Pathways by Which Circulating IL-1β Signals the Brain

The transport of soluble substances across vascular compartments occurs via either paracellular or transcellular mechanisms. Within the cerebrovasculature, the paracellular route is particularly impermeable because of the blood–brain barrier (BBB). The BBB consists primarily of nonfenestrated endothelial cells that are connected by tight junctions. Furthermore, the large molecular sizes (13–15 kDa) and hydrophilic nature of cytokines preclude their transcellular movement by simple diffusion to any appreciable extent, and early studies concluded that the BBB was impermeable to IL-1β. It is nevertheless possible that endogenous cytokines diffuse across the BBB during extreme periods of fever or in presence of high levels in plasma during a long period of time.

Regions relatively devoid of BBB permit cytokine interaction with the neuronal elements. The circumventricular organs (CVOs) contain capillaries with rather greater permeability than the rest of the CNS, and the vascular density in these regions is extraordinarily high. Therefore, the CVOs have been proposed as potential sites of action, in particular the structure lining the anteroventral third ventricle region, namely the organum vasculosum of the lamina terminalis. The subfornical organ, median eminence, and area postrema are the other potential target CVOs. On the other hand, a medullary group of cells may play an important role in processing visceral sensory information carried out by the vagus and glossopharyngeal nerves. The vagus nerve has indeed been proposed to provide a rapid communication pathway for cytokine signaling between the periphery and brain, but this pathway depends on dosage and route of administration.

On the other hand, a strong body of evidence now supports the concept that cytokines, particularly IL-1, act on the microvasculature, with consequent release of local signaling molecules, namely PGs. Indeed, brain microvessels exhibit constitutive expression levels of IL-1 type 1 receptor transcript, and systemic

Figure 1 Innate immune response evoked by endotoxic lipopolysaccharide (LPS). LPS is a major component of the outer membranes of Gram-negative bacteria, which is the best-characterized example of innate recognition associated with a robust inflammatory response by phagocytic cells. Secretion of cytokines by circulating monocytes/neutrophils and tissue macrophages by LPS requires a series of mechanisms in cascade, the first step being the binding of the LPS with the serum proteins LPS-binding protein (LBP) or septins. The newly formed complex may then activate different populations of cells by binding to its CD14 receptor and toll-like receptor 4 (TLR4). The latter is the actual signaling receptor for LPS. Two forms of CD14 receptors can be found. The first is present on the surface of myeloid cells (mCD14) and acts as a glycosyl-phosphatidylinositol (GPI)-anchored membrane glycoprotein; the other form is soluble in the serum (sCD14) and lacks the GPI properties, though it can bind LPS to activate cells devoid of mCD14, such as endothelial cells. LBP is not essential for LPS signaling, but the LPS–LBP complex is particularly powerful in activating cells of myeloid origin, that is, neutrophils, monocytes, macrophages, and microglia. One of the well-known consequences of such activation is the production of proinflammatory cytokines, such as interleukin (IL)-1β (IL-1β), tumor necrosis factor alpha (TNF-α), and IL-6. These cytokines may, in turn, bind to their cognate receptors expressed on the surface of cells forming the blood–brain barrier, but they are not essential for mediating the effects of LPS in the central nervous system. LPS is an exogenous ligand for cerebral tissue that expresses both LPS receptors. Such an innate immune/inflammatory response also takes place during tissue injuries and in presence of more complex pathogens (e.g., bacteria and viruses). See text for details. COX-2, cyclooxygenase 2; EP_4, a prostaglandin E receptor; PGE2, prostaglandin E_2; R, receptor.

IL-1β injection causes a rapid and profound transcriptional activation of the gene encoding COX-2 in cells lining the CNS blood vessels. Circulating IL-1 also induces microsomal PGE synthase (mPGES-1), which co-localizes with COX-2 in the perinuclear region of the cerebral endothelium. Of great interest are the data that mPGES-1-deficient mice failed to develop fever in response to either systemic LPS and IL-1, but not to centrally administered PGE_2. These data clearly underline the critical role of the PGE_2 machinery in the endothelium of the brain's blood vessels to activate the autonomic functions during systemic inflammation.

Biosynthesis of PGs

Prostanoids are a group of 20 carbon-unsaturated fatty acid derivates that are produced via a complex enzymatic cascade. First, COX activity adds molecular oxygen to the unsaturated fatty acid arachidonic acid, generating PGG_2. PGG_2 is then converted to PGH_2 by the peroxidase activity of the enzyme.

Once generated, PGH_2 is rapidly converted to PGs (PGD_2, PGE_2, and $PGF_{2\alpha}$), prostacylin, and thromboxane A_2 by tissue-specific synthases. PGE synthase has recently been identified and designated as mPGES and cytosolic PGES (cPGES). These molecules or their derivatives interact with specific receptors to modulate cell function. The diversity of the tissue-specific synthases and receptors gives rise to a wide range of potential biologic functions for the prostanoids. PGG, PGH, prostacyclin, and thromboxane A are chemically unstable and are degraded into inactive products under physiological conditions, with a half-life of 30 s to a few minutes. Other PGs, although chemically stable, are metabolized quickly. It is therefore believed that prostanoids work locally, acting only in the vicinity of the site of production to serve as potent autocrine and paracrine mediators in a wide variety of physiological processes. Although PGE_2 rises in blood promptly after the entry of microorganisms or in response to the endotoxin LPS and cytokines, it is now generally accepted that the PGE_2 detected in the brain is not derived from the blood but rather is produced directly within the CNS.

It is therefore proposed that circulating LPS and cytokines bind to their cognate receptors onto endothelial and/or monocytic cells lining the BBB, which leads to proinflammatory signaling and transcription of the enzymes responsible of the PGE_2 formation in the cerebral tissue. It is interesting to note that systemic inflammatory insults induce COX-2 and mPGES in a rather unspecific manner across the cerebral blood vessels and small capillaries, whereas the neuronal activity is limited to selective nuclei, including the endocrine hypothalamus. It is thus possible that expression of specific PGE_2 receptors within parenchymal cells adjacent to the site of production determines the action of the PG in the brain.

PGE_2 Sites of Action

Classic prostanoid receptors comprise a family of eight encoding transmembrane G-protein-coupled receptors. These receptors are classified on the basis of selective affinities for naturally occurring prostanoids. There are distinct receptors for thromboxane A_2, prostacylin, $PGF_{2\alpha}$, and PGD_2 and four different receptors for PGE_2 (EP_{1-4}). Multiple alternatively spliced isoforms exist for the PGE_2 EP_3 receptor ($EP_{3\alpha}$, $_{3\beta}$, $_{3\gamma}$). They share common extracellular and membrane-spanning regions but differ in intracellular and C-terminal domains. Each receptor is associated with a unique G-protein and consequently a unique second messenger system, namely, elevation of intracellular Ca^{2+} (EP_1) and stimulation (EP_2 and EP_4) or inhibition of (EP_3) of adenylate cyclase. Despite the presence of some conserved sequences, overall homology among the prostanoid receptors is quite limited, ranging from 20–30%. On the other hand, the homology of a given type or subtype of receptor among various species is considerably higher. Each of the eight types and subtypes of receptors shows selective ligand binding specificity that distinguishes it from the others. In addition to transmembrane receptors, the peroxisome proliferator-activated receptor-γ is a member of the nuclear receptor family of transcription factors that can be activated by binding to PGD derivates, such as 15-deoxy-Δ12,14 PG J_2.

In 1988, the distribution of [^{3}H] PGE_2-binding sites, presumably PGE_2 receptors, was first demonstrated in the monkey diencephalon, and more-detailed analysis of [^{3}H] PGE_2-binding sites in rat brain ensued. PGE_2-binding sites were located in a number of discrete brain regions, including thalamic and hypothalamic nuclei, ventral hippocampus, central gray, superior colliculus, parabrachial nucleus, locus coeruleus, raphe nuclei, spinal trigeminal nuclei, and nucleus of the solitary tract (NTS). *In situ* hybridization was thereafter used to determine the exact distribution of each PGE_2 receptor subtype. The hypothalamic paraventricular (PVN) and supraoptic nuclei exhibited EP_1-expressing cells, but a wide distribution was found for the gene encoding the EP_3 subtype. Investigators have reported a very distinct pattern of EP_2- and EP_4-expressing neurons throughout rat brain; that is, EP_2 receptor messenger RNA (mRNA) was detected in the bed nucleus of the stria terminalis, lateral septum, subfornical organ, ventromedial hypothalamic nucleus, central nucleus of the amygdala, locus coeruleus, and area postrema, while EP_4 receptor transcript was located mainly in regions involved in the control of neuroendocrine and autonomic activities. Moderate doses of LPS or IL-1β activate EP_4 neurons, and this activation is prevented when animals are pretreated with COX inhibitors.

All four PGE_2 EP receptor mRNAs are expressed in the anteromedial preoptic region that plays a crucial role in the febrile response. Among these, only EP_4 receptor mRNA is strongly expressed throughout the PGE_2-sensitive regions, including the organum vasculosum of the lamina terminalis, ventromedial preoptic nucleus (VmPO), and median preoptic nucleus. These EP_4-expressing neurons are also activated by systemic inflammation, whereas EP_2- and EP_3-positive neurons do not respond. EP_1 receptor mRNA is present in PGE_2-sensitive regions, but its expression level is weak. Thus, EP_4 may be the key binding and functional receptor for PGE_2 in the brain to activate the circuits involved in autonomic control.

Nevertheless, pharmacological and genetic mutation experiments suggest otherwise. Drugs with

agonist and antagonist properties for each EP receptor have been used in rats. Injection icv of 17-phenyl-ω-trinor-PGE_2 (an EP_1 and $EP_{3\alpha}$ receptor agonist), but not butaprost, M&B28767, or 11-deoxy-PGE_1 (EP_2, $EP_{3\alpha}$, and EP_4 receptor agonists, respectively), induced fever, and SC19220 (an EP_1 receptor antagonist) prevented the febrile response to PGE_2. Another pharmacological study indicated that EP_2 or EP_3 receptor might be the receptors necessary to produce fever. In mice bearing genetic deletions of the EP_{1-4} receptors, only EP_3-knockout animals failed to show the early phase of fever (up to 1 h) after LPS iv or PGE_2 icv. It is important to note, however, that EP_4-deficient mice do not survive and have to be intercrossed in a different background. It is therefore quite difficult to compare them with the other gene-deficient mice, and inducible EP_4 knockout mice will be essential to clearly define the role of this receptor in the brain of mature animals. The relative lack of specificity of EP_4 antagonists and agonists in the species studied may also explain the pharmacological data. It is nevertheless possible that the anatomy and circuits unraveled by functional indices of neuronal activity have little to do with the physiological outcomes, namely, fever and increased activity of the HPA axis.

Functional Circuits by Intraparenchymal PGE_2

Without such anatomical work, however, it is not possible to clarify the exact pathways and groups of neurons involved in neural–immune interaction. Indeed, the final picture is far from complete. The following cascade of events is based on the data described above, but a few steps still remain to be fully validated and should therefore be considered working hypotheses:

1. Endotoxin LPS reaches the bloodstream and binds to the serum protein LPS-binding protein (LBP). The newly formed complex then binds to membrane CD14 and TLR4 receptors located on the surface of myeloid cells, triggering NF-κB signaling, nuclear translocation, and cytokine gene transcription (Figure 1). Pro-IL-1β and-TNF-α have to be cleaved by specific cytosolic enzymes before being transported into the extracellular environment. Recent data suggest a critical role of extracellular adenosine triphosphate and the P2X7 receptor in this final secretion process. Once in the bloodstream, both IL-1β and TNF-α can act on distant organs to trigger different physiological responses by binding to their respective type I receptors.

2. The endothelial and perivascular cells are the most obvious target cells in the CNS because they constitutively express numerous cytokine receptors and they are highly sensitive to low circulating levels of proinflammatory molecules. It is important to note that circulating LPS is also a direct ligand for these cells and that the release of circulating cytokines is not a prerequisite for LPS activation of the endothelial and perivascular cells lining the BBB.

3. Circulating LPS/LBP, IL-1, and TNF initiate COX-2 and mPGES transcriptions through a NF-κB and mitogen-activated protein kinase (MAPK) pathway, which is activated within seconds on ligand–receptor interaction. This leads to PGE_2 synthesis and release by the endothelium and pericytes of the brain capillaries. The PG may therefore diffuse across the brain parenchymal elements and bind to specific EP receptors at the surface of the neurons controlling the autonomic functions.

4. Whether one or more EP receptors participate in the neuronal response to PGE_2 is still a matter of great debate, but the neuroanatomy weighs in favor of the EP_4 receptor subtype. This receptor is found in key regions that control fever, HPA axis activity, and other autonomic functions. EP_4-expressing neurons are activated (as revealed by spontaneous induction of the immediate-early gene c-*fos*) in response to centrally injected PGE_2 and systemically administered IL-1 and LPS. Selective and nonselective COX inhibitors have the ability to prevent such functional activation of these neurons. EP_4-expressing neurons display an integrated circuit associated with the control of autonomic functions. The EP_4 receptor is associated with G_s-protein and stimulation of cyclic adenosine monophosphate (cAMP), which is the most potent transduction pathway involved in the release of corticotropin-releasing factor (CRF) from the PVN and increase in HPA axis activity. There is also evidence in support of cAMP signaling in thermosensitive neurons of the VmPO.

5. On the other hand, PGE_2 may inhibit major inhibitory neurons (e.g., γ-aminobutyric acid (GABA)) projecting to the nuclei that control the autonomic circuits. This would explain the data that only EP_3-deficient mice fail to exhibit a febrile response to inflammatory stimuli. This particular receptor is associated with a G_i-coupled protein inhibiting cAMP on its activation, which may take place in GABA neurons that innervate the VmPO and PVN. Obviously, these neurons would not express c-*fos* or other indices of neuronal activation in response to PGE_2. Functional anatomical data supporting this concept are nevertheless lacking, because there are as yet no reliable tools to assess inhibition rather than stimulation *in vivo*. If interaction of PGE_2 with its EP_3 receptor blocks the activity of GABA neurons innervating the VmPO and PVN, then the spontaneous induction of immediate-early genes in these regions may be indirectly attributable to GABA inhibition rather than to a direct interaction of PGE_2 with its EP_4 receptor. This is a chicken-and-egg problem that will have to be resolved with appropriate tools and animal models.

Alternative Pathways

PGE_2 production in the CNS may rely on two different pathways: (1) a fast transient production in endothelial cells and CVOs dependent on activation (possibly through MAPK p38 phosphorylation) of available constitutive PGE_2 synthesis enzymes ($cPLA_2$, COX-1, cPGES, and mPGES-2), independent of transcription and NF-κB activation (Figure 2), or (2) a slow, sustained PGE_2 synthesis in the endothelial cells and perivascular microglia (equipped to respond to cytokines and pathogens) involving the robust induction of the principle enzymes involved in PGE_2 synthesis (especially secretory phospholipase A_2 ($sPLA_2$-IIA), COX-2, and mPGES-1) that are NF-κB- and MAPK-mediated gene products. The slow transcription-mediated response would be massive but could offer a way through which glucocorticoids would then exert their negative feedback on NF-κB activity to shut down the CNS production of PGE_2. The fast response could be involved in priming the later delayed response and prevent drastic changes to homeostatic processes that the delayed response would have problems overcoming. A study looking at the effects of specific COX-1 and COX-2 inhibitors supports such a role for the COX-1-dependent early response since the ablation of COX-1 activity following LPS administration led to a fast hypothermic response, which could not be overcome by the later COX-2-dependent fever response. This study emphasizes the importance of the coordination between the fast and delayed responses.

Figure 2 Hypothetical model for the fast prostaglandin E_3 receptor (EP_3)-dependent prostaglandin E_2 (PGE_2) response in the brain. Circulating inflammatory factors (interleukin (IL)-1, tumor necrosis factor (TNF), lipopolysaccharide (LPS)) bind to their receptors expressed on the surface of endothelial cells of the brain microvasculature. This leads to a rapid use of available constitutive enzymes (cyclooxygenase (COX)-1, cytosolic phospholipase A_2 ($cPLA_2$), cytosolic prostaglandin E synthase (cPGES)) and arachadonic acid (AA) stores to transiently produce and release PGE_2 (possibly through mitogen-activated protein kinase (MAPK) p38 mechanisms). This PGE_2 acts on its EP_3 receptor on γ-aminobutyricacidergic afferences to the hypothalamic paraventricular nucleus, which rapidly turns off the inhibition of the corticotropin releasing factor (CRF)-releasing neurons. A similar scenario may happen at the medial preoptic area (POA), C1 catecholaminergic neurons of the rostral ventrolateral medulla (VLM), and C2 catecholaminergic neurons of the solitary tracts nucleus, where the binding of PGE_2 to the EP_3 receptor inhibits excitation of these GABAergic projections of PVN neurons. ACTH, adrenocorticotropic hormone; CORT, corticosterone; GABA, γ-aminobutyric acid; R, receptor; TLR4, toll-like receptor 4.

The population of cells containing the enzymes responsible for PGE_2 synthesis during systemic inflammation is still debated. Numerous papers have provided clear evidence that both COX-2 and mPGES-1 transcripts and proteins are expressed essentially within the endothelium of the brain blood vessels. On the other hand, few studies have shown that perivascular myeloid cells are responsible to deliver PGE_2 in response to systemic inflammatory stimuli. The action of this PG may therefore be dependent on its cellular source, the endogenous pool of PGE_2 in endothelial cells, and the receptor subtypes expressed on their cellular targets. It has been shown that EP_4 is present on the postsynaptic sites of hypothalamic stimulatory neurons, whereas GABA neurons contain presynaptic EP_3 receptors in their terminals. Activation of both EP_3 and EP_4 receptors is actually involved in the excitatory regulation of supraoptic neurons by PGE_2. These data may suggest that both receptors contribute to the activation of PVN neurons during systemic inflammation, but at different times. Stimulation of the $cPLA_2$–COX-1–cPGES pathway would lead to rapid secretion of PGE_2 from endothelial cells and then cause an immediate activation of the CRF neurons through inhibition of GABA afferents that contain EP_3 receptors (Figure 2). The hypothalamic PVN receives robust innervation from GABA neurons that play a critical role in the control of the HPA axis during stress. Inhibition of GABAergic neurons by EP_3 may take

Figure 3 Delayed prostaglandin E_4 (EP_4)-dependent prostaglandin E_2 (PGE_2) response in the brain during systemic immune insults. The delayed PGE_2 response requires transcription of the inducible enzymes (secretory phospholipase A_2 ($sPLA_2$-IIA), cyclooxygenase (COX)-2, microsomal prostaglandin E synthase (mPGES)-1) through nuclear factor-kappa B (NF-κB) and area postrema-1-mediated transcriptional mechanisms. These enzymes permit the massive production of PGE_2 that acts on the EP_4 receptors in the paraventricular nucleus and at the adrenergic A1 region of the caudal ventrolateral medulla (cVLM) and A2 region of the nucleus of the solitary tract (NTS) to enhance corticotropin-releasing factor (CRF) and vasopressin (AVP) release into the infundibular system. This leads to the release of adrenocorticotrophic hormone (ACTH) and subsequently biosynthesis and secretion of corticosterone (CORT) from the adrenal medulla. The latter hormone acts as negative feedback on the transcription of the enzymes responsible for the production of PGE_2 and prevents overproduction of inflammatory molecules during innate immunity. IL-1, interleukin-1; R, receptor; TLR4, toll-like receptor 4; TNF, tumor necrosis factor.

place locally at the level of the nerve terminals within the PVN or through distal inhibition of GABA projections originating from different areas, such as the preoptic area, parabrachial nucleus, rVLM, and/or NTS.

PGE_2 synthesis under the control of the $sPLA_2$-IIA–COX-2–mPGES-1 pathway would take the relay and trigger different populations of neurons (Figure 3). Enzymes of this pathway are not constitutively present and have to be induced by the proinflammatory signal transduction pathways. It is also possible that both endothelial and microglial cells contribute to the PGE_2 production in the delayed phase. Once secreted, PGE_2 would maintain CRF activity via EP_4 stimulation either directly or through activation of the A1 and A2 catecholaminergic circuits from the caudal ventrolateral medulla and NTS, respectively. These mechanisms fit nicely with the hypothesis of a fast and delayed PGE_2 response, in which the fast phase could be associated with the disinhibition of CRF-releasing neurons of the PVN, without the need for time- and energy-hungry transcription. This response could also prime the PVN to become more receptive to the massive release of PGE_2 by endothelial and perivascular microglial cells with their newly transcribed PGE_2-synthesizing enzymes. In support of this hypothesis is the specific increase in EP_4 mRNA levels in CRF neurons and catecholaminergic afferents to PVN following a systemic immune challenge. The sustained glucocorticoid release provides direct inhibitory feedback on these events at the level of transcriptional machinery, which is the most powerful endogenous immunosuppressive mechanism. This innovative dual regulation of PGE_2 production and action in the brain could have important implications for an appropriate control of fever, HPA axis, and other autonomic functions.

Concluding Remarks

More work is clearly needed to unravel the fine-tuning of the circuits and signal transduction pathways that participate in the neural–immune interface. There is, however, no doubt that PGE_2 plays a determinant role in activating or inhibiting the key populations of neurons that are together involved in engaging the physiological responses necessary for the organism to restore health during illness. An appropriate febrile response and a time-dependent release of glucocorticoids are major phenomena in which the brain has a direct impact on the systemic innate immune system. Imbalances in these two regulatory systems are actually becoming hallmarks of autoimmune diseases and neurodegenerative disorders. Clarifying the exact mechanisms and circuits that allow such fine neurophysiological outcomes will obviously be essential for designing appropriate therapeutic strategies when dysfunction occurs during the acute-phase response. The best guess at this time points to the key kinases controlling the proinflammatory signal transduction pathways in cells of the BBB, PGE_2 biosynthetic machinery and release, and specific EP receptor subtypes expressed on the surface of the neuronal populations that control endocrine and autonomic functions.

Induced Seizures as Therapy in Man

M Fink, State University of New York, Stony Brook, NY, USA

Of all the peculiar therapies suggested for the relief of madness, few match the bizarre nature of inducing seizures. For centuries seizures have been viewed as signs of individual wickedness and of God's displeasure, and efforts have been aimed at their extinction. Yet, ever since reports appeared showing that chemically induced seizures relieved catatonic schizophrenia, a small cadre of neurologists and psychiatrists have induced seizures in consenting patients to defeat the depressions of melancholia, the agitated and excited states of delirious mania, the mutism and negativism of catatonia, and the delusions of acute psychoses. Despite doubts of the professions and challenges from the public, despite terrifying images in films, despite legislative restrictions, and despite challenges from device manufacturers and their consultants who hawk nonseizure brain stimulation methods as replacements, seizures continue to be induced for the relief of madness. Indeed, interest in convulsive therapy is undergoing a renaissance in Europe and Asia, with the next generation of clinicians enthusiastically offering the treatment to an ever-growing public who is desperate for the relief of severe psychiatric disorders that are not alleviated by the plethora of medications, ever-more imaginative psychotherapies, and electronic devices.

Soon after Meduna's induction of seizures with analeptic agents (camphor, pentylenetetrazol), an electrical induction was developed and has been the mainstay of the treatment. Shock therapy, electroshock, electroconvulsive therapy (ECT), electroseizure therapy (EST), and convulsive therapy are terms for inductions in humans. Electroconvulsive shock (ECS) is the term applied to seizures induced in animals.

The repeated induction of bilateral grand mal seizures is the core process. Patterned electroencephalogram (EEG) changes and the release of brain hormones into the blood and cerebrospinal fluid (CSF) define effective inductions. EEG seizure durations longer than 20 s with characteristic buildup of amplitudes, spike and wave formations, runs of high-voltage slow waves, and a sharp end to the discharge define the seizure. Elevated serum levels of peptides derived from the hypothalamus and pituitary, such as prolactin and adrenocorticotropin (ACTH), reflect effective inductions.

A successful treatment course in patients with mood disorders requires from 8 to 12 treatments, spaced 48–72 h apart. For patients with more severe psychoses, 12–25 induced seizures may be necessary. In malignant catatonia (MC) and delirious mania, three to five daily treatments are often sufficient.

The principal benefits are the rapid relief of disordered mood, improvement in vegetative functions, and reduction in suicidal drive. Seizure inductions are remarkably safe and are well tolerated at all ages, in pregnancy, and in the systemically ill. The principal risks of the seizure are fractures, headache, and acute deliria. These risks are relieved by anesthesia and muscle relaxation. In long courses of treatment and in the elderly, cognitive impairment (memory loss) is the most widely cited complaint. For many patients, especially those whose illness is characterized by dementia, cognition improves after successful treatment.

History

In the 1920s, reports that epilepsy and schizophrenia were rarely found in the same patient suggested a biological antagonism between the two disorders. Glial concentrations in postmortem brain samples of schizophrenic subjects were lower than in normal subjects, and overabundant in the brains of epileptics. These observations led Ladislas Meduna, a Hungarian neuropsychiatrist, to develop convulsive therapy. The first patient was treated on 24 January 1934, using intramuscular camphor injections to induce seizures. In 1938, the Italian psychiatrists Ugo Cerletti and Lucio Bini demonstrated the merits of inducing the seizure through alternating electrical currents through bitemporal electrodes.

Convulsive therapy was introduced at the same time as insulin coma therapy (ICT) and leucotomy (lobotomy, psychosurgery). The efficacy of ICT was well established for the more severe forms of schizophrenia. Antipsychotic drugs replaced its use. A 10–20% of comas were accompanied by grand mal convulsions, and its mode of action was based on these events and not a direct effect of cerebral hypoglycemia. Leucotomy was a gross procedure whose efficacy was not demonstrated; it was also replaced by antipsychotic drugs.

In ECT, brief pulse stimuli replaced alternating electrical currents for lesser confusional effects. In the mid-1950s, seizure inductions using the inhalant flurothyl (Indoklon) were equally effective, but more cumbersome. In 1961, seizures induced through unilateral electrode placement over the nondominant hemisphere were associated with less immediate cognitive effects and seeming equivalent efficacy. The

placement was widely adopted. To achieve equivalent efficacy requires excessively high energies, at least 6–8 times the calibrated seizure threshold. At these high energy levels, the cognitive advantages of unilateral electrode placement are lost.

Indications

The American Psychiatric Association's classification of mental disorders (DSM-IV) is the standard nomenclature for psychiatric disorders. The disorders for which ECT is acknowledged to be effective (Table 1) and ineffective (Table 2) are listed.

Table 1 DSM-defined clinical diagnoses in which ECT is effective

Major depressive disorder	
Single episode	[296.2x]
Recurrent	
Bipolar disorder	[296.3x]
Mania	
Depressed	[296.0x]
Mixed type	[296.5x]
Not otherwise specified	[296.70]
Atypical psychosis	[298.90]
Schizophrenia	
Catatonic	[295.2x]
Schizophreniform	[295.40]
Schizoaffective	[295.70]
Catatonia	
Schizophrenia, catatonic type	
Catatonic disorder due to a medical condition	[293.89]
Malignant catatonia	[293.89]
Neuroleptic malignant syndrome	
Delirium	
Due to a general medical condition	[293.0]
Due to substance intoxication	[291.0]

Table 2 DSM diagnoses in which ECT is ineffective

Dementia and amnestic disorders	[293.0, 290.xx, 294.xx]
Substance-related disorders	[303.xx, 291,x, 304.x, 292.x]
Anxiety and somatiform disorders	[300.xx]
Factitious disorders	[300.xx]
Dissociative disorders	[300.1x, 300.6]
Sexual dysfunctions	[302.xx, 625.8, 608.89, 607.84, 608.89, 625.8]
Sleep disorders	[307.xx, 780.xx]
Impulse disorders	[312.3x]
Adjustment disorders	[309.xx]
Personality disorders	[301.xx]

Depressive Mood Disorders

Disorders dominated by sadness, hopelessness, fears, and thoughts that life is no longer worth living respond rapidly and well to ECT. At least four varieties are recognized: melancholia (dominated by motor and vegetative abnormalities), psychotic depression (psychosis), pseudodementia (cognitive deficit), and catatonia.

Melancholia A well-established syndrome of depressive mood dominated by motor signs (retardation or agitation) and vegetative symptoms of inability to sleep, feeding, and weight loss. Suicide thoughts are common. Hypercortisolemia, measured by the dexamethasone suppression test (DST), is characteristic as the patients exhibit elevated serum levels of cortisol, obtunded diurnal rhythmicity, and failure of serum levels to fall with an administered dose of dexamethasone. The DST normalizes with adequate treatment and becomes abnormal again with relapse.

In the 1990s, Parker and his associates focused attention on motor signs as melancholia's primary expression. They described a useful rating scale of motor behaviors to define the syndrome. After an extensive review of the literature, Taylor and Fink concluded that classifying mood disorder patients as either melancholic or nonmelancholic offered more homogeneous populations with better outcomes with tricyclic antidepressants (TCAs) and ECT than did the DSM classification of major depression and bipolar disorder. In their formulation, melancholia is a syndrome of depressive mood, with motor and vegetative abnormalities, and with evidence of cortisol abnormality.

Delusional (psychotic) depression Patients who are overwhelmed by feelings of helplessness, hopelessness, and worthlessness, believing others are watching or talking about them, report voices when no one is present, and imagine events depicted on a television or movie screen apply directly to them are suffering from psychotic depression. The syndrome was demarcated when depressed patients failed to respond to adequate dosing of antidepressants but did respond to ECT.

Many reviews verify that psychotic depression has a more severe pathophysiology and using the same treatments as for nonpsychotic depression, even at much higher doses, is not adequate. Yet, bitemporal ECT is remarkably effective. In a four-hospital ECT study, of 253 patients with unipolar major depression, 77 were psychotic depressed. Their remission rate was 95% compared to 83% for the nonpsychotic depressed, with the speed of response faster for the psychotic depressed patients.

Pseudodementia (reversible dementia) Because the depressed patient ignores daily events, little of what happens to him is registered and memory is compromised. The condition is hardly distinguishable from Alzheimer's dementia. It should be considered in any patient with the rapid onset of severe dementia, especially if the patient had prior depressive episodes. The dementia responds to effective antidepressant medications and to ECT.

Because the syndrome is not well known, patients are often sent to nursing home care. An example of a 58-year-old woman who developed a reversible dementia and was not adequately treated for 8 years is reported. Antidepressant treatment relieved the syndrome and returned the patient to a more normal family life.

Catatonia When the patient is mute, sitting rigidly in a chair or lying motionless on his bed, and unresponsive to questions and commands, appearing as if in a stupor, the state is catatonia or depressive stupor. Catatonia is seen among patients with many DSM diagnoses. It is discussed below.

Manic Mood Disorders

A mood disorder dominated by grandiosity, expansiveness, and increased energy and excitement may last for hours, days, or weeks. The disorder alternates or combines with depression. When switches between mania and depression occur within one or a few days, the experience is labeled rapid cycling, a malignant form of the illness. Bipolar disorder is the label applied to both mania and mixed forms of the illness.

Disturbances in eating and sleeping, thinking, memory, and movement are features of mania. Patients do not sleep, eat poorly, lose weight, and concentrate thoughts poorly. Memory is impaired, often severely, and patients may appear demented and delirious. Variations of melancholia, psychosis, pseudodementia, and catatonia occur.

Delirious mania (manic delirium) is a striking form. An otherwise normal person becomes excited, restless, sleeps poorly, and is fearful that he is being watched. He hides in the house, dresses inappropriately, and wanders about the streets. Confusion, mutism, posturing, and repetitive movements, as well as physical exhaustion to the point of death occur.

ECT was the first effective treatment. Of manic patients treated with ECT, 371/562 (66%) remitted or showed marked clinical improvement. The introduction of chlorpromazine replaced ECT for its ease of use. Effective doses were high, resulting in sudden death, neuroleptic malignant syndrome (NMS), tardive dyskinesia, and tardive dystonia. Lithium was next introduced followed by anticonvulsant drugs. Despite these agents, many patients fail medications. At such times, ECT is the effective treatment. For patients in delirious mania, ECT is a primary indication.

Catatonia

Catatonia is a motor syndrome associated with thought and mood disorders. Muscular rigidity, posturing, negativism, mutism, echolalia, echopraxia, and stereotyped mannerisms are characteristic signs. Catatonia is recognized in patients with depression and mania, in patients with systemic disorders, and in toxic brain states caused by hallucinogenic drugs.

For decades, the prevailing (and erroneous) belief was that each instance of catatonia represented schizophrenia. The DSM and International Classification of Disease (ICD) classification systems assigned patients with catatonia to the diagnosis of schizophrenia, catatonic type, with antipsychotic medications as the logical treatment. In the 1970s, various reports described catatonia in patients with manic-depressive illness and toxic states. The association with schizophrenia is unfortunate, since anticonvulsant sedatives (barbiturates, benzodiazepines) and ECT are more effective and safer but these are not usually considered for schizophrenia.

Catatonia is defined by the persistence of two or more characteristic motor signs for more than 24 h in a patient with a mental disorder. While posturing and staring can be observed, most signs are elicited in examinations described in catatonia rating scales. An intravenous challenge of lorazepam or amobarbital verifies the diagnosis in more than two-thirds of patients; a positive test response augurs well for high-dose benzodiazepine therapy. When this treatment fails, ECT is effective, although the treatment schedule may require daily treatments.

Catatonia may be transitory or may persist for months or years. It appears in many guises. Prominent examples are MC (pernicious) with a high risk of death and the NMS that follows on the administration of neuroleptic drugs.

Patients who develop an acute febrile delirium with excitement or stupor, catatonia, and vegetative dysregulation suffer from MC. ECT is the life-saving treatment. The NMS is a variant of MC. It is elicited by all neuroleptics, most commonly with the high-potency agents like haloperidol, fluphenazine, and thiothixene, but also with atypical neuroleptics. The toxic serotonin syndrome (TSS), an acute febrile and autonomic response with prominent catatonia features with prominent gastrointestinal symptoms, is another MC variant. The diagnosis and treatment follows the protocol for MC.

Psychosis

Delusions are a feature of many psychiatric conditions, notably psychotic depression, postpartum depression, toxic psychosis, and delirious mania. For delusions encapsulated within the DSM diagnostic system, the treatment is defined by the diagnosis, and the role of ECT may or may not be considered. Yet, the efficacy of ECT in relieving delusions (and hallucinations and other disorders of thought) compels its consideration as an effective antipsychotic treatment regardless of the associated mood, motor, or cognitive signs. Despite the efficacy of antipsychotic agents, including clozapine, a cadre of 'medication-resistant' psychotic patients has developed. For these patients, augmentation of the antipsychotic with ECT is often effective.

Delirium

Acutely ill psychotic patients exhibit disturbances in consciousness and appear confused. Delirium is common in toxic states, either drug induced (alcohol being the most common), or secondary to drug withdrawal, or associated with systemic illnesses. Delirium is a feature of acute manic states (e.g., delirious mania). With few resources to treat acute psychoses, ECT was applied with favorable results.

Mode of Action

The mode of action of induced seizures in relieving psychiatric disorders is an unanswered question. Much is known about the process, sufficient to define a strategy to understand the mechanism.

The Role of the Seizure

The induction of a grand mal seizure is essential to effective treatment. Two measures of this effect are known. Characteristic ictal EEG patterns are the best index that have a direct effect on the brain. Persistent interseizure EEG effects are indices of the long-term effects. The release of hypothalamic and pituitary peptides in the CSF and blood also are evidence of effective treatments.

Neither the motor elements of the convulsion nor the physiologic effects (heart rate, blood pressure) nor the psychological aspects (fear, cognition) of the intervention are essential to outcome. Although modern treatment depends on an anesthetic and muscle relaxant to minimize the risks, these are not in the therapeutic chain, as unmodified inductions are clinically effective. Although electricity is the most widely used induction agent, it offers little benefit over chemical inductions other than ease of use, ready availability, and least expense.

A single seizure is rarely successful. Repeated seizures from 7 to 25 inductions are effective in acute courses, varying with psychopathology. Once to twice weekly in the elderly depressed to daily for MC is the range of inductions. Many illnesses resolve quickly, indicating that the mechanism is of immediate moment. Relapse is frequent, indicating that the mechanism needs continuous reinforcement. Medication combinations are useful in continuation, but optimal results require continuation ECT. Durations vary from a few months to years.

While the focus is on the seizure, the therapeutic effect depends on the brain effects for which the seizure is the outward sign. Manipulations of the seizure characteristics by varying electrode location and stimulus strength affect treatment efficacy. Seizures induced through unilateral electrode placement and electrical doses just over threshold (to minimize effects on memory that reside in the dominant temporal lobes) are minimally clinically effective. They affect the EEG asymmetrically and elicit smaller brain hormone discharges. Once energies are elevated to levels sufficient to affect brain hormones, the advantages in cognitive effects are lost. The difference in efficacy between unilateral stimulation (RUL ECT) and bilateral stimulation (BT ECT) encourages the conclusion that the benefits of the seizure reside in the brain's centrencephalic regions.

Recent attempts to stimulate brain regions by repeated magnetic impulses (rTMS) or retrograde stimulation of the left vagus nerve (VNS) or stimulation through brain-implanted electrodes (DBS) have not approached the therapeutic effect of ECT. These experiences are based on the expectation that stimulation of brain loci or at levels not sufficient to elicit a bilateral grand mal seizure will be as effective as inducing a seizure. Similar earlier attempts have also failed to replicate the effects of convulsive therapy: subconvulsive electrical stimulation, nonseizure doses of analeptic agents, prolonged isoelectric brain stimulation under isoflurane anesthesia; nonconvulsive electrotherapy, electroanesthesia, and direct current cerebral stimulation.

What Does the Seizure Signify?

Seizures are a characteristic of all mammalian forms. Their biological significance is unknown. In convulsive therapy, the electrical patterns of a grand mal seizure are markers of brain changes that are essential to behavioral change. The motor and systemic aspects of the seizure do not have the same significance.

Neuroendocrine features are central The release of peptides from the hypothalamus and pituitary into the CSF and measurable in the blood are essential to

clinical outcome. The metabolism of peptides is measurable in hours and days. While epinephrine, serotonin, and dopamine brain concentrations change with seizures, their levels persist for very short periods and are localized to the brain regions of stimulation. At one time, acetylcholine was considered in the therapeutic chain in convulsive therapy. Changes in cholinesterases were associated with behavioral change and behaviors were modified by cholinergic and anticholinergic substances.

The blood–brain barrier The blood–brain barrier is compromised with seizures, suggesting that substances released into the brain and CSF more easily leak to other body tissues.

Continuation treatments are necessary The changes in behavior are measurable in hours after one or two seizures, in days with more seizures, and persistent after a successful series of induced seizures. But the measures of change (EEG and serum peptides) revert to baseline levels in days or weeks after a series of seizure inductions. Such reversion is associated with behavioral relapse, seen in more than half the patients when reexamined over 6 months. Seizure inductions must be continued for periods up to 6 months in most patients and lifelong in some to sustain a clinical benefit.

The diabetes analogy While seizures are induced under anesthesia, giving the appearance of a surgical procedure, ECT is not comparable to surgery in that a single treatment is not successful. A more comparable analogy is that of diabetes; the failure of the pancreas to deliver adequate amounts of insulin is a chronic condition that is best alleviated by repeated administrations of insulin or insulin-active substances. A converse of this analogy is that the disorders in mood, thought, and motor functions result from deficiencies in brain hormones, most likely of hypothalamic pituitary origin.

The Neuroendocrine Theory of the Mode of Action of ECT

The neuroendocrine explanation views the responsive behavior disorders as evidence of deficiencies in the release of hypothalamic–pituitary peptides. Inducing seizures stimulates central brain nuclei to release peptides in greater amounts. Falls in CSF and serum calcium are indirect evidence that hormone release is massive. With repeated stimulation, brain and tissue peptide levels normalize. If these become abnormal again, relapse occurs. The compromise of the blood–brain barrier allows greater penetration of the newly formed peptides. A useful index of abnormality in depressed patients is elevated serum cortisol, reflected in measurement of the DST. Acetylcholine release and the response in cholinesterases are another evidence of the brain abnormality and normalization.

Alternative Theories

Many hypotheses of the mode of action have been postulated, beginning with memory change and the suppression of unconscious conflicts. Of the alternative hypotheses, the interest in the stimulation of brain cell growth, as in increase in neurogenesis, is now the most active.

Procedures

Recommendation for Treatment

Referral of patients for ECT is generally a last resort, except for the most acutely ill hospitalized patients. Professional inexperience, lack of facilities, and public repugnance for electroshock make referral difficult. Its use is impeded by the demand that patients explicitly sign a consent document that defines the aims of the treatment, the reasons it is now recommended, who will administer the treatments, how many treatments are accepted, and the explicit statement that the patient may discontinue treatment at any time. For patients who do not comprehend the seriousness of their illness and cannot voluntarily consent, calls on the state courts for consent, a complex and expensive procedure, must be made. Such involuntary application was less than 5% of treatments in the US in the 1990s.

Procedure

An intravenous line is established; an anesthetic (methohexital, propofol, etomidate, ketamine), and the muscle relaxant succinylcholine are administered; an airway is established; and the patient is ventilated with 100% oxygen. Electrodes are applied either bitemporally or bifrontally. Current dosages are defined as about 50% above the minimum necessary to achieve a seizure.

Seizure duration is monitored by the EEG, the motor activity in a limb isolated from succinylcholine by a blood pressure cuff inflated above the systolic pressure, or by heart rate. Seizure durations less than 25 s are considered inadequate and are usually repeated. Durations over 180 s are considered prolonged and are terminated by intravenous diazepam.

Treatments are given either 3 or 2 times a week, with full courses ranging from 6 to 25 treatments, with an average of seven to nine for mood disorders and larger series for psychoses.

Devices used to stimulate a seizure are now limited to brief pulse, square wave currents, with parameters

of 0.5–1.0 ms pulse width, 30–70 Hz frequency, for stimulus durations of 0.5–8.0 s, delivering between 25 and 500 millicoulombs of energy. Alternating current devices are associated with greater memory impairment and are no longer endorsed.

Following a successful treatment course, continuation treatment for 3–6 months is recommended. It is usually accomplished by antidepressant drugs, lithium, or continuation ECT, with the latter increasingly favored.

Consequences

The principal behavioral changes are a heightening of mood and affect, relief of abnormal mood, and suicidal ideation. Delusional ideation gradually disappears. Motor excitement, withdrawal, and apathy are relieved, and vegetative functions improve.

Bone fracture, organic mental syndrome, and cardiovascular complications leading to death are the principal risks. Fractures are rare under present conditions of anesthesia; as is death, which is reported in less than 4 of 100 000 treatments. Cognitive impairment, seen as persistent complaints of memory loss, is reported in about 1% of patients. The incidence is greater in patients treated with sinusoidal current devices and bilateral electrode placements. Recall of recent events around the period of hospitalization and of the acute illness is most disrupted. Remote memory, learned skills, and memory of events after the treatment course are not affected.

Neuropsychological tests, including memory, motor functions, reaction time, and perception, are progressively impaired during the treatment course, but recover within 4–6 weeks after the last seizure. In patients who are relieved of their depressive illness, motor performance and cognitive tests improve over pretreatment values.

During each seizure, the EEG exhibits high-voltage, high-frequency spike activity with slow-wave bursts. In interseizure records, frequencies slow, amplitudes increase, and fast frequencies are reduced. Following treatment, slow-wave frequencies are reduced and synchronized alpha activity increases.

During each seizure, there is transient hypertension, tachycardia, and in many subjects, arrhythmias.

Transient increases in cerebral catecholamines, acetylcholine, and peptides, including prolactin, vasopressin, adenocorticotropic hormone, and thyrotropin releasing hormone (TRH) occur during each treatment. These values return to baseline levels within 2 h in the first treatments but persist for longer periods with increased number of inductions. Increases in cholinesterase and monoamine oxidase in the CSF and a reduction of calcium in plasma, CSF, and blood may persist for longer periods. Catecholamine turnover and receptor sensitivity increase, particularly dopamine synaptic activity. In patients with evidence of neuroendocrine dysregulation (as abnormal cortisol and failure to suppress with dexamethasone, abnormal growth hormone response to apomorphine, or thyrotropin-stimulating hormone response to TRH), these responses normalize with treatment.

Social Factors

ECT is remarkably effective and, with modern methods of anesthesia, remarkably safe. For many severe mental illnesses, it is more effective and safer than alternate therapies. While 8–10% of patients admitted to academic in-patient psychiatric services in the US receive ECT, the treatments are infrequently used in municipal, state, and federal facilities. This disparity in access reflects the treatment's 'bad press,' as it has been the target of the antipsychiatry movements throughout the world.

Introduction

Neuronal apoptosis has been recognized for more than 10 years as one of the pathologic hallmarks of neurodegenerative disease associated with HIV-1 infection of the central nervous system (CNS), but mounting evidence suggests it has little to do with symptoms of neurologic disease associated with neurodegeneration. Studies of HIV-1-associated dementia (HAD) suggest that neurologic and cognitive function becomes impaired primarily as a result of injury to dendrites and synapses, often occurring long before cell death. HAD appears to develop not from loss of neurons but because of loss of communication between neurons and perhaps glia as well. This distinction has important implications for disease progression and treatment; dead neurons are not likely replaceable, except perhaps in areas of the CNS that may benefit from neurogenesis, but dendrites and synapses can recover from severe structural and functional injury as long as the neuronal cell body survives. With synaptic injury and clinical symptoms often preceding the extensive neuronal loss of late-stage disease by months or years, therapeutic strategies that provide synaptic protection have potential to improve neurologic function and perhaps reverse the course of the disease.

Dramatic recovery of neurologic function in patients with HAD beginning antiretroviral therapy demonstrates that a temporal window for reversibility of neurologic deficits does exist. HAD develops following HIV-1 infection of brain macrophages and microglia, and cognitive and motor symptoms include impaired concentration, apathy, memory loss, psychomotor slowing, weakness, tremor, and ataxia. These symptoms can be severely debilitating, but antiretroviral therapy that decreases HIV-1 burden in the brain and the periphery can ameliorate and even reverse many of these symptoms, at least temporarily. For example, an early report described a patient diagnosed with HIV-1 infection and HAD after presenting with 6 months of progressive memory and attentional deficits that had become so severe that she could no longer work, dress herself, or be left unsupervised. After 12 weeks of antiretroviral therapy that decreased viral burden and associated inflammatory markers in the plasma and cerebrospinal fluid, her performance on cognitive and motor testing had dramatically improved and most, although not all, her presenting deficits were reversed. Similar clinical recovery, accompanied by significant improvement of cerebral atrophy documented by neuroimaging, was reported after antiretroviral therapy in a HIV-1-infected child with language, attention, and motor deficits that had caused him to lose developmental milestones and prevented him from communicating with others at school and at home. Studies following cohorts of patients beginning highly active antiretroviral therapy (HAART) provide further evidence of a large reversible component in HAD.

HAART modifies the disease course but does not cure or prevent HAD. The prevalence of HAD and other neurologic disease in patients receiving HAART is the same as in the pre-HAART era. HAART has changed the phenotype of the disease, causing it to develop more slowly and shifting the pattern of clinical deficits, perhaps reflecting involvement of different brain areas: functional neuroimaging studies in the HAART era suggest substantial cortical involvement in a disease once considered to be primarily subcortical. The persistent 30–40% prevalence of HAD in HIV-positive cohorts despite HAART indicates that therapies targeting mechanisms that are independent of the viral life cycle with the goal of preventing synaptic injury are likely necessary for long-term treatment of HIV-1-associated neurologic disease.

How HIV-1 damages synaptic architecture and function is not known, and understanding mechanisms of synaptic injury in HIV-1 neurologic disease is necessary for identifying therapeutic approaches to protect synaptic function. Similarities in disease pathology and neurotoxic mechanisms suggest that this understanding might provide insight into treatment for other neurodegenerative disorders with an infectious etiology.

HIV-1-Associated Dementia and Prionoses Are Diseases of Synaptic Architecture

Evidence that neurologic impairment in HAD is caused by synaptic injury comes largely from correlations of neuropathologic studies with neurologic and neuropsychological testing. HIV-1 infection is associated with neuronal apoptosis, dramatic decreases in numbers of presynaptic terminals and postsynaptic dendritic spines, dendritic injury, and signs of HIV encephalitis, which include HIV-1-infected monocyte–macrophages, multinucleated giant cells, activated

microglia, astrocytosis, and myelin pallor. Only synaptic loss and microglial activation correlate with the presence of neurologic deficits. While the multinucleated giant cells and myelin pallor of HIV encephalitis were seen only in patients with dementia, 50% of patients developed HAD in the absence of either of these findings. Similarly, premortem neurocognitive function did not correlate with the presence of microglial nodules, astrocytosis, or HIV-infected mononuclear cells in autopsy tissue.

In contrast, loss of pre- and postsynaptic structures correlates well with neurologic impairment across a range of severity of HIV-1 neurologic disease. Studies of patients with HAD and milder forms of HIV-1-associated neurologic impairment, as well as unimpaired HIV-1-seropositive controls, found that global ratings of neuropsychologic function derived from an extensive battery of tests significantly correlated with synaptic density estimated by presynaptic synaptophysin immunoreactivity as well as with postsynaptic microtubule-associated protein 2-positive dendritic area. Loss of synapses was not simply a result of neuronal death; neuronal loss consistently failed to correlate with neurologic impairment in a number of studies. While neuronal death clearly has an impact on neurologic function, these studies suggested that neuronal loss occurs late in the disease and that synaptic injury prior to neuronal death is the major determinant of HIV-associated neurologic disease. This is supported by morphologic studies that show extensive injury to the dendritic arbor, including focal swelling, or beading; loss of dendritic branches; and 40–60% reductions in densities of dendritic spines along remaining branches, all occurring on surviving neurons in HAD. The additional correlation between neurologic impairment and microglial activation, a general marker of neuroinflammation, suggests that inflammatory processes might contribute to synaptic injury.

Similar evidence suggests that synaptic injury underlies neurologic deficits in other neurodegenerative diseases including the prionoses. Loss of synapses preceding neurodegeneration has been demonstrated in scrapie-infected murine hippocampus, with the major neuropathologic finding of abnormal pyramidal synapses in the scrapie-infected murine hippocampus. Loss of synapses and neurologic impairment correlates in the ME7 murine model of prion disease, and studies demonstrate similar synaptic pathology in patients with Creutzfeldt–Jakob disease (CJD) at both a light microscopic and ultrastructural level. Indeed, one of the most striking ultrastructural findings in a study of the CJD prionoses was dark profiles or 'tombstones' of synaptic terminals.

In addition to loss of synaptic structures, functional impairment of existing synapses might further disrupt neural processing in HAD. In addition, electrophysiologic studies in brain slices prepared from several different animal models of HAD have revealed deficits in synaptic plasticity, often occurring early in the disease and before overt neuropathological changes. It is interesting that in the ME7 model of prionoses, abnormalities in synaptic plasticity, while temporally contiguous with deposition of protease-resistant protein, scrapie-type (PrP^{Sc}), occur before overt changes in behavior or frank neuropathologic hallmarks of the prionoses such as vacuolation are evident.

While much attention has been focused on neuroimaging techniques, including diffusion weighted images and fluid-attenuated inversion recovery images for the diagnosis of the prionoses, no studies have characterized progression of neurologic deficits and related it to changes in functional neuroimaging parameters, probably because of the difficulty in diagnosing this class of diseases in the asymptomatic phase and the rapid, inexorable progression of the disease once neurologic symptoms are apparent. In contrast, functional studies in patients with HIV-1 are consistent with impairment of synaptic processing even when there is no overt sign of neuropsychologic or neurologic deficit. HIV-1-positive patients with varying degrees of neurologic impairment showed increased areas of brain activation on functional magnetic resonance imaging during attention and working memory tasks. During simpler tasks, brain activation increased but performance did not deteriorate, whereas during more-complex tasks, larger increases in brain activation correlated with decreased performance. This finding supports the hypothesis that patients with impaired processing recruited additional neural substrate, or cognitive reserve to complete the tasks. It is interesting that cognitively asymptomatic HIV-1-positive patients recruited larger brain areas, in the same regions as patients with HAD, compared to HIV-1-seronegative controls, suggesting that the former might already have had impairment of neural processing which was compensated by increased recruitment of cognitive reserve. Electroencephalographic studies during an auditory processing task support this conclusion. Patients with HIV-associated neurologic disease had longer latencies of event-related potentials that reflect impaired frontal cortical processing. Latencies increased with more-severe neurologic deficits and were also significantly longer in cognitively intact HIV-seropositive patients compared than in seronegative controls, again suggesting subclinical functional impairment during the asymptomatic phase of the disease.

Taken together, these diverse studies suggest that neural processing is impaired in preclinical stages of

HAD and worsens throughout disease progression in tandem with the development of progressively more severe synaptic pathology. Neuronal cell death likely becomes significant in late-stage disease, well after the onset of neuropsychologic impairment. These findings strongly support the hypothesis that synaptic injury is the primary determinant of neurologic impairment in HAD and very possibly the substrate for early neurologic disease in the prionoses. Thus, understanding mechanisms of synaptic injury and dysfunction in these diseases might be crucial to preserving neurologic function.

Inflammation and Excitotoxic Synaptic Injury

How synapses are injured in prionoses is not well understood. Evidence for excitotoxic damage to synapses and neuronal cell bodies in the prionoses is equivocal, arguably because of the difficulty in understanding how PrP^{Sc} interacts with different cellular moieties germane to glutamate-mediated neurotransmission, and the finding that mice with a targeted deletion of the normal cellular prion protein do not display abnormalities in the kinetics of γ-aminobutyric acid and glutamate receptor-mediated currents. It is interesting that plasminogen, a pro-protease that may participate in glutamate-mediated excitotoxicity, selectively binds PrP^{Sc}. However, neuropathologic studies of expression of excitatory amino acid transporter-1 (EAAT-1) in brain macrophages and microglia in patients with prion disease were unable to establish a clear relationship between EAAT-1's ability to clear extracellular glutamate and the extent of neuronal apoptosis or spongiform neuropathologic changes.

In contrast, *in vitro* studies have revealed many potential neurotoxic mechanisms for the pathogenesis of HAD, but investigation of how these contribute to synaptic dysfunction and destruction *in vivo* has been hampered by the slow progression of synaptic injury in these diseases. Nevertheless, multiple lines of evidence suggest that synaptic damage in HAD is likely due to chronic neuroinflammation associated with mitochondrial dysfunction, disrupted intracellular calcium homeostasis, and oxidative stress in vulnerable neurons that increase synaptic vulnerability to glutamate excitotoxicity.

HIV-1 rarely, if ever, infects postmitotic neurons. It exerts its neurotoxic effects largely by triggering brain inflammation. By infecting brain macrophages, microglia, and to a lesser extent astrocytes and secondarily activating uninfected microglia and astrocytes, HIV-1 causes release of cytokine and other inflammatory mediators, including tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), interleukin-6, arachidonic acid metabolites, platelet-activating factor (PAF), and complement proteins, in addition to secreted HIV-1 proteins. This inflammatory milieu is toxic to neurons *in vitro*, as demonstrated by experiments with cerebrospinal fluid (CSF) from patients with HAD and conditioned media from HIV-infected macrophages. In patients with HIV, brain inflammation appears to relate closely to cognitive dysfunction: severity of dementia correlated well with numbers of activated microglia and macrophages and with TNF-α mRNA expression in the brain, but not with numbers of HIV-1-infected cells, and decreases in CSF TNF-α protein levels coincided with neurologic recovery in a patient beginning HAART.

Evidence from *in vitro* studies suggests that HAD inflammatory mediators damage neurons by making them vulnerable to Ca^{2+}-dependent glutamate excitotoxicity. Supernatants containing the soluble mediators released by HIV-1- or amyloid-β-activated macrophages and microglia can kill cultured neurons in a manner that depends on activation of *N*-methyl-D-aspartate (NMDA)-type glutamate receptors. Many factors may contribute: proinflammatory molecules PAF, TNF-α, and IL-1β, as well as amyloid-β and the secreted HIV proteins gp120 and Tat, each exert neurotoxic effects largely by promoting glutamate excitotoxicity. Several studies are consistent with a role for excitotoxicity *in vivo*: NMDA receptor-dependent neuronal loss and neurotransmitter depletion have been observed, respectively, in rats injected with amyloid-β and a retroviral (LP-BM5) murine model of HAD. It is intriguing that studies with the LP-BM5 murine leukemia retrovirus (MuLV) model demonstrate production, probably by molecular mimicry, of virally induced auto-antibodies to alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor subunits, which are responsible in part for the neurodegenerative disease in this model. Furthermore, NMDA receptor antagonists prevent decline in synaptic function in the severe combined immunodeficiency mouse models of HIV-1 encephalitis and HAD. Glutamate excitotoxicity is widely believed to depend on Ca^{2+} influx into neurons via ionotropic glutamate receptors and subsequent uptake by mitochondria, leading to mitochondrial depolarization and dysfunction, including free radical generation and dysregulation of intracellular Ca^{2+} homeostasis, which can culminate in neuronal injury or death. HIV mediators likely contribute to this process at multiple stages. HIV-1, gp120, TNF-α, and amyloid-β can all inhibit glutamate uptake by cultured astrocytes, leading to higher extracellular glutamate concentrations in the brain. TNF-α, which can have toxic or protective effects depending on which receptors it activates, likely augments AMPA receptor-mediated glutamate toxicity

in neurons by increasing the membrane expression of Ca^{2+}-permeable AMPA receptors. PAF increases neuronal glutamate release and promotes coupling of NMDA receptor activation with production of nitric oxide (NO), which links Ca^{2+} influx to mitochondrial dysfunction. Amyloid-β and HIV proteins can increase NO production and can lead to mitochondrial dysfunction and free radical generation in cultured neurons. Signs of mitochondrial dysfunction and oxidative stress have been found in patients with HAD compared with cognitively normal controls. In addition, treatment of cultured neurons with CSF from HIV-infected patients disrupts intracellular Ca^{2+} homeostasis, with higher Ca^{2+} concentrations at baseline and dramatically increased Ca^{2+} responses to glutamatergic stimulation.

Impaired uptake of extracellular glutamate and increased sensitivity of neurons to glutamate-triggered Ca^{2+} influx and its downstream sequelae provide a compelling basis for the proposal that glutamate excitotoxicity mediated by ionotropic glutamate receptors might be a final common pathway to neuronal injury in HAD. This has led to considerable interest in therapeutic interventions that target NMDA receptor activation. However, the sequence of events leading to excitotoxic injury in chronic neurodegenerative disease is far from clear and could have important implications for the ability of glutamate receptor antagonists to mitigate excitotoxic injury. Many investigators have speculated that NMDA receptors are tonically activated in these diseases by chronically elevated glutamate concentrations in the synaptic cleft due to impaired astrocytic uptake of glutamate and/or by partial depolarization of neuronal membranes, perhaps due to mitochondrial dysfunction and impaired energy metabolism, that eliminates the voltage-dependent Mg^{2+} blockade of NMDA receptors and leads to sustained Ca^{2+} influx. This scenario provides the rationale for the therapeutic use of memantine, an uncompetitive NMDA receptor antagonist that blocks tonic but not transient activation. Direct evidence for this scenario *in vivo* is scarce, but indirect support comes largely from efficacy of treatment with memantine in disease models and in patients. Memantine has been shown to improve synaptic function and learning, respectively, in mouse models of HAD, but its ability to ameliorate symptoms of HAD is unclear.

One way of explaining this surprising conundrum is that at early disease stages, neurons and astrocytes are not sufficiently dysfunctional to cause the tonic NMDA receptor activation that is most amenable to memantine blockade. Alternatively, effects of HAD inflammatory mediators might promote synaptic injury following more physiologic glutamate release. Recent work has demonstrated that high-frequency synaptic stimulation, sufficient to generate long-term potentiation (LTP) in hippocampal slices, can instead initiate calcium- and caspase-dependent dendritic injury, with failure of LTP in slices exposed to cPAF, a PAF analog resistant to catabolism by tissue acetylhydrolases. Patch clamp recordings from postsynaptic neurons show no change in duration or extent of glutamate receptor activation during stimulation in cPAF-treated or control slices, suggesting that similar patterns of glutamatergic activity might induce physiologic plasticity or synaptic injury depending on whether neuroinflammation is present. Because we found that dendritic injury could be prevented and LTP restored by preconditioning with a mitochondrial adenosine triphosphate-sensitive K^+ channel antagonist, and that blockade of Ca^{2+} influx or postsynaptic caspase activation prevented structural injury but failed to restore LTP to cPAF-treated slices, we have concluded that abnormal NMDA receptor activation might not be sufficient to protect against synaptic injury during neuroinflammation. Rather, we believe that chemical preconditioning might provide a promising strategy for preventing activity-dependent synaptic injury while preserving physiologic plasticity.

To date, most preclinical studies of neurotoxic mechanisms in HAD have used neuronal death as their endpoint. Thus, it would not be surprising if these studies offered more insight into end-stage disease, where cell death is far more prominent, than into earlier stages, where injury is restricted to synapses. Thus, development of model systems to investigate perturbation of synaptic structure and function in the absence of neuronal death might be important for identifying therapeutic strategies to prevent synaptic degeneration before it occurs irreversibly.

Synaptic Degeneration and Recovery

Neuropathologic findings make clear that synapses degenerate before neurons die, but this progression is not inevitable. Abundant experimental evidence demonstrates that neurotoxicity can originate in and can be confined to pre- and postsynaptic elements and that synaptic structure and function can largely recover after removal of the neurotoxic insult. Molecular events associated with cell death, including caspase activation, mitochondrial calcium uptake and depolarization, free radical generation, loss of membrane asymmetry, and membrane blebbing, can occur locally in synapses exposed to glutamate, amyloid-β, prion protein, staurosporine, or Fe^{2+}-induced oxidative stress. Similar events may occur in presynaptic terminals and axons following loss of postsynaptic targets.

Apoptotic responses can be generated in the synapses and dendrites, independent of the cell body,

as demonstrated by application of toxins to isolated synaptic compartments or restricted portions of neurites. Though experiments with cytosolic extracts from synaptosomes show that synapse-derived signals can trigger apoptotic changes in cell nuclei, studies in intact neurons suggest that they remain localized to sites of excitotoxic exposure. Synapses and dendrites appear to be especially vulnerable to injury as cellwide exposures to sublethal doses of glutamate, amyloid-β, and prion protein can cause dendritic beading, caspase activation, and loss of membrane asymmetry in the dendrites while leaving the neuronal cell bodies relatively unaffected.

Injured neurites have a remarkable capacity for recovery. In cultured neurons and hippocampal slices, sublethal doses of excitotoxins glutamate, kainate, or NMDA can dramatically disrupt dendritic architecture with large focal swellings and retraction of spines, accompanied by loss of synaptic transmission and changes in mitochondrial structure and function that can all recover following removal of the excitotoxin. Dendritic injury in these experiments reflects in part swelling due to ion influxes and osmotic changes, which can recover within minutes, and in part Ca^{2+}-mediated toxicity that can last from hours to days; nevertheless, dendrites can recover from both when the cell body is spared.

Synaptic repair correlating with neurologic recovery has been observed in chronic neuroinflammatory disease models. In mice with experimental autoimmune encephalitis, a model for multiple sclerosis, beading of motor neuron dendrites and loss of immunostaining for pre- and postsynaptic markers accompanied episodes of motor dysfunction, and all returned to normal with remission of neurologic deficits.

The remarkable regenerative potential of dendrites and synapses suggests a likely basis for the reversibility of HAD neuropsychologic symptoms in patients beginning HAART. Although such reversal has not been demonstrated in patients with other neurodegenerative diseases, or even in patients with HAD who have received long-term treatment with HAART, the potential for functional neurologic recovery in this patient group warrants further investigation with neuroprotective strategies that either reduce neuroinflammatory burden on synapses or precondition them to withstand this type of stress. This is even more compelling when one realizes that HAART fails to prevent HAD in the long run. Identifying potential targets for such therapies will require a better understanding, not of pathways to neuronal death, but of how HIV and inflammatory neurotoxins lead to synaptic injury and loss of function.

Inflammation in Neurodegenerative Disease and Injury

M G Tansey and S G Kernie, The University of Texas Southwestern Medical Center, Dallas, TX, USA

Overview

Features of Neuroinflammation

Inflammation can be defined in clinical, pathological, and molecular terms. The four cardinal signs of inflammation described by Celsius in AD 25, dolor, tumor, calor, and rubor (i.e., pain, swelling, heat, and redness), are not present in patients with neurodegenerative disease. Neuropathological and neuroradiological studies indicate that inflammation in neurodegenerative diseases is characterized by a glial response that in certain diseases may be present prior to significant loss of neurons. It was once believed that the blood–brain barrier (BBB) prevented access of immune cells to the brain and, as a result, the immune and central nervous system were relatively independent of each other. However, it has become clear that the permeability of the BBB can be regulated under normal conditions and may increase or become dysregulated in disease states. The inflammatory reaction in the brain associated with most acute or chronic neurodegenerative diseases is often termed 'neuroinflammation.' Neuroinflammation consists mainly of an innate immune response involving activation of glial cells and central production of cytokines, chemokines, prostaglandins, complement cascade proteins, and reactive oxygen species and reactive nitrogen species (ROS/RNS) in response to a central or peripheral immune challenge. The features of neuroinflammation include the presence of reactive astrocytes and activated microglial cells in the central nervous system (CNS). In certain neurodegenerative diseases, infiltration of lymphocytes (B and T cells) and polymorphonuclear cells occurs when the re is extensive breakdown of the BBB.

Glia: Microglia and astrocytes Microglia are the monocyte-derived resident macrophages of the brain responsible for immune surveillance. An initial physical or pathogenic event in the CNS is expected to elicit activation of microglia and secretion of factors that promote neuronal survival, with the purpose of limiting injury, protecting vulnerable neuronal populations, and aiding in repair processes. When the permeability of the BBB increases, recruitment of peripheral macrophages to the CNS results in expansion of the brain microglia population. Activated microglia produce ROS and RNS such as nitric oxide (NO) and secrete prostaglandins, chemokines, and cytokines, as well as neurotrophic factors (including glial-derived neurotrophic factor family ligands, or GFLs) that promote neuronal survival. If glial activation persists for extended periods, a cycle of chronic neuroinflammation may result and lead to elevation of local levels of cytokines, chemokines, prostaglandins, and other inflammatory mediators that can contribute to tissue damage. The mechanisms that regulate microglial activities in the brain are poorly understood. In recent years, a more thorough understanding of the functional link between microglial activation markers and specific cellular functions has evolved. New information about the mechanisms that regulate the balance of neuroprotective microglial activities (e.g., neurotrophic factor production, phagocytosis of debris, amyloid or senile plaque removal) and neurotoxic microglial activities (i.e., ROS/RNS, prostaglandin, cytokine, and chemokine overproduction) will be required to understand how dysregulation of this balance hastens the death of vulnerable neuronal populations.

A second type of glial cell, the astrocyte, resides in the CNS and is important for regulation of the permeability of the blood–brain barrier. The cellular processes of astrocytes make intimate contact with essentially all areas of the brain and are functionally coupled to neurons, oligodendrocytes, and other astrocytes. This tight coupling enables astrocytes to regulate the homeostatic environment (including regulation of the excitatory neurotransmitter glutamate) and promote proper functioning of the neuronal network. Inflammation in the CNS may disrupt this process either transiently or permanently, as cytokines have important roles in reprogramming gene expression in glia (both in microglia and in astrocytes) during injury and recovery. Upregulation of glial fibrillary acidic protein (GFAP) in astrocytes denotes reactive astrogliosis in the CNS and may be part of a response to acute injury or neurodegeneration that can lead to permanent scarring and tissue damage. It is becoming increasingly evident that astrocytes also have important roles in neurological disorders. Mouse models of disease have revealed astrocyte-specific pathologies that contribute to neurodegeneration. Development of animal models in which astrocyte-specific proteins and pathways have been manipulated has contributed to our understanding of the normal biology of astrocytes. It is expected that development of targeted therapies for pathways in which astrocytes participate to the detriment of neurons will be possible in humans and should ultimately influence the clinical treatment of neurodegenerative disorders.

Cytokines, chemokines, and lymphokines Cytokines, chemokines, and lymphokines are multifunctional immunoregulatory proteins secreted by cells of the immune system. Within the CNS, cytokines, most notably tumor necrosis factor-α (TNF-α), the interleukin-1 (IL-1) and interleukin-6 (IL-6) families, interferon-γ (IFN-γ), and transforming growth factor-β (TGF-β) act in context-dependent ways to modulate inflammatory processes that affect the permeability of the BBB. Cytokines can exert neuroprotective effects independent of their immunoregulating properties and some of them (e.g., TNF-α) have been shown to modulate neurotransmission. However, under certain conditions, cytokines and chemokines promote apoptosis of neurons, oligodendrocytes, and astrocytes as well as damage to myelinated axons. The outcome of cytokine action in the brain depends on the dynamics, cellular source, degree of compartmentalization of cytokine release, pathophysiological context, and presence of co-expressed factors. The levels of several cytokines (including TNF-α, IL-1, and IL-6) become elevated in a wide range of CNS disorders, including ischemia, trauma, multiple sclerosis, Alzheimer's disease (AD), and Parkinson's disease (PD). While there is no evidence to support a role for any of them in triggering any of these diseases, cytokine-driven neuroinflammation and neurotoxicity may modify disease progression in a number of neurodegenerative diseases (see later).

What Triggers Neuroinflammation?

Neuroinflammation may be triggered by protein aggregation and formation of inclusions arising from mutations (i.e., α-synuclein) or disruption of the ubiquitin–proteasome system (UPS), immunologic challenges (bacterial or viral infections), neuronal injury (brain trauma or stroke), or other epigenetic factors. Chronic inflammatory syndromes (rheumatoid arthritis, Crohn's disease, and multiple sclerosis) and environmental toxins (pesticides and particulate matter) are the most notable epigenetic factors likely to trigger neuroinflammation. These insults can increase the permeability of the BBB to allow infiltration of lymphocytes and macrophages into the brain parenchyma. The immune reactions initiated by viruses and bacteria may contribute to latent vulnerabilities which could become manifest with future immunologic challenges. Depending on context, duration, and type of inflammatory response, inflammation may be detrimental or beneficial to the individual. During trauma to the CNS, acute inflammatory responses are mounted to limit injury and to aid in neuronal repair. However, when inflammation becomes chronic, it may lead to tissue damage and is likely to be detrimental to neuronal survival. Acute injury in most tissues is followed by release of histamine, with resulting increases in vascular permeability (i.e., exudation of fluid into the injured tissue and neutrophil infiltration). In the brain, such a response could result in increased intracranial pressure and would be detrimental within the confines of the skull. Thus, it is possible that the downgraded response of resident microglia is an evolved response that permits the CNS to respond to injury in a way that will result in minimal brain damage.

How Does Neuroinflammation Affect Neurons?

At the molecular level, acute inflammation in the CNS is believed to involve the neuroprotective actions of microglia, and to be beneficial because it acts to limit tissue damage (as in ischemic stroke). In contrast, chronic neuroinflammation is more likely to involve microglial activities that promote ROS/RNS generation, enhance the unfolded protein response (UPR), and contribute to neurotoxicity. Inflammatory challenges may trigger clinical symptoms of neurological or psychiatric conditions. High levels of certain microglial-derived inflammatory mediators (e.g., TNF-α) often lead to enhanced oxidative stress in neurons because they contribute to glutathione depletion. In addition,, several of the downstream signaling pathways (including caspases) activated by inflammatory factors may converge to elicit mitochondrial dysfunction and death of vulnerable neuronal populations through apoptosis or other forms of programmed cell death.

Evidence for Inflammation in Neurodegenerative Diseases

Neurodegenerative diseases are characterized by the loss of specific neuronal populations and often by intraneuronal as well as extracellular accumulation of fibrillary materials. Formation of intracellular inclusion bodies may result from abnormal protein–protein interactions, aberrant protein folding, and/or dysregulation of the UPS. These conditions, often referred to as 'proteinopathies,' are thought to have a central role in the neuronal dysfunction that characterizes several neurodegenerative diseases. One common way in which a number of divergent molecular or cellular events (e.g., mutations, oxidation, protein misfolding, truncation, or aggregation) may all contribute to death of neurons is via activation of resident microglial populations in specific brain regions. If the host is unable to eliminate the initiating trigger (i.e., proteinopathy caused by a mutation), chronic activation of microglia and chronic neuroinflammation-derived

oxidative stress may contribute to progressive neuronal dysfunction. If neuroinflammation is in fact contributing to neurodegeneration of vulnerable populations, then timely use of certain anti-inflammatory drugs should offer neuroprotection and limit progression of disease. However, human clinical trials with anti-inflammatory drugs have had very limited success in the management of several neurodegenerative diseases to date. Possible reasons for the failure of these trials could be the timing of the treatment and the dosing regimens chosen for the trials; further investigation in this area is warranted before dismissing the possibility of potential long-term benefits of anti-inflammatory drugs.

Clinical and Epidemiological Evidence for Inflammation in PD

Over the past decade, a great wealth of new information has emerged to suggest that inflammation-derived oxidative stress and cytokine-dependent neurotoxicity are likely to contribute to nigrostriatal pathway degeneration and lead to idiopathic PD in humans. Postmortem analyses of brains from PD patients have confirmed the presence of inflammatory mediators in the area of substantia nigra (SN), where maximal destruction of vulnerable melanin-containing dopamine (DA)-producing neurons occurs in PD patients. Signs of inflammation included activated microglia and accumulation of cytokines (including TNF-α, IL-1β, IL-6, and IFN-γ). The advent of technologies (such as positron emission tomography brain scans) that can be conducted in living humans confirms that patients with idiopathic PD have markedly elevated microglia activation in the pons, basal ganglia, striatum, and frontal and temporal cortical regions, irrespective of the number of years with the disease, compared to age-matched healthy controls. As stated earlier, activated microglia overproduce cytokines (including TNF-α, IL-6, and IL-1β) which exert neurotoxic effects on DA neurons; and SN dopaminergic neurons may be uniquely vulnerable to neuroinflammatory insults that enhance oxidative stress. Elevated levels of cytokines may act in an autocrine manner to maintain activation of abundant numbers of microglia in the midbrain, potentiating inflammatory responses (autoamplification of ROS, NO, and superoxide radicals to form highly oxidizing peroxynitrite species) and creating an environment of oxidative stress which further hastens damage of DA neurons. Although the genes for various cytokines, chemokines, and acute-phase proteins have been surveyed and individual reports demonstrate that certain single nucleotide polymorphisms are overrepresented in certain cohorts of individuals affected with PD, most of these findings have not been replicated in independent studies. Meta-analyses of multiple such association studies are crucial to assess the overall genetic effect of cytokine gene polymorphisms on disease.

Evidence for Oxidative Stress and Inflammation in Experimental Models of PD

A better understanding of the extent to which environmental factors that elicit chronic inflammation modify the known genetic risks for developing PD is needed. The two neurotoxins most widely used to induce nigral DA neuron loss in rodents are 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and 6-hydroxydopamine (6-OHDA). These neurotoxin models are accompanied by a robust glial reaction. Studies with nonhuman primates exposed to MPTP indicate that the cycle of neuroinflammation triggered by these neurotoxins persists long after the initial insult abates and may contribute to the progressive degeneration of the nigrostriatal pathway. Although each neurotoxin may trigger different initial cascades of events, they all consistently involve oxidative stress as the critical mechanism that elicits DA neuron death. In addition, there are endogenous toxins that can contribute to nigral DA neuron loss and to the risk of developing PD. These include tetrahydroisoquinolines (TIQs), which are produced via the reaction of DA with aldehydes and act to decrease dopaminergic neurotransmission, generate ROS, and trigger apoptosis. Nitric oxide (NO) also contributes to DA neuron death through mechanisms that, while not completely understood, are likely to involve mediation of excitotoxicity, activation of poly(ADP ribose) polymerase-1 (PARP-1), DNA damage, activation of caspase-dependent and-independent cell death, and/or nitrosylation of proteins, including α-synuclein and Parkin. Thus, general synthetic antioxidants as well as natural products with antioxidant properties (including green tea, omega oils, curcumin, and various varieties of berries) are being intensely investigated for their ability to provide DA neuroprotection in experimental models of PD and in the clinic.

Findings obtained from histopathologic, genetic, and pharmacologic studies in animals implicate a role for cytokine-driven inflammation and neurotoxicity in loss of nigral DA neurons induced by MPTP, 6-OHDA oxidative neurotoxin, and bacteriotoxin. Rapid increases in cytokine levels are detectable in rodent midbrain SN within hours of *in vivo* administration of 6-OHDA or MPTP. Pharmacologically, chronic infusion of various anti-inflammatory compounds, including cyclooxygenase-2 (COX-2)-selective nonsteroidal anti-inflammatory drugs (NSAIDs) or soluble TNF-selective inhibitors, rescues nigral DA

neurons from progressive degeneration and death. The higher sensitivity of nigral DA neurons to injury induced by neuroinflammatory mediators may be secondary to reduction of endogenous antioxidant capacity (i.e., glutathione depletion). In summary, an overwhelming number of studies now indicate that chronic elevation of certain cytokines in the CNS can contribute to progressive degeneration of nigral DA-producing neurons. These findings raise the interesting possibility that environmental triggers initiate cytokine-driven neuroinflammation and contribute to the development of PD in humans.

Anti-inflammatory Drugs and PD

Additional strong evidence that inflammatory processes modulate PD risk came from a prospective study of hospital workers; the study indicated that the incidence of sporadic PD among chronic users of over-the-counter NSAIDs was 46% lower than in age-matched non-NSAID users. NSAIDs scavenge free oxygen radicals and inhibit cyclooxygenase-2, which is known to participate in oxidation of DA. Although the specific NSAID target(s) that mediate(s) the effect associated with lower PD risk remain(s) unidentified, these findings suggest that neuroinflammatory processes contribute to DA neuron loss and development of PD in humans. In concert with findings derived from experimental models, these epidemiological findings raise the possibility that anti-inflammatory therapy could delay or prevent onset of PD.

Steroids have anti-inflammatory properties and have been shown to rescue DA neurons in rodent models of PD; however, because of their well-established side effects, they are not likely to be suitable for long-term use in humans. Clinical trials in PD patients using short-term administration of immunophilin ligands (which lack immunosuppressive properties of the parent compounds) have also had limited success. At the time of this writing, minocycline, the tetracycline derivative which readily crosses the BBB and is well-tolerated in humans, was under evaluation in phase III clinical trials to determine if it could alter long-term progression of PD and other neurodegenerative diseases. A reexamination of available classes of anti-inflammatory agents may be needed to identify other compounds that can cross the BBB. Alternatively, novel modes of therapeutic delivery for introduction of promising anti-inflammatory compounds that cannot readily cross the BBB will need to be developed. Time will tell if successful development and timely use of anti-inflammatory approaches can modify the progressive course of this disease and afford therapeutic benefit in patients with early signs of PD.

Inflammation in Acute CNS Injury: Traumatic Brain Injury

Inflammation is a hallmark of all forms of acquired brain injury (i.e., traumatic brain injury (TBI), cerebral ischemia or stroke, and spinal cord injury). Worldwide, millions of people are treated each year for significant head injury; a substantial proportion die, and many more are disabled. The progressive tissue damage that occurs following TBI has been attributed to cerebral inflammation and apoptotic cell death. Strategies to inhibit one or both of these pathways are being investigated as potential therapies for TBI patients (see later), though current therapy for TBI remains entirely supportive. The rationale behind mechanism-based drug design is to provide some degree of neuroprotection by preventing injured or vulnerable nerve cells from dying and/or to stimulate regenerative processes that could lead to the restoration or the formation of new connections lost on account of the injury. However, in the case of TBI, although it is clear that microglia activation occurs, the role of microglia in limiting versus promoting injury has not been clearly established. To add to an already complex scenario, significant activation of astroglia also occurs in TBI and recent evidence suggests that astrocytes may also participate in the neuroinflammatory process by regulating expression of heme oxygenase-1 (HO-1) in microglia and limiting ROS/RNS production.

Although there are no clinical treatments yet available to enhance repair of the damaged brain after trauma, a number of potential therapies have been investigated with varying degrees of success. For many years, corticosteroids had been used to treat head injuries in the emergency room. This popular practice was based on the rationale that if these drugs could reduce mortality by 1–2% they would have a significant impact given the large numbers of people that incur TBI each year. However, the largest head injury trial conducted to date has provided conclusive data to indicate that global immunosuppression of innate immune responses with corticosteroids actually negatively affects outcome after TBI. In 2001, after a successful pilot study, the Medical Research Council of Great Britain funded the CRASH (Corticosteroid Randomization after Significant Head Injury) trial to examine the effect of corticosteroids on death and disability after injury. Data obtained for nearly 10 000 patients at 6 months postintervention showed that the risk of death was higher in the corticosteroid group than in the placebo group, as was the risk of death or severe disability, with no evidence that the effect of corticosteroids differed by injury severity or time since injury. On the basis of this definitive study, it was concluded that corticosteroids

should not be used routinely in the treatment of head injury. Another large randomized, controlled trial using therapeutic hypothermia in the setting of moderate to severe TBI also failed to show an improvement. However, recent data suggest that one way that hypothermia may be helpful is when it is administered early enough to be an immune modulator. Based on this, there is currently another National Institutes of Health (NIH)-funded phase I clinical trial looking at the efficacy of hypothermia initiated early following TBI in children.

Given that TBI can induce progressive neurodegeneration in association with chronic inflammation and that chronic treatment with the nonsteroidal anti-inflammatory drug, ibuprofen, had been shown to improve functional and histopathologic outcome in mouse models of AD, ibuprofen was also investigated for its ability to improve long-term outcome following experimental TBI. Disappointingly, chronic ibuprofen administration was found to worsen cognitive outcome following TBI. These data may have important implications for TBI patients who are often prescribed NSAIDs for chronic pain.

Minocycline, a tetracycline derivative with anti-inflammatory properties, has been intensely studied and found to be therapeutically effective in various models of CNS injury and disease via mechanisms involving suppression of inflammation and apoptosis. Although individual studies have shown some positive effects with minocycline, further studies on minocycline in TBI are necessary in order to consider it as an effective therapy for brain-injured patients.

The neuroprotective properties of progesterone (PROG) and its enantiomers (ent-PROG) or its metabolite (allopregnanolone) have been investigated after TBI. Studies have shown that a single injection of progesterone can attenuate cerebral edema when administered during the first 24 h after TBI in rats, but this regimen did not always produce functional benefits. In contrast, steady-state progesterone treatment after TBI decreased edema and anxiety and increased activity, thus enhancing behavioral recovery. Therefore, chronic pharmacological administration of progesterone may prove to be more beneficial in translational and clinical testing compared to bolus injections over the same period of time. In addition, ent-PROG treatment has been shown to decrease cerebral edema, cell death mediators, inflammatory cytokines, and reactive gliosis, and to increase antioxidant activity in experimental models of TBI. Based on these compelling experimental data supporting the neuroprotective properties of progesterone, a phase II randomized, double-blind, placebo-controlled clinical trial was conducted at an urban level I trauma center to assess the safety and potential benefit of administering progesterone to patients with acute TBI. The study showed that patients with moderate TBI who survived their injury were more likely to have a moderate to good outcome if they received progesterone than were those who received the placebo.

The pro-apoptotic cytokine TNF as well as the impact of TNF neutralization has been extensively investigated following TBI in a number of different experimental models (e.g., percussion injury and controlled cortical injury) with a number of different outcomes, depending on the timing of the intervention. Overall, TNF was found to have dual effects: in certain instances it enhanced survival and in others it promoted apoptosis during secondary damage after TBI. These findings are not surprising given that TNF signaling activates numerous downstream pathways that have the capacity to differentially regulate activation of microglia – nuclear factor-kappa B (NF-κB)- and c-Jun N-terminal kinase (JNK)/AP-1-dependent gene transcription. Multiple studies have suggested that the protective effects of hypothermia following TBI may be mediated via TNF-R1 activation of the JNK and caspase-3 pathways.

Last, it is worth noting that repetitive TBI has been linked to the development of AD. Development of diffuse β-amyloid (Aβ) deposits and tau pathology approximately 1–3 weeks after head trauma has been reported clinically, and head trauma is the environmental factor most consistently associated with AD or PD risk. The mechanisms underlying this process are not clear but are likely to be influenced by apolipoprotein E (apoE) gene status. The ε4 allele of the *APOE* gene (*APOE* ε4), which confers higher AD risk to individuals, has been associated with both the vascular risk factors and the consequences (cognitive impairment, dementia) of white-matter lesions (WMLs), suggesting that *APOE* ε4 carriers may have diminished capacity for neuronal repair after TBI. Further studies are warranted to clarify this relationship.

Conclusions

Over the past decade, the concept of the brain as an immune-privileged organ has been rejected in light of unequivocal evidence that the permeability of the blood–brain barrier can be regulated under normal conditions and may become dysregulated in chronic and acute neurodegenerative conditions. Reactive astrocytes, activated microglial cells, and overproduction of inflammatory mediators orchestrate neuroinflammatory responses that either promote or compromise neuronal survival, depending on type, duration, and context. In general, acute inflammatory responses during trauma to the CNS involve the neuroprotective actions of microglia aimed at limiting injury and enhancing neuronal repair. When

inflammation becomes chronic, microglial activities create an environment that often enhances oxidative stress in neurons, contributes to neuronal dysfunction, and hastens neurodegeneration. While there is no evidence to support a role for any specific inflammatory mediator in the etiology of any neurodegenerative disease, cytokines in the brain and/or cerebrospinal fluid become elevated in a wide range of CNS disorders, including ischemia, trauma, multiple sclerosis, AD, and PD, raising the possibility that they modify (i.e., accelerate) disease progression. Collectively, whether cytokine action has beneficial or harmful outcomes in the brain depends on the dynamics, cellular source, degree of compartmentalization of cytokine release, pathophysiological context, and presence of co-expressed factors. Nigral DA neurons may be uniquely vulnerable to neuroinflammatory insults that enhance oxidative stress; and over the past decade, a great wealth of new information has emerged to suggest that inflammation-derived oxidative stress and cytokine-dependent neurotoxicity may contribute to nigrostriatal pathway degeneration and increase the risk for development of idiopathic PD in humans. Following acute TBI, cerebral inflammation and apoptotic cell death contribute to progressive tissue damage and may increase the risk for development of AD by promoting diffuse deposits of Aβ. No highly effective clinical treatments are available to enhance repair of the damaged brain, and use of high-dose steroids is now contraindicated in the management of TBI. Further basic science and more clinical research are needed to establish a causal link between neuroinflammation and neurodegeneration. If one is found, timely use of anti-inflammatory drugs may prove effective in slowing down the progressive neuronal death in chronic neurodegenerative disease and acute CNS injury.

Information Coding

B J Richmond, National Institute of Mental Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Neuronal Codes

Neural coding describes the study of information processing by neurons. Such studies seek to learn what information is used, and how information is transformed as it passes from one processing stage to another. The field of neural coding seeks to synthesize information arising from many levels of analysis and to explain how integrated behavior arises from the cooperative activity of the neurons in the brain.

Much is known about the biophysics of neuronal responses – that is, how a spike is generated, how the spike acts on the axonal terminal to cause transmitter release, and how transmitters act on the target neuronal receptors. However, the impact of series of spikes is not well known, and it is even less clear what information has been encoded and how that information will be utilized in subsequent processing stages.

It is natural to consider the brain as an information processing machine. It takes in information from physical changes in the environment, including light, touch, and sound, integrates this information with remembered or genetically coded information and then produces organized behavior. In any information processing system, issues to be considered are what is being encoded, what is the code used to transmit the information, how reliable (noisy or not) is the code, and how the information is utilized or decoded.

At the base of this cascade of information processing is the information transformed and transmitted by single neurons. The signal on dendrites and cell body is reflected in fluctuations in the potential difference across the membrane. The signal that is transmitted down the axon is quite different; it is the action potential. This action potential propagates rapidly down the axon. At the axon terminal the arrival of the action potential generally causes the release of a transmitter that affects the membrane of the target neuron. The action potentials mark times at which the cell membrane at the neuronal cell body reaches the firing threshold. Thus, there is a sequence of action potentials containing information about the membrane potential at the neuronal cell body, and it is the information carried by the train of action potentials that provides information at the projection targets for the neurons. This train of action potentials (the spike train) can be considered as elements of a neural code.

Average Rate Codes

The number of action potentials, or 'spikes,' is the critical feature of the neural code. For example, for primary visual cortex, the number of spikes provides information about the orientation of a bar, as shown in Figure 1, or, for primary motor cortex, the direction of reaching. For the two examples, the tuning curve can be parameterized by some simple function (e.g., as has been done for reaching direction in primary motor cortex with a cosine or some other similar smooth, unimodal function). This 'tuning curve' then provides a means to estimate the direction of the bar (or movement) from the neural response (Figure 2). In higher brain regions (e.g., inferior temporal cortex of the monkey), the neurons respond most strongly to a particular complex object, sometimes a single face or a hand, and a tuning curve for this 'spike count code' can be determined empirically. So far it is generally not possible to parameterize the tuning curve as simply as is done with the aforementioned directional tuning examples. However, for considering the principles underlying neural codes, parameterizing the tuning curve is not critical. Decoding can be studied in any brain region for which the equivalent of this 'tuning curve' is available. The results of experiments using measured tuning curves only become easier to interpret as the knowledge about the tuning function improves. Hence, over the history of single neuronal recording, there has been appropriate emphasis on measuring such 'tuning curves.'

If every presentation of a stimulus elicited the same response, decoding the response would be straightforward; it would only be necessary to measure the response and look up which condition or conditions elicit that response. However, as can be seen in Figures 1 and 2, the responses are variable. Many of the possible responses emitted by the primary visual cortical neuron could have been elicited by any of the orientations of the bar (here measured in spike count). In the face of such variability, it is not possible to know unequivocally which stimulus elicited the response. It is possible, however, to determine how likely or probable any particular stimulus might be. In the case shown in Figures 1 and 2, one can pick the stimulus that is most likely to have elicited the particular response, and it then becomes possible to estimate how many neurons would be needed to decode the orientation of the stimulus. Thus, even though variability limits the information that a single neuron can encode, a probabilistic estimate of the orientation can be developed. Then, based on these probabilities, some rule for choosing a stimulus can be identified.

Figure 1 Example of orientation sensitivity of a neuron in primary visual cortex. The black bar at the top of each panel was flashed onto the receptive field (i.e., the position in the visual field that, for that neuron, is sensitive to visual stimulation) of the neuron for 600 ms. The dots in each horizontal row in the panels represent the times that the neuron emitted an action potential. Each row shows a different presentation of the stimulus. Time on the *x*-axis is relative to the stimulus appearance. The third black bar from the left (top and bottom) elicited the most intense response (the largest activity) from this neuron. The large variation in responsiveness from one stimulus presentation to the next can be seen in that successive rows of dots have different numbers of dots, and the dots are in different places for all of these black bars. The smooth black line in each panel is a smoothed average of the spikes across all of the stimulus presentations. This is taken as an estimate of the overall driving of this neuron by its inputs. Modified from Doya K, Ishii S, Pouget A, and Rao RPN (eds.) (2007) *Bayesian Brain: Probabilistic Approaches to Neural Coding*. Cambridge, MA: MIT Press.

The usual rule, and the easiest to implement, is to choose the stimulus that is most likely to have elicited the response; this is the maximum likelihood estimate.

It is because of the response variability that tools from signal processing, statistical pattern recognition, and information theory have become important for studying neural coding. Even though it is obvious that the pattern of spikes can carry additional information, it is easiest to start with the assumption that the spikes are distributed randomly through time, and that only the spike count changes. It then becomes straightforward to add information from the time sequence of the spikes after developing the principles by which to assess the code.

As a first approximation, assume that there is no information in the pattern of spikes. Then measure the information using the spike count alone as a neural code. The only process for which the spikes are equally likely at all times – that is, there is no correlation over time – and hence for which there can be no information in the timing is a Poisson process. A Poisson process is a special case of point process – that is, a process in which there are discrete events that can all be considered identical occurring over time. The only number needed to characterize a Poisson process is the average rate of the events. The variability is proportional to the mean firing rate (Figure 3), with the variability being higher when the firing rate is higher, although the mean is not equal to the variance, as would be the case for a pure Poisson process. The source of this variability is not really known, although if a

Figure 2 Orientation tuning for the neuron in **Figure 1**. The plot shows the bar angle on the *x*-axis and number of spikes on the *y*-axis. Each small square is the number of spikes emitted in response to one stimulus presentation. The large circles show the average, and the line connects the averages for each viewing. This illustrates the wide variation in the number of spikes emitted even for the same bar on different presentations (the squares in each column). Nonetheless, there is a clear and reliable tendency across trials. Trial-by-trial estimation of the bar orientation can only be done in a probabilistic way, making it necessary to consider how the responses of populations of neurons might be read and decoded. Modified from Doya K, Ishii S, Pouget A, and Rao RPN (eds.) (2007) *Bayesian Brain: Probabilistic Approaches to Neural Coding*. Cambridge, MA: MIT Press.

Figure 3 Scatter plot of means vs. variances. Each black dot represents the mean (*x*-axis) and variance (*y*-axis) elicited across many presentations of a single black and white stimulus on the receptive field of a V1 neuron. The solid line is the regression line, and the dashed line is the equality line where the points would lie if the responses arose from a Poisson process. The regression line is parallel to and above the line expected for a Poisson process. From this it can be concluded that the responses have some internal timing structure. From experience it is known that this type of overdispersion is related to point processes in which the points have a tendency to be in groups or 'bursts.'

visual stimulus changes very rapidly, responses can be considerably less variable. It is obvious that the pattern of the spikes over time might be carrying information, and simple considerations of the biophysics of information across synapses make it clear that this temporal 'coding' could easily influence the target neuron.

Two methods commonly used to quantify the effect of this variability are classical analysis of variance (ANOVA), with each stimulus being one level in the stimulus factor (or if a continuous parameter is used to characterize the signal, linear regression), and information theory, which estimates how much the uncertainty about the stimulus being shown is reduced by seeing the response. In ANOVA, in addition to the *p*-value (the probability that all of the levels are the same), the amount of variance explained by each factor (in our example, the orientation) is calculated, and the amount of variance that is left unexplained in this 'model' of the data is also given. Thus, ANOVA (or linear regression) allows the calculation of the signal-to-noise ratio (the explained variance divided by the residual variance). This is a powerful and straightforward approach to quantifying the relation between a set of experimental conditions and the discriminability among conditions that can be achieved using the neural responses. Thus, for the example in **Figures 1**

and 2, 70% of the variance can be accounted for, by orientation, and rest is unexplained (for, the purpose here, noise).

Temporal Codes

If it were certain that the responses could be characterized by the spike count or rate alone, tools from linear statistical modeling, such as regression or ANOVA (with possibly some generalization to other types of statistical linear modeling), would be adequate to quantify the relations between stimuli or experimental conditions and responses. However, the responses occur over time, and, as can be seen in Figure 4, the rate varies as a function of time. It is natural to ask how much better the stimulus can be determined by using the time course of response, as compared to using the response strength alone. In the example shown in Figure 4, the total number of spikes and the variances of these two sets of responses are the same when counted during the whole period of stimulus presentation. It is evident that the variability in both the number and timing of spikes will limit the information carried by the responses. However, it is also clear that the envelope of the firing rate (the low-pass filtered version of the spikes) is different across the two stimuli. Thus, even though these two sets of responses have the same number of spikes over the whole counting interval, the time course of when the spikes occur appears to be different.

There is an ongoing debate about how precisely the timing of spikes needs to be measured to capture all of the information in spike trains. The way for an analysis to become sensitive to the time course of the response is to break the response into epochs of different lengths, and ask whether the information increases as the epochs become smaller. This makes the measurement of the time course more and more precise – that is, as the measurement of the time course becomes more precise. As the epochs become shorter (and there are more of them), the variations in the response that is represented become finer: the response has more 'wiggles.' The difficulty with this approach is that as the epochs become shorter, there are more of them, and the estimate of the firing in each epoch becomes less certain.

One straightforward way to study the temporal pattern of the responses is to use the principal components of the set of responses. The principal components are the eigenvectors of the data domain covariance matrix, and form an orthogonal set of, in this case, temporal waveforms derived from the data. Each response can be represented as a weighted sum of principal components. Information theory is a valuable tool for assessing these types of multidimensional codes, or codes with more than one element. To use information theory, the basic definition of transmitted or mutual information is required. The mutual or transmitted information, $H(r, s)$, is the difference between the entropy of the spike train (or stimulus),

Figure 4 Raster dot diagrams and average spike densities for two stimuli eliciting responses with the same number of spikes. It is clear from this diagram that the pattern of spikes over time, or the pattern of the driving force over time, is different, and ought to be useful for using the spike trains to distinguish the stimuli.

$H(r)$, and the entropy of the response when a stimulus is presented, $H(r|s)$; $H(s, r) = H(s) - H(r|s)$. The entropy is

$$\sum_s p(s)\log(p(s))$$

and the entropy of the stimulus given the response is

$$\sum_s p(s,r)\log(p(s|r))$$

The r and s can be interchanged because mutual information is symmetrical with regard to the sender and receiver of a message, even if the physical channel might not actually be symmetrical (or bidirectional). Information has the strength that the representation of the stimulus and/or the response can be multivariate. With this approach it is possible to compare transmitted or mutual information from different codes. This, then, provides measurements to assess whether one assumed code carries more information than another assumed code.

The responses in Figure 4 are decomposed using their first few principal components; in Figure 5, it can be seen that the value of the first principal component is similar for the two responses, as the spike counts are. The coefficients of the second principal components, however, here have opposite signs. This is because the second principal component has a shape that readily represents the dip (Figure 4, left) or lack of it (Figure 4, right) seen in these two responses. The weights then become the code elements. The information from one, two, or more principal components can be used as candidate neural codes. Using more than the first two principal components adds little, if any, additional information in this example. For the cases where the principal

Figure 5 Principal decomposition of the two responses shown in Figure 3. The principal components were derived from the covariance matrix calculated from all of the responses to all of the patterns. The average spike densities are shown at the top. The middle panels show the weightings of the first five principal components (PC). The bottom panels show the shapes of the principal components (the eigenvectors of the covariance matrix), as modulations over time. The time-dependent mean (shown as the first waveform, labeled 'Average firing') was subtracted from each response before the covariance matrix was built. The second principal component (labeled 'Second PC') has a shape that, when added to the average, will accentuate the peak or blunt it (by subtracting or inverting this waveform).

components have been used to distinguish responses, the number of them that carry independent information over the preceding ones has been small, between 2 and 5.

In general, slow changes in the neuronal firing are represented by the lower numbered principal components, and as the principal component number goes up, the precision of the timing patterns increases. The need for this small number of principal components suggests that the spikes do not generally need to be represented very exactly in time – that is, blurring them out in time does not hurt the potential decodability of the responses. In the visual system, several experiments have shown that the precision of the spike timing is on the order of 10–20 ms, or longer in these experiments using stimuli that appear and remain on. In contrast to these measurements, if the stimulus is rapidly changing (i.e., if we repeatedly hit the system hard), the responses have spikes tightly time-locked to some temporal feature of the stimulus time series.

The need for more than one principal component suggests that more than one feature of the stimulus (or experimental condition) is encoded (i.e., information is multiplexed). One question is whether different parts of the neuronal responses can be identified with different stimulus characteristics. There are two types of response structures in primary visual cortex that have been given such identifications. These structures are single versus doublet spikes (i.e., whether spikes tend to be grouped into pairs or whether they occur singly). It has been shown that, for complex cells, the amount of clustering is related (tuned) for spatial frequency, and the single spikes are tuned for contrast. It has also been shown for complex cells that the response strength is closely tuned for orientation across a wide range of contrasts, whereas the latency changes substantially with contrast and response strength changes substantially less.

An alternative explanation for the variability is that it arises from encoding sources within the nervous system that do not covary with the stimulus (e.g., arousal or focal attention). These factors might then give rise to unaccounted for variability that is not true noise. At a minimum, the variability will have to be described and its influence on the organization of neuronal responses must be taken in account. The variability is seen both in the number and timing of spikes. Although it was for a long time not completely appreciated, it is now clear that the variability in the number of spikes influences our estimates of relating the number of spikes to their timing.

It is known that the variance becomes greater as the spike count increases. If we plot the coefficients of the variance of the second principal component against its mean for each stimulus, there is only a weak linear relation. The variance of the second principal component, however, is related to the spike count. This can be understood in stochastic terms. Consider stochastic sampling of a uniform point process. If the spikes are placed stochastically, the number of combinations of spikes that arise by chance is

$$\frac{n!}{k!(n-k)!}$$

or, n choose k, where n is the number of bins for the time period (usually taken to be 1 ms) and k is the number of spikes to be placed in the bins. If the number of spikes changes, the number of patterns that occur by chance necessarily also changes; n, the number of bins, is constant, and, k, the number of spikes, changes stochastically across stimulus presentations. For example, 200 choose 2 yields 19 900 combinations of spikes by chance, and 200 choose 3 yields 1 313 400 combinations. Since a small change in spike count can dramatically change the number of spike patterns expected by chance, any effort to describe what happens must first and carefully account for the variability in spike count. This then leads to a line of work to evaluate the impact of this necessary relation between spike count and numbers of spike patterns.

Finally, there is one more indication of this relation between the number of spikes and the number of spike patterns. If the coefficients of the first and second principal components from one neuron are placed on a scatter plot, they fill a cone, with the apex at the lowest spike count. This shows that the number of response types grows with the spike count (and would continue to grow until half the bins could be filled). Thus, when there are only a few spikes, there are only a relatively few spike patterns available for coding.

For a random process, even if not strictly Poisson, the null hypothesis that the spikes are randomly placed so that the overall rate is duplicated can be constructed using order statistics. Order statistics give the unconditional probability distributions for the kth event out of n events. For example, we can calculate the probability distribution for the third event or spike out 10. Order statistics explicitly needs the counts, the density of events (peristimulus time histogram, or PSTH), and the cumulative distribution, all of which we can estimate from data. However, we do not just want this unconditional distribution. Rather if the conditional distribution is available, a decoder or an accurate simulator can be constructed.

The basic equation of order statistics is as follows:

$$h(t) = \binom{n}{k} kF^{k-1}(t)f(t)[1 - F^{n-k}(t)]$$

Figure 6 Decoding the spike train at the top for the two responses shown in Figure 4. The spike densities are shown again at the bottom in red and black. The *x*-axis on all three panels is time (in milliseconds) after stimulus appearance. The vertical axis on the top panel is the probability of guessing stimulus 1 (black) or stimulus 2 (red). For this spike train, shown by the black vertical tick marks above the top panel, the guessing probability rises quickly (and is correct). Note that the confidence of the guess can decrease at times. It turns out that the latency difference is a key feature for correct decoding in this example. Having a delay in the appearance of the first spike makes the likelihood of stimulus 1 very high.

where $h_1(t)$ is the probability of the spike k at time t; n choose k times k is a normalizing factor, and $F(t)$ is the cumulative distribution from $f(t)$, the rate function over time (estimated as the spike density or peristimulus time histogram). By working recursively, the conditional estimate, based on the time or spikes that have already gone by, can be constructed. This is simplified to be the probability of the first spike over time, $h_1(t)$.

With this recursive relation each successive spike can be considered the next first spike. Next, to construct the probability of the stimulus, regardless of the spike count, the order statistics are weighted by the probability of that spike count occurring, and these are summed. Then the probability of a stimulus s, at time t, through Bayes' theorem, can be estimated, and from this, the probability of the stimulus $p(s, t)$, at time t, can be calculated. Using these new probabilities as the new $p(s|t)$ for $p(s)$, decoding the spike train can be carried out spike by spike. Stepping through the spike train, $p(s)$ is updated. Using a maximum-likelihood rule, for example, a guess is made as to what stimulus is eliciting the spike train (Figure 6).

Population Coding

It is certain that activity must be coordinated among large ensembles of neurons, but it is not yet known how information is handled in ensembles. The simplest hypothesis is that the responses of neurons are summed or averaged, with the weight being the experimental condition that is weighted by the tuning in the tuning curve. This vector coding approach is the most influential model of population coding. It is relatively easy to compute. The experimenter can even measure the activity of neurons at different times. It is also straightforward to calculate how many neurons with independent noise are needed to decode from the responses in any condition. This approach is very important, also, for understanding the assumptions underlying mass population measurement approaches such as functional imaging (which actually measures blood flow changes in most cases) and field potentials. These are popular surrogates for having measurements of neural activity, spike trains, membrane potentials, and/or synaptic activity. These approaches assume that the average (presumably some sort of vector average, as in the vector coding approach) reveals functional properties.

The vector averaging code is powerful and is very convenient for computing the results from measuring the tuning curves of lots of neurons. However, it seems likely that the patterns of activity that occur simultaneously, or at least in a coordinated manner, might play an important role. The issue is whether spikes arriving from different inputs to a target neuron have different effects on the target, depending on their relative arrival times. The biophysics of neurons suggests that this should be the case. Before going forward, it is important to point out that the precision with which the coordinated activity must occur is not settled, so there are many investigators trying to make the needed measurements.

Another consideration is whether it matters which neuron carries the spikes. Can the spikes from different neurons be mixed without any loss of information? In the measurements made to this time, the information is greater when the spikes from two neurons are kept separate – that is, it helps to know which neuron carried the spike. This measurement has only been made a couple of times, and must be repeated because it suggests that population measures that only make use of the ensemble average activity will underestimate the information-carrying capacity of the tissue being considered.

A great deal of work has been carried out to look at coordination or synchronization of spikes. The question remains about how precisely the spikes must be represented to account for the information they carry. It is especially important but difficult to determine whether there is information that depends on codes across neuron (e.g., imagine a code based on the difference between the responses of two or more neurons). An intriguing hypothesis about cortical processing is

that there are patterns of spikes hidden within the apparently noisy responses of the aforementioned sort. This hypothesis, the synfire chain hypothesis, arises from strong theoretical considerations, in turn arising from straightforward, elegant considerations about cortical connectivity and neuronal biophysical properties. There is some evidence supporting this type of coding, but the number of these hidden patterns is small even in the best examples, so, although this is an elegant idea, the support is not yet very strong.

Another intriguing code that has been suggested is the order of neuronal recruitment. This code gets theoretical consideration, and there is a small amount of evidence that it could be used, at least in the peripheral somatosensory system. It is elegant and simple, but in the face of neurons with ongoing background activity it might be difficult to implement in practice, but it is mentioned here because it emphasizes that latency to onset of firing might (almost certainly does) play an important role in coordination of responses across neurons.

Finally, it seems plausible, and some would say even likely, that there might be dynamically changing neuronal ensembles, especially during learning, and under those circumstances there might be patterns of spikes within and across neurons that are strongly related to cognitive events. A lot of new work is being carried out to collect data from several neurons, even tens of neurons. The evidence about how signals are combined is not at all conclusive. With the advent of new tools from molecular genetics, it is becoming possible to visualize individual members of simple ensembles and make optical recordings of them. Now will come the exciting work of learning how the neural codes from different members of an ensemble are related.

Inherited Macular Degenerations: Animal Models

Macular degenerations constitute a heterogeneous group of diseases that involve mainly the macular region of the eye (Figure 1), ultimately causing a defect in central vision. In contrast to global retinal diseases and cone predominant degenerations, macular dystrophies tend to have normal full-field electroretinograms (ERGs; tests that measure the electrical responses generated by various cell types in the retina when it is stimulated by increasing amounts of light) and peripheral visual fields (the total area in which objects can be seen in the peripheral vision while the eye is focused on a central point). Pathologically, they are characterized by atrophy of the retinal pigment epithelium (RPE) and photoreceptor degeneration. As a whole, macular degenerations are the most common cause of irreversible blindness in the general population, particularly among the elderly in the Western world.

Recent technological advances have led to significant developments in genetic engineering and have allowed researchers to manipulate the expression of genes and generate accurate and reproducible disease models. This is critical for identifying the underlying mechanisms by which diseases occur. Here, we summarize the most significant macular degenerations that are currently known and describe the animal models that are available for their study.

Best Disease

Best disease, also known as vitelliform macular dystrophy, is an autosomal-dominant congenital disease that affects the central retina. Its name is derived from the appearance of the classic vitelliform (or egg yolk-like) lesion seen in the macula on clinical examination (Figures 2(a) and 2(b)), which results from excess lipofuscin (the name given to fine yellow-brown pigment granules composed of lipid-containing residues of digested cellular material) in the RPE cells across the fundus as well as the presence of degenerating RPE cells located between the foveal RPE and Bruch's membrane. In addition to the vitelliform lesion, there is a loss of foveal photoreceptors in this disorder.

The eye has a standing electrical potential across it, with the front of the globe positive and the back negative, that is generated largely by the transepithelial potential across the RPE. Retinal illumination causes an initial rapid fall in the standing potential (the fast oscillation), followed by a slow rise (the light response). The clinical electro-oculogram (EOG) measures the amplitude of the standing potential and light response. The ratio of the light peak to the dark trough is called the Arden ratio. The diagnosis of Best disease is based on a reduced Arden ratio on the EOG (Figure 2(c)).

It is now known that Best disease is caused by a mutation in the *VMD2* gene found on chromosome 11q13. *VMD2* encodes a protein called bestrophin, which acts as a chloride channel in the basolateral membrane of the RPE.

Model of Best Disease

Recently, an acute model of Best disease was generated in rats. Constructs containing mutant forms of bestrophin (W93C or R218C) in replication-defective adenoviral vectors were subretinally injected into rat eyes, resulting in transient overexpression of the bestrophin mutants in the RPE. The treated animals had all the electrophysiological characteristics of Best macular dystrophy – diminished light peak response in the absence of a-wave, b-wave, and c-wave abnormalities. Although *VMD2* has been identified as the major gene responsible for Best disease, a stable genetic model has yet to be reported.

Stargardt Disease

Unlike the other common macular dystrophies (most of which have a dominant inheritance pattern), Stargardt disease has an autosomal recessive mode of inheritance. It is characterized by an abnormally high accumulation of lipofuscin in the RPE that leads to atrophy and the appearance of a bull's eye-like lesion on the fundus (Figure 3). Yellowish flecks (usually called fish-tail flecks) are also seen at the level of the RPE – a phenomenon known as fundus flavimaculatus, another name given to Stargardt disease. *ABCA4*, also known as *ABCR*, is the gene responsible for Stargardt disease. The *ABCA4* gene encodes a protein called rim, which is a transmembrane protein involved in the transport of vitamin A intermediates, specifically N-retinylidine-phosphatidylethanol-amine (N-RPE), to the RPE. As its name suggests, the rim protein is expressed in the rims of photoreceptor disc membranes (Figure 4). An alteration in the normal function of *ABCA4* leads to the accumulation of N-RPE in the outer segments of the photoreceptor cells, which in turn causes the formation of the lipofuscin component, N-retinylidene-N-retinylethanolamine (A2E). As a result, high levels of lipofuscin accumulate in the RPE, causing the

Figure 1 The target area of macular degenerations is the macula: (a) composite color fundus photograph of the eye; (b) retinal cross-sectional profile for one B-scan of the macular region, positioning the fovea and foveola (corresponds to the foveal minimum, light blue arrow); (c), spatially encoded frequency domain OCT image with 3-μm axial resolution (arrows point to the foveal depression). The macula is defined clinically as a central retinal area 5.5 mm in diameter within the boundaries of the superior and inferior temporal vascular arcades (white circle in (a)). The macula has the highest density of photoreceptor cells, both rods and cones. The fovea is a central depression within the macula approximately 1.5 mm in diameter, highly enriched in cones (blue smaller circle in (a)). The foveola is a rodless region within the fovea. Attached to the photoreceptors is a monolayer of pigmented epithelial cells, the retinal pigment epithelium (RPE), which is vital to the integrity and health of the visual cells. Bruch's membrane separates the RPE from the choroid (formed by a network of blood vessels, nerves, immune cells, and fibroblasts), which supplies the RPE and the photoreceptors with all their nutrients. Macular thickness can be determined using optical coherence tomography (OCT), a noninvasive technology that provides *in vivo* high-resolution measurements of the retina, nerve fiber layer, and optic disk. OCT is a clinical tool that is very useful in the diagnosis and monitoring of eye diseases such as macular degenerations. In OCT, a single point of light reflected off the retina forms an A-scan that contains information about the axial location of tissue interfaces within the eye. Data from these single points of light can be laterally aligned to form B-scan images (b). Currently, a spatially encoded frequency domain OCT device can capture 256 B-scans in rapid succession, resulting in a dense three-dimensional cube of OCT information (c). GCL, ganglion cell layer; NFL, nerve fiber layer; PR, photoreceptor inner and outer segments.

subsequent photoreceptor degeneration seen in Stargardt disease.

Model of Stargardt Disease

Based on the discovery of the role of *ABCA4* in Stargardt disease, an *abca4* knockout mouse was generated with the purpose of expanding our knowledge of this disease as well as identifying possible targets for therapeutic intervention. *Abca4* −/− mice lacking rim protein develop delayed dark adaptation and increased all-trans-retinaldehyde following light exposure. In addition, there is increased accumulation of both lipofuscin and A2E, the toxic lipofuscin fluorophore, within the RPE cells. Although in humans the compromise of the RPE due to A2E accumulation causes secondary degeneration of the photoreceptors, this has not been observed in the *abca4* −/− mouse. To date, this is the only genetic model of recessively inherited Stargardt disease.

Sorsby Fundus Dystrophy

Sorsby fundus dystrophy (SFD) causes visual loss in affected individuals beginning around the fourth decade of life. Transmission is autosomal dominant and has been linked to mutations in the tissue inhibitor of the metalloproteinases-3 (*TIMP3*) gene, which encodes a TIMP3 protein that inhibits the action of matrix metalloproteinases. Affected patients typically present with problems transitioning between light and dark, followed by central vision abnormalities and late loss of peripheral vision. Clinically, drusen (tiny yellow or white accumulations of extracellular material that build up in Bruch's membrane) are seen along with choroidal neovascularization (new blood vessels originating from the choroid) that grows into the subretinal space through a thickened Bruch's membrane (Figure 5). The presence of a few small (hard) drusen is normal with advancing age, and most people over 40 have some hard drusen. However, the presence of larger and more numerous drusen in the macula is a common early sign of age-related macular degeneration (AMD). In view of their location between the RPE and its vascular supply, the choroid, it is possible that drusen deprive the RPE and photoreceptors of oxygen and nutrients. As a result, SFD has garnered much interest because of its clinical similarities to the much more prevalent AMD.

Model of Sorsby Fundus Dystrophy

Currently, only one model of SFD has been reported, a knock-in mouse carrying the Ser156Cys mutation in the *TIMP3* gene, generated using site-directed mutagenesis and homologous recombination in embryonic stem cells. After 8 months of life, these mice showed abnormal morphology in both Bruch's membrane and

the RPE, but no neovascularization. Scotopic and photopic ERGs were normal throughout the life span of affected *Timp3*$^{S156C/S156C}$ mice.

Stargardt-Like Macular Dystrophy

Stargardt-like macular degeneration is an autosomal-dominant variation of Stargardt disease. Like classic Stargardt disease, ERG findings can vary, but in general they are fairly normal. In contrast, the appearance of a dark choroid, commonly seen on fluorescein angiography in recessive Stargardt disease patients, is absent in Stargardt-like macular dystrophy. Stargardt-like macular degeneration is much less common than recessive Stargardt disease, and it was not until 2001 that *ELOVL4* was identified as the gene responsible for this disorder. *ELOVL4* encodes an enzyme that is highly expressed in photoreceptor cells and is involved in the elongation of very long-chain fatty acids, hence its name. In particular, it is hypothesized that the ELOVL4 protein is involved in photoreceptor function and membrane composition because of its role in the synthesis of the polyunsaturated fatty acids of the outer segment. Genetic analyses of various pedigrees of Stargardt-like macular dystrophy have demonstrated that a 5-bp deletion or two 1-bp deletions result in the formation of a similarly truncated ELOVL4 protein that causes macular disease.

Model of Stargardt-Like Macular Dystrophy

The identification of *ELOVL4* as the gene responsible for Stargardt-like macular dystrophy led to the development of a transgenic mouse that expresses the mutant form of human ELOVL4 resulting from a 5-bp deletion. Similar to the *abca4* knockout mouse,

Figure 3 Stargardt disease. Autofluorescence imaging of right eye with hyperfluorescent flecks and hypofluorescent, diseased retinal pigment epithelium (RPE).

elovl4 transgenic mice show the accumulation of phagosomes (membrane vesicles found in RPE cells and formed by the inward folding of the cells' membranes to hold phagocytized photoreceptor outer-segment fragments) and lipofuscin in the RPE. However, photoreceptor degeneration and abnormal ERG changes are seen subsequently in these mice. As a result, the *elovl4* transgenic mouse model exhibits features of both Stargardt-like macular dystrophy and the atrophic form of AMD.

Age-Related Macular Degeneration

AMD is the leading cause of visual impairment in the elderly population of the United States and other developed countries. As its name suggests, this progressive disease is localized to the macular region of the retina. Its end result is the complete loss of central vision. AMD is broadly categorized into two types: atrophic (also known as dry or nonexudative) and exudative (also known as wet). The atrophic form is characterized by the deposition of drusen between the RPE and Bruch's membrane (Figure 6). The accumulation of A2E and its isomers and subsequent RPE death leads to secondary degeneration of the photoreceptors. Eventually, the retina thins and visual impairment occurs. Exudative or wet AMD (Figure 7) is characterized by choroidal neovascularization (CNV). Rapid visual impairment occurs when newly formed vessels leak into the subretinal space and damage the retina. The exudative form of AMD is responsible for most cases of severe visual loss, even though it is much less common than the dry form. Dry AMD does not usually progress to wet AMD. There is some debate as to whether both forms are related or represent separate disease processes; however, polymorphisms in complement factor H (CFH) have been linked to both types, suggesting an association between the two forms.

Although association studies have clearly implicated the role of genetics in the development of AMD, this disease is believed to have a multifactorial etiology with both genetic and environmental components (e.g., smoking and diet) contributing to it. One of the main hurdles in studying AMD has been the lack of precise animal models that would allow the elucidation of the genetic components involved.

Rodent Models of Age-Related Macular Degeneration

Rodents, specifically mice, are currently the primary species used to study AMD. Although rodents lack a macula, they offer several advantages for studying retinal disease. They are cheap and easy to handle, and, as a result, they can be used in large numbers for experiments. In addition, their relatively short life span allows for timely and efficient study of diseases of the elderly, such as AMD. A wide variety of hereditary retinal degenerations occur in mice, and many of the genes causing these diseases possess a corresponding human equivalent. Furthermore, genetic manipulation in mice is fairly simple, reproducible, and well established in the medical literature.

As already mentioned, the *abca4* $^{-/-}$ and the *elovl4* transgenic mice are useful models of Stargardt disease and Stargardt-like macular dystrophy, respectively. The pathologic features seen in these mice as well as studies showing the association of the human *ABCA4* and *ELOVL4* genes with AMD also make them useful for the investigation of AMD, particularly nonexudative AMD. In addition, partial loss of *abca4* in heterozygous +/− *abca4* mice constitutes another mouse model for AMD because these animals have a phenotype similar to those of Stargardt disease and AMD. For this reason, it has been suggested that the Stargardt disease carrier state may be a predisposing factor to the development of AMD. Furthermore, some researchers also consider the *Timp3* transgenic mouse generated to study SFD useful for AMD due to the overlap of clinical features in both diseases.

Hypercholesterolemia and diet have been implicated in the pathogenesis of AMD. As a result, it is not surprising that several models of AMD have been developed which involve impaired cholesterol and/or lipid metabolism. One model that used the concept of impaired lipoprotein metabolism is a knockout mouse of the very low-density lipoprotein

Figure 4 Micrographs of the retina and a photoreceptor cell: (a) light micrograph of a retina section, showing the retinal layers; (b) electronmicrograph of the outer segment of a photoreceptor cell, showing the rims of the membranous disks where the rim protein is localized. As shown in (a), the outer nuclear layer is formed by the nuclei of the photoreceptor cells, which also have inner and outer segments. RPE, retinal pigment epithelium.

(VLDL) receptor gene. A homozygous mutation in the VLDL receptor gene (*Vldlr*^{tm1Her}) causes retinal angiomatous proliferation, a form of occult CNV. In a similar model generated by deleting the low-density lipoprotein (LDL) receptor from the mouse genome, lipid particles accumulated in Bruch's membrane and increased with fat intake. In addition, vascular endothelial growth factor (VEGF) expression in the outer retinal layers of affected mice had a direct correlation with the amount of lipid particle deposition on Bruch's membrane. However, evidence of neovascularization has not been reported in this mouse model. Hyperlipidemia also developed in transgenic C57BL/6 mice that overexpressed the APO B100 gene, the major apolipoprotein associated with LDL cholesterol. When these mice were fed a high-fat diet and exposed to blue light, sub-RPE deposits developed. Deposits did not form in the absence of blue light exposure, and they were prevented by pretreatment with the antioxidant α-tocopherol, suggesting that oxidant injury is responsible for their presence. As confirmed by the examples described next, most experimental mouse models that use the impairment of cholesterol or lipid metabolism show the formation of basal laminar deposits or drusen.

The *ApoE* gene, which encodes apolipoprotein E, has been identified as a risk factor for AMD. As a result, transgenic mice carrying the human APO*E3-Leiden gene (which expresses a dysfunctional form of Apo-E3 discovered in a family from

Figure 5 Sorsby pseudoinflammatory dystrophy angiogram demonstrating classic choroidal neovacularization in the right eye.

Figure 6 Nonexudative age-related macular degeneration (AMD). Color fundus photograph of the right eye showing drusen and nonexudative AMD.

Leiden) were developed and found to have basal laminar deposits that were more severe in mice consuming a high-fat and high-cholesterol diet. In another animal model for AMD, the *apoE* knockout mouse, electron-lucent deposits on Bruch's membrane observed at the ultrastructural level were similar to basal laminar deposits seen in humans with AMD. Very interesting results were obtained with *apoE* knock-in mice expressing *apoE2, apoE3,* or *apoE4*. These animals were used in a study that combined the presence of the *apoE* genotype with the known AMD risk factors of advanced age and a high-fat, cholesterol-rich diet. Mice deficient in *apoE4* were the most severely affected and developed many pathological changes characteristic of AMD. These included the thickening

Figure 7 Exudative age-related macular degeneration (AMD). Color fundus photograph of a left eye with exudative AMD, showing a disciform scar and choroidal neovascularization.

of Bruch's membrane, atrophy and changes in the pigmentation of the RPE, drusenoid deposits, and, in some cases, CNV, a characteristic of wet AMD.

Based on the finding that iron levels are elevated in the RPE of AMD patients, a mouse deficient in both ceruloplasmin (Cp; a ferroxidase localized in mouse RPE that facilitates iron export from cells) and hephaestin (Heph; another ferroxidase of the RPE with 50% identity to Cp) was generated. RPE iron levels of *Cp*−/−*Heph-/Y* mice, as well as the levels of ferritin (an iron-storage protein) increased in an age-dependent manner, causing RPE hypertrophy and death, photoreceptor degeneration, and subretinal neovascularization. Thus, combined *Cp* and *Heph* deficiency leads to retinal degenerative changes similar to many of those that are features of AMD. However, the lack of clinically observable drusen is one shortcoming of this model.

Increased amyloid beta (Aβ) is typically associated with neurodegenerative diseases such as Alzheimer's. Because drusen from patients with AMD has been shown to contain Aβ, a neprilysin gene-disrupted model in mice was used to examine its role in the pathogenesis of AMD. Neprilysin is a zinc metallopeptidase that has a rate-limiting role in Aβ catabolism. Lack of this enzyme in senescent neprilysin −/− mice increased Aβ deposition, leading to RPE degeneration and basal laminar and linear deposits beneath the RPE. In addition, it decreased the expression of pigment epithelium-derived growth factor (PEDF) and CRALBP, a marker for the differentiation of RPE cells, but despite causing an upregulation of VEGF, there was no observable CNV. Thus, amyloid fibrils may be associated with pathological symptoms in

different age-related diseases, but their specific way of inducing these disorders may vary depending on the tissue. Nevertheless, some of the therapeutic approaches that are being used for Alzheimer's disease may be effective against the development of AMD.

Impairment of macrophage mobilization is another genetic modification that has been used to create models of AMD. Knockout mice deficient in monocyte chemoattractant protein-1 (Ccl2), as well as another line of mice deficient in C-C chemokine receptor-2 (Ccr2), showed phenotypic features similar to those in AMD, including thickening of Bruch's membrane, subretinal deposits, drusen, and lipofuscin accumulation. Immune complexes accumulated in the retinas of these mice, as in humans with AMD, and it is thought that abnormalities in macrophage trafficking contributed to the formation of drusen. In addition, *Ccl2*$^{-/-}$ and *Ccr2*$^{-/-}$ mice exhibited photoreceptor atrophy, outer nuclear layer cell loss, and increased amounts of A2E.

The RPE is rich in lysosomal enzymes that degrade the photoreceptor outer-segment fragments ingested daily as part of the renewal process of the visual cells. Cathepsin D (CatD) is one of these enzymes. Because the accumulation of debris resulting from the abnormal breakdown products of photoreceptor outer segments could produce changes in the RPE similar to those observed in AMD, a homozygous transgenic mouse (*mcd/mcd*) carrying a two-amino-acid deletion in CatD, was developed. Progeny of this mouse showed age-dependent RPE proliferation and atrophy, photoreceptor degeneration, shortened outer segments, appearance of lipofuscin and basal laminar and linear deposits, and a significant reduction in the ERG a- and b-wave amplitudes. Thus, this is another mouse model that presents several features of nonexudative AMD.

Choroidal neovascularization, one of the characteristics of wet AMD, has been associated with the expression of vascular endothelial growth factor (VEGF). VEGF is known to stimulate the proliferation of endothelial cells in blood vessels, and it is one of the major growth factors participating in angiogenesis (the physiological process involving the growth of new blood vessels from preexisting vessels). The choroidal vessels grow through breaks in Bruch's membrane and proliferate under the RPE and retina, leaking serum and blood. One of the first models of choroidal neovascularization was a transgenic mouse generated by introducing a murine *Vegf* cDNA coupled to the RPE-specific RPE65 promoter into the mouse genome. This mouse overexpressed Vegf in the RPE and choroid. However, although choroidal neovascularization and blood vessel leakage were observed, these vessels did not penetrate Bruch's membrane into the subretinal space.

Another mouse model of exudative AMD was developed using endocrine-gland-derived VEGF (EG-VEGF, also called prokineticin 1 (hPK1)) coupled to the rhodopsin promoter. This led to the expression of hPK1 in the retina of the resulting transgenic mouse. Because hPK1 is a mitogen of fenestrated endothelium, its expression caused the enlargement of the fenestrated choroidal vascular bed without affecting the nonfenestrated retinal vasculature. In addition, the hPK1 transgenic mice showed the accumulation of the major lipofuscin fluorophore, A2E, but not enough to cause visible RPE damage or the invasion of a CNV-like region into the subretinal space.

The most recent mouse model of AMD involves the impairment of superoxide radical dismutation in the retina, a tissue that is particularly susceptible to oxidative stress because of its high consumption of oxygen, high concentration of polyunsaturated fatty acids, and light exposure. Cu, Zn-superoxide dismutase 1 (SOD1) is one of the main antioxidant enzymes in the retina. Senescent SOD1 −/− mice developed thickening of Bruch's membrane, drusen, and choroidal neovascularization, all of which worsened over time. RPE cells showed signs of oxidative damage and degeneration on histology, and the localization of β-catenin and N-cadherin, adherence junction proteins that are involved in making up the barrier integrity of the RPE, was altered. Furthermore, photoreceptor cell loss was seen in a subset of affected mice, consistent with histopathological findings in human eyes with AMD. Overall, all the pathological features of the Sod −/− mouse model tend to be progressive with age, much like human AMD.

To date, only one rat model of long-lasting CNV has been developed by injecting an adeno-associated viral construct containing human VEGF into the subretinal space of rats. These rats developed extensive subretinal neovascularization, photoreceptor degeneration, and leaking blood vessels on fluorescein angiography, and they showed decreased ERG a- and b-wave amplitudes.

Nonrodent Models of Age-Related Macular Degeneration

One of the primary challenges in the study of macular diseases such as AMD, is the anatomic differences between human eyes and those of animals. In particular, the absence of a macula in nonprimate species makes them less than ideal for studying a geographical-specific disease such as AMD. However, the high costs of nonhuman primates and the difficulty in handling them compared to smaller species are some of the drawbacks in the use of primates as AMD models.

The only naturally occurring, nonrodent animals that were found to have abnormalities consistent with

human aging and AMD were reported to be in a colony of aged adult rhesus monkeys at the Caribbean Primate Research Center (CPRC). These monkeys had drusenlike deposits found in both the inner and outer collagenous zones of Bruch's membrane, and they have dense bodies found in both Bruch's membrane and the RPE cytoplasm. A follow-up study of the same monkey colony showed that none of the sampled animals showed signs of exudative AMD or disciform scarring. Thus, these animals are suitable only for the study of dry AMD. Because this is not a disease of simple Mendelian genetics, no gene was identified that could account for the monkeys' AMD phenotype. It should be noted that the relative long life span of monkeys requires that they be tracked over a lengthy period of time before they develop signs of macular disease. Although this monkey colony presents a unique opportunity to study AMD in a naturally occurring disease model, the drawbacks of using primates for research (already mentioned) limit the practicality of their use.

Conclusion

In conclusion, we can state that studies using animal models, in combination with progress in the field of molecular genetics, have improved our understanding of the pathways leading to macular degenerations. As future research uncovers more details about specific genetic defects and generates increasingly accurate animal models, we hope that novel therapeutic strategies will be developed to prevent, treat, and even cure these blinding and debilitating diseases.

Inhibitory Control over Action and Memory

Functions of Inhibitory Control

The ability to suppress strong habitual (prepotent) responses supports at least two broad computational functions necessary for the effective control of behavior: selection and stopping. Selection refers to the act of isolating one representation among competitors vying for the control of behavior or thought. Selection is necessary at all stages of cognitive activity. In memory, selection must occur to retrieve a target memory trace in the face of many competing memories activated by the cues guiding retrieval. In action, a stimulus may initiate multiple compatible physical actions, only one of which should guide behavior. Stopping refers to the need to either preempt or override a mental or physical activity that is inappropriate in a certain context or that, in the course of execution, has become undesirable. For instance, reflexively reaching to catch a falling object might be abruptly stopped when it is realized that the falling object is a hot pan or a potted cactus. The general models of both functions are depicted in Figures 1(a) and 1(b).

In both selection and stopping, the ability to limit the influence of unwanted representations is mediated by a top-down control process acting directly or indirectly on this entity, rendering it temporarily less accessible. In this article, we refer to the brain structure originating the top-down control signal as the source of the inhibitory control and the area representing the to-be-controlled representation or process as the site of inhibition. Broadly, research indicates regions in the lateral prefrontal cortex (either the ventrolateral prefrontal cortex (VLPFC), Brodmann's area 44/45, or the dorsolateral prefrontal cortex (DLPFC), Brodmann's area 9/46) as likely candidates for the source of control, whereas differing cortical and subcortical targets constitute control sites, depending on the content to be controlled.

Paradigms Used to Study Inhibitory Control

Behavioral paradigms used in research with human subjects have taken two approaches to measuring inhibitory control. Many studies measure subjects' ability to implement control by quantifying the accuracy or speed with which selection or stopping is achieved. This approach provides a straightforward measure of behavioral control. Other studies, however, focus on the aftereffects of selection or stopping on the stopped representations. If a response is suppressed, there should be measurable consequences on the ability to subsequently access the representation, reflecting persisting inhibition. For instance, if a motor action is inhibited, people should be slower to emit that same response later, or if a memory has been inhibited, it should become more difficult to retrieve. Methods that measure the inhibitory aftereffects of response override have the advantage of not presupposing inhibition as the mechanism. For example, although inhibition may be engaged to stop a motor action, stopping may instead be achieved by facilitating an antagonistic response that precludes the execution of the to-be-stopped action. Measures based on the first approach cannot conclusively confirm that inhibition is involved in stopping the rejected representation. Examples of both methods are discussed here.

Inhibitory Control of Action

Inhibitory control of actions has been studied in the contexts of selection and stopping, and it is typically measured with functionally oriented tasks. The use of these paradigms, accompanied by various imaging and electrophysiological techniques has established that inhibitory control engages the lateral prefrontal cortex (LPFC). Further, inhibitory control depends on the integrity of this region, as revealed by studies of patients with LPFC damage, studies using transcranial magnetic stimulation (TMS), and lesions in nonhuman primates.

Inhibitory Control in Selective Responding

A variety of paradigms have focused on the role of inhibitory control in selecting one response in the face of interference from prepotent competitors. One approach used to investigate response selection across a variety of stimulus modalities and response types is to manipulate the compatibility of perceived stimuli and their associated responses. Tasks measuring stimulus–response (S–R) compatibility effects have two conditions: (1) trials in which S–R mappings (i.e., associations) are compatible and exploit innate biases, and (2) trials characterized by incompatible S–R mappings which require that the tendency to make the natural response be overcome and the task-appropriate response selected. For example, subjects might see an arrow in the center of a screen pointing left or right and be required to indicate

Figure 1 Two situations that require response override in human action and thought and commonly used paradigms: (a) selection; (b) stopping; (c) S–R compatibility paradigm; (d) stop-signal paradigm; (e) selection to inhibit the interference of a memory; (f) stopping the retrieval of a memory. The top row represents a schematization of these two situations. In each instance, a stimulus is associated with one or more responses, such that when the stimulus appears, the responses become active in proportion to their associative connection to the cue (represented by thickness of the line). In selection (a), the weaker response must be made, despite the existence of a strong competitor that becomes more active and threatens to capture control of behavior. In stopping (b), there is only one response, but it must be prevented. As shown in (c), sometimes the prepotent action is not the correct response, and a nondominant movement must instead be made (e.g., S–R compatibility and antisaccade tasks). As shown in (d), if no alternative response is warranted, the movement can simply be canceled (e.g., go/no-go, stop-signal, and countermanding saccade tasks). As shown in (e), sometimes inhibition must be initiated to selectively retrieve a memory with a weaker association to a cue that is shared by another trace (e.g., retrieving today's parking spot and suffering interference from the memory of yesterday's; RIF). In other circumstances (f), confronting a cue may activate an unwanted memory, leading the person to stop retrieval. For instance, when the sight of the World Trade Center initiates retrieval of the memory of the events of 9/11, retrieval might be stopped. This process can be assayed by TNT tasks. RIF, retrieval-induced forgetting; S–R, stimulus–response; TNT, think/no-think.

which direction the arrow is pointing by pressing one of two keys. If the instructions require subjects to press a key with their left hand in response to left-pointing arrows and a key with their right hand in response to right-pointing arrows, the S–R mappings are compatible. If, however, subjects must press a key with their right hand in response to a left-pointing arrow (doing the converse for the right-pointing arrow), the S–R mappings are incompatible. In a nonspatial variant, subjects are presented two consecutive color patches and asked to judge and report whether they are the same or different. In the incompatible mapping condition, subjects are instructed to say 'same' when the colors actually differ. The response selection requirement of such tasks is illustrated in Figure 1(c). The reduced accuracy and increased reaction time (RT) of stimulus-incompatible responses are the measurable costs of resolving the interference created by the prepotent compatible response.

Human imaging work suggests that the LPFC contributes to the resolution of this interference. Response selection appears to be subserved by both the DLPFC and VLPFC, together with a network of regions often observed in attentional control tasks, including the superior parietal cortex, anterior cingulate cortex (ACC), and lateral premotor cortex. A number of imaging studies have sought to differentiate the contributions of these areas, and converging evidence from S–R compatibility and other response selection designs is consistent with the view that the ACC contributes to the detection of response conflict, signaling the need for greater top-down control to the LPFC. In contrast, the LPFC – specifically, BA46 within the DLPFC – is thought to be instrumental in achieving response selection. Consistent with this, lesions and TMS of the human DLPFC compromise response selection. Intriguingly, cellular and neuroimaging studies in nonhuman primates emphasize the VLPFC over the DLPFC as the principal source of response selection. There is also conflicting evidence for the generality of response selection. Considerable behavioral evidence from dual-task interference indicates that response selection constitutes a central processing bottleneck spanning varied stimulus and response modalities. These findings are corroborated by neuroimaging findings that reveal overlapping neural activation across many stimulus and response demands. However, response selection appears in some situations to be lateralized according to stimulus characteristics, with spatial tasks associated with increased activation in the right hemisphere and nonspatial stimuli causing left lateralized activations. Thus, it is unclear whether response selection is a unitary process across all input and output modalities, although most research points to the importance of the LPC in achieving this function.

Inhibitory control over motor action has also been studied in the context of oculomotor response selection. In human subjects, saccade termination similarly appears dependent on the DLPFC. In oculomotor inhibition paradigms, subjects intentionally try to override a reflexive foveal orientation to a stimulus, and the number of failed suppressions is measured. For example, in antisaccade tasks, subjects are instructed to look away from visual targets when they abruptly appear instead of toward them. This requires the inhibition of the visually triggered saccade that ordinarily orients subjects' eyes to the onset stimulus. Although the DLPFC is not necessary to execute accurate saccades, numerous lesion studies show that damage to this area, and to BA46 in particular, markedly increases antisaccade errors, suggesting its importance in their cancellation. Similar patterns of errors have been reported in nonhuman primates following lesions of the DLPFC homolog (dorsal bank of the principal sulcus). Further, substantial neurophysiological work done in nonhuman primates has identified neurons within the DLPFC and frontal eye field (FEF) that show preferential activity during antisaccade trials. In human neuroimaging studies, increased activation for antisaccade trials has been found bilaterally in the DLPFC. Based on these findings, the DLPFC is believed to originate a top-down signal that acts on the FEF and possibly the superior colliculus (SC), which serve as the sites of the inhibition.

Taken together, research from these paradigms and others, including task-set switching, Stroop, and flanker tasks, consistently implicate the LPFC in implementing the top-down signal by which prepotent responses are suppressed to achieve selective motor response. Additional work is required to ascertain the relative involvement of the DLPFC and VLPFC, their respective roles, and the extent to which response selection is general or lateralized by content.

Inhibitory Control in Motor Stopping

Intended actions can be stopped, and some cognitive process must support this function, perhaps inhibition. To study stopping, many paradigms ask subjects to occasionally prevent a response they have been trained to complete, and then they measure the effectiveness or efficiency with which this is done. In the go/no-go (GNG) task, participants are presented with a stimulus to which they must make a motor response. On a minority of trials, a special no-go stimulus is presented, for which subjects must prevent their response. For example, people might be

presented with a series of letters on a screen. For every letter, they might be asked to press the same key as quickly as possible, unless they see the letter X, for which they must withhold their response. The percentage of no-go trials successfully withheld is a metric of inhibitory control ability. Another approach used to study motor stopping is the stop-signal paradigm developed by Gordon Logan, illustrated in Figure 1(d). In this paradigm, subjects typically perform a simple perceptual discrimination (e.g., deciding whether a letter is X or O), to which they must make a motor response (e.g., pressing the key corresponding to X or O) as quickly as possible. On a minority of the trials, a stop signal (typically a tone, but visual and tactile signals are sometimes used) occurs at some point after the stimulus, indicating that subjects should withhold their motor response (commonly a key press, although hand, arm, and eye movements; verbalization; and hand squeezes have been used). Over trials, the delay between the appearance of the stimulus and the stop signal is modulated by a dynamic tracking algorithm that adjusts the stop-signal delay (making it longer or shorter, depending on subjects' accuracy) until stopping performance is at chance. Using the average go trial RT and the average stop-signal delay latency required for an equal probability of successful and failed inhibition, the stop-signal RT (SSRT) can be computed. The SSRT, which is approximately 200 ms for manual responses, quantifies the speed of the stopping process itself and is commonly used as a measure of inhibitory control ability. Stop signal and GNG paradigms have been used to study inhibitory control across the life span, in neuropsychological patients, and as a way to study the neural basis of inhibitory control in nonhuman subjects such as monkeys and rats.

Considerable evidence from motor-stopping paradigms indicates that response inhibition is mediated by the VLPFC and DLPFC, with a right lateralization tendency, at least in humans. For example, work by Aron and colleagues showed that, in patients with damage to the right VLPFC or DLPFC (and not the left), SSRT is significantly slowed and the degree of slowing is correlated with the lesion volume. Work with a variety of other techniques yielded similar conclusions. For example, TMS over the right VLPFC disrupts motor stopping in human subjects, and lesions to a VLPFC homolog (the inferior frontal convexity) in nonhuman primates disrupts performance on GNG tasks. Electrophysiological studies in nonhuman primates have demonstrated a no-go potential originating in the dorsal bank of the principal sulcus (homologous to the DLPFC in humans) and in the rostroventral corner of the PFC (see Figure 2). The no-go potential is an electrical signature of the behavioral no-go response. Strikingly, when stimulation is applied during go trials in which the monkey should respond, the response is cancelled or delayed, concomitant with reduced electrical activity in the motor cortex. The strength of the suppressive effect depends on the stimulation timing, with the maximal suppressive effect observed when the no-go potential would have peaked (75–125 ms), and occurs exclusively in the regions of the PFC in which the no-go potential is generated. As might be predicted from the foregoing findings, response inhibition activates the DLPFC and VLPFC in neuroimaging studies, very often right laterally, although sometimes bilaterally, and frequently accompanied by a network of areas implicated in attentional control. Further, direct comparisons of the neural correlates of three inhibitory tasks (the GNG and two response selection tasks, a S-R compatibility task and a flanker task) within-subjects revealed the DLPFC to be a region activated by these distinct cognitive control tests. Taken as a whole, these findings indicate that both the DLPFC and VLPFC contribute to a top-down signal for inhibiting prepotent motor responses, although some investigators have emphasized the primacy of the right VLPFC.

Although the lateral PFC appears to be the source of a top-down signal that suppresses prepotent motor responses, the site of action, and the circuit through which that site is influenced depends on the nature of the response. In the case of manual motor responses, stopping activates the expected control areas of the VLPFC and dorsomedial PFC, and the regions on which that control is exerted within the motor system. Subcortically, the control of movement within the basal ganglia is conceptualized using the brake–accelerator model. The accelerator is the direct pathway in which the cortex acts on the striatum and internal pallidum, increasing the activation of the motor cortex by the thalamus. Braking is accomplished by the same structures with the critical addition of the subthalamic nucleus (STN), which indirectly inhibits the thalamus and hence the motor cortex. Recent work suggests that a faster inhibitory mechanism, the cortico-subthalamo-pallidal hyperdirect pathway, may be contributing to response stopping. In this conception, the VLPFC interprets the stop signal and (circumventing the striatum) increases the activation of the STN, and thus the internal pallidum, resulting in the inhibition of the thalamus and, consequently, the motor cortex. Consistent with this possibility, a recent stop-signal neuroimaging study conducted by Aron and Poldrack revealed that the amount of activation in the STN (and not the striatum) predicted SSRT. Thus, in the case of manual motor response inhibition, the VLPFC may control action by exciting structures that inhibit motor cortex.

Figure 2 Stimulation of the DLPFC and VLPFC homologs suppresses motor responses in nonhuman primates. Monkeys were rewarded for completing manual responses to a light stimulus and learned to respond accurately. Responses to another light stimulus were unrewarded, and the monkeys learned to withhold their responses. No-go activity coincides with no-go behavior and is characterized by surface-negative, depth-positive field potentials generated 110–150 ms after presentation of the visual stimulus. Emergence of no-go potential is contingent on learned discrimination of light stimuli. Moreover, stimulation of specific lateral PFC loci induces no-go behavior. **(I)** Lateral (left hemisphere) and coronal (right hemisphere) views of the frontal lobe illustrate electrode localization. Surface (S) and depth (D) electrodes were placed in the monkey homologs of the DLPFC (dorsal bank of the principal sulcus; A, open circle with central dot), VLPFC (rostroventral corner of the prefrontal cortex; B, open circle), and forelimb area of the motor cortex contralateral to responding hand (C, filled diamond). (II) Field potentials consistent with no-go potential at S and D electrodes and S-D at prefrontal loci A and B during go (left column) and no-go (right column) trials for a single monkey. (III) S-D field potential data for each of the three recording regions across both conditions; A, B, and C in go (left column) and no-go trials (right column). Specificity of no-go potentials to regions and A and B, illustrated by lack of potential in area C. In addition to field potentials, movement (as measured by mechanogram (MECH)), and reaction times (RT) are also reported for each condition. (V) Presentation of go stimulus produces typical field potentials, movement, and reaction times, whereas the go stimulus coupled with bilateral stimulation of areas A and B prevented response, as is typical of no- to trials (compare to III). Arrows indicate onset and offset of visual stimulus. DLPFC, dorsolateral prefrontal cortex; PFC, prefrontal cortex; S.A., sulcus arcuatus; S.C., sulcus centralis; S.P., sulcus principalis; VLPFC, ventrolateral prefrontal cortex. Reproduced from Sasaki K, Gemba H, and Tsujimoto T (1989) Suppression of visually initiated hand movement by stimulation of the prefrontal cortex in the monkey. *Brain Research* 495(1): 100–107, with permission from Elsevier.

Suppressing unwanted eye movements, like suppressing manual responses, engages the LPFC, and in particular the DLPFC, as noted in the discussion of antisaccade research. The site acted on by LPFC, however, is different than in the case of manual responses. For instance, research on the cellular dynamics of motor inhibition with nonhuman primates points to the importance of the FEF. An adaptation of the stop-signal paradigm, called the countermanding saccade task, is often used. The monkeys learn a saccade RT task and are subsequently trained to stop their saccadic eye movements whenever an infrequent stop signal is administered. Thus, the performance of this task requires two processes: (1) initiation of the intended saccades and (2) revocation of the to-be-cancelled saccade. Both of these processes are believed to be supported by the FEF, although movement cancellation is also supported by the SC and the supplementary eye fields. In particular, within the FEF and SC, movement neurons drive go processes,

whereas fixation neurons are implicated in stop processes. Whether a saccade is executed or not depends on the relative activity of these types of neurons. Increasing activation and the rate of that increase in movement neurons are predictive of commitment to saccade initiation and the timing of the initiation, respectively. In contrast, fixation neurons demonstrate activity that is reciprocal to that of movement neurons; their activity is gradually reduced before saccade initiation and increases with saccade suppression. Thus, movement and fixation neurons implement saccade initiation and termination in the FEF. Together with the work on antisaccade performance in human subjects, this suggests that inhibitory control of eye movements is implemented by an interaction between the DLPFC and regions of the FEF involved in initiating and canceling eye movement responses.

Thus, whereas the source of inhibitory control in LPFC may well be shared across different motor-stopping tasks, the site of action depends on the effector system being controlled. Next we discuss evidence indicating that this principle is not limited to the control of physical actions but also applies to the control of internal cognitive acts, such as long-term memory retrieval.

Inhibitory Control in Long-Term Memory

Inhibitory control over memory retrieval provides a model system for the role of inhibitory control in cognition; it has also been studied in selection and stopping. Human behavioral studies have revealed that overcoming the influence of prepotent traces in long-term memory retrieval yields an inhibitory aftereffect such that suppressed traces are subsequently less accessible. Neurobiological research indicates that retrieval suppression, like motor stopping, engages the LPFC, which modulates the activation in the hippocampus and other medial temporal regions associated with memory and emotion. The similarities between the systems engaged by memory and action control suggest that the same or perhaps isomorphic computational solutions may exist for solving response-override problems for physical and cognitive actions.

Inhibitory Control in Selective Retrieval

One procedure that has been designed to study inhibitory control is known as the retrieval–practice paradigm, developed by Anderson and colleagues. In a typical version of this procedure, subjects encode six exemplars from each of eight taxonomic categories (e.g., fruits-orange, fruits-banana, and drinks-gin) in a study phase. Following the initial study, subjects perform directed retrieval practice on a subset of exemplars from some of the studied categories (e.g., three of the six fruits) via category-plus-stem cued recall tests (e.g., fruit or___). Subjects are then tested on all exemplars from all categories. On the final test, subjects can either be cued with the category name and asked to recall all studied exemplars or be given a recognition memory test on all items. Of interest are the effects of practicing some category exemplars on the ability to recall the remaining unpracticed exemplars of those categories. Repeatedly retrieving some exemplars of the category impairs the subjects' ability to recall the remaining unpracticed exemplars, relative to their performance on baseline categories that were also studied, but none of whose exemplars were retrieved in the interim. This effect, known as retrieval-induced forgetting (RIF) is thought to reflect the consequences of an inhibitory process that suppresses unpracticed competitors during retrieval practice, causing enduring impairment of those items on subsequent tests. RIF has been induced with verbal and visuospatial stimuli, and across levels of complexity ranging from simple word pairs to complex factual knowledge and even eyewitness events. RIF affects episodic, semantic, and implicit memory as measured by conceptual fluency and lexical decision. Further, RIF appears on tests of episodic recall and recognition memory. Thus, RIF may be an example of inhibitory control aiding in the function of selection during the retrieval process by suppressing interfering items during retrieval of a target. The selection requirements of RIF are illustrated in Figure 1(e).

RIF exhibits functional properties that firmly establish the involvement of an inhibitory control process that overcomes interference. First, it is retrieval-specific; repeated study of some associates of a cue does not impair the recall of related items, even when repeated retrieval of those same items does. Further, RIF is interference-dependent, with larger RIF effects observed for competitors that cause interference during retrieval, consistent with the view that inhibitory control is engaged to suppress interfering competitors. Finally, RIF is cue-independent; the impairment of a competing memory item generalizes to novel cues used to test the inhibited items, indicating a generalized reduction in the accessibility of the suppressed trace. Thus, in the domain of memory control, theoretically focused behavioral research based on inhibitory aftereffects has firmly established the involvement of inhibition.

A large body of work establishes the role of the VLPFC in selective retrieval of verbal semantic knowledge under conditions of interference. Moreover, patients with LPFC damage show heightened susceptibility to proactive interference in long-term episodic memory retrieval, as revealed in work by Shimamura

and colleagues. Nevertheless, only recently has work begun to tie the LPFC to inhibitory aftereffects measured in RIF. Consistent with executive control literature, the ACC appears central to the detection of conflict between competing memories associated with a cue, signaling the need for top-down control to resolve competition; in contrast, the VLPFC appears to initiate control processes that resolve that conflict through inhibition. These principles can be seen in a study by Kuhl and colleagues, who hypothesized that because RIF is a consequence of resolving interference from competing items during target retrieval, inhibited items should cause less interference on later retrievals of the target items. Indeed, more activation was observed in the bilateral VLPFC and right DLPFC during early than during late retrieval practice trials, and the more activation decreased over trials in the right VLPFC and ACC, the more memory inhibition was found. Moreover, subjects showing higher inhibition exhibited elevated activation in the ACC and hippocampus during early trials that gradually diminished with repeated retrievals; low-inhibition subjects did not show this pattern. Thus, subjects who experience the greatest initial competition between the medial-temporal representations of the target and competitors (as indexed by medial temporal lobe (MTL) and ACC co-activation) show the greatest engagement of control and, consequently, the greatest RIF.

Similar conclusions have been reached using other techniques, such as electrophysiology. For example, more positive going event-related potentials (ERPs) are observed over frontal electrode sites during selective retrieval of target items than in a passive practice condition with the same targets. The magnitude of this retrieval-specific ERP effect on the PFC predicts the amount of RIF observed on the final test. These findings indicate that some functional requirement uniquely associated with retrieval, such as the need to resolve competition, engages the PFC and induces RIF, as before. Mounting evidence points to the involvement of the LPFC in the induction of RIF and the importance of this process in achieving selective retrieval, echoing the role of inhibitory processes in selective motor responding.

Inhibitory Control in Retrieval Stopping

Another method used to study inhibitory control of memory is known as the think/no-think (TNT) procedure, developed by Anderson and colleagues. Modeled after the GNG task, TNT measures the inhibitory aftereffects of stopping memory retrieval. Subjects learn a collection of cue-target pairs, so that whenever they are presented with the cue, they can recollect its associated target item. Following encoding, subjects participate in the TNT phase, during which a single cue item from one of the earlier pairs is presented on each trial. For some of these cues, the subjects are directed to think of the associated target memory and keep it in mind for as long as the cue is on the screen. For other cues, subjects are directed to not think about the associated target memory, keeping it out of mind for as long as the cue is on the screen. The latter no-think task requires that the subject override the retrieval process and prevent the associated declarative memory from entering awareness, despite the tendency for the cue to elicit that memory (see **Figure 1(f)** for an example of memorial stopping). Subjects are then tested on their memory for all cue–target pairs. In the typical design, one-third of the original pairs participate in the think trials in the TNT phase, one-third in the no-think trials, and one-third are reserved as baseline items against which to measure the effects of retrieval and retrieval suppression on later memory performance.

Repeatedly presenting participants with reminders of an event and asking them to stop retrieval of that event has several notable effects. First, it eliminates the normally beneficial effects of reminders in enhancing a memory's later accessibility, so that reminders can be presented over a dozen times with little apparent benefit in accessibility of the associated traces. Second, stopping retrieval very often impairs the ability to recall the associated trace, relative to other baseline cue–reminder pairs that were trained at the same time but that did not have their reminders presented in the interim during no-think or think trials. Thus, repeated exposure to reminders coupled with an effort to stop declarative memory retrieval impairs access to the associated trace. Third, the impairment of the excluded trace occurs even when that trace is tested with a novel cue, indicating a generalized impairment of the trace, consistent with the idea that the trace has been inhibited. Most of these effects have been observed with both verbal cue–target pairs and visual pairs such as face–scene pairs, and the effects appear to generalize to target items with emotional content. Thus, stopping unwanted retrievals appears to be effected in part by suppressing the associated memory, consistent with inhibitory control. As such, the TNT paradigm provides an example of the role of inhibitory control that is analogous to the GNG and stop-signal paradigms.

Neuroimaging studies have established several key findings about the neural systems involved in stopping long-term memory retrieval. First, as can be seen in **Figure 3**, suppressing retrieval of an episodic memory in response to a reminder engages the LPFC, including the VLPFC and DLPFC, often bilaterally,

Figure 3 fMRI results during no-think trials and think trials: (a) brain regions that significantly differed in activation between the no-think trials and think trials during the TNT phase ($n = 24$); (b) successful recruitment of the DLPFC, which predicts individual differences in memory inhibition (the inhibitory aftereffect of stopping retrieval); (c) inhibitory aftereffects for four subject groups, differing in DLPFC activation. In (a), areas in yellow were more active during no-think trials than during think trials, whereas areas in blue were less active during no-think trials ($P < 0.001$). The white arrows highlight the reduced hippocampal activation in the no-think condition. In (b), plotted in warm colors are the regions that predict the magnitude of the inhibitory aftereffect observed on the final memory tests (the white arrows indicate the DLPFC; VLPFC was also observed in this study but not in a later study involving photographs). In (c), the greater the DLPFC activity shown by a subject group, the more impaired was the later recall of no-think items on the final test, compared to the recall of baseline items that were learned at the same time but that did not appear during the TNT phase. DLPFC, dorsolateral prefrontal cortex; fMRI, functional magnetic resonance imaging; TNT, think/no-think; VLPFC, ventrolateral prefrontal cortex. From Anderson MC, Ochsner KN, Kuhl B, et al. (2004) Neural systems underlying the suppression of unwanted memories. *Science* 303(5655): 232–235.

although sometimes with right lateralization. VLPFC engagement parallels the activations observed for RIF and for motor-response suppression, although the DLPFC appears to be more consistently engaged in retrieval stopping. Second, individual differences in the engagement of the DLPFC (and sometimes the VLPFC) during suppression predict memory inhibition, with inhibition increasing with increasing activation, as might be expected if the DLPFC originated a top-down signal responsible for memory

impairment. Third, suppressing retrieval reduces activation in the hippocampus, compared to engaging retrieval, suggesting that inhibitory control modulates functional activity in structures involved in declarative memory. Recent work indicates that activation is reduced below the levels observed during passive fixation, with the extent of this reduction predicting memory failure. Finally, retrieval suppression engages the full network of regions associated with endogenous attention, including the lateral premotor cortex, ACC, and intraparietal sulcus, indicating common brain systems may support controlled attention during perception and memory tasks. With emotional memories, suppression also significantly reduces amygdalar activation, probably reflecting control over emotional aspects of the negative memories. Taken together, these findings indicate that functional interactions between the LPFC and MTLs support inhibitory control over memory retrieval.

As already discussed, imaging studies indicate that suppressing retrieval of an episodic memory significantly reduces activation in the hippocampus, compared to retrieval and a passive fixation baseline. The hippocampus has widely acknowledged involvement in episodic memory, and many studies indicate that it is also involved in the recollection of recently encoded events. As such, reduced hippocampal activation may reflect the successful control of conscious recollection by inhibitory control processes. Electrophysiological studies using the TNT procedure also support the conclusion that conscious recollection (as measured by an ERP component, the parietal old/new effect) may not merely be reduced, but may be eliminated by retrieval suppression. The extent of the modulation of this component predicts subsequent forgetting of no-think items, consistent with the view that regulating recollection induces later forgetting. Thus, both hemodynamic and electrophysiological measures converge on the conclusion that inhibitory control can be engaged to modulate the neural machinery responsible for generating episodic recollection.

The foregoing research illustrates the strong functional and neurobiological similarities between the control of action and memory. Both engage a common frontal region – the LPFC – to override the influence of unwanted neural activity in support of selection and stopping. What differs between motor and memory control (and, indeed, between different forms of motor control) appears to be the sites of control and, perhaps, the means of achieving that control (see the section titled 'Neural architecture of inhibitory control'). The work on memory control adds the unique and theoretically significant contribution of showing that both selection and stopping induce inhibitory aftereffects on rejected representations, verifying and quantifying the involvement of inhibition in achieving control. To the extent that memory control may be used as a model system for cognitive control, these findings suggest the existence of a domain general system for controlling action and thought via inhibition. Consistent with this possibility, the LPFC is engaged in an extraordinarily diverse collection of cognitive tasks, and Duncan and colleagues have shown that it predicts individual differences in fluid intelligence (gF, or psychometric g). A common theme running throughout these tasks appears to be the management of interference, consistent with the putative role of this region in inhibitory control. Nevertheless, it remains possible that there is not one mechanism of control in the LPFC but many content-specific ones, localized similarly, the differences between which cannot yet be ascertained in the absence of direct comparisons between cognitive and motor control. Even, so, lateral prefrontal-posterior interaction remains a valid organizing principle that characterizes our understanding of the networks underlying inhibitory control.

Neural Architecture of Inhibitory Control

Many investigators agree that inhibitory control supports the regulation of behavior by limiting the influence of undesired representations on ongoing behavior by functionally altering the state of the undesired representation. Although the brain clearly solves the computational problems of stopping and response selection, there is not yet widespread agreement on how they are solved or on whether they are solved in a unitary manner. There are two general views on how inhibition may be achieved: direct inhibition and biased competition. Direct inhibition hypothesizes that an inhibitory process targets the unwanted representation or system (either directly or by exciting inhibitory interneurons), degrading its control over behavior. In contrast, biased competition hypothesizes that attentional control signals facilitate the representations of desired actions and that, as a result, competing representations are inhibited through local reciprocal inhibitory projections. The evidence base for biased competition is well developed, and Miller and Cohen have argued that this computational principle may be a primary means of implementing executive control. It is established, however, that both types of inhibitory control take place in the nervous system. For example, as reviewed by Sotres-Bayon and colleagues, excitatory projections from the medial frontal cortex terminate on inhibitory interneurons in the amygdala that modulate the functioning and output of that structure and, correspondingly, suppress conditioned emotional

responding. Similarly, the frontal cortex excites inhibitory neurons in the reticular nucleus of the thalamus, which inhibit the thalamus, gating sensory input to the cortex. The fronto-subthalamic circuitry underlying motor-response suppression (discussed earlier) may be another such example. Thus, inhibitory control may often be accomplished, not by facilitating a competing response but by inhibitory modulation of the brain system underlying the undesired process. The types of situations in which these mechanisms of control operate are an interesting area for future study.

Concluding Comments

The capacity to override unwanted actions and memories is a fundamental component of the effective control of behavior and thought. The pervasiveness of selection and stopping as computational problems has led to the proposition that individual variation in the efficiency with which people inhibit may underlie differences in intellectual functions of many sorts (e.g., attention, working memory, long-term memory, reading, reasoning, and behavioral control) and may even be an important contributor to some psychological disorders. When a population exhibits perseverative tendencies, difficulties managing interference, or distractibility, investigators often consider the potential contribution of frontal lobe dysfunction (and, consequently, inhibitory dysfunction). These proposals, often referred to as inhibitory deficit theories, have been advanced to explain a range of phenomena. For example, because of the late development and early decline of the PFC in the life span, alterations in inhibitory control efficiency have featured prominently in theories of cognitive development and cognitive aging. Clinically, it has been proposed that inhibitory deficits contribute to psychopathologies, including obsessive–compulsive disorder, depression, schizophrenia, attention deficit/hyperactivity disorder, addiction, and chronic posttraumatic stress disorder. It seems unlikely that these diverse conditions are produced by the same deficit and, indeed, that even the various deficits within each population are produced by a single underlying deficiency. Nevertheless, the overlap between systems engaged during motor and memory inhibition suggests that generalized inhibitory control deficits are possible. If so, elucidating the neural systems that subserve inhibitory control is not merely of theoretical interest but has the potential for broad impact on problems of clinical importance.

Insulin-Like Growth Factor Signaling and Actions in Brain

V C Russo and G A Werther, Royal Children's Hospital and University of Melbourne, Parkville, VIC, Australia

© 2009 Elsevier Ltd. All rights reserved.

The Discovery of the Brain IGF System

In 1957, Salmon and Daughaday reported a serum factor (or factors) that mediated the cartilage sulfation and longitudinal bone growth activity of the somatotrophic hormone (growth hormone, GH). This factor was termed 'sulfation factor' and was produced by hepatic cells after exposure to GH (see Figure 1). These circulating factors, which also showed insulin-like activity not suppressible by anti-insulin antibodies, were later found to have a biochemical structure similar to that of the β chain of insulin. Their structural homology with proinsulin led to their current designation as insulin-like growth factors 1 and 2 (IGF-1 and IGF-2).

In the middle 1980s, a variant of IGF-1, then called des(1–3) or 'truncated' IGF-1, was identified in brain tissue. This truncated IGF-1 variant lacks the first three amino acids and is more potent than intact IGF-1 in various cell culture systems, probably due to its lower affinity for IGF-binding proteins (IGFBPs).

This finding suggested brain synthesis of IGF-1 or its truncated variant. Following the isolation of IGF-1 messenger RNA (mRNA) from postnatal rat brain, a number of *in situ* hybridization studies demonstrated that IGF-1 and IGF-1 receptor (IGF-1R) mRNA is synthesized in the rat brain in specific regions, namely, olfactory bulb (Figure 2), hippocampus, and cerebellum.

In addition, IGF-carrier proteins, later named as IGFBPs, were found to be expressed in similar brain regions. The finding of IGF-1 mRNA co-localization with IGF-1 receptors and the presence of IGFBPs suggested a paracrine or autocrine role for IGF-1, potentially modulated by IGFBP, in the developing brain (Figure 3).

IGF System Expression in the Nervous System

IGF Ligands

IGF-1 plays a key role in the development of the nervous system, with demonstrated effects in many stages of brain development, including cell proliferation, cell differentiation, and cell survival. Although recent reports have demonstrated that postnatal circulating IGF-1 might exert neurogenic and survival activity, systemic IGF-1 is not readily transported through the blood–brain barrier, and therefore local production of IGF-1 is considered the primary source of the ligand (autocrine and paracrine action) for brain cells.

During embryogenesis, IGF-1 mRNA expression is detectable in many brain regions, with its expression being particularly high in neuron-rich regions such as the spinal cord, midbrain, cerebral cortex, hippocampus, and olfactory bulb (Figure 1). IGF-2 mRNA is abundantly expressed in the embryonic rat central nervous system (CNS); however, data are conflicting on IGF-2 expression in cells of neuroepithelial origin. IGF-2 is the most abundantly expressed IGF in the adult CNS, with the highest level of expression found in myelin sheaths, but it is also expressed in leptomeninges, microvasculature, and the choroid plexus, all nonneuronal structures that enable diffusion of growth factors to their sites of activity.

IGFBPs

The mRNA expression profiles and location of the most abundant IGFBPs, 2, 4, and 5, in the normal developing and adult CNS are well defined, suggesting an important role for IGFBPs in the nervous system.

IGFBP-1 is not expressed in the CNS, but its expression is induced under certain experimental conditions. IGFBP-2 is expressed early in embryogenesis and by embryonic day 10 is highly expressed in discrete neuroectoderm structures. Later in development, IGFBP-2 mRNA is highly abundant throughout the brain, particularly in brain regions undergoing continuous remodeling, as is the olfactory bulb (Figure 2), the cerebellum, and the hippocampus. IGFBP-2 expression correlates with and complements that of IGF-2, and both IGFBP-2 and IGF-2 protein are highly abundant in the cerebrospinal fluid and choroid plexus.

IGFBP-2 associates to cell surface proteoglycans in rat brain tissue and neuronal cells, and IGF-1–IGFBP-2–proteoglycan complexes have been identified in rat brain tissue; their role is not yet well understood. Such findings suggest that IGFBP-2 may be involved in targeting IGFs to their cell surface receptors in the brain. The absence of a 'brain phenotype' in the IGFBP-2 –/– mouse suggests functional redundancy in the IGFBP family during development of the CNS.

IGFBP-3 is normally expressed at a low level in the CNS, mainly in nonneuronal structures, including epithelial cells. The effects of IGFBP-3 gene deletion on CNS are either unknown or have not been reported. IGFBP-3 is found to be upregulated in rat

Figure 1 The somatomedin hypothesis. The circulating factor that was originally proposed to mediate the effects of growth hormone on longitudinal bone growth was subsequently found to be insulin-like growth factor 1 (IGF-1). However, the presence of IGF-1 and IGF-1 messenger RNAs in multiple tissues has necessitated the revision of the original 'somatomedin hypothesis' to include both autocrine and paracrine actions of IGF in addition to its classical endocrine aspects. The IGF-binding proteins (IGFBPs) present in serum and expressed in most tissues actively contribute to the endocrine, paracrine, and autocrine action of IGF-1. GH, growth hormone; GHRH, growth hormone-releasing hormone.

Figure 2 The insulin-like growth factor (IGF) system in the rat brain olfactory bulb. IGF-1 is expressed and synthesized in distinct areas of the rat brain, adjacent to regions rich in IGF-1 receptors (IGF-1Rs) and insulin-like growth factor binding proteins (IGFBPs; e.g., olfactory bulb, as shown). This provides strong evidence for an autocrine and paracrine action of the IGFs in the nervous system. IGF action is modulated by locally expressed IGFBPs. ONL, Olfactory nerve layer; GL, glomerular cell layer; EPL, external plexiform cell layer; MI, mitral cell layer; GRL, granular cell layer. Section A-A shows a hematoxylin–eosin staining of olfactory bulb. Area in the rectangle is enlarged and represented in the main drawing. Reproduced from Russo VC, Gluckman P, Feldman EL, and Werther GA (2005) The insulin-like growth factor system and its pleiotropic functions in brain. *Endocrine Reviews* 26(7): 916–943. Copyright 2005, The Endocrine Society.

Figure 3 Circulating (endocrine) or locally expressed (i.e., in autocrine or paracrine system) insulin-like growth factor (IGF) complex. IGF-binding proteins (IGFBPs), in addition to regulating transport, diffusion, and half-life of IGFs, provide specific binding sites for the IGFs in the extracellular and pericellular space. This pericellular localization might contribute to the modulation of IGFs' interactions with their receptors and downstream cellular signaling. The effects of the IGFBPs are also regulated by the presence of specific IGFBP proteases, which cleave the binding proteins, generating fragments with reduced or minimal binding affinity for the IGFs. ECM, extracellular matrix; IRS, insulin receptor substrate; rec, receptor.

cerebral cortical cells following GH stimulation. GH promotes proliferation of neural precursors, neurogenesis, and gliogenesis; these responses appear to be mediated in part by locally produced IGF-1 and its modulator IGFBP-3. No change in brain growth or phenotype has been reported in IGFBP-3 transgenic mice.

IGFBP-4 is normally expressed at a very low level in the CNS, where its mRNA is found in a variety of brain cell types, including meningeal cells, astrocytes, and fetal neuronal cells. Whether ablation of the IGFBP-4 gene affects the CNS has not been reported.

IGFBP-5 gene expression is highly abundant during early brain development. In rodents, IGFBP-5 appears to be co-expressed with IGF-1 in principal neurons of sensory relay systems, cerebellar cortex, hippocampal formation, and many other neuron-rich regions, including the olfactory bulb (Figure 2). Furthermore, *in vivo*, IGFBP-5 expression is specifically regulated by IGF-1. In *Xenopus*, IGFBP-5, together with three IGFs expressed in the early embryo, promotes anterior development by increasing growth of the head region. Thus, both IGF signal activation and IGFBP-5 appear to be required for anterior neural induction in *Xenopus*. Whether IGFBP-5 has similar functions in early mammalian neural development is not known. The effects of IGFBP-5 gene ablation in the brain have not been reported.

IGFBP-6 is poorly expressed in the nervous system, and information regarding its mRNA expression distribution, in both the developing and adult nervous system, is limited. IGFBP-6's unique property of preferential binding to the IGF-2 ligand, coupled with the fact that this ligand is the most abundantly expressed IGF in the adult CNS, raises the possibility that the IGFBP-6–IGF-2 complex may have a unique role in modulating IGF-2 function in the adult brain. Preliminary analysis of the IGFBP-6 transgenic mouse shows reduced cerebellum size and weight, combined with altered differentiation of astrocytes. Abnormalities in the hypothalamus and pituitary were also reported. The effects on the brain of IGFBP-6 gene ablation remain unknown.

IGF Receptors

Type 1 IGF receptors are highly expressed in many specific brain regions and cell types, particularly in plastic regions such as the developing cerebellum, midbrain, and olfactory bulb (Figure 2) and in the ventral floor plate of the hindbrain. Given that IGF receptors are expressed from early embryogenesis and throughout life and that their ligands also show a similar 'temporal–spatial' pattern of expression, it is evident that local brain IGF circuits are crucial modulators of the processes activated during brain

development. The level of IGF-1R decreases to adult levels soon after birth but remains relatively high in the choroid plexus, meninges, and vascular sheaths. It is thus not surprising that knockout of the IGF-1R gene produced, in addition to *in utero* growth retardation, is a clear brain phenotype, namely, a small brain.

The type 2 IGF receptor, which has low affinity for IGF-1, but a high affinity for IGF-2, and also binds mannose-6-phosphate, is selectively expressed in all major brain regions. It is therefore possible that the IGF-2–mannose-6-phosphate receptor, in addition to its role in transporting lysosomal enzymes, might also participate in control of postnatal brain development and possibly repair.

Various atypical IGF-1R subtypes possessing distinct structures or binding properties have also been described (hybrid insulin–IGF-1Rs with the ability to bind insulin as well as IGFs). However, the physiological significance of hybrid and atypical IGF receptors is unclear.

Early studies demonstrated that some brain regions (i.e., olfactory bulb and choroid plexus) expressing both the IGF-1 and IGF-2 receptors are also rich in insulin receptors. Insulin receptor density is elevated in the choroid plexus, olfactory bulb, limbic system, and hypothalamus, all regions concerned with olfaction, appetite, and autonomic functions. More recently, ablation of the insulin receptor in nestin-positive neurons has suggested a role for insulin in control of appetite suppression and reproduction.

IGF Signaling and Action in Brain

Binding of IGF-1 (or IGF-2) to the α subunit of the type-IGF-1R (cysteine-rich domain) induces comformational changes of the intracellular β subunit with consequent induction of tyrosine kinase activity. Two major substrates, insulin receptor substrates 1 and 2 (IRS-1 and IRS-2), interact with the IGF-1R and become phosphorylated on multiple residues (Figure 4). Phosphorylated IRS-1 is then able to recognize and bind to the 'Src homology polypeptide domain' (SH domains) present in various signal transduction proteins (Figure 4). Molecules that bind IRS-1 include the growth factor receptor-bound (Grb-2), the adaptor oncogenic protein containing

Figure 4 A model of key pathways and interactions involved between the insulin-like growth factor (IGF) and bcl-2 systems in glucose-deprived neuronal cells. Neuronal cell responses to glucose withdrawal (glucopenia) include activation of acute responses such as increased translocation of glucose transporter (GLUT) to cell surface and modulation of mitochondrial activities. These responses are followed by sustained activation of the extrinsic (death receptor cascade) and the intrinsic (mitochondrial cascade) proapototic pathways. These effects are potently regulated by IGF-1 via the phosphoinositide-3 kinase (PI3K) pathways, which lead to the upregulation of GLUT transcription and translocation, recovery of mitochondrial activities, and inhibition of intrinsic and extrinsic proapototic processes. A key element of IGF antiapoptotic action is Bcl-2, which promotes mitochondrial functions and potentiates glucose uptake. Akt, protein kinase B; IRS, insulin receptor substrate.

one SH2 and three SH3 domains, the protein tyrosine phosphatase Syp (SH-PTP2), and the p85 *β-subunit* domain of PI3K (see the section titled 'The mitogenic pathway').

The Mitogenic Pathway

The IGF-1R mitogenic pathway begins with Grb-2, which is a small cytoplasmatic protein and acts as an 'adapter molecule' that links the guanidine nucleotide exchange factor for $p21^{ras}$, termed mSOS (homologous to the *Drosophila* protein son of sevenless (SOS)), to IRS-1. The Grb-2–SOS complex can thus activate Rouss avian sarcoma (Ras), which recruits Raf (serin/threonin protein kinase), and they proceed to activate the mitogen-activated protein kinase (MAPK) pathway (MEK kinase, MEK, extracellular signal-regulated kinase (ERK) kinase, p90) and transcription factors and eventually induce activation of genes such as the early growth response genes *c-jun* and *c-fos*.

Therefore, whether the IGFs are produced locally or reach brain cells systemically, binding to their receptor activates intracellular signaling, promoting neurotrophic, neurogenic, and neuroprotective/antiapoptotic activities. A large number of *in vitro* studies have demonstrated that IGF-1 promotes mitogenesis and differentiation in glia, oligodendrocytes, neuronal cells, adult stem cells, and brain explants and regulates axon myelination via activation of MAPK, also known as ERK. There is also clear evidence that IGF-1 activation of the MAKP/ERK pathways enhances growth cone motility and promotes neurite outgrowth, suggesting that this pathway is likely to be involved in neurogenesis, migration, and repair.

Supportive evidence for the importance of IGF and IGF receptor signaling and activation of downstream effectors has come from a number of studies in IGF null (−/−) mice. These studies have clearly demonstrated that most of the IGF functions determined *in vitro* also apply to the *in vivo* situation, affecting a wide range of brain cells. Thus IGF-1 null mice have reduced brain size and altered brain structures, including alteration of myelination processes. Furthermore, ablation of the *Igf-1* gene has revealed deficits in the numbers of specific neurons and oligodendrocytes in the olfactory bulb, dentate gyrus, and striatum and in cochlear ganglion neurons. In addition to gross structural brain abnormalities, IGF null mice also show alteration of important brain metabolic functions such as reduced glucose uptake, the major source of energy for neuronal cells. These *in vivo* models also show that the IGF system affects several steps involved in development and organization of CNS architecture, including number of cells, connections, and regulation of the extracellular matrix.

It is important to emphasize that the IGFs do not act in isolation or only discretely activate specific pathways. It is well recognized that the actions and effects of IGF signaling are influenced by or affect a large number of other growth factor/cytokine sytems and that IGF-induced IGF-1R phosphorylation activates complex and integrated intracellular signaling.

The Survival and Metabolic Pathway

Binding of the IGFs to the IGF-1R may also activate signaling through the PI3K cascade (Figure 4). Protein kinase B (PKB), also known as serine/threonine kinase Akt, is one of the primary downstream targets of PI3K, and it is well characterized for its involvement in modulation of cell survival. Activated PKB/Akt in turn phosphorylates and inhibits several proapoptotic proteins, such as Bad, caspase-9, and the winged-helix family of transcription factors (FKHRL1, FKHR, and AFX), leading to cell survival in various systems, including hippocampal neurons.

Activation of PKB/Akt appears to be also involved in the modulation of brain metabolic events such as glucose transport and utilization in neuronal cells. As mentioned earlier, IGF-1 is a major regulator of glucose uptake and utilization in brain. In an *in vitro* model of glucose stress (glucopenia), mimicking *in vivo* hypoglycemia, activation of PKB/Akt by IGF-1 was involved in both survival (inhibition of proapoptotic genes) and upregulation of glucose transporters at transcriptional and posttranslational levels (**Figure 4**).

Another target of IGF-1, via the PKB/Akt pathway, is the glycogen synthase kinase 3β (GSK3β). IGF-1, similar to insulin, stimulates the phosphorylation of GSK3β, thus promoting glycogen and protein synthesis. Accumulation of glycogen, normally associated with astrocytes in mature brain, is abundant in IGF-1-positive projecting neurons and postnatally in neurons in IGF-1-rich areas, suggesting that local autocrine and paracrine IGF-1 signaling via the PI3K/Akt pathway is involved in glucose metabolism and storage.

The GSK3β substrate tau, involved in formation of the intracellular neurofibrillary tangles that contribute to the neuronal degeneration seen in Alzheimer's disease, is hyperphosphorylated in IGF-1-null mice. Furthermore, GSK3β promotes apoptosis in neurons via mechanisms involving phosphorylation of tau and β-catenin. Thus IGF-1-induced inhibition of GSK3β, via the PI3K/Akt pathway, appears to be a critical mechanism of IGF-1 action in the brain.

The IGFs Are Neurotrophic Factors

IGF-1 is involved in brain plasticity processes, and it specifically modulates synaptic efficacy by regulating synapse formation, neurotransmitter release, and neuronal excitability. IGF-1 provides constant trophic support to neuronal cells in the brain and in this way maintains appropriate neuronal function. Alteration of this trophic input may contribute to brain disease as seen in neurodegenerative disorders such as Alzheimer's disease, ataxia telangiectasia, Huntington's disease, and Parkinson's disease, all variably responsive to IGF-1 treatment. Recent studies have shown that neurogenesis declines in brains of aged mice but is efficiently restored following IGF-1 administration via intracerebroventricular infusion.

The IGF System and Neuroendocrine Signaling Cross Talk in Brain

In vivo, growth factors such as IGF-1 do not exist in isolation. Hence, the presence of other growth factors may further modulate IGF's biological activity and cellular responses. This modulation can be seen in IGF's neurogenic activity, which may be optimal only in the presence of such cytokines as fibroblast growth factor-2 (FGF-2) and a range of other local growth factors.

In primary cultures of hypothalamic cells, FGF-2 combined with IGF-1 significantly increased the number of neurite-bearing cells above that seen when either one of the two growth factors was added in isolation. Their effects appear to be synergistic since blocking IGF-1 from binding with an antibody abrogates FGF-2's effects. In contrast, a recent study in neuroblastoma cells demonstrated that FGF-2 overrides IGF-1 mitogenic and survival activity via induction of neuronal differentiation and blockade of IGF-1's antiapoptotic response. Interactions among local brain growth factors are thus complex and may vary under differing conditions.

Recent reports have highlighted the importance of a number of serum (in contrast to brain-produced) growth factors, which included IGF-1, FGF-2, and other blood-borne neurotrophic factors (neurotrophins), in neuroprotective surveillance. All these factors exerted a tonic trophic input on brain cells, providing defense mechanisms ranging from blockade of neuronal death to upregulation of neurogenesis.

Increased interest has thus recently been devoted to the interaction of IGF-1 with other 'classic' neurotrophic factors. Of a number of neuroprotective factors including IGF-1, glial cell-derived neurotrophic factor (GDNF), brain-derived neurotrophic factor (BDNF), neurotrophin-4 and -3 (NT-4/5, NT-3), and ciliary neurotrophic factor, only IGF-1, GDNF, and NT-4/5 were found to be potently neuroprotective of motor neurons. These findings point to the potential combined use of these neuroprotective factors in treatment of neurodegenerative diseases. Results from a number of phase III clinical trials with nerve growth factor, BDNF, and IGF-1 have indicated that these neurotrophic factors may find an application in degenerative disorders or injury of peripheral nerves and motor neurons.

IGF-1 and GH

Although GH gene expression also occurs in the central and peripheral nervous systems, with brain GH imunoreactivity not affected by hypophysectomy, the potential cross talk between the IGF system and GH in the nervous system has not been fully investigated. Several experimental models, *in vivo* and *in vitro*, support a key role for GH in brain development. The Snell dwarf mouse (Pit1) and the GH-releasing hormone receptor-deficient little mouse exhibit microcephalic cerebra with hypomyelination and retarded neuronal growth with poor synaptogenesis. Postnatal GH administration normalizes neuronal growth in these mice. Recent *in vivo* studies have demonstrated that GH is involved in neuroprotection during hypoxic or ischemic brain injury. In these studies, GH-like immunoreactivity was demonstrated on injured brain cells, and it was shown that GH administered intracerebroventricularly is capable of preventing brain cell loss. Whether the neuroprotective effects of GH involve IGF-1 induction is not clear. However, some recent *in vitro* studies have demonstrated that GH promotes proliferation and differentiation of fetal cerebral cortical cells in primary culture and that these effects are mediated by IGF-1.

There is some evidence that the GH-related hormone prolactin also possesses neurogenic properties. In female mice during pregnancy, prolactin stimulates production of neuronal progenitors in the forebrain subventricular zone. Whether prolactin's neurogenic properties are a direct effect of its action or are mediated by other factors, including IGF-1, remains to be determined.

IGF-1 and Erythropoietin

Erythropoietin (EPO) is traditionally known as a hematopoietic cytokine produced by the fetal liver and adult kidney in response to hypoxia. However, the expression of EPO and EPO receptors in the CNS and the upregulation of EPO by hypoxic–ischemic insult suggest that this cytokine is an important mediator of the brain's response to injury. In fact, *in vivo* EPO administration protects hippocampal CA1 neurons and retinal neurons from ischemic damage and prevents brain injury

following a number of 'insults' by mechanisms involving both inhibitions of apoptosis and neurotrophic actions. In the brain, EPO expression, regulated by hypoxia-inducible factor-1α (HIF-1α), is mainly found in astrocytes.

IGF-1 protection of primary neuronal cells exposed to low-oxygen concentration correlates with activation of HIF-1α expression. In the same studies using an *in vivo* model of hypoxic or ischemic brain injury, it was also shown that IGF-1 transcriptional activation correlates with that of HIF-1α, suggesting that HIF-1α might mediate some of the IGF-1 responses. Another study has shown that IGF-1 induces HIF-1α transcriptional activity in rat cerebral cortex and neuronal cells (PC12) and that this induction is abolished by a selective IGF-1R antagonist (JB-1). Furthermore, studies in hepatoma cells have shown not only that insulin, IGF-1, and IGF-2 induced HIF-1α expression but that HIF-1α is required for expression of IGF-2, IGFBP-2, and IGFBP-3.

These findings suggest the presence of a potential complex synergistic cross talk between the IGF and the EPO systems, involving both activation of common intracellular signaling pathways and regulation of gene expression. The presence of synergistic cross talk between the IGF and the EPO systems in neuronal cells has recently been demonstrated by showing that EPO can exert a more immediate neuroprotective action when administered in concert with IGF-1. The neuroprotective mechanism, following coadministration of EPO and IGF-1, involved synergistic activation of the PI3K/Akt pathway. These findings further support the concept that the coadministration of synergistic neuroprotective agents, rather than a single agent, might provide improved therapeutic outcome. Thus, treatment with appropriate combinations of EPO and IGF-1 could be a future therapeutic strategy for a variety of acute neurological events.

IGF-1 and Sex Steroids

Among the numerous endocrine systems regulating brain physiology, sex steroids play an important role. However, it appears that some of the effects of these hormones on the brain are mediated by trophic factors, including IGF-1. Estradiol and IGF-1 increase survival and differentiation of developing fetal rat hypothalamic neurons. In this case, estrogen-induced activation of the estrogen receptor requires the presence of IGF-1; both estradiol and IGF-1 use the estrogen receptor to mediate their trophic effects on hypothalamic cells. *In vivo* sex steroids affect IGF-1 levels in the endocrine hypothalamus, arcuate nucleus, and median eminence.

Furthermore, increased clinical and basic evidence suggests that gonadal steroids affect the onset and progression of several neurodegenerative diseases and schizophrenia, as well as recovery from traumatic neurological injury such as stroke. Similarly, in the brain, both estrogen synthesis and estrogen receptor expression are upregulated at sites of injury. The neuroprotective effects of estrogen may be exerted independent of the classical nuclear estrogen receptors, involving modulation of IGF-1 signaling. This is supported by the fact that estrogen receptors and IGF-1R interact in the activation of PI3K and MAPK-signaling cascades and possibly in the promotion of neuroprotection. It is therefore possible that the decrease in estrogen and IGF-1 levels with aging may thus result in an increased risk for neuronal pathological alterations. These findings thus suggest the presence of potential complex synergistic cross talk between the IGFs and sex steroids involving activation of common intracellular signaling pathways; however, the precise mechanism remains unclear.

Future Directions

Since 1957, a considerable body of investigation has been devoted to defining the role of the IGF system in many tissues, including the brain. There is no doubt that these pleiotropic factors, in concert with their receptors and binding proteins, are involved in controlling key processes in brain development and traumatic or degenerative disorders of the nervous system.

Although the development of *in vivo* models such as the transgenic and knockout mice or disease and injury models have contributed to providing unique information about the growth-promoting, neurogenic, and neuroprotective actions of the IGF system, many questions remain. In particular, analysis of the signaling pathways activated by IGFs and their integration and cross talk with other brain growth factor systems is critical. Such insights will potentially lead to the development of improved approaches to prevention, management, and effective treatment of destructive, neurodegenerative, and malignant process of the nervous system.

Intermediate Filaments

In the nervous system, the shape of neurons and astrocytes is largely maintained by structures built with intermediate filaments (IFs). Intermediate filaments comprise a common gene family divided into five classes of structures which display such unusual degrees of cell specificity that they are often used as markers of cellular differentiation. All five gene classifications share homology in a core rod domain, which contains multiple α-helical domains that can form coiled coils. There are conserved regions with sequence homology of common domains that have such similarity that some antibodies can recognize all known intermediate filaments from mammals through a wide range of invertebrates. IFs are also similar in ultrastructural form between all five classes, and they form 8 to 10 nm ropelike filaments that may be several micrometers long. Exclusively expressed in neurons are class IV neurofilaments (NFs). The class III intermediate filament protein, glial fibrillary acidic protein (GFAP), is expressed in astrocytes and Schwann cells. Class III and IV intermediate filament proteins are the two main members of the cytoskeleton proteins that act together to form and maintain cell shape and facilitate the transport of particles and organelles within the cytoplasm. NFs are different from the other IF classes in that they have side arms that project from the surface. These side arms result in less dense packing and give spacing between NFs. In nonneuronal cells, IFs are seen as densely packed bundles. Vimentin is the most widely expressed type III IF and is found in a variety of cell types, such as fibroblasts, microglia, and smooth muscle cells, as well as in embryonic cell types, including neuronal and glial precursors. Vimentin is transiently expressed during oligodendrocyte cell development. Unlike NFs, the type III IF GFAP homopolymer is shorter and denser because it lacks side arms which project from the sides. Nestin is the most divergent of the IFs that form filaments and is sometimes considered to be a distinct IF type. Although nestin is specific to the nervous system, it is expressed in multipotent neuroectodermal precursors and suppressed during subsequent development. For this reason, it can be used as an early marker for differentiation of precursor cells. Keratins are type I and II intermediate filaments which are found in epithelial cells throughout the body in various stoichiometries characteristic to the individual tissue type. The type IV NFs are heteropolymers and share sequence homology in the rod domains and have common exon and intron structures different from the type I–III classes. Nuclear lamins are IFs, polypeptides which form the walls of the nuclear envelope structure, and are the type V class. Only cells with a nucleus (eukaryotes) express type V IFs. Bacteria (prokaryotes) do not have the class type V IFs. An entire phylum in the animal kingdom, arthropods, expresses only type V nuclear lamins, and arthropod cells have no IF cytoskeletal structures. Otherwise, nearly all somatic cells have IFs, although some are only expressed transiently during development.

Three other IFs are seen transiently in neuronal development: α-internexin, peripherin, and nestin. These three IFs are most prominently expressed during development and then downregulated in selected neurons and neuronal precursors. Based on sequence and gene structure, peripherin is a type III IF, whereas α-internexin is a type IV IF. Whereas the NF triplet proteins and α-internexin may be components of both central nervous system (CNS) and peripheral nervous system (PNS) neurons, peripherin appears to be expressed preferentially in PNS neurons. Both α-internexin and peripherin can coassemble with the NF triplet proteins *in vitro* and may do so *in vivo* but can also form homopolymeric filaments. Both are expressed at higher levels in a variety of developing neurons, and expression becomes more restricted as neurons mature. Many neurons cease to express α-internexin following maturation. However, a few neurons retain the expression of IFs containing α-internexin. Notably, IFs of parallel fibers in the cerebellar cortex contain only α-internexin subunits. α-Internexin continues to be expressed in some peripheral neurons into maturity. In contrast to NF subunits, α-internexin and peripherin self-assemble into homopolymers and coassemble with NF subunits.

Neuronal Intermediate Filaments

Many traditional histological techniques have visualized neurons using metal stains that have specific interactions with NFs. Using electron microscopy, invented in 1931 by Max Knoll and Ernst Ruska in Germany, IFs of all classes appear as 8–12 nm solid ropelike fibers and look densely packed in all cells except the neurons. NFs which are only found in neurons, as visualized by electron microscopy, appear as 10 nm fibers that can be hundreds of microns long. NFs have phosphorylated side arms that prevent dense packing, and these projections give axons

their cytoplasm volume. NFs constitute the most abundant structures in large myelinated neurons and can account for 12% or more of total protein in these neurons. NFs are formed from three subunit proteins known as the NF triplet: NF high-molecular-weight subunit (NFH; 180–200 kDa), NF middle-molecular-weight subunit (NFM; 130–170 kDa), and NF low-molecular-weight subunit (NFL; 60–70 kDa. Each of the NF subunit proteins is coded for by a separate gene. The NF triplet proteins have a characteristic domain structure. The N-terminal regions of all three subunits interact via α-helical coiled coils to form the core of the filament. NFM and NFH also have long C-terminal regions, which project from the core filaments as side arms. NFH and, to a lesser extent, NFM have a large number of these Lys-Ser-Pro (KSP) consensus phosphorylation sites for proline-directed kinases in this C-terminal extension (>50 on NFH and >10 on NFM in many species). Almost all (>99%) of the assembled NFs in myelinated internodal regions are known to be stoichiometrically phosphorylated in the KSP repeat domain; cell bodies have less phosphorylated NF. In large myelinated axons, most, if not all, of these sites are phosphorylated. This phosphorylation of NFH and NFM C-terminal NF side arms alters the charge density on the NF surface, repelling adjacent NFs with similar charge. Electrostatic repulsion of adjacent neurofilaments, the mutual repulsion by the side arms of NFs, is thought to be a major determinant of axonal caliber. Some neurons lack NFs. Finally, NFs have an unusual degree of metabolic stability which stabilizes and maintains neuronal morphology.

Neurofilament Response to Injury and Disease

The neuronal response to injury has been studied in some detail to gain a better understanding why mammalian CNS neurons regenerate poorly or not at all, whereas PNS neurons regenerate effectively. Although regeneration is often described as paralleling developmental growth of neurons, the distinctive pattern of changes in the neuronal cytoskeleton during regeneration differs in some important ways from that during development. First, there is a coordinate downregulation in NF subunit expression following injury. NFH, NFM, and NFL protein and mRNA levels in the perikarya decline rapidly after injury and do not recover until after reconnection with an appropriate target cell has occurred. Concurrent with the reduction in NF protein following injury, both tubulin and actin increase significantly. During the elongation phase of regeneration tubulin and actin protein expression and associated increased expression of microtubule-asssociated proteins (MAPs) and microfilaments are high, but the NF protein expressions are low.

Alterations in the cytoskeleton are frequent hallmarks in neuropathology. A definitive diagnosis for many neurological disorders depends on a histological examination. Abnormal accumulation of NF is detected in many human neurodegenerative disorders, including amyotrophic lateral sclerosis (ALS), Alzheimer's disease (AD), dementia with Lewy bodies, Parkinson's disease (PD), and diabetes. These disorders show accumulations of neurofilaments in neurons. The identifying characteristic for a number of neuropathological conditions is a disrupted or aberrant cytoskeleton. This is a feature of many toxic neuropathies and a number of neurodegenerative conditions, including motor neuron disease and AD. Although other neuronal functions may also be affected and the initial cause of the disease may not directly involve the cytoskeleton, the associated pathogenic disruption of cytoskeletal function may be a key element in the loss of neurons or neuronal function.

PD was first described by English physician James Parkinson in 1817. PD, the shaking palsy, is caused by degeneration of the pigmented neurons in the substantia nigra (SN) of the brain and results in decreased dopamine availability. Clinical symptoms include decreased spontaneous movement, gait difficulty, postural instability, rigidity, and tremor. The major neuropathological change in PD is an accumulation of somal protein in SN neurons called the Lewy body. The Lewy body is composed of several proteins, being the three NF subunits and α-synuclein protein. Abnormal phosphorylated NFs form a compacted skein in neuronal soma of affected SN neurons. Point mutations in the Parkin gene account for many familial PD cases. It seems that mutations in NF genes may account for some inherited forms of PD.

A key hallmark of ALS is intraneuronal aggregates of NFs in degenerating motor neurons. Several ALS-like diseases with different pathogenic mechanisms have been associated with disruptions of axonal NFs. NFs accumulate in the cell bodies of motor neurons in patients with ALS and related motor neuron diseases. The latter example is particularly interesting because the symptoms of motor neuron disease can be produced in animal models in several very different ways. Some of these animal models have little obvious relevance to the cytoskeleton, such as those resulting from point mutations in a superoxide dismutase gene. Others directly involve NFs, such as transgenic mice that express defective NF subunits or overexpress normal NF subunits. Regardless of how these animal models are produced, a characteristic feature of motor neuron pathology is the

accumulation of poorly phosphorylated NFs in cell bodies and initial segments of the axon. It has been proposed that alterations in NF homeostasis are directly relevant to the pathogenesis of ALS.

Other diseases with disruptions in NF organization include diabetic neuropathy and Charcot–Marie–Tooth disease. For these diseases, the disruption of NFs is a secondary effect. In most cases, neuronal degeneration is an eventual consequence, but neuronal function may be impaired prior to substantial loss of neurons. Generally, disruption of NFs has the most severe consequences in large motor neurons, which is consistent with the fact that the largest neurons have the highest NF expression.

Diabetes is a disease in which the body does not produce or properly use insulin. The cause of diabetes is unknown, although both genetics and environmental factors such as obesity and lack of exercise appear to play roles. Diabetes is associated with symmetrical distal axonal neuropathy. The neuropathy is predominately in sensory neurons or dorsal root ganglia. Drug-induced diabetes by streptozocin increases phosphorylation of NF specific to the lumbar region dorsal root ganglion neurons. These drug-induced changes are not seen in other types of neurons. Pathologically, neurites from dorsal root ganglia are swollen with disorganized aggregates of NF and other proteins. The neuropathy associated with diabetes includes well-documented impairment of axonal transport, a reduction in axon caliber, and a reduced capacity for nerve regeneration.

Phosphorylation of cytoskeletal proteins has also been linked to various neuropathological conditions. For example, the NF accumulations seen in many diseases have aberrant phosphorylation patterns. Another significant change may be the hyperphosphorylation of a MAP such as tau, which appears to be a key step in the formation of neurofibrillary tangles in AD. These tangles contain distinctive paired helical filaments that are extremely resistant to solubilization and analysis. They were initially thought to be aberrant NFs based on their dimensions, but a careful immunochemical and biochemical dissection showed that the primary polypeptide present in the tangles was tau, the axonally enriched MAP. The tau in neurofibrillary tangles is differentially phosphorylated, and this misphosphorylation is thought to play a role in the formation of tangles. Although the precise etiology of neurofibrillary tangles and their relationship to the deposition of amyloid are not certain, the appearance of these tangles is closely correlated with loss of neurons, and their number is a good indication of how far the disease has advanced. Clearly, disruption of the cytoskeleton is an important component of the AD neuropathology.

Glial Intermediate Filaments

The abundant and most extensively studied intermediate filament in astrocytes is GFAP. The term evolved from 'plaque' protein, glial fibrillary protein, to GFAP or GFA protein and was originally based on its high acidic amino acid content and its morphological fibrous appearance. Its rapid response to injury and insult, and its highly antigenic properties, has permitted extensive chemical, biological, and molecular biological investigations on CNS development, function, and disease.

Properties of GFAP

GFAP shows species-specific amino acid sequence heterogeneity, and its molecular weight ranges from 48 kDa for mouse to 49 kDa for human, 50 kDa for bovine, and 51 kDa for rat. The relatively slow metabolic turnover rate for GFAP is consistent with a structural role for glial filaments in the cytoplasm. GFAP is composed of three distinct regions: an N-terminal HEAD region, a central ROD region, and a C-terminal TAIL region. The ROD regions are highly conserved among IF proteins, whereas the size and amino acid sequences of the HEAD and TAIL regions vary. The head region of porcine GFAP is composed of 35-amino-acid residues and has β-turn structure. It contains eight arginine residues that characterize this highly basic region. The ROD region of GFAP is composed of 345 amino acid residues, containing long tandem repeats of seven amino acid sequences called 'heptad repeats.' This region is essential for the packing of the α-helical coil which is important for the formation of 10 nm filaments. The tail region of approximately 50-amino-acid residues has a globular structure and may be involved in the interactions between IF and other proteins.

Posttranslational modification to the N- and C-terminal domains of IFs are common, whereas those within the central α-helical domain are rare. The posttranslational modification of greatest functional and structural significance arises from the action of various kinases on serine and threonine embedded within specific recognition sequences. The phosphorylation events which have a regulatory role in the assembly and turnover of most IFs *in vivo* are confined to the N- and C-terminal domains of the chains. Phosphatases, which dephosphorylate the chains, have an equally important role in governing assembly and function. In cytokeratins, vimentin, and lamins, the effect of phosphorylation is to disassemble the IFs, whereas dephosphorylation allows spontaneous self-assembly to proceed. These changes typically occur during cell division. Phosphorylation and dephosphorylation of the IF HEAD regions have a critical

role for the maintenance and reconstruction of IFs. GFAP filaments disassemble into a soluble form when the amino acids in the HEAD are phosphorylated. The HEAD region of GFAP is positively charged due to the many arginine residues. The mechanism of GFAP assembly regulation may be related to regulation of the electric charge in the HEAD domain by phosphorylation. The sites of second messenger-dependent protein kinases have been identified in the HEAD region of GFAP. Four serines (Ser8, Ser13, Ser14, and Ser34) and one threonine (Thr7) are known to be phosphorylated by different protein kinases: cyclic-AMP-dependent protein kinase (A kinase), Ca^{2+} calmodulin-dependent kinase II (CaM kinase II), C kinase, and Rho kinase. A kinase phosphorylates Thr7, Ser8, Ser13, and Ser34 residues of the HEAD region. CaM kinase II phosphorylates Ser8, Ser17, and Ser34. cdc2 kinase phosphorylation of GFAP did not cause disassembly, whereas CaM kinase II phosphorylation did induce disassembly of the phosphorylation of vimentin, and Rho kinase inhibited GFAP filament formation *in vitro*.

Molecular Biology of GFAP

GFAP gene The molecular cloning of the mouse gene opened a new and productive area for GFAP studies. Genomic clones have been obtained from human, mouse, and rat GFAP genes. Each gene is composed of nine exons distributed over approximately 10 kb of DNA and yields a mature mRNA of approximately 3 kb. The coding sequences for the three genes are highly homologous. Strong homology also extends upstream of the RNA start site for approximately 200 bp, recurs between approximately-1300 and -1700 (RNA start point = +1), and is present in some intronic regions. The primary sites for the initiation of RNA and protein synthesis are essentially identical for the three genes, and each contains a TAT-like sequence (CATAAA or AATAA) in the expected 5′-flanking position. In addition to GFAP-α, two additional mRNAs that start at different sites have been identified, GFAP-β and GFAP-γ. The different tissue distributions of GFAP-α, -β, and -γ mRNAs suggest that the synthesis of each is subject to unique control. All transcriptional studies to date either have explicitly measured GFAP-α or have not distinguished among the possible mRNA isotypes. In the PNS, GFAP-β RNA is thought to be the predominant form of GFAP, whereas, GFAP-α is the predominant form in the CNS. The GFAP-β mRNA has been found in both CNS and non-CNS tissues, including mouse bone marrow and spleen. One report suggests the possible existence in rat brain of a novel GFAP mRNA isoform, GFAP-δ, that differs in the C-terminal tail domain. GFAP transgenes have been used extensively to study signaling pathways that operate during development, disease, and injury – all states that increase GFAP gene activity.

GFAP promoter A major contribution of GFAP transcription studies has been the identification of DNA sequences that can target transgene expression to mouse astrocytes. The entire GFAP genomic clone and a gfa2 promoter have been utilized. The use of the GFAP promoter has resulted in the initiation of a range of studies, including *in vivo* tests of various gene products on astrocyte function, use of astrocytes as factories for bioactive molecules, and creation of disease models.

GFAP and Vimentin Knockout Mice

GFAP knockout mice The technique of gene knockout has been used to examine intermediate filaments in mice and has provided the first evidence that intermediate filaments are directly involved in cell resilience and the maintenance of tissue integrity. To investigate the structural role of GFAP *in vivo*, mice carrying null mutations in GFAP have been created by disrupting the GFAP gene in embryonic stem cells. These mice were completely devoid of GFAP but exhibited normal development and showed no obvious anatomical abnormalities in the CNS. Studies examining the anatomy and synaptic function of the cerebellum of GFAP-deficient mice have shown that long-term depression (LTP) is deficient in the GFAP mutant cerebellum without any detectable anatomical abnormalities. Furthermore, GFAP mutant mice exhibited significant impairment of eyeblink conditioning without any detectible deficits in motor coordination tasks. Another study suggested that GFAP expression is essential for normal white matter architecture and blood–brain barrier integrity, and its absence leads to late-onset CNS dysmyelination. GFAP null mice also showed subtle changes in astrocyte morphology and enhanced LTP in hippocampal neurons. Mice lacking GFAP are hypersensitive to cervical spinal cord injury caused by sudden acceleration of the head.

Vimentin knockout mice Animals homozygous for the vimentin knockout mouse develop and reproduce without an obvious phenotype but show a cerebellar defect and impaired motor coordination. Fibroblast derived from these mice are also mechanically weak and severely disabled in their capacity to migrate and to contact a three-dimensional collagen network. Wounds in the vimentin null adult mice showed delayed migration of fibroblasts into the wound site. The GFAP network in the vimentin

null mice has disrupted GFAP and fails to assemble into a filamentous network in astrocytes that normally co-express GFAP and vimentin (i.e., corpus callosum and Bergmann glia).

GFAP and vimentin double knockout mice In studies on the reaction to injury in the CNS, glial scar formation appeared normal after spinal cord or brain lesions in GFAP null or vimentin null mice but was impaired in double null mice that developed less dense scars frequently accompanied by bleeding. These studies have suggested that GFAP and vimentin are required for proper glial scar formation in the injured CNS and that some degree of functional overlap exists between these IF proteins. Reactive astrocytes devoid of IFs exhibit clear morphological changes and profound defects in cell motility. Culture studies have shown that astrocytes in mice deficient for both GFAP and vimentin cannot form IFs even when nestin is expressed and are thus devoid of IFs in their reactive state. Additional studies with the double mutant have suggested a role for the cytoskeleton in astrocyte volume regulation and the involvement of intermediate filaments in the process. The rate of glucose uptake through facilitative hexose transporters was not affected by the depletion of GFAP or vimentin, nor was ascorbate uptake and efflux.

Alexander's Disease

Alexander's disease (AxD) is a rare disease of unknown origin which is often fatal to infants, juveniles, and adults. The pathological hallmark of AxD is the presence of Rosenthal fibers, cytoplasmic inclusions in astrocytes that contain increased amounts of GFAP in association with stress proteins. Six lines of transgenic mice have been generated that carry added copies of the human GFAP (hGFAP) gene in order to determine the properties of astrocytes containing increased GFAP without external stimulation and activation. The discovery that mice expressing an hGFAP transgene formed abundant Rosenthal fibers suggested that mutations in the GFAP gene were a cause of AxD. Sequencing results from a number of laboratories identified GFAP coding mutations in most cases of the disease, including the infantile and juvenile forms. These mutations were found in the 1A, 2A, and 2B segments of the conserved central ROD domain of GFAP and also in the variable TAIL region. All changes detected were heterozygous missense mutations, and none were found in any parent of a patient who had been tested. These data indicate that most cases of AxD arise through *de novo*, dominant, GFAP mutations. The authors suggest that the gain of function is due to a partial block of filament assembly that leads to accumulation of an IF that participates in a toxic interaction. AxD is the only known primary disease of astrocytes.

GFAP in Reactive Gliosis

Astroglia in the CNS and PNS reacts to injury by hypertrophy and, in some cases, proliferation. The functions of reactive astroglia are still not well understood. A common feature of these cells is expression of GFAP. In the CNS of higher vertebrates, following injury as a result of trauma, disease, genetic disorders, or chemical insult, astrocytes become reactive and respond in a typical manner, termed astrogliosis. Reactive astrogliosis is a prominent feature of astrocytes adjacent to injury. Astrogliosis is characterized by rapid synthesis of GFAP intermediate filaments. Numerous *in vitro* and *in vivo* studies on the molecular profiles of substances which are upregulated during astrocyte activation document the complex and varied responses of astrocytes to injury. Increased protein content or immunostaining of GFAP has been found in experimental models involving gliosis. These include the cryogenic lesion in the brain, stab wounds, experimental allergic encephalomyelitis (EAE), hyperthermia, electrically induced seizures, and toxic lesions. Increase of GFAP mRNA has been associated with scrapies, AD brains, and Creutzfeldt–Jacob disease and was observed in 6-hydroxydopamine lesion of the substantia nigra in rat, in a mechanical lesion to rat cerebral cortex, in entorhinal cortex lesions, in corticospinal axotomy, in EAE, in the lesioned dentate gyrus, and in cerebral freeze injury.

Three diseases which show intense gliosis are multiple sclerosis, an inflammatory demyelinating disease characterized by demyelinating plaques composed of bare axons and extensive reactive astrogliosis; adrenoleukodystrophy, a hereditary disorder of lipid metabolism; and AD, characterized by extensive gliosis and Rosenthal fiber deposits. Reactive gliosis occurs with any type of injury to the CNS. Neuropathological differences and severity of gliosis and time course of disease development are characteristic to the affliction and can be useful in differentiating between the following diseases: ALS, Gerstmann–Straussler syndrome, Huntington's disease, Wilson's disease, Pick's disease, PD, AD, and Down's syndrome. Astrocytic gliosis is a prominent neuropathologic change in AD, most frequently in association with neuritic plaques.

Interstitial Axon Branching/Collateral Elimination

Introduction

During development, growing axons navigate over long distances to reach distant targets. They are guided by highly motile growth cones at axon tips that respond to attractive and inhibitory guidance cues in the environment. In this way, growth cones steer toward and recognize their correct targets. However, in many central nervous system (CNS) pathways, the growth cone of the primary axon does not extend directly into targets. Instead, after the primary growth cone has grown past the target, branches develop interstitially from the axon shaft at the correct locations to extend into their appropriate targets (Figure 1). Collateral branching, like growth cone turning, changes the direction of axon outgrowth and is thus an important form of axon guidance. Axon branching enables a single neuron to connect with multiple targets and is therefore essential for the assembly of complex neural circuits. Interstitial branching has been well documented in mammalian CNS pathways such as the corpus callosum and corticospinal tract that arise from the cerebral cortex and innervate the contralateral cortex and spinal cord, respectively.

Given the fundamental importance of axon branching for establishing specific synaptic connectivity, surprisingly little is known about how branching is regulated. However, recent evidence suggests that axon guidance at the growth cone and at branch points share common mechanisms. Guidance factors, acting through receptors in the cell membrane, are attractive or repellent to growth cones during pathfinding and also promote or inhibit axon branching. Directed growth from the growth cone and branching from the axon shaft are also mechanistically linked by similar changes in the dynamics of the actin and microtubule cytoskeleon and their associated intracellular signaling pathways.

Studies *in vivo* and *in vitro* have shown that axon branching often occurs after the primary axon has stopped elongating. Independent axon outgrowth and branching have been demonstrated in CNS pathways. For example, direct visualization of fluorescently labeled axons extending in living brain slices revealed that in the corpus callosum the primary axonal growth cone enlarges and pauses beneath the contralateral cortex while axon branches extend dorsally toward cortical targets. However, the mechanisms that slow or stop extension of the primary axon along its pathway while permitting growth of the axon's collaterals into targets are not well understood. Establishment of neural connectivity during development involves not only neurite outgrowth but pruning of excess or inappropriate axon branches by retraction or degeneration. Some axons in adult animals are also capable of robust sprouting after injury which may involve mechanisms similar to those that regulate CNS axon branching during development. However, the focus of this article is on development of axon collateral branches rather than on branch elimination or collateral sprouting after injury.

Effects of Growth and Guidance Factors on Axon Branching

Attractive and Inhibitory Guidance Molecules

Families of evolutionarily conserved guidance cues have been discovered that either attract or repel axonal growth cones by chemotropism, defined as guidance directed by a gradient of a diffusible factor. Repulsive guidance molecules cause growth cones to collapse, inhibiting their advance or causing growth cones to turn away from the source of the repellent cue. For example, Slit proteins repel axons at the midline in *Drosophila* and regulate midline crossing in regions of the mammalian CNS such as the optic chiasm and corpus callosum. Surprisingly, while Slit proteins collapse and repel growth cones, they can induce branching on dorsal root ganglion (DRG) sensory axons. Semaphorin 3A (Sema3A) has also been shown to promote branches from retinal axons after growth cone collapse. Both the Slit proteins and the semaphorins, particularly Sema3A, are expressed at high levels in the developing mammalian cortex and act as chemorepellants for cortical axons *in vitro*. Application of Sema3A to cultures of early postnatal cortical neurons not only collapsed growth cones but also reduced the development of axon branches by half. While Sema3A reduced branch length, it had no effect on the length of the primary axon. Thus, Sema3A specifically reduces cortical axon branching but has no effect on axon outgrowth *per se*. Interestingly, recent studies have shown that Sema3A and the Slit proteins repel cortical axons but respectively attract or promote the growth and branching of their dendrites. Thus, in many situations, the growth of

Figure 1 A model for interstitial axon branching. Schematics represent different stages in axon branching *in vivo*. (a) Growth cone of an axon is advancing along a pathway toward its target, indicated by the yellow circle. (b) In response to target-derived signals, the primary growth cone pauses in the vicinity of the target and enlarges. (c) After the primary growth cone has resumed forward advance, remnants of the reorganized growth cone appear as filopodial or lamellar activity along the axon shaft. (d) A branch from these active membrane regions extends toward the target after various time delays. Typically, branches extend interstitially some distance behind the primary growth cone.

dendritic versus axonal processes can be differentially regulated by a single guidance factor.

Other guidance molecules such as the ephrins can also induce growth cone repulsion and regulate axon branching. For example, members of the Eph family of receptor tyrosine kinases and their ephrin ligands play important roles in the development of the retinotectal projection. Retinal axons initially overshoot

Figure 2 Netrin-1 induces axon branching from filopodial protrusions. (a) Phase-contrast image of a single postnatal day 1 cortical neuron observed over 12 h in time lapse. Branches emanating from filopodial protrusions are marked with an orange arrowhead; branches forming from spread lamellar regions of the axon shaft are marked with a green arrowhead. The distal tip of the primary axon is marked with a blue arrowhead in all frames. (b) Composite tracings of the neuron in (a) overlaid on the previous time point showing the progression of branch formation and extension. Note that the primary axon does not increase in length. The time points are color coded for clarity and correspond to the color of the tracing of the neuron. Scale = 50 μm.

their future targets in the optic tectum during development. Topographic specificity is achieved not by guidance of terminal growth cones to tectal target neurons but by interstitial axon branching of retinal axons at appropriate locations in the tectum. Gradients of ephrinAs regulate development of this topographic map, and map formation is thought to depend on a combination of branch-promoting and branch-suppressing activities. Studies using anatomical mapping of retinotectal connections in EphA7 mutant mice revealed that opposing gradients of ephrinAs and EphA7 are required for development of appropriate retinotectal topographic mapping. Formation of appropriate termination zones in the tectum depends upon suppression of retinal axon branching by EphA7 anterior to future termination zones.

The netrin family of guidance molecules can guide growth cones in many regions of the nervous system. Studies of cortical axon outgrowth in explant cultures, for example, have shown a potent effect of netrin-1 in attracting growing axons. Netrin-1 can also elicit a large and rapid increase in axon branching. In cultured cortical neurons, spontaneous development of axon branches typically requires several days and involves pausing and enlargement of the primary growth cone at future branch points. In contrast, netrin-1 applied to hippocampal or to cortical neurons promoted formation of filopodia directly from the axon shaft within minutes. Over several hours, many of these filopodia on cortical axons developed into branches tipped by growth cones (Figure 2).

Growth Factors

Growth factors such as nerve growth factor (NGF), fibroblast growth factor (FGF-2), brain-derived neurotrophic factor (BDNF), and neurotrophin-3 that promote axon outgrowth are also potent stimulators of axon branching. Injection of BDNF into the optic tectum of living tadpoles increased the branching and complexity of optic axon arbors, whereas neutralizing antibodies to BDNF reduced their arborization and complexity. These effects occurred rapidly and were specific to BDNF. Interestingly, BDNF had opposite effects on dendritic arbors of retinal ganglion cells. Injection of BDNF into the tadpole retina reduced dendritic arborization whereas function-blocking antibodies increased arbor complexity. Target-derived NGF also promotes axonal sprouting. Localized

sprouting of axon collateral branches, that began as filopodia, was induced on cultured DRG neurons when NGF covalently conjugated to polystyrene beads was applied directly to the axons. FGF-2 locally applied in the form of coated beads induced cortical axon branching in regions where the beads contacted the axon shaft. However, in contrast to the rapid effects of locally applied netrin-1, development of axon branches in close proximity to the FGF-2 coated beads required several days in culture.

While growth and guidance factors can evoke filopodial protrusions and branches directly from the axon shaft, observations in living cortical slices and in dissociated cell cultures have shown that pausing behaviors and enlargement of the primary growth cone can demarcate branch points along cortical axons from which branches later develop interstitially. Moreover, effects on branching by global application of FGF-2 and Sema3A to cortical neurons are mediated by effects on the primary growth cone. Thus, FGF-2 increased axon branching by inducing growth cones to pause and enlarge, whereas Sema3A collapsed cortical growth cones and the resulting absence of large pausing growth cones reduced branching by about 50%. Bath application of netrin-1 actually decreased the numbers of large paused growth cones, and many branches resulting from netrin-1 treatment extended directly from the axon shaft rather than from expanded branch points. The rapid growth of branches on axons of netrin-1-treated neurons, in contrast to the growth of branches over several days in control and FGF-2-treated cultures, suggests that different intracellular signaling mechanisms may be involved. Branching of cortical axons in response to cues from pontine targets can occur by extension of filopodial processes directly from the axon shaft. Recent evidence suggests that axon pruning also involves diverse axon remodeling processes including selective retraction and local degeneration of axon branches. It seems likely that in different contexts axon branches may also develop by different cellular mechanisms.

Many of the factors that influence axon branching have no effect on axon length. Thus, netrin-1 increased number of branches as well as branch length, whereas Sema3A decreased branch numbers and length, but neither treatment affected axon length. Although it is generally the case that cues attractive or repellent to cortical axons increase or decrease their branching, respectively, these results suggest that axon outgrowth and axon branching are independently regulated. This is consistent with the situation *in vivo* where axons can stop elongating while collaterals of the same axon are extending into their targets.

Cytoskeletal Reorganization in Growth Cones and Branches

Cytoskeletal Dynamics

As motile growth cones extend toward their targets they advance, retract, turn, and branch. Growth cone steering and extension of axon branches require reorganization of the microtubule and actin cytoskeleton. Microtubules are long hollow polymers of tubulin that form dense bundles in axons and dendrites. They not only lend structural support to neuronal processes but also serve as railways along which materials are transported from the cell body into neurites. The dynamic properties of microtubules, that is, their ability to grow and shrink in dynamic instability, enable them to explore growth cone lamellipodia and filopodia. In growth cones, the fast-growing (plus) ends of microtubules face outward toward the periphery. Actin filaments play an essential role in driving motility and guidance of the growth cone. In veil-like lamellipodia actin filaments form a meshwork, but within filopodia (the spiky finger-like protrusions from the growth cone periphery that are important for exploring the environment) actin filaments form straight bundles (Figure 3). Actin filament dynamics involve cycles of net assembly of actin filaments at the leading edge of the growth cone and disassembly of filaments proximally.

Figure 3 A large pausing cortical axonal growth cone *in vitro*. Microtubules, pseudocolored green, are stained with an antitubulin fluorescent antibody. Actin filaments, pseudocolored red, are stained with rhodamine phalloidin. Microtubules are bundled together in the axon, splay apart in the central region of the growth cone, and form a prominent loop surrounding the central region. Actin filaments extend into the lamellipodia and form straight bundles in spiky filopodia. In the transition region between the growth cone center and periphery, microtubules overlap (yellow) with actin filaments.

Visualizing fluorescently labeled microtubules and actin filaments in living neurons with high-resolution time lapse microscopy has revealed the dynamic cytoskeletal changes that underlie growth cone motility and guidance behaviors as well as axon branching. Microtubules are bundled together in the axon shaft and also extend into the central and peripheral regions of the growth cone. They are splayed apart in growth cones that are extending, but when growth cones stall microtubules form prominent loops surrounding the central region (Figure 3). Similarly, at axon branch points, microtubules undergo localized debundling. Microtubule reorganization at the growth cone and at axon branch points are strikingly similar. Along the axon shaft, microtubules splay apart and locally fragment prior to development of branches. During transitions of the growth cone from pausing to growth states, microtubules reorganize from looped to splayed configurations followed by fragmentation. Reorganization and fragmentation permit short microtubules to explore new directions of growth with forward and backward movements within the growth cone periphery and in branches extending from the axon shaft (Figure 4). Observations of long-term branching events showed that microtubules invaded and remained in branches favored for further growth but withdrew from branches that regressed, suggesting that microtubules can stabilize developing branches. Thus, cytoskeletal mechanisms underlying axon branching involve the reorganization of the microtubule array into a more labile form whereby microtubules can become debundled and fragmented. This plasticity would permit microtubules to explore the growth cone periphery and newly forming branches.

Figure 4 Schematic model for microtubule reorganization during axon outgrowth and branching. (a) Microtubules (blue) in the pausing growth cone form a loop in the central region. As microtubules splay apart in a region of the loop, short microtubules fragment from longer microtubules and explore the lamellipodium. (b) A branch is emerging from the axon shaft in a region where local splaying and fragmentation of microtubules occurs. Short microtubule fragments invade the developing branch. (c) The axon branch is extending as microtubules elongate within it. Arrows indicate directions of microtubule movement. P and D refer to proximal and distal segments of the axon.

Actin–Microtubule Interactions

Microtubules and actin filaments are highly dynamic, undergoing continual cycles of growth and shortening during polymerization and depolymerization. At the same time, actin filaments and microtubules can also move and undergo dramatic changes in their organization and location within the growth cone. In cortical neurons, branching from the growth cone and the axon shaft was preceded by splaying apart of looped or bundled microtubules accompanied by localized accumulation of F-actin. Dynamic microtubules co-localized with F-actin in transition regions of growth cones and axon branch points. Interactions between microtubules and actin filaments involved their coordinated polymerization and depolymerization. Drugs that attenuated either microtubule or actin dynamics abolished F-actin–microtubule interactions at the growth cone and at axon branch points, inhibiting axon branching without affecting axon length. Similar findings in the growth cones of invertebrates showed that actin–microtubule interactions are essential for initiating growth cone steering. These results imply that factors, such as extracellular cues that influence the dynamics of either F-actin or microtubules, may affect both cytoskeletal elements through bidirectional signaling pathways.

Effects of Growth and Guidance Molecules on Cytoskeletal Dynamics

Growth and guidance factors such as Sema3A, FGR-2, and netrin-1 regulate axon branching through changes in cytoskeletal dynamics. Sema3A applied to growth cones depolymerized bundled actin in filopodia and attenuated motility and protrusion of lamellipodia (Figure 5). Microtubules decreased their exploratory behaviors and collapsed centrally, suggesting that reduced actin dynamics attenuated microtubule dynamics. The failure of microtubules to invade the growth cone periphery and delineate new directions of growth decreased axon branching. FGF-2 which increased cortical axon branching and enlarged growth cones over time promoted actin polymerization and the formation of microtubule loops. Netrin-1 also increased actin polymerization causing microtubules to splay apart in the axon shaft and the growth cone, thereby permitting dynamic microtubules to interact with the newly polymerized actin bundles and initiate outgrowth in new directions. A recent study of KIF2A, a kinesin family member that interacts directly with microtubules by inhibiting their ability to elongate, showed the importance of cytoskeletal dynamics in regulating axon branching. When KIF2A was knocked out in mice, hippocampal axons had much longer collateral branches than in wild-type neurons. This suggests that KIF2A is required for suppressing supernumerary branches on hippocampal axons. In mice lacking KIF2A, microtubule depolymerizing activity was lower, suggesting that KIF2A normally depolymerizes microtubules and may suppress outgrowth of collaterals by regulating microtubule dynamics. Thus the absence of KIF2A would result in overextension of axon branches.

In neuronal growth cones and at axon branch points, the actin and microtubule cytoskeleton is the ultimate target of intracellular signaling pathways activated by extracellular guidance cues via cell surface receptors. Although these signaling pathways have been the subject of intense study, it is still not well understood how guidance cues modulate the dynamics of actin filaments and microtubules and regulate their interactions. However, it is known that, through the actions of cytoskeletal-associated regulatory proteins, reorganization of the cytoskeleton and changes in cytoskeletal dynamics underlie the ability of growth cones to turn toward gradients of attractive guidance cues (such as netrin-1) or turn away from repulsive cues (such as Sema3A). This model of growth cone guidance (Figure 6) could also apply to the promotion or inhibition of axon branching by growth and guidance cues.

Regulation of Axon Branching by Calcium Signaling

Axon Guidance and Branching

Growth and guidance cues are known to elicit calcium activity in neuronal growth cones. For example, in response to gradients of netrin-1, intracellular Ca^{2+} concentrations are elevated in the growth cone to regulate changes in guidance behaviors. Attractive turning is preceded by protrusion of lamellipodia and filopodia. These effects involve relative Ca^{2+} concentrations that form a gradient across the growth cone such that attractive turning may occur in the direction of higher Ca^{2+} concentrations (although growth cones can also be repelled toward higher Ca^{2+} levels). Rapid and extensive axon branching induced by netrin-1 was also found to occur through changes in Ca^{2+} activity in the form of repetitive transients. Netrin-1 evoked repetitive Ca^{2+} transients in restricted regions of cortical axons *in vitro*. Netrin-1 could also modulate endogenous Ca^{2+} activity by increasing the frequency of Ca^{2+} transients. These transients could be evoked in the entire axon or begin in localized axon regions and spread throughout the axon. Moreover, experimental reduction of Ca^{2+} levels in the culture medium revealed that Ca^{2+} signaling is essential for netrin-1-induced axon branching. Ca^{2+} transients often occurred in patterns, frequencies and amplitudes that were different in the axon and its branches, raising the possibility that Ca^{2+} transients of different frequencies and amplitudes could differentially regulate the growth of different branches on the same axon (Figure 7) or the growth of the primary axon and its branches. This is consistent with the finding in several studies that higher levels of electrical activity confer a competitive advantage on the growth of one axon branch over another. The role of netrin-1 in axon branching has not been demonstrated *in vivo*. However, it seems likely that similar calcium signaling mechanisms elicited by gradients of chemotropic target-derived cues such as netrin-1 may promote branching to topographically appropriate targets at specific locations along the axon.

Downstream Targets of Calcium Signaling during Axon Branching

Changes in the frequency of Ca^{2+} transients are known to activate different downstream intracellular targets. Different frequencies as well as patterns of Ca^{2+} transients may activate genes for different neurotransmitters and also target different kinases and phosphatases in the cytoplasm to elicit different

Figure 5 Sema3A rapidly decreases the number of F-actin bundles and dynamic microtubules in the peripheral region of the growth cone without collapse of the growth cone. (a, b) Images of a living large paused growth cone from a postnatal day 3 cortical neuron co-injected with Alexa488 phalloidin to label F-actin and with rhodamine tubulin to label microtubules (MTs). Within 1 min after application of Sema3A, many of the actin bundles in the growth cone disappear, concomitant with the loss of dynamic microtubules extending from the central microtubule loop. By 10 min after Sema3A application, the intensity of an F-actin ring surrounding the peripheral microtubule loop increases. (c) Merged images of the same growth cone in (a) and (b), where F-actin is pseudocolored red and microtubules are green. (d) A differential interference contrast (DIC) image of the same growth cone in (a)–(c) showing that the filopodia and broad lamellar region have not retracted. (e) Graph plotting the number of actin bundles over time. Semaphorin addition resulted in a significant decrease in actin bundles over time compared with supernatant collected from AP vector-infected cells (*$p < 0.05$; paired t test). All error bars are ±SEM. Scale = 10 μm.

cellular responses. Thus, specific cellular events may be regulated by calcium transients at optimal frequencies. For example, calcium/calmodulin-dependent protein kinase II (CaMKII) is known to function as a Ca^{2+} spike frequency detector. Mitogen-activated protein kinases (MAPKs) are also sensitive to intracellular Ca^{2+} changes. Ca^{2+} oscillations are self renewing, repetitive, and persistent. Moreover, the

Figure 6 Model for cytoskeletal reorganization and dynamics in growth cones responding to attractive and repellent cues. The side of the growth cone facing away from guidance cues is the unstimulated side. The growth cone contains bundled stable microtubules in the center, a meshwork of actin filaments in the lamellipodium, actin filament bundles that penetrate filopodia, and dynamic microtubules that extend into the periphery to interact with actin filaments. The attractive cue netrin-1 increases the number of filopodia and promotes actin filament elongation by actions of anticapping proteins. (Capping proteins normally terminate actin filament elongation.) In the growth cone periphery, an increased number of actin filaments bundles promotes interaction with dynamic microtubules and their associated proteins (such as plus end tracking +TIP proteins that bind to and stabilize microtubules). These interactions could lead to attractive turning behavior. The repellent cue Sema3A causes a dissolution of actin filament bundles and the subsequent loss of dynamic microtubules, which leads to growth cone collapse and repulsive turning. Slit might induce similar microtubule looping leading to growth cone pausing and/or repulsion. This model is also applicable to the promotion or inhibition of axon branching by growth and guidance cues.

mechanism of frequency modulation to decode information from calcium signals has advantages over mechanisms based on changes in amplitude of Ca^{2+} concentration alone, because discrete Ca^{2+} oscillations can be more easily distinguished by calcium decoders such as CaMKII. CaMKII and MAPK, both of which are known to be influenced by frequencies of Ca^{2+} transients in functions related to memory and synaptic plasticity, were recently shown to be major components of the netrin-1 calcium signaling pathway essential for axon branching. Overexpression of CaMKII promoted cortical axon outgrowth as well as axon branching, whereas MAPK increased axon branching but not axon outgrowth. Activation of specific kinases could be a mechanism whereby netrin-1-induced Ca^{2+} signaling promotes axon branching independent of axon outgrowth. Accordingly, Ca^{2+} may activate different downstream targets to elicit opposing effects on the axon such as inhibiting axon outgrowth but promoting the development of new branches.

Effects of Calcium Signaling Pathways on the Cytoskeleton

Ultimately, signaling pathways activated by guidance cues must converge on the actin–microtubule cytoskeleton to induce changes in growth cone behaviors and axon branching. Axon branching requires dynamic actin–microtubule interactions and netrin-1 elicits filopodial protrusion through actin polymerization. Netrin-1 is known to activate Rho GTPases, which regulate actin polymerization, as well as activating MAP1B (microtubule-associated protein), which is thought to play a role in actin–microtubule interactions. Thus, netrin-1-induced calcium signaling could influence regulators of cytoskeletal dynamics required for axon branching. CaMKII is a major target of netrin-1-induced calcium signaling. Studies of regulation of dendritic morphology and plasticity suggest that CaMKII may be an important link to the cytoskeleton. In dendritic filopodia, resembling spines, αCaMKII was shown to interact with βCaMKII and

Figure 7 (a, b) DIC images and C-I time lapse images in pseudocolor showing changes in calcium activity in an axon (red arrowhead) and its two branches (green and black arrowheads) after local application of netrin-1 from the pipette shown in (b) and indicated by the green arrows in the fluorescence images. Localized calcium transients occur in one branch at 4 min (e), in another smaller branch at 4:10 (f), and in the primary axon at 25 min (h). (j) Measurements of calcium transients in the axon (red), a large branch (black), and a small branch (green) corresponding to the arrows in the DIC image in (a). Calcium transients induced by netrin-1 can occur at different frequencies and at different times in an axon and its branches.

translocate to dendritic spines, thereby targeting CaMKII to the actin cytoskeleton. This is consistent with the role of CaMKII in stabilizing dendritic arbors. In this way, repetitive calcium transients induced by netrin-1 could provide a mechanism for translocating CaMKII to actin filaments in nascent axonal filopodia. However, it is not completely understood how major targets of calcium signaling, such as CaMKII and MAPK, regulate cytoskeletal dynamics required for development of new branches.

Activity-Dependent Regulation of Axon Branching

The involvement of Ca^{2+} signaling, a measure of electrical activity, suggests a role for activity-dependent mechanisms in the regulation of axon branching. During development, electrical activity shapes the growth and branching of axon arbors and thus the formation of neural circuits. The importance of electrical activity in concert with molecular cues was

demonstrated in refining the retinoptopic map *in vivo*. In the absence of spontaneous retinal waves, the refinement of retinal ganglion axon arbors into a precise map in the superior colliculus was degraded. In newborn rat visual cortical slices, imaging of axons extending horizontally in layers 2/3 of the cortex combined with electrophysiological recording showed that the complexity of axon branching gradually increased over time with a concomitant dramatic increase in frequency of spontaneous firing. When spontaneous action potential firing was silenced with tetrodotoxin (TTX) or synaptic transmission was blocked with pharmacological manipulation of glutaminergic transmission, the numbers of axon branches fell to about half that of control slices, suggesting that neural activity plays a role in regulating the early development of branches on cortical neurons.

Electrical activity is known to shape axon arbors by regulating retraction or elimination of axon branches. Recently, direct observation has shown that activity also controls the extent and rate of branch formation. Imaging of retinal axon arbors *in vivo* in the developing optic tectum of zebra fish revealed how suppression of activity influences axon branching. Transfection of retinal ganglion cells individually with a specific type of potassium (K^+) channel made it possible to electrically silence the transfected cells by hyperpolarization. Overexpression of the inward rectifier K^+ channel was found to suppress calcium spiking associated with spontaneous electrical activity. In these neurons, arbor length and complexity were reduced in comparison with adjacent untransfected cells with normal electrical activity. These results show that competitive mechanisms based on relative activity influence the development of functional networks through growth of axon arbors. Importantly, the competition effect is expressed in the formation of new axon branches rather than on the stability of branches. Studies of axon branching *in vitro* also support a model of competitive growth of branches based on electrical activity. In cultures of sympathetic neurons in the presence of NGF, local depolarization of axon collaterals enhanced their growth whereas unstimulated inactive axon collaterals from the same or neighboring neurons were at a competitive disadvantage for growth. Depolarization by patterned electrical stimulation, resulting in pulses of increased intracellular calcium, mediated this effect through the activation of a CaMKII–MEK signaling pathway. These findings suggest a mechanism for selection of one axon branch over another through electrical activity that promotes the growth of one set of axon branches while inhibiting growth of unstimulated axon collaterals.

Conclusions

The growth of collateral axon branches into appropriate targets during development is essential for establishing CNS connectivity. Branches can arise along the length of the axon as interstitial collaterals as well as forming terminal arbors. Although pathfinding by axonal growth cones and branching from the axon shaft are independently regulated, both serve to steer axons in new directions toward their targets. Therefore it is not surprising that growth cone guidance and axon branching involve similar extracellular guidance cues, cytoskeletal dynamics, and intracellular calcium signaling pathways. The terminal growth cone and developing axon branches are often at long distances from each other and from the cell body. Many of the cytoskeletal and signaling events that cause the growth cone to turn or a branch to form are therefore highly localized. It is not well understood how gradients of target-derived cues elicit branching at correct locations or inhibit inappropriate branching along the axon to ensure appropriate target innvervation. The signaling events that transform the relatively static axon shaft to one of dynamic motile protrusions during axon branching await further discovery.

Intracellular Calcium and Neuronal Death

M Gleichmann and M P Mattson, National Institute on Aging Intramural Research Program, Baltimore, MD, USA

Published by Elsevier Ltd.

Subcellular Electrochemical Ca^{2+} Gradients

The physiological extracellular Ca^{2+} concentration is 1.3 mM, whereas the resting cytosolic Ca^{2+} concentration in neurons ranges from 50 to 200 nM. In order to understand the importance of Ca^{2+} in neuronal death and survival, one has to know the molecular mechanisms that are involved in the regulation of cellular Ca^{2+} homeostasis, the most basic of which are briefly outlined in the following section.

Calcium ATPases and Sodium Calcium Exchangers

Plasma membrane Ca^{2+} ATPases (PMCA 1–4) pump Ca^{2+} out of the cytoplasm into the extracellular space at the expense of ATP. In addition, sodium calcium exchangers (NCX 1–3) use the Na^+ gradient to extrude Ca^{2+} from the cytosol to the extracellular space by in return allowing Na^+ into the cytosol (forward mode). Under conditions of high intracellular Ca^{2+}/low extracellular Na^+, they operate in reverse mode (i.e., pump out Na^+ for Ca^{2+}). As the extracellular/cytosolic Na^+ gradient is the main driving force for the NCX, its function is tightly coupled to other proteins that affect this gradient, like sodium–potassium ATPase and sodium-proton exchanger.

Voltage-Gated and Ligand-Gated Calcium Channels

Ca^{2+} can enter from the extracellular space into the cytoplasm via voltage-gated Ca^{2+} channels (L-, P-, Q-, R-, N-, and T-type Ca^{2+} channels) and ligand-gated cation channels such as glutamate receptors. Glutamate receptors can be separated (according to their selectivity for glutamate analogs) into *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), and kainate receptors. NMDA receptors are heterotetramers of an NR1-subtype dimer and another dimer composed of any combination of the other subtypes, NR2A-D and NR3A-B. They have a high permeability for Ca^{2+} and a low permeability for Na^+, and in neurons NMDA receptor activation will cause more Ca^{2+} entry than activation of voltage-gated Ca^{2+} channels. AMPA receptors are heterotetramers of subtypes GluR1–4 and generally have high conductance for Na^+ and low conductance for Ca^{2+} unless they do not contain subtype GluR2. GluR2 mRNA editing will result in an exchange of glutamine to arginine and this Q/R change will cause a block for Ca^{2+} ions. Kainate receptors are heterotetramers of subtypes GluR5–7 and/or KA 1–2 and, like AMPA receptors, have high permeability for Na^+ and low permeability for Ca^{2+}.

Endoplasmic Reticulum

The second main source for Ca^{2+} influx into the cytosol is the endoplasmic reticulum (ER), which constitutes a tubular organellar system throughout the neuron including dendrites, axons, and synapses. Ca^{2+} concentrations in the ER are variable (and may vary within subregions of the ER) but generally range from 0.5 to 1 mM. The ER membrane, in contrast to the plasma membrane, has considerable Ca^{2+} leakage, which is also a source of Ca^{2+} influx into the cytosol. Ca^{2+} is pumped into the ER by sarcoplasmic/endoplasmic reticulum ATPases (SERCA 1–3), which are activated by low Ca^{2+} concentrations in the ER. NCXs are not known to play a role in ER Ca^{2+} homeostasis. Ca^{2+} release occurs via ryanodine receptors (RRs) and inositol-3-phosphate receptors (IP_3Rs). Both RRs and IP_3Rs are regulated by Ca^{2+} itself in a way that they are activated by cytosolic Ca^{2+} increases (with the IP_3R1 isoform being inactivated at higher Ca^{2+} concentrations). This feedforward mechanism is known as calcium-induced calcium release and is believed to give the ER excitable and regenerative properties, similar to the plasma membrane, which may allow for Ca^{2+} release to spread throughout the ER within a cell. Notably, ER-associated Ca^{2+} oscillations can be found in neurons.

Mitochondria

Mitochondria are not believed to be a major Ca^{2+} source under physiological conditions. However, their proton gradient constitutes an electrochemical driving force for cations and, in situations of high cytosolic Ca^{2+} concentrations, mitochondria accumulate Ca^{2+}, thus acting as Ca^{2+} buffers. They are also closely connected to ER Ca^{2+} release sites and are believed to remove Ca^{2+} from those local sites.

Calcium as a Second Messenger in Physiological Conditions

The steep extracellular/cytosolic gradient makes Ca^{2+} a useful second messenger, especially in excitable cells. Depolarization-induced Ca^{2+} entry causes synaptic vesicle release at the synapse making Ca^{2+}

the integrating mechanism that controls neuronal signal propagation. In the cytosol, a variety of Ca^{2+}-binding proteins such as calbindin and calmodulin act as calcium sensors and via interaction with other proteins such as calcium/calmodulin kinases (CamK's) and/or the calcineurin phosphatase affect phosphorylation status of numerous other proteins (e.g., transcription factors, ion channels, other kinases). A basic feature of cytosolic Ca^{2+}-binding proteins is that they usually have a low K_D, thus also acting as Ca^{2+} buffers (calpains being an exception). Calcium-binding and buffering proteins also provide a rationale for the concept of different Ca^{2+} concentrations within the cytosol. In the vicinity of voltage-gated Ca^{2+} channels, the Ca^{2+} concentrations are believed to increase up to 100 μM under physiological conditions while calcium-binding proteins buffer Ca^{2+} at further distances.

CREB

One well-established Ca^{2+}-associated signaling cascade involves calmodulin kinase (CaMK) and cAMP response element binding protein (CREB). CREB is an important transcription factor for neuronal differentiation, survival, and long-term potentiation (LTP)-mediated synaptic plasticity. It is activated upon phosphorylation at Ser 133 by CaMKII and IV. The nuclear Ca^{2+} determines CREB phosphorylation status and transcriptional activity much more than cytosolic Ca^{2+} making somal Ca^{2+} rises more likely to affect CREB activity than Ca^{2+} in distant dendrites. The nucleus is surrounded by the nuclear envelope, from which the ER is believed to be produced. Therefore, Ca^{2+} at distant synapses could cause ER-mediated Ca^{2+} release, which in certain cases might spread from dendritic ER region all the way to the nuclear envelope, causing an increase in nuclear Ca^{2+} and thus nuclear CREB phosphorylation.

CREB activity is closely associated with neuronal activity and neuronal survival during development. During development neurons are generated in excess, and the early postnatal period of rodents is a phase where dispensable neurons are eliminated by apoptosis. During this developmental period, synaptic activity is the key determinant of a neuron's survival (as neurons without synaptic activity are unlikely to be important for CNS function, this survival criterion appears useful in the context of brain function). A very well established *in vitro* model of this paradigm is the potassium deprivation-induced cell death of cerebellar granule neurons, where granule neurons are isolated from the cerebella of 8-day-old rat pups and cultivated under moderately depolarizing conditions with elevated potassium. A switch to normal potassium concentrations will induce cell death in these granule neurons. In this model of developmental activity-dependent neuronal survival, it has been shown *in vitro* and *in vivo* by conditional knockout and use of dominant negative mutants that CaMKIV and (phospho)CREB activity are essential in conveying the survival message. However, if CREB is knocked out at later stages of life, rodents develop a neurodegenerative phenotype where neuronal loss in hippocampus and striatum happens at a slower pace than during CREB knockout in development. Interestingly, CREB has also been linked to rodent models of trinucleotide repeat diseases such as Huntington's disease in which a decreased expression of the transcriptional cofactor CREB binding protein (CBP) has been observed, which would result in decreased CREB transcriptional activity.

While CREB plays an important role in neuronal survival, Ca^{2+} and CaMK are not the only factors phosphorylating CREB. Activation of the Ras/extracellular receptor kinase (ERK) or the PI_3K/Akt cascades results in CREB phosphorylation as well. On the other hand, most signals that will activate ERK or Akt are closely linked to Ca^{2+}, although Ca^{2+} may not be required itself for activation. One example for this is NMDA receptor-mediated activation of ERK. The exact molecular mechanism of NMDA receptor-mediated ERK activation is not fully understood, but there is some evidence that it is not Ca^{2+} itself that is required, but rather molecular interactions and conformational changes mediated by other proteins that also bind to the scaffold proteins at the postsynaptic density, such as the postsynaptic density protein of 95 kDa (PSD95), via its so-called postsynaptic density and zonula occludens (PDZ) domains. This also offers an explanation for observed differences in synaptic versus nonsynaptic NMDA receptor-mediated signaling, with only the former activating ERK.

BDNF

Another activator of neuronal survival signaling, ERK and Akt phosphorylation, and Ca^{2+} is brain-derived neurotrophic factor (BDNF). BDNF is a neurotrophic factor expressed throughout the CNS and, just like CREB, its function is important for neuronal differentiation, survival, and synaptic plasticity. Moreover, CREB and BDNF are interconnected as BDNF signaling will result in CREB-mediated transcriptional activation and CREB activation will increase transcription from the BDNF gene. BDNF binding to its high-affinity receptor TrkB will cause receptor dimerization and autophosphorylation. The ensuing signaling cascade involves activation of Ras and ERK,

PI_3K and Akt, as well as phospholipase C (PLC). PLC activation will result in the generation of IP_3, which in turn will open IP_3Rs in the ER membrane causing Ca^{2+} release. Therefore, similar to NMDA receptors, BDNF/TrkB signaling is closely associated with Ca^{2+}, although not all downstream cascades strictly require Ca^{2+} for activation.

Neuronal Activity and Ca^{2+} Sustain Trophic Signaling Cascades

From the data gathered so far on Ca^{2+}, CREB, CaMK, and BDNF, a picture emerges with considerable feedforward potential. Thus, glutamate release will induce Ca^{2+} influx via NMDA receptors, leading to CaMKII+IV/CREB activation, ERK and Akt phosphorylation, increased production of BDNF, and via Ca^{2+}-mediated vesicle release BDNF secretion. BDNF in turn activates ERK + Akt and induces ER Ca^{2+} release, thus enhancing synaptic strength (and LTP) and further facilitating glutamate signaling. Glutamate will also activate the metabotropic glutamate receptors which results in PLC activation and ER Ca^{2+} release. In such a scenario, Ca^{2+} would sustain active synapses and overall para- and autocrine release of neurotrophic factors. It provides the rationale for a broader concept which sees neuronal activity as a key factor in neuronal survival and Ca^{2+} plays a central role in this concept. This concept is also reflected in less scientific slogans of brain function such as "brain jogging" or "use it or lose it". However, as appealing as these ideas may be, one has to keep in mind that apart from the developmental situation, such theories are not settled knowledge and more evidence is required to convincingly make the case for neuronal activity and Ca^{2+} as a neuroprotective strategy in aging and neurodegenerative disorders.

Ca^{2+} in Pathological Conditions

As with most aspects of biology, there is a flip side to the Ca^{2+} coin as well. Ca^{2+} can have detrimental effects on neurons under pathological conditions, and this is closely (though not exclusively) linked to the process of excitotoxicity. Excitotoxicity describes toxic effects of high intensity and/or sustained activation of excitatory neurotransmitter receptors on neurons.

Glutamate Excitotoxicity

In cell culture concentrations of 100 μM, glutamate will cause massive cell death. Because glutamate treatment only for a few minutes with subsequent glutamate washout (or glutamate receptor blockade) and switch to normal culture conditions will cause no prominent morphological changes in phase-contrast microscopy but later on will result in massive neuronal death, the term 'delayed glutamate toxicity' was coined, which may be somewhat misleading as glutamate excitotoxicity (both *in vitro* and *in vivo*) actually is a fast process.

NMDA receptors and Ca^{2+} are key mediators of glutamate toxicity The finding of glutamate excitotoxicity was followed by the discovery that in the absence of Ca^{2+} glutamate causes considerable less cell death, whereas in the absence of Na^+ it remains highly toxic, leading to the idea that high and sudden increases in cytosolic Ca^{2+} cause neuronal death, whereas a cytosolic Na^+ increase poses less of a problem. With the development of specific receptor antagonists it was shown that NMDA receptor blockade prevents glutamate excitotoxicity, whereas AMPA and kainate receptor blockade proves to be less effective. These findings still remain undisputed basic knowledge on glutamate excitotoxicity and make a lot of sense in the light of the ion-regulating physiology of neurons, since Ca^{2+} efflux has to proceed against a higher electrochemical gradient than Na^+ efflux and NMDA receptors are the main source for glutamate-induced Ca^{2+} entry. However, the downstream events in glutamate excitotoxicity are less clear.

Source specificity theory of glutamate toxicity Although the evidence for Ca^{2+} as a key mediator of glutamate excitotoxicity is compelling, a paradox remains. Cultured neurons can be depolarized by means of elevated extracellular potassium concentrations to the extent that cytosolic Ca^{2+} concentrations and total cellular Ca^{2+} uptake are equivalent to the amounts seen in glutamate toxicity, yet such elevated potassium concentrations do not cause cell death. This observation has led to the formulation of the source specificity theory of glutamate toxicity. It claims that not the total amount of Ca^{2+} entering the cell but rather the source of entry determines neuronal fate. However, elevated potassium causes Ca^{2+} influx only, whereas glutamate increases Na^+ and Ca^{2+}. This has not been fully appreciated in the source specificity theory.

Nitric oxide and reactive oxygen species Calcium influx through NMDA receptor channels is coupled to activation of neuronal nitric oxide (NO) synthase (nNOS), which is located close to synaptic NMDA receptors by binding to PSD95 via PDZ domains. Activation of nNOS might lead to excessive NO and reactive oxygen species (ROS) formation, thus

contributing to glutamate toxicity and potentially explaining the source specificity of glutamate excitotoxicity. Moreover, increased NO and ROS generation after glutamate treatment have been documented by many groups. However, although it is generally accepted that ROS formation contributes to glutamate toxicity, it is more controversial as to how much ROS are at the core of glutamate toxicity.

Mitochondrial Ca^{2+} overload Once glutamate receptors and voltage-gated calcium channels open and Ca^{2+} enters the cytosol in large amounts, the Ca^{2+} will enter the mitochondrial matrix due to the mitochondrial membrane potential which constitutes an electrochemical driving force for cations. In the mitochondrial matrix, Ca^{2+} will form a complex with phosphate ($CaPO_4$) so that the concentration of free Ca^{2+} remains constant and more Ca^{2+} can enter the mitochondria. In this way, mitochondria act as a sink for Ca^{2+} and their total Ca^{2+} uptake exceeds that of the free Ca^{2+} concentration both in cytosol and mitochondrial matrix by orders of magnitude. Mitochondrial Ca^{2+} uptake may continue to the point where $CaPO_4$ will precipitate from a gel-like to a crystalline form, causing the mitochondrial permeability transition pore to open. However, the latter mechanism does not explain the source specificity of excitotoxicity, and it is unclear to what extent such a mechanism applies to all types of neurons.

Calpain activation and Ca^{2+} efflux Another concept of glutamate toxicity focuses on calpain activation. Calpains are calcium-activated papain-like proteases. Unlike most other cytosolic calcium-binding proteins, calpains have K_D's in the micromolar and millimolar range (μ-calpain and m-calpain), concentrations which under physiological conditions are unlikely to occur anywhere other than in the close proximity to voltage-gated calcium channels or glutamate receptors, especially since endogenous inhibitors, calpastatins, prevent uncontrolled calpain activation. However, in cases of massive glutamate release, calpain activation increases far beyond levels observed under physiological conditions, where nontoxic NMDA receptor activation and processes such as neurite outgrowth are associated with limited calpain activation. Importantly, calpain inhibition decreases glutamate toxicity. Calpain activation leads to cleavage of the NCX3 isoform, thus impeding Ca^{2+} efflux and causing cell death. This concept puts Ca^{2+} efflux into the equation, an important aspect that so far has not received much attention.

The complexities of glutamate excitotoxicity The concepts outlined above represent only some of the glutamate excitotoxicity mechanisms, and so far no generally accepted chronological series of downstream events has been established in glutamate excitotoxicity. However, it is important to stress that the existing concepts are not mutually exclusive and it is quite possible that each concept covers part but not all of the story. For example, it is conceivable that calpain activation is specifically linked to glutamate receptor opening (if one assumes that the local Ca^{2+} concentrations in their vicinity are higher than at the calcium channels), thus linking the source specificity with calpain activation. Also, it is possible that death pathways may be multiple and redundant, such that some neurons die from mitochondrial Ca^{2+} overload while others die from calpain overactivation. In the latter scenario, inhibiting one pathway (e.g., calpain activation) might rescue only a small population of neurons, while other neurons undergo a different route toward cell death (e.g., mitochondrial Ca^{2+} overload). If this is the case, then downstream rescue strategies would require combination approaches, an area that so far has not been systematically tested. Interestingly, such a conversion from one cell death pathway to another exists between apoptosis and necrosis in glutamate excitotoxicity such that apoptosis inhibition will result in necrosis.

Ca^{2+}, Glutamate, and Stroke

Although glutamate excitotoxicity in its purest form is an *in vitro* model, it is believed to be of importance in many pathological *in vivo* situations, the most prominent of which is stroke. In stroke, neurons undergo energy depletion due to ischemia and this will result in collapse of the membrane potential and release of large amounts of glutamate, contributing to cell death in the so-called penumbra region where blood supply is not completely absent but critically reduced. Glutamate concentrations in stroke areas have been reported to reach levels of 100 μM, and NMDA receptor antagonists are protective in rodent stroke models. Also, many downstream events observed in glutamate excitotoxicity are found in rodent stroke models (and postmortem human brain tissue) including increased NO and ROS generation, calpain activation, and (so far only in rodent models) NCX3 cleavage. Similarly, the *in vitro* model of combined hypoxia and hypoglycemia shows a broad overlap with glutamate excitotoxicity when done in neurons. Unfortunately, NMDA receptor antagonists do not work in stroke therapy in humans, the problem being that they cause acute psychotic episodes, preventing the drug from being administered in the required dose.

So, while direct NMDA receptor antagonists are regarded as a dead end road in stroke treatment,

the jury is still out on treatment strategies that target more downstream events of glutamate excitotoxicity. However, targeting downstream events is no easy task because of the existence of multiple pathways that will likely require polypharmacy approaches.

Glutamate Excitotoxicity and Other Neurodegenerative Diseases

Although glutamate excitotoxicity is most closely linked to stroke, it is also believed to play a role in many other diseases. Importantly, certain features of glutamate excitotoxicity, including cellular calcium overload, calpain activation, and ROS generation, are observed in many different neurodegenerative disorders. However, it is not clear whether such changes reflect late events taking place after neurons have passed the point of no return, or actually are early pivotal events. While hippocampal damage in chronic epilepsy is a case where glutamate release (due to epileptic discharge) is located at the beginning of events (and NMDA blockade is helpful in rodent models), in other diseases like Alzheimer's disease (AD), Parkinson's disease (PD), amyotrophic lateral sclerosis (ALS), HIV-associated dementia (HAD), or the trinucleotide repeat diseases the connection is not that obvious. One concept that involves glutamate excitotoxicity and Ca^{2+} deregulation and can be applied to a number of diseases centers around a vicious cycle of increased ROS generation, protein damage, mitochondrial dysfunction, reduced ATP generation, impaired Ca^{2+} homeostasis, and increased (synergistic) glutamate toxicity. In this scenario, it is conceivable that the disease process starts slow and progresses to a point where otherwise nontoxic glutamate levels cause cell death. More disease-specific mechanisms have been found that link glutamate excitotoxicity and neuronal death. For example, in the case of AD, a synergistic *in vitro* toxicity of amyloid beta and glutamate exists, as well as a specific impairment of the NCX (but not the sodium/potassium ATPase). Also, the NMDA receptor open channel blocker memantine is approved for AD therapy and may actually slow down the disease process. Memantine has also been approved for the treatment of HAD, and may also be a viable approach for the treatment of PD.

In ALS, glutamate excitotoxicity was at the center of research for a long time, although this changed to some degree with the discovery that mutations in the SOD1 gene cause some cases of inherited ALS. Nevertheless, glutamate levels in the cerebrospinal fluid (CSF) of ALS patients are increased and the only drug that has been approved so far in ALS, riluzol, has (among other properties) agonist properties for the excitatory amino acid transporter 2 (EAAT2) protein, which is expressed on glial cells and is supposed to scavenge excess glutamate from the extrasynaptic space. In addition, there appears to be a specific loss of expression of EAAT2 expression in ALS.

Calculating the Balance: Is Ca^{2+} Good or Bad?

Taken together, there exist two seemingly contradictory concepts, one of which stresses the role of Ca^{2+} and depolarization in sustaining neuronal function, the other pointing to Ca^{2+} as the key factor in excitotoxicity and associated neurodegenerative diseases. Both concepts have accumulated considerable data for their support, so one might ask if Ca^{2+} is preventing or causing neuronal death. To formulate the question in this way probably is not useful because one has to separate between early development and older age. Moreover, Ca^{2+} has multiple functions, the net effect of which likely depends on the molecular context of its signaling. For example, it seems that massive Ca^{2+} entry via NMDA receptors is more harmful than via voltage-gated channels, but the status of Ca^{2+} efflux capability and NCX function also have to be taken into account. On the other hand, NMDA receptors are more likely to cause ERK phosphorylation when located synaptically and nuclear Ca^{2+} appears to be particularly helpful in sustaining CREB transcriptional activity. If these concepts hold true, then simple approaches like activating or antagonizing NMDA receptors should not be the most effective approach. Instead, a combination of NMDA receptor antagonist plus a neurotrophic factor like BDNF would make more sense, as the neurotrophic factor might compensate for loss of signaling through ERK and Akt kinases. Similarly, one might consider combining partial NMDA or AMPA receptor agonists with antioxidants and think about ways to specifically target synaptical NMDA receptors. Future research will be required to establish whether such calcium-based approaches are effective.

Invertebrate Models to Study Learning and Memory: Lymnaea

P R Benjamin and G Kemenes, University of Sussex, Brighton, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Associative conditioning studies are predominant in the *Lymnaea* model system. Integration between behavioral, neural circuitry, and molecular biological approaches are key features of the *Lymnaea* work. Learning occurs within more complex circuits involving central pattern generators (CPGs) rather than the reflexive circuits often used in other mollusks. An attractive feature of the *Lymnaea* system is the ability to carry out one-trial reward conditioning. Mechanistic studies have focused on feeding and respiration building on the detailed information of the neural circuitries involved.

The Feeding Circuit

Feeding in *Lymnaea* consists of a sequence of repetitive movements called rasps (Figure 1(a)). During each rasp, the mouth opens and a toothed radula is scraped forward over the food substrate (protraction phase). Food is then lifted into the mouth (retraction phase), which closes while the food is being swallowed (swallow phase), and the sequence is repeated. Rhythmic movements of the feeding muscles are driven by a network of motor neurons (B1–B10) that, in turn, are driven by synaptic inputs from a feeding CPG network of interneurons. Each phase of the feeding rhythm is generated by one of three main types of CPG interneurons, N1 (protraction), N2 (retraction), N3 (swallow), providing sequences of excitatory and inhibitory synaptic inputs to motor neurons active in different phases of the feeding rhythm. CPG-driven rhythmic electrical activity can be recorded in the feeding network even in the absence of feeding muscles and this is called fictive feeding. Activity in the motor neurons and CPG neurons is modulated by identified higher-order interneurons, such as the cerebral giant cells (CGCs) and cerebral ventral 1 cells (CV1s). These higher-order neurons have been the focus of the learning and memory studies. The CGCs act as gating neurons in the feeding circuit. Increased CGC spiking activity during feeding facilitates feeding responses to food. The CV1 cells are members of a larger population of neurons called the cerebrobuccal interneurons (CBIs) that are command-like neurons involved in the activation of feeding.

Sucrose is an effective chemical stimulus for feeding and is therefore used as the unconditioned stimulus (US) in associative (Pavlovian) reward conditioning. At the cellular level, sucrose applied to the lips in semi-intact preparations induces fictive feeding in motor neurons and interneurons of the feeding network. As well as the CPG neurons, the modulatory CGC and CV1 cells are also activated in the sucrose-driven fictive feeding rhythm.

The conditioned stimulus (CS) for reward conditioning in *Lymnaea* is either a chemical (amyl acetate, pear drops) or a tactile stimulus (a gentle brush stroke applied to the lips). Recently, visual stimuli have also been used and the success of a black-and-white checkered pattern as a CS indicates that the eyes are involved. The chemical CS was previously thought to have no effect on feeding ('neutral stimulus'), either at the behavioral or electrophysiological levels, but has recently been shown to have stimulatory or inhibitory effects in naive animals depending on concentration. Touch to the lips, monitored either at the behavioral or the electrophysiological level, cannot initiate or maintain feeding but nevertheless produces a complex sequence of inhibitory and excitatory synaptic inputs on all neurons of the feeding network.

The Respiratory Network

The aquatic pulmonate snail *Lymnaea* can breathe either through the skin or through a simple lung (Figure 1(b)). As the name implies, *Lymnaea stagnalis* populations often live in stagnant water, and when the environment becomes hypoxic the snails float to the surface and perform rhythmic opening and closing movements of their pulmonary opening, the pneumostome. This aerial respiration behavior is controlled by a respiratory CPG, the three main components of which are the right pedal dorsal 1 (RPeD1), input 3 (IP3), and visceral dorsal 4 (VD4) interneurons. These provide synaptic inputs to identified motor neurons (I and J, opener; and K, closer) innervating pneumostome opener and closer muscles. The chemosensory stimulus (hypoxia) that triggers pneumostome opening first activates sensory cells in the pneumostome-osphradial area, which in turn provide excitatory afferent inputs to RPeD1. Through its synaptic connections with the other members of the CPG network, activation of RPeD1 initiates CPG activity which underlies the respiratory rhythm.

Figure 1 The neuronal networks for feeding and respiration in *Lymnaea*. (a) The neuronal network underlying rhythmic feeding behavior. Chemosensory neurons (SNs, yellow squares) located in the lip structures detect the presence of food or chemostimulants, such as sucrose. Excitatory inputs from the sensory pathways are distributed in parallel to modulatory neurons (orange circles), including the paired cerebral giant cells (CGCs), the single slow oscillator (SO) interneuron and the group of cerebral-buccal interneurons (CBIs), and also to N1 type CPG interneurons (green circles). The CGCs may presynaptically modulate certain types of chemosensory inputs to the CBIs (see Figure 4). The complex synaptic connectivity between the modulatory and N1 interneurons leads to activation of the whole CPG, with the protraction (N1), rasp (N2, blue circles), and swallow (N3, pink circles) phases of the feeding cycle following in sequence due to the synaptic connectivity within the CPG and their intrinsic properties. Several subtypes of each of the N cells have been characterized but because of the complexity of their synaptic connections with modulatory interneurons and motor neurons, only a generalized representative of each N-type is shown. The rhythmic pattern generated by the CPG drives protraction, rasp, and swallow phase motor neurons, such as B7 (green squares), B3 (blue squares), and B4 (pink squares), leading to sequences of muscular activity and feeding movements. (b) The neuronal network underlying respiratory behavior. Activation of sensory neurons (SNs, yellow squares) located in the pneumostome-osphradial area, leads to activation of the respiratory CPG, comprised of RPeD1 (green circle), VD4 (blue circle), and IP3 (pink circle). VD4 drives activity in K MNs (motor neurons, blue squares), responsible for pneumostome closing (inspiration) and IP3 drives activity in I/J MNs (pink squares), responsible for pneumostome opening (expiration). Filled circle, chemical inhibitory synapses; vertical bar, chemical excitatory synapses; horizontal bar, peripheral sensory endings; zig-zag lines, electronic connections.

Tactile stimulation of the pneumostome area evokes pneumostome closure and stops aerial respiratory behavior. This response, which is mediated by an identified whole-body withdrawal neuron (RPeD11), is an important component of the withdrawal response in *Lymnaea*, and therefore tactile stimulation of the pneumostome is used as an aversive US in the operant conditioning experiments.

Reward Classical Conditioning of Feeding to a Tactile CS

Lymnaea can be classically conditioned by repeatedly pairing touch to the lip with food (5–15 trials) (Figure 2(a)). This type of learning shares important characteristics with associative conditioning in vertebrates, such as stimulus generalization and discriminative learning, classical–operant interactions and strong dependence on both external and internal background variables, such as novelty versus familiarity of the environment or hunger versus satiety.

Two approaches have been used to investigate the neural basis of tactile reward classical conditioning in *Lymnaea*. One approach was based on the development of an *in vitro* preparation where electrophysiological manipulation of neuronal pathways aims to mimic the behavioral conditioning paradigm. In this study, a lip touch stimulus was paired with intracellular activation of the modulatory SO neuron, which can drive fictive feeding. After 6–10 pairings, presentation of the touch stimulus could activate a robust fictive feeding rhythm in feeding motor neurons.

A second approach used behavioral conditioning followed by electrophysiological analysis to record changes in electrical activity that follow long-term memory (LTM) formation. In the semi-intact preparation, electrophysiologically recorded fictive feeding patterns were used as a systems-level correlate of the repetitive feeding behavior seen in the intact snail (Figure 2(b1)). A feeding motor neuron, such as the B3 (Figure 1(a)), was routinely used as a monitor of fictive feeding in the whole network (Figure 2(b2)). This cell is easy to identify, plays no role in pattern generation, but receives synaptic inputs from all three types of CPG interneurons and so can be used as an indirect monitor of the conditioned activation of the CPG. It also receives an easy-to-identify early compound excitatory postsynaptic potential (EPSP) input that results from stimulation of the CS pathway. Other motor neurons such as the B1 salivary gland motor neuron were also recorded (Figures 2(b2) and 2(b3)) to check that all the feeding motor neurons are activated during conditioned fictive feeding. Most recently, recordings were made from modulatory interneurons such as the CV1 cells (Figures 2(b2) and 2(b3)) to see if they also undergo changes following conditioning.

Figure 2 Electrophysiological correlates of the LTM trace after classical conditioning in *Lymnaea*. (a) The behavioral response to the touch CS, which was calculated as the postminus prestimulus difference in feeding activity, is significantly (*) stronger in the conditioned versus the control group. (b) Behavioral classical conditioning produces a CS-induced increase in the systems-level electrical activity (fictive feeding response). (b1) The electrophysiological response to the touch CS, which was calculated as the postminus prestimulus difference in fictive feeding activity, is significantly (*) stronger in the conditioned versus the control group. (b2) The lip touch CS evokes rhythmic fictive feeding activity in a CBI, CV1 (CV1a subtype) and motor neurons B1 and B3 in a preparation from a conditioned animal. (b3) The lip touch CS evokes no rhythmic fictive feeding activity in a preparation from a control animal. Note that CV1a is more depolarized in the preparation from the conditioned animal than in the preparation from the control animal, a consistent observation in this type of experiment.

Using the lip touch behavioral training protocol snails were subjected to 15 training trials over 3 days and then these and control animals were dissected for electrophysiological analysis, starting on the day after the last training trial. Touching the lips of the intact snails from the experimental group after training induced a pattern of feeding movements significantly greater than controls (Figure 2(a)). Similar significant differences (Figure 2(b1)) were seen between experimental (Figure 2(b2)) and control animals (Figure 2(b3)) at the level of the electrophysiologically recorded fictive feeding pattern in motor neurons, recorded from the same snails.

The CPG-driven activity in the motor neurons depends ultimately on activity of neurons at all levels of the feeding network, so the conditioned fictive feeding recorded in the motor neurons is a systems-level 'readout' of the memory trace in the whole feeding system. However, more detailed changes can also be recorded in different parts of the network. One of these is the early EPSP that occurs in the B3 motor neuron before the onset of the fictive feeding pattern. The amplitude, but not the latency and duration of the EPSP, was significantly enhanced after conditioning. In sated snails, the conditioned fictive feeding response to touch was lost but the increase in the EPSP amplitude persisted. This suggests that there is unlikely to be a causal link between increases in amplitude in B3 and generation of the fictive feeding pattern.

Electrical correlates of tactile conditioning were recorded also at other levels within the feeding circuit and these could all be potential sites of plasticity. That sites, quite early in the CS pathway, could be involved in conditioning was revealed by extracellularly recording mechanosensory fibers located in the connective between the cerebral and buccal ganglia. Tactile responses could be recorded in these fibers and, following conditioning, the number of spikes occurring early in this response increased, compared with controls.

Interestingly, a correlate of tactile conditioning could also be recorded in the CPG network. A long-lasting sequence of inhibitory synaptic inputs that occurs in the N1 CPG interneurons in response to lip touch in naive animals (Figure 3(b)) changes to a strong sustained depolarizing synaptic input after conditioning (Figure 3(a2)), and this drives a sustained

Figure 3 Learning-induced modification of mechanosensory inputs to a CPG interneuron of the *Lymnaea* feeding system. (a1) After behavioral classical conditioning with a tactile CS (touch to the lips) and food US (sucrose), the CS induces rhythmic activity in the CPG interneuron N1M, which is known to lead to fictive feeding activity in the entire feeding network. (a2) The CS-evoked inputs on an expanded time base. A brief hyperpolarization is followed by a strong maintained depolarization. (b) Synaptic inputs to the N1M in a preparation from a naive animal, evoked by the same touch stimulus that was used as the CS in the experiment shown in (a2). The tactile inputs have a strong maintained hyperpolarizing effect on N1M, a consistent observation in naive preparations.

plateauing pattern in the N1 cell (Figure 3(a1)). This is an example of synaptic plasticity affecting an important interneuronal component of the feeding network.

One candidate for initiating CPG activity following conditioning is the CBI cell type known as CV1. This neuron is capable of driving a fictive feeding pattern via its connections with the N1M cells of the CPG network, and activity in these cells normally accompanies unconditioned feeding patterns stimulated by sucrose. After conditioning, the CV1 cells are significantly more active following touch in conditioned snails (Figure 2(b2)) compared with controls (Figure 2(b3)), and they show the typical patterned activity seen with sucrose (US) application. More detailed experiments on the role of CV1 cells in tactile conditioning have revealed that nonsynaptic electrical changes play a role in memory. A long-lasting membrane depolarization of 11 mV on average was recorded in CV1s from conditioned compared with control snails that persisted for as long as the electrophysiological and behavioral memory trace. The depolarization makes the cells more responsive to the CS and can account for the activation of the feeding response after conditioning via the CV1 cell's strong excitatory synaptic connection with the CPG. The importance of this result is emphasized by experiments in which the membrane potential of the CV1 cells is manipulated to either reverse the effect of behavioral conditioning or mimic the effects of conditioning in naive snails. These experiments showed that the persistent depolarization of the CV1 cells was both sufficient and necessary for the conditioned response in the feeding network.

Reward Classical Conditioning of Feeding to a Chemical CS

In the original successful formulation of chemical reward conditioning in *Lymnaea*, snails were subjected to a chemical conditioning protocol using amyl acetate as the CS and sucrose as the US. Following training, the explicitly paired (CS–US) experimental group showed significantly greater feeding responses to amyl acetate over their own naive responses and all the standard control groups (random, explicitly unpaired, CS alone, US alone). As might be predicted for appetitive conditioning, both age and motivational state (hunger vs satiety) influenced learning. Both hungry and sated young snails could acquire the conditioned response, but in the latter group its expression was only apparent when the animals were starved before testing. On the other hand, old snails could only acquire the conditioned response if they were maintained in a hungry state during training. The significance of motivational state became even more apparent when it was realized that if snails were starved long enough (for 5 days) before and throughout the experiment, even a single pairing of amyl acetate and sucrose resulted in LTM which lasted for at least 19 days. This is a remarkable example of single-trial learning that is used now for analyses of the time course of the mechanisms underlying LTM formation.

An electrophysiological correlate of the conditioned response to amyl acetate was recorded as changes in the fictive feeding responses in motor neurons, as in tactile conditioning, but electrical activity following conditioning has also been recorded in other parts of

the feeding system in attempts to localize sites of plasticity. The cell bodies of chemosensory neurons are located in lip epithelial tissue and project to the cerebral ganglia via the lip nerves where they synapse with cerebral ganglion neurons like the CBIs. Extracellularly recorded spike responses to both the CS and US can be recorded in the lip nerves from naive animals and these responses do not change after conditioning. In contrast, neuronal output from the cerebral ganglia is significantly enhanced in response to the CS after conditioning. This indicates that chemical conditioning affects central but not peripheral processing of chemosensory information, with the cerebral ganglia being an important site of plasticity. The fibers that were recorded extracellularly to indicate cerebral plasticity were originating from the CBI interneurons, so their activation is particularly significant. Confirmation that the CBIs do increase their activity after conditioning was obtained by showing increases in feeding patterns to the CS in CV1 neurons, a specific CBI cell type. From this work, it is suggested that the synapses between the primary chemosensory neurons and the CBIs are a major site of plasticity. Two other CS pathways are present in naive animals but these are not affected by conditioning.

The current network model for chemical conditioning (Figure 4) also includes nonsynaptic plasticity. The CGCs are persistently depolarized by about 10 mV after behavioral conditioning. This indirectly increases the strength of postsynaptic responses to CGC stimulation by a process that involves an increase in intracellular calcium concentration. The local target for CGC depolarization are the CBI cells, and artificial depolarization of the CGCs in naive snails increases the response of the CBI cells to the CS, mimicking the effects of behavioral conditioning. It appears that the CGCs are increasing the strength of the CS to CBI synapse by presynaptic facilitation, as shown in Figure 4. The onset of the CGC depolarization is between 16–24 h after training and it persists for at least 14 days, as long as the behavioral memory trace was present. There is an early behavioral memory trace from 2 h after conditioning, so the CGCs cannot be involved in memory expression immediately after training. It is more likely that the CGCs are involved in the maintenance of the LTM after the trace has already been consolidated and encode information that is important for memory recall. Interestingly, the CV1 cells that show a persistent change in membrane potential after tactile conditioning show no change after chemical conditioning.

At the molecular level, we know that the protein synthesis-blocker anisomycin (ANI) injected 10 min (but not at 1, 2, 3, 4, 5, and 6 h) after conditioning blocks the 24 h memory trace and an earlier 5 h memory trace is blocked by both protein synthesis and RNA synthesis blockers (Actinomycin D, Act-D), confirming that LTM is present as early as 5 h after conditioning. Regulation of gene expression during memory consolidation is known to involve transcription factors like the cyclic AMP-responsive element-binding protein (CREB) and the highly conserved CREB gene and CREB-like proteins have been identified recently in *Lymnaea*. Consistent with a role for CREB in *Lymnaea* LTM is the observation that levels of phosphorylated CREB are increased in the CGCs following reward conditioning.

Consolidation of the 24 h memory trace is dependent on the nitric oxide (NO)-GMP signaling pathway. There is a critical period of sensitivity up to 5 h after conditioning when blocking this pathway by drug injection prevents behavioral LTM formation. Further evidence for a role of NO in LTM came from experiments on the CGCs. These neurons express mRNA transcripts from two related nNOS genes (*Lym-nNOS1* and *Lym-nNOS2*). Six hours after one-trial conditioning, *Lym-nNOS1* is upregulated

Figure 4 A cellular model of LTM based on the results from chemical classical conditioning in *Lymnaea*. (a) In naive animals, the excitatory connections between the sensory neurons (SNs) and the command-like CBIs are weak and the chemical CS (amyl acetate) cannot activate feeding. The CGCs are at normal membrane potential (~65 mV), and the presynaptic modulatory input from the CGCs to the SNs is inactive or weak. (b) In conditioned animals, the CGC soma is depolarized by ~10 mV compared to naive animals, and this leads to an enhancement of the CGC presynaptic modulatory inputs to SNs and a strengthening of the SN to CBI excitatory inputs, which enables the feeding response to the CS. Black lines, inactive connections; green lines, active connections. Thin bars, weak excitatory synapses; thicker bars, stronger/enhanced excitatory synapses. The thicker outline of the CGC in (b) indicates learning-induced nonsynaptic plasticity (membrane depolarization).

compared with controls. This upregulation of the NOS coding transcript may be due to an earlier downregulation of the *Lymnaea anti-NOS* transcript at 4 h that is known to be inhibitory on NOS transcript production.

Other highly conserved molecular pathways that have been implicated in LTM in *Lymnaea* are the protein kinase A (PKA) and mitogen-activated protein kinase (MAPK) signaling pathways. Inhibition of PKA catalytic subunit activity or MAPK phosphorylation without blocking sensory or motor pathways blocks LTM and 30 min after conditioning levels of both PKA activity and MAPK phosphorylation were increased, with PKA activation first detected in an even earlier time window (5 min). Whether there is any linkage between the NO, PKA, and MAPK signaling pathways is yet to be examined.

An interesting new observation is that memory reconsolidation after retrieval at 6 h posttraining is both PKA and protein synthesis dependent, whereas reconsolidation after retrieval at 24 h depends on protein synthesis but not on PKA activity. This finding indicates that depending on the 'age' of the consolidated memory, different molecular pathways are activated by memory retrieval and contribute differentially to memory reconsolidation.

Reward Classical Conditioning of Feeding to a Visual CS

Feeding also can be conditioned by pairing visual stimuli (CS) with sucrose (US). *Lymnaea* has a lens that is capable of forming an image on the retina under water and visual approach and reaching behavior can be evoked by a black-and-white check pattern. One-trial conditioning is possible when snails approaching a black panel along a gutter are stimulated with sucrose. After conditioning, approaching the black pattern elicited more rasping movements compared with un-reinforced trials. Successful reward conditioning was also obtained with a checkered pattern that was discriminated from a gray pattern of equal luminance, but in this experiment multiple trials were necessary (four trials per day for 4 days). A memory trace for this visual stimulus was recorded 4 days after conditioning.

Aversive Classical Conditioning of Feeding to a Chemical CS

Aversive classical conditioning in *Lymnaea* (conditioned taste aversion or CTA) is based on pairing sucrose with an aversive stimulus such as KCl, which inhibits feeding and evokes a withdrawal response. After eight trials, trained animals show a significantly weaker feeding response to sucrose than did controls and this memory lasted for over 1 month.

A neural analysis of CTA was carried out on isolated brains dissected from conditioned and control animals. In particular, the synaptic connection between the modulatory CGCs and the CPG interneuron, N1, was examined. In conditioned animals compared to controls, a significant increase in the size of IPSPs recorded in the N1 was observed following an artificial depolarization of the CGCs. Since the CGCs are known to play a critical gating role in feeding behavior and the N1 is a pivotal member of the feeding CPG, this enhanced IPSP may be an important cellular correlate of the CTA learning. Like reward chemical conditioning, aversive chemical conditioning appears to involve PKA and the CREB transcriptional regulatory system. The injection of cAMP or PKA into the soma of the CGCs led to a long-term enhancement of the synapse between the CGC and a follower motor neuron, B1. The injection of a CRE oligonucleotide into the CGCs 1 h prior to the injection of cAMP blocked the expression of long-lasting synaptic plasticity. CTA also has a requirement for the transcription factor, CCAAT/enhancer binding protein (C/EBP) and this was shown in the B2 gut motor neuron. Levels of phosphorylated LymC/EBP increased in B2 after CTA consolidation although paradoxically transcriptional levels were reduced in the same neuron.

Aversive Classical Conditioning of Whole-Body Withdrawal Responses to a Visual CS

Lymnaea do not normally respond to a light flash (CS) but after pairing with body rotation (US) the CS evokes a whole-body withdrawal response. This type of learning requires an interaction between two sensory organs, the eyes and the vestibular organs (the statocysts), and so this type of learning is called 'visuo-vestibular conditioning' or VVC. Spaced training, at least 10 trials over 3 days, is required, and it results in an LTM lasting for at least 1 week. The latency for a withdrawal response following the CS is measured and the reciprocal of the latency is used as the behavioral index for VVC and compared with response in controls where either random application of the CS and US are applied or naive animals receive no stimulus. Neural analysis has so far concentrated on analysis of sensory processing of the CS and US in the eye and statocyst, respectively, and their interactions in naive animals and this work forms the background for future mechanistic studies on LTM formation.

Operant Conditioning of the Respiratory Network to a Tactile CS

The aerial respiratory behavior of *Lymnaea stagnalis* has been used in a series of experiments investigating the behavioral and neuronal mechanisms of operant conditioning. Hypoxia triggers pneumostome opening and this was used as the operantly conditioned behavior. Tactile stimulation of the pneumostome area evokes pneumostome closure and stops aerial respiratory behavior. Animals were tested and trained in an artificially created hypoxic N_2-rich environment to increase the level of respiratory behavior. In the operantly trained group, a tactile stimulus was applied to the pneumostome area each time aerial respiration was attempted by the animal. Suitable yoked and hypoxic control groups were also used. The number of openings, latency to first opening, and total breath durations were recorded in pre- and posttraining periods. Only the operantly conditioned group showed significant changes between the pre- and posttraining behaviors, with significant reductions in openings and total breathing time and significant increases in the latency to first breath. It has since been demonstrated that a memory for this conditioned response could persist for at least 4 weeks when a spaced training procedure was used. Both intermediate memory (ITM) and LTM have been described based partly on the length of time the memory persists and also on the sensitivity to protein and mRNA synthesis blockers. ANI prevents the formation of both ITM and LTM, whereas Act-D only prevents LTM. Both reconsolidation and extinction have been studied following operant conditioning and both have been shown to be dependent on new RNA and protein synthesis. Extinction is viewed as a new type of associative memory that 'covers up' but does not replace the original memory. Thus, following extinction trials, the loss of memory at 2 h is followed by full 'spontaneous recovery' at 24 h.

Neural changes associated with this learned behavior have been identified in the isolated CNS derived from operantly conditioned animals. Specifically, spontaneous patterned activity in the IP3 interneuron, which is involved in pneumostome opening (see **Figure 1(b)**), showed a significant reduction compared to activity in the IP3 neurons of brains derived from yoked controls. Furthermore, a higher percentage of RPeD1 CPG interneurons, which are important in the onset of the respiratory cycle, were silent in conditioned versus control preparations. A reduction in the ability of the RPeD1 cells to induce IP3 activity was also observed. More direct evidence for the role of RPeD1 in memory formation came from somal ablation experiments. Removal of the soma 2 h prior to conditioning prevented LTM but had no effect on ITM, without affecting the ability of the snail to carry out respiratory behavior; this suggested that the RPeD1 soma was necessary for LTM formation. Removal of the RPeD1 soma 1 h after conditioning had no effect on LTM, indicating that the effects of soma ablation were not related to memory access or retrieval. Interestingly, both extinction and reconsolidation also require the presence of the soma of RPeD1, indicating that RPeD1 is involved in the formation of more than one type of memory trace.

Conclusions

Lymnaea can be trained to respond to a wide variety of sensory cues: visual, touch, and chemical. This pond snail is a generalist feeder, meaning that it is not restricted to any particular food and it would be an advantage for it to learn about potentially useful foods using several different modalities. Visual stimuli are provided by floating plants that the animal feeds on by locomoting to the water surface. Tactile cues potentially provide information about physical properties such as texture. Touch is known to provide a normal component of the food stimulus to the lips although touch alone is ineffective in initiating feeding in naive animals. Chemical cues provided by food are also useful indicators of nutritionally valuable material objects and presumably this is why they are such an effective CS. Both visual and chemical cues can be used in single-trial reward conditioning providing a useful model for studying the neuronal and molecular temporal changes occurring during and in the immediate period after training.

All the types of associative conditioning described here are capable of inducing LTM. ITM has been described for operant conditioning but has not yet been examined in other paradigms. Reconsolidation and extinction in operant conditioning have been shown to have similar general molecular requirements to LTM formation. More detailed molecular studies of LTM in chemical conditioning have emphasized that regulation of gene expression by transcription factors such as CREB and C/EBP and the PKA and MAPK signaling pathways. The importance of these molecular pathways in *Lymnaea* provides further evidence for the generality of these highly conserved mechanisms in molluskan learning. NO has been shown to be important in memory consolidation in chemical reward conditioning and this appears to involve regulation of nNOS gene expression in a specific cell type, the CGCs.

Neuronal analysis has emphasized that changes following learning can be recorded at multiple sites in the feeding and respiratory circuits. How

molecular and electrical changes in specific cells like RPeD1 in the respiratory circuit and the CGCs in the feeding circuit can translate to circuit level and behavioral changes is still a major question. This can be partly understood in the feeding circuit by recent results showing that persistent changes in membrane potential in the CGCs induced by conditioning can facilitate CS sensory synaptic pathways to command neurons for feeding. However, this is unlikely to be the only mechanism because other pathways originating in the buccal ganglia CPG are also likely to be important. The involvement of both synaptic and nonsynaptic electrical changes in reward conditioning of feeding is proving to be a major feature of LTM formation in other invertebrate and vertebrate models of learning and memory.

Invertebrate Neurohormone GPCRs

Introduction

The invertebrate nervous systems use, in principle, the same classes of compounds for chemical neurotransmission as the vertebrate nervous systems do: amino acids, acetylcholine, adenosine triphosphate (ATP), monoamines, neuropeptides, and protein hormones. Whereas the first three compounds or compound classes are mainly used for fast neurotransmission, the last three are used for slow transmission, neuromodulation, and paracrine and endocrine signaling. This slow transmission is made possible by the relatively high metabolic stability of monoamines, neuropeptides, and protein hormones. Furthermore, it is intuitively clear that lower invertebrates (Figure 1(a)) are not fast movers. Many cnidarians, for example, obtained their names in the eighteenth century from flowers (e.g., sea anemone, sea pansy, and Anthozoa) because they were colorful and apparently immobile. Thus, it comes as no surprise that lower invertebrates mainly use biogenic amines, neuropeptides, and protein hormones as their neurotransmitters or neurohormones.

In this article, we confine ourselves to the receptors for biogenic amines, neuropeptides, and protein hormones. We call these three compound classes neurohormones because, in addition to their role as neurotransmitters in the central and peripheral nervous systems, these molecules mainly function as neurohormones, being released into the circulation and mediating the control of the nervous system on overall physiological processes such as development, reproduction, feeding, and homeostasis. The receptors for the three classes of neurohormones are nearly exclusively G-protein-coupled receptors (GPCRs), which are transmembrane proteins, consisting of seven transmembrane α-helices, an extracellular N-terminus, and an intracellular C-terminus (Figure 2). Ligand binding occurs at the extracellular parts of the receptor, whereas the intracellular parts transduce the receptor activation to the intracellular G-proteins, leading to second-messenger cascades. There exist several classes or families of GPCRs: family-A (also called rhodopsin family, or family-1), family-B (family-2), and family-C (family-3). Most neurohormone GPCRs belong to family-A or -B. The GPCR families differ by certain amino acid consensus sequences; for example, the family-A GPCRs have a characteristic DRY motif (or similar sequences such as the DRF or ERY sequences) in their second intracellular loop just after the third transmembrane α-helix (Figure 2).

Most animals belong to one of two evolutionary lineages: Protostomia and Deuterostomia (Figure 1(a)). Mammals, vertebrates, and some invertebrate groups (e.g., sea urchins) belong to the deuterostomian lineage, whereas most invertebrates (among them insects) belong to the protostomian lineage. Some very basal invertebrate groups such as cnidarians (e.g., *Hydra*, sea anemones, and corals) evolved before the split of Protostomia and Deuterostomia (Figure 1(a)).

If we consider the number of animal species living on Earth, it is evident that most (90%) of all animals are invertebrates (Figure 1(b)). Only 1–2% of all animal species are mammals, although it is in these species that most neuroscience research is being carried out. Therefore, addressing our attention to the invertebrates is clearly justified.

Seventy-five percent of all animals are insects. Thus, we mainly focus in this article on insect GPCRs and then relate these data to findings from some other invertebrate groups, such as mollusks, nematodes, and cnidarians (Figure 1).

Insect GPCRs

Insects are ecologically and economically extremely important because most flowering plants (and also food plants) depend on insects for their pollination. But insects can also be agricultural pests and vectors (intermediate pathogen carriers) for major diseases, such as malaria, elephantiasis, sleeping disease, Chagas disease, dengue fever, and yellow fever. During the last 8 years, the genomes from 24 insect species have been sequenced or are in the process of being sequenced (Figure 3). Some of these species are medically important, such as the malaria mosquito *Anopheles gambiae*, the yellow fever mosquito *Aedes aegypti*, and the blood-sucking bug *Rhodnius prolixus* (which transmits Chagas disease). Other insects are agriculturally important, and one insect, *Drosophila melanogaster*, is a well-known model organism.

The presence of these sequenced insect genomes has greatly facilitated the identification of insect neurohormone GPCRs. This is because gene-finding computer programs can detect most genes in a sequenced genome, and the characteristic GPCR

Figure 1 Animal evolution and number of animal species. (a) Phylogenetic tree, showing the two evolutionary lineages of multicellular animals that split shortly after the Cnidaria: Protostomia (blue) and Deuterostomia (red). The major phyla are highlighted in bold and their approximate species numbers are given in thousands of species (K). The majority of invertebrates belong to the Protostomia branch. Cnidarians are the first phylum, where a nervous system evolved; there are no nervous or endocrine cells in Porifera. (b) Schematic representation of the number of each species belonging to each animal phylum or order. Insects (class insecta or Hexapoda) account for 75% of all animal species living on Earth. Invertebrates account for approximately 90%, and mammals for only 1–2%.

Figure 2 Topology of a neurohormone G-protein-coupled receptor (GPCR), belonging to family-A. This membrane protein has seven transmembrane α-helices, an extracellular N-terminus and an intracellular C-terminus. The extracellular loops 1 and 2 are connected by a cystine bridge. The DRY sequence shortly after transmembrane α-helix 3 is a hallmark for family-A GPCRs, as are other residues within several of the seven transmembrane α-helices. The C-terminus is often connected via a palmitoylated cysteine residue to the cell membrane. G-proteins interact with the three intracellular loops and the proximal region of the receptor C-terminus to initiate a second-messenger response after receptor activation.

Figure 3 The evolutionary relationships of insects with a fully sequenced genome and those for which a whole genome-sequencing project is in progress. Insects for which the genome sequencing has been completed (at least 8–9 times coverage) are highlighted in green. Insects for which the genome sequencing is in progress are highlighted in blue. Adapted from Grimmelikhuijzen

topology (Figure 2) makes it possible to identify some of these genes as coding for neurohormone GPCRs. Of course, after the initial predictions (annotations), the identity of the predicted GPCR has to be experimentally confirmed (by cloning) and the cloned GCPR has to be deorphanized (its ligand to be identified). Ligand identification occurs after heterologous expression of the GPCR cDNA in cells in cell culture or in frog oocytes and the measurement of second messengers or second-messenger-mediated responses after addition of potential ligands.

Because *D. melanogaster* was the first insect whose genome was completely sequenced, most neurohormone GPCRs were first discovered and deorphanized in this fruitfly. As can be seen in Figure 4, *Drosophila* has 21 biogenic amine receptors (the *Drosophila* receptor genes are indicated by CG numbers; the Am numbers refer to the honey bee *Apis mellifera*). From these 21 receptors, 15 (71%) have been deorphanized (the identified ligand appears after the CG numbers in the figure). All the *Drosophila* biogenic amine receptors (Figure 4) are family-A GPCRs. The neuropeptide receptors given in Figure 5 are also family-A GPCRs; those in Figure 6 are family-B GPCRs. Together they show that *Drosophila* has 48 neuropeptide and protein hormone receptors. From these 48 GPCRs, 31 (65%) have been deorphanized. These deorphanized GPCRs are invaluable for our understanding of *Drosophila*, but they can also be used to annotate similar (ortholog) receptors in other insects with a sequenced genome.

Most insects belong to one of two evolutionary lineages: Holometabola (insects with a complete metamorphosis during development: larvae, pupae, adults) and Hemimetabola (insects with an incomplete metamorphosis: the early developmental stages, also called nymphae, resemble the adults). The holo- and hemimetabolous insects have a common evolutionary origin, which lies about 340 million years back in

Figure 4 Phylogenetic tree analysis of the *Drosophila* and honey bee biogenic amine GPCRs. The *Drosophila* genes are indicated by their official CG identification numbers, whereas the honey bee genes are numbered Am 1–19. The tree is rooted by the *Drosophila* FMRFamide receptor gene, CG2114. The length of each branch represents the distance between each receptor and the common ancestor of that receptor and its neighbor. The units at the bottom represent the number of amino acid residue substitutions corresponding to this length. GPCR, G-protein-coupled receptor. Reproduced from Hauser F, Cazzamali G, Williamson M, Blenau W, and Grimmelikhuijzen CJP (2006) A review of neurohormone GPCRs present in the fruitfly *Drosophila melanogaster* and the honey bee *Apis mellifera*. *Progress in Neurobiology* 80: 1–19.

time (Figure 3). The holometabolous insects consist of four major orders: Diptera (flies), Lepidoptera (moths and butterflies), Coleoptera (beetles), and Hymenoptera (bees, wasps, and ants) (Figure 3). Figure 1(b) shows that more than half of all animals (more than 80% of all insects) are holometabolous insects. Recent genome comparisons show that Diptera are the most advanced and Hymenoptera the most basic holometabolous insects (Figure 3).

Because most available information on insect GPCRs is from *Drosophila*, we have used the *Drosophila* (Diptera) neurohormone GPCRs to

Figure 5 Phylogenetic tree analysis of the *Drosophila* and honey bee neuropeptide and protein hormone GPCRs belonging to family-A. The honey bee receptors are numbered Am 20–52. The tree is rooted by the *Drosophila* metabotropic glutamate receptor, CG11144. GPCR, G-protein-coupled receptor; LGR, leucine-rich repeats-containing GPCR. Reproduced from Hauser F, Cazzamali G, Williamson M, Blenau W, and Grimmelikhuijzen CJP (2006) A review of neurohormone GPCRs present in the fruitfly *Drosophila melanogaster* and the honey bee *Apis mellifera*. *Progress in Neurobiology* 80: 1–19.

annotate neurohormone GPCRs in the genome from the honey bee *A. mellifera* (Hymenoptera). The results of these comparisons are shown in Figures 4–6. Whereas *Drosophila* has 21 biogenic amine receptors, the honey bee has 19 (Figure 4). The 15 deorphanized *Drosophila* biogenic amine GPCRs all have a honey bee ortholog, so we know by this annotation effort what the likely ligands for these 15 honey bee GPCRs are.

A similar comparison for the peptide and protein hormone GPCRs shows that, whereas *Drosophila* has 48 GPCRs of this kind, the honey bee has 37 (Figures 5 and 6). The major reason for this larger number in *Drosophila* is gene duplication, which occurred during late fly evolution (e.g., note the two *Drosophila* allatostatin-A and two allatostatin-C receptors, which both have only one honey bee ortholog, Am 30 and Am 31, in Figure 5).

Evolution of Insect Neurohormone GPCRs and the Possibility of Co-Evolution with Their Ligands

From Figures 5 and 6, it is clear that the neuropeptide and protein hormone GPCRs occur in clusters with common origins. This suggests that during evolution new receptors originated by gene duplication. These duplicated receptors could use the same ligands. For example, the *Drosophila* GPCRs encoded by CG13803 and CG8985 (Figure 5, top) both use myosuppressin as their ligand. We could imagine that, in some cases, it would be impractical for the two new receptors to use the same ligand, because the two systems would interfere. In this case, a new ligand could be generated by gene duplication, followed by mutations (amino acid substitutions). Examples of this are the pyrokinin receptors (Figure 5, top). Pyrokinins are insect neuropeptides with the C-terminal consensus sequence **FXPRLamide**. *Drosophila* has two pyrokinins with slightly different C-terminal structures, pyrokinin-1 (TGPSASSGLW**FGPRLamide**) and pyrokinin-2 (SVP**FKPRLamid**e), and three different pyrokinin receptors, CG9918, CG8784, and CG8795. Pyrokinin-1 strongly activates its receptor CG9918 (Figure 5) but, although structurally related, it does not activate CG8784 and only very weakly CG8795. Similarly, pyrokinin-2 strongly activates its receptors CG8784 and CG8795 (Figure 5), but only weakly CG9918. Thus, for neuropeptide (and protein hormone) GPCRs, it appears to be possible to create new receptor–ligand couples by gene duplication of receptor and ligand, followed by mutations and subsequent amino acid substitutions.

Figure 6 Phylogenetic tree analysis of the *Drosophila* and honey bee neuropeptide and protein hormone GPCRs belonging to family-B. The honey bee receptors are numbered Am 53–56. The tree is rooted by the *Drosophila* metabotropic glutamate receptor, CG11144. GPCR, G-protein-coupled receptor. Reproduced from Hauser F, Cazzamali G, Williamson M, Blenau W, and Grimmelikhuijzen CJP (2006) A review of neurohormone GPCRs present in the fruitfly *Drosophila melanogaster* and the honey bee *Apis mellifera*. *Progress in Neurobiology* 80: 1–19.

This type of co-evolution between receptors and ligands apparently does not occur during biogenic amine GPCR evolution (Figure 4). The reason for this is probably that the biogenic amine molecule is relatively small and that it is not as easy to modify this ligand as it is for peptides. For neuropeptides, it only takes one nucleotide mutation in its gene to change an amino acid residue, whereas for biogenic amines a new (decarboxylating, hydroxylating, etc.) enzyme system has to become active. Furthermore, the ligand binding pocket in the biogenic amine GPCR might be small and tolerate only little structural variation of the ligand. In short, what we see in Figure 4 is that gene duplications also occur during the evolution of biogenic amine GPCRs. Sometimes the same ligands are used by the duplicated (paralog) receptors; for example, CG15113 and CG16720 (Figure 4, middle) both use serotonin. However, the use of serotonin as a ligand is not confined to evolutionary-related GPCRs because serotonin is also used by a distantly related receptor CG1056 (Figure 4, bottom). Another example is dopamine, which is used by CG18314 (Figure 4, bottom) and two other groups of distantly related receptors: CG9652 + CG17004, and CG18741 (Figure 4, middle and top). Thus, during biogenic amine GPCR evolution, new GPCRs evolved that needed new ligands. Because of structural or biosynthetic constraints, the only way to obtain such new ligands was by borrowing from other systems. This caused a ligand hops during biogenic amine GPCR evolution.

When we look at honey bee biogenic amine GPCRs, we find that nearly every *Drosophila* receptor has a honey bee ortholog that probably uses the same ligand. For some instances, this has been confirmed by deorphanizing the honey bee receptor (e.g., Am 6, Am 8, and Am 9 use dopamine as a ligand; Figure 4). Thus, the ligand hops have occurred before the split of the evolutionary lineages leading to present-day flies and honey bees, which is about 340 million years ago (Figure 3).

The Bursicon Story

Only very few protein hormone GPCRs have been deorphanized in *Drosophila*, one of them being the receptor for bursicon. Bursicon was described more than 40 years ago as a hormonal activity from the insect brain that causes tanning and hardening of the soft exoskeleton (cuticle) in a newly hatched insect after adult ecdysis (molt). Later studies showed that bursicon also steers a motor program needed for the final phase of metamorphosis, including wing expansion, and that it causes apoptosis of the wing epithelial cells after wing expansion is completed. The neurohormone bursicon has recently been identified as being a heterodimer, consisting of two different but related cystine-knot proteins. Also, the *Drosophila* receptor for bursicon has recently been identified, CG8930 (Figure 5, bottom). This receptor belongs to the family of leucine-rich repeats-containing GPCRs (LGRs), of which we found four members in *Drosophila* (DLGR1–4). LGRs have a large leucine-rich repeats-containing, horseshoelike structure in the extracellular N-terminus, which represents the ligand-binding part of the receptor. The *Drosophila* LGRs have orthologs in mammals, where they are the receptors for follicle-stimulating hormone, luteinizing hormone/choriogonadotropin, thyroid stimulating hormone, and relaxin, which are all hormones involved in reproduction or development.

The honey bee has a close ortholog (Am 47) to the *Drosophila* bursicon receptor, which suggests that Am 47 (Figure 5, bottom) is the receptor for a honey bee bursicon. This is corroborated by the presence of a bursicon gene in the honey bee genome.

GPCRs in Other Invertebrates

Because LGRs are present in both insects and mammals, it can be concluded that they must have evolved before the split of Protostomia and Deuterostomia, in other words, very early in animal evolution (Figure 1(a)). This is exactly what we find because LGRs have also been cloned from cnidarians – in this case, from the sea anemone *Anthopleura elegantissima*. The ligand of the sea anemone LGR has not been identified yet, so the receptor is still an orphan. Other orphan LGRs have been reported in nematodes (the roundworm *Caenorhabditis elegans*) and mollusks (the snail *Lymnaea stagnalis*), so this family of protein hormone receptors appears to be ubiquitous in the Animal Kingdom.

Information on neurohormone GPCRs in invertebrates other than insects is rather scarce and fragmented, and this is probably due to the lack of completed genome projects. Although no molluskan genome project has been completed, approximately eight neuropeptide GPCRs have already been identified in this phylum, mainly in the pond snail *L. stagnalis*. Among them is the receptor for an FMRF-like peptide (LyCEP); this is not, however, the receptor for the authentic molluskan FMRFamide neuropeptide, which remains elusive. Both in *L. stagnalis* and in *Octopus vulgaris*, molluskan variants of oxytocin (OT) and vasopressin (VP) occur, and their corresponding GPCRs have been identified. Similar OT- and VP-like peptides and their GPCRs have been found in annelids. OT and VP also clearly occur in deuterostomians, which suggests that the OT-VP system has ancient evolutionary roots (before the split of Deuterostomia and Protostomia; Figure 1(a)).

The genome of a lower invertebrate and model organism, *C. elegans*, has been fully sequenced (together with three other *Caenorhabditis* species). Bioinformatic screening of the *C. elegans* genome yielded approximately 18 biogenic amine and 50 neuropeptide GPCRs. These are similar to the numbers found in insects. Still, no global annotation has been performed of neurohormone GPCRs comparable to the ones carried out in *D. melanogaster* and *A. mellifera* (Figures 4–6). Twenty-nine genes (*flp*-1 to *flp*-29) in *C. elegans* encode preprohormones for FMRFamide-like peptides (flp), yielding altogether 68 distinct flp variants. It comes as no surprise, therefore, that all four neuropeptide GPCRs cloned and deorphanized in this nematode are flp receptors. The gene of one of these flp receptors (NPR-1) has two allelic variants, of which one is responsible for social and the other one for solitary feeding.

In addition to the four flp receptors, nine biogenic amine GPCRs have been deorphanized in *C. elegans*: three for serotonin, three for acetylcholine, two for octopamine/tyramine, and one for dopamine. These biogenic amine receptors and their ligands control various aspects of behavior. The serotonin receptor SER-1, for example, controls egg laying and mating behavior. The information obtained from studies in *C. elegans* so far suggests that the set of neurohormone GPCRs in lower invertebrates is not much different from that in higher invertebrates (insects) (Figure 1(a)). The numbers of biogenic amine and neuropeptide GPCRs is about the same, and similar biogenic amines occur in insects as in nematodes (acetylcholine, serotonin, dopamine, tyramine, and octopamine). The only difference between lower and higher invertebrates may be that flp neuropeptides and their receptors are biased in nematodes. This is understandable, however, because this class of neuropeptides is abundant and widespread in basal invertebrates, such as cnidarians, suggesting that it is evolutionarily very old.

Inwardly Rectifying Potassium Channels

H T Kurata and C G Nichols, Washington University School of Medicine, St. Louis, MO, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

'Inwardly rectifying' K^+ (Kir) channels are expressed in a variety of cell types and are involved in regulating numerous physiological processes. Examples range from roles in regulating insulin release from pancreatic β-cells to regulating electrolyte balance in the kidney to maintaining a stable resting membrane potential in many tissues. In addition, spontaneous or inherited mutations in genes encoding Kir channels have been shown to underlie a number of genetic disorders, emphasizing the breadth and importance of the role of Kir channels in physiology and normal cellular function.

As a functional descriptor, the term inwardly rectifying broadly refers to the preferential conduction of currents in the inward direction. Most K^+ channels that exhibit inward rectification are members of the Kir channel family, can be categorized as Kir channels, which are distinguished from other classes of K^+ channels based on important features of their primary sequences and overall structures. Functionally, inward rectification of Kir channels arises from voltage-dependent channel blockade by intracellular cations such as Mg^{2+} or polyamines. Structurally, each subunit of a Kir channel comprises two transmembrane helices and a large cytoplasmic domain formed by the N- and C-termini. The absence of a voltage-sensing domain is an important structural distinction from the six transmembrane segments present in the voltage-gated class of K^+ channels (Kv channels). Although the gating behavior of Kir channels is not intrinsically voltage-dependent, this class of channels exhibits a rich tapestry of regulation by a number of physiological ligands/factors, including nucleotides, auxiliary subunits, protons/pH, phospholipids, and $G_{\beta\gamma}$ subunits. In this article, we review current understanding of the structural features of Kir channels and some of the mechanisms that underlie their regulation.

Molecular Architecture of Kir Channels and Channel Complexes

Like all members of the cation channel superfamily, the membrane-spanning region of Kir channels is a tetrameric arrangement of a core pore-forming unit. Kv channels contain additional transmembrane helices with charged residues that form a voltage-sensing domain and underlie the voltage-sensitivity of these channels. Two-pore K^+ (K2P) channels lack a voltage-sensing domain structure and comprise two pore-forming units arranged in tandem. Kir channel subunits, in contrast, contain only the core pore-forming domain in a single copy (Figure 1(a)). Crystal structures have been determined for a full-length bacterial inward rectifier (KirBac1.1) and for fragments of two eukaryotic Kir channels (Kir2.1 and Kir3.1), advancing our understanding of Kir structure to atomic resolution (Figures 1(b) and 1(c)). The two transmembrane helices of the core pore-forming domain are named M1 and M2 and correspond to the pore-forming S5 and S6 helices in Kv channels (Figure 1(b)). In some Kir channels, the M2 helix contains an acidic residue that has been identified as a critical determinant of polyamine sensitivity and is frequently referred to as the rectification controller (see the section titled 'Inward rectification'). Kir channels also exhibit the characteristic reentrant pore loop structure, containing a K^+-channel signature sequence that forms the selectivity filter of the channel. Within the selectivity filter, K^+ ions are dehydrated and stabilized by backbone carbonyl oxygen atoms contributed by each subunit of the channel. The selectivity filter underlies the ability of the K^+ channels to selectively permeate K^+ in the presence of other physiological cations such as Na^+. The rotationally symmetric arrangement of these pore-forming domains forms a single K^+-selective pore that spans the plasma membrane (Figure 1(c)).

Beyond the central transmembrane pore domain are cytoplasmic N- and C-termini. These two ends of the channel assemble into a large cytoplasmic domain consisting mostly of β-sheet structures, with the N-terminus of one subunit interacting primarily with the C-terminus of an adjacent subunit. This feature is illustrated in the cutaway image of a channel in Figure 1(b), where the N-terminus of the red subunit interacts with the large C-terminus of the blue subunit. The cytoplasmic domain extends the transmembrane pore-forming domain well beyond the width of the plasma membrane, such that the obligatory K^+ ion permeation pathway is approximately 70 Å in length. This extended pore region contains multiple pore-facing acidic residues (as many as four per subunit in Kir2.1), which play a role in determining both unitary conductance and sensitivity to various blocking cations. In addition, the Kir N- and C-termini together form binding sites for multiple physiologically

Figure 1 Kir channels: (a) molecular architecture; (b) side-view atomic resolution structure of a bacterial channel (KirBac1.1); (c) top-view atomic resolution structure of the bacterial channel. In (a), Kir channels are shown as tetrameric arrangements of a core pore-forming domain. Squares represent the canonical pore-forming K^+ channel domain, with each color representing a distinct subunit. K^+ channels exhibit rotational symmetry around a central K^+-selective pore. In Kv channels, an additional modular voltage-sensing domain is attached to the core pore-forming domain, whereas in two-pore (K2P) channels, two core domains are arranged in tandem. In (b), a cutaway side view of the channel is shown (the cytoplasmic domain of the yellow subunit and the transmembrane domain of the blue subunit have been removed for clarity). Together the primarily α-helical transmembrane domain and the β-sheet-rich cytoplasmic domain form a pore over 70 Å in length. The shaded box represents the approximate dimensions of the plasma membrane, with the slide helix located near the interface of the membrane and cytoplasm.

important channel ligands, including $G_{\beta\gamma}$ subunits in Kir3 channels and adenosine triphosphate (ATP) in Kir6 channels.

A final interesting structural feature of Kir channels is the slide helix, an α-helical segment that is apparent in the full-length KirBac 1.1 crystal structure. This segment precedes the M1 helix and runs parallel to the plane of the plasma membrane. Structures analogous to the slide helix were absent in the earliest K^+-channel crystal structures determined for KcsA and MthK, and at present a definite functional role for the slide helix has not been established. This structure could be considered equivalent to the S4–S5 linker in Kv channels, which has been proposed to play an important role in coupling of the pore-forming domain to conformational changes in the voltage-sensing domain. Along these lines, one possibility is that the slide helix plays a critical role in coupling ligand binding in the cytoplasmic domain to gating events in the transmembrane domain of Kir channels. A second possibility is that the slide helix underlies some channel interactions with membrane phospholipids.

Adding complexity to the molecular arrangement of the pore-forming Kir channel subunits is their assembly with various auxiliary proteins. Among the best-described examples of Kir auxiliary subunits is the obligate coassembly of Kir6 channel subunits with the sulfonylurea receptor (SUR). This coassembly is required for adequate trafficking of either binding partner to the plasma membrane, and it is thought to arise from mutual shielding of polybasic endoplasmic reticulum (ER) retention signals (RXR motifs) present in both Kir6 and SUR subunits. Apart from a trafficking

role, coassembly with SUR subunits plays a critical role in determining the response of the channel complex to various nucleotides. Other examples of channel assembly with associated proteins include the association of Kir2 channels with SAP97 and the association of Kir4.1 with the dystrophin–glycoprotein complex, although these binding partners are generally not considered to be channel subunits and their impact on channel gating has not been determined. Finally, recent work has suggested that the G-protein-regulated Kir3 subfamily channels (GIRKs) may remain intimately associated with heterotrimeric G-proteins before and after the activation of G-protein-coupled receptors (GPCRs), with this preassociation of signal complexes playing an important role in the generation of specificity of channel responses to extracellular signals.

Inward Rectification

Historically, inward rectification – the preferential conduction of currents in the inward direction – was the identifying functional property of Kir channels. It is now understood that inward rectification is not an intrinsic property of Kir channels but, rather, is a consequence of a voltage-dependent block by intracellular Mg^{2+} or polyamines (e.g., spermine, spermidine, cadaverine, and putrescine). As a consequence, removal of channels from the cellular environment (e.g., in an excised patch-clamp experiment) results in the loss of apparent rectification properties, and these can be restored by the application of exogenous polyamines or Mg^{2+} (Figure 2(a)). Significantly, the various cloned Kir channels exhibit a spectrum of the degree or strength of rectification. These differences in rectification arise due to different sensitivities to intracellular blocking cations and are reflected in the different functional roles of each channel type. In strongly-rectifying channel types, rectification is so dramatic that very little current flows through them at potentials more positive than the reversal potential of K^+ (Figure 2(a)). This classical, strong inward rectification has been most widely studied in channels from the Kir2 subfamily, although Kir4 channels and heteromultimers of Kir4 and Kir5.1 channels also exhibit a steeply voltage-dependent and highly potent block by spermine. The physiological relevance of strong inwardly rectifying K^+ channels is especially apparent in tissues characterized by rapid or repetitive excitation, such as skeletal myocytes and neurons in the central nervous system, and in tissues that exhibit prolonged action potentials, such

Figure 2 Mechanism of inward rectification: (a) normalized current–voltage relationships; (b) pore-lining acidic residues that interact with polyamines and potential spermine binding sites. In (a), the normalized current–voltage relationships are recorded from inside-out patches in symmetrical 150 mM K^+ solutions for a strongly rectifying Kir channel (Kir2.1, red trace) and a weakly rectifying Kir channel (Kir6.2, green trace) in the presence of 100 μM spermine applied to the cytoplasmic side of the membrane patch. In the absence of spermine, Kir channels behave essentially as ohmic resistors and exhibit little or no inward rectification (cell-free, black trace). In (b), strongly rectifying Kir channels possess a pore-lining acidic residue in the transmembrane domain, referred to as the rectification controller residue. Kir channels also possess multiple acidic residues in the cytoplasmic domain (charged cytoplasmic residues) that influence the kinetic and equilibrium features of polyamine block. Acidic residues that are present in wild-type KirBac1.1 channels are colored red, whereas acidic residues that are absent in KirBac1.1 but present in the strong rectifier Kir2.1 are colored yellow at the homologous position. Polyamines block Kir channels by entering and occluding the central permeation pathway, and several models have been suggested to describe the stable polyamine binding site underlying strong rectification. The shallow blocking model suggests that polyamines bind at a shallow site between the cytoplasmic charged residues and the rectification controller. Recent evidence favors the deep blocking model, which suggests that polyamines bind very deep in the pore, between the rectification controller and the selectivity filter.

as cardiac myocytes. In these cell types, channels exhibiting strong inward rectification underlie the maintenance of a stable resting potential, but the significant and rapid reduction of K^+ conductance on depolarization beyond the K^+ reversal potential allows action potentials to take place. Other subfamilies, such as Kir1, Kir6, and Kir7 channels, exhibit much weaker rectification and conduct substantial currents in the outward direction, even in the presence of high concentrations of spermine or other polyamines (Figure 2(a)).

Molecular Determinants of Polyamine Block

The early mutagenesis studies of inward rectification provided important clues to the molecular determinants of polyamine block, but the recent determination of Kir structures at atomic resolution has revitalized studies aimed at elucidating the detailed structural basis of inward rectification. Structure–function studies demonstrated that the negatively charged rectification controller residue, present in the pore-lining M2 helix, ensures steeply voltage-dependent and highly potent rectification in the presence of intracellular spermine (Figure 2(a)). Sequence homology with crystallized K^+ channels such as KcsA or KirBac suggests that this residue lines the pore and interacts electrostatically with positively charged amines in spermine or other blocking cations. In strongly rectifying channels, such as Kir2.1, neutralization of this residue (D172 in Kir2.1) invariably weakens rectification, but does not abolish the block by intracellular polyamines or Mg^{2+}. However, in weakly rectifying channels, the introduction of a negative charge at the equivalent position is generally sufficient to reconstitute the most important features of strong inward rectification (i.e., high voltage dependence and high spermine potency). This effect is apparent in the N171D mutation in Kir1.1 and the N160D or N160E mutations in Kir6.2. Furthermore, replacement of this residue with a positively charged lysine causes a loss of both polyamine- and Mg^{2+}-dependent inward rectification. Significantly, although the rectification controller residue is conserved among strongly rectifying channels, there does not appear to be a strict requirement for the location of the negative charge to confer strong rectification. In Kir6.2 channels, for example, the introduction of negatively charged glutamate residues at any pore-lining position in the M2 helix is sufficient to confer high polyamine sensitivity and steeply voltage-dependent polyamine block.

In addition to the rectification controller, mutagenesis studies and the recent structural determination of the cytoplasmic domain of Kir2.1 have identified negatively charged residues beyond M2, within the cytoplasmic domain of the channel, that affect sensitivity to blockade by polyamines, the kinetics of polyamine block, or both. In Kir2.1, at least four acidic pore-lining residues have been identified in the cytoplasmic domain (E224, D255, D259, and E299) that have a significant effect on the properties of spermine block (Figure 2(a)). In the tetrameric arrangement of an intact channel, each of these residues forms a ring of negative charge that lines the pore. Neutralizing or charge-reversing mutations at any of these sites can alter the kinetic and steady-state properties of the Mg^{2+} and polyamine block. In Kir6.2 channels, a nearby protonatable site (residue H216) also regulates the properties of the polyamine block, resulting in a weakened block at acidic pH. Significantly, the number of pore-lining negative charges in the cytoplasmic domain varies among different channel types, although all inward rectifiers (weak or strong) have at least one pore-lining acidic residue in the cytoplasmic domain. Therefore, the presence of negatively charged residues in the cytoplasmic domain is not sufficient to confer properties of strong rectification.

Characterization of the kinetic and steady-state features of spermine block of Kir channels demonstrated that there are at least two sequential steps involved. An initial, weakly voltage-dependent step leads to spermine binding at a shallow location in the pore, near the intracellular entrance to the channel, probably within the cytoplasmic domain. Kinetic modeling of experimental data indicates that the affinity of this shallow binding site is dramatically reduced by the neutralization of the acidic residues in this region. The shallow binding step is followed by a much more strongly voltage-dependent step, involving the entry of spermine into a stable binding site deep in the pore. It is this second deep-binding step that is responsible for most of the overall voltage dependence of spermine block. Significantly, although spermine is a polyvalent cation, the effective valence of the block by spermine and other polyamines in Kir2.1 exceeds the charge carried by the blocker. This observation suggests that much of the voltage dependence of spermine block does not arise from the blocker traveling across the membrane electric field but, rather, from coupled movement of occupant K^+ ions ahead of the blocker. The movement of these permeant ions through the selectivity filter accounts for a significant fraction of the voltage dependence of polyamine blockade.

With the identification of critical residues involved in the stabilization of polyamines in the Kir channel pore, many studies have attempted to determine the precise physical location of spermine binding,

particularly in its deepest, most stable binding site. Two models of spermine block have received the most attention. One model of shallow spermine binding suggests that the stable spermine binding site necessary for steep voltage-dependent rectification is formed by negative charges in both the inner cavity and cytoplasmic domain. In this model, spermine lies between the rectification controller (in the inner cavity) and the pore-lining acidic residues in the cytoplasmic domain (see Figure 2(b)). An alternative model of deep spermine block suggests that steep rectification involves spermine entry to a very deep site on the pore, near or within the selectivity filter (see Figure 2(b)). Although the location of stable spermine binding in the Kir pore is not yet established by a crystal structure, recent studies demonstrated that stably bound spermine (in Kir2.1 or Kir6.2 N160D channels) significantly interferes with methanethiosulfonate ethylammonium (MTSEA) modification of cysteine residues substituted between the rectification controller and the selectivity filter but not at sites closer to the cytoplasmic entrance of the channel. These data strongly support the second model of deep spermine binding, in which the leading amine of spermine could be stabilized within the selectivity filter, with the trailing amine(s) interacting with the rectification controller in the inner cavity.

Ligand Gating of Kir Channels

Apart from intracellular blockade by Mg^{2+} and polyamines, very critical physiological roles of Kir channels relate to their regulation by a variety of ligands. Many Kir channels are strongly inhibited at acidic pH, a feature most widely studied in the ROMK1 (Kir1.1) channel. Kir3 family members (or GIRK channels) are activated by interactions with $G_{\beta\gamma}$ subunits on activation of the GPCRs, whereas Kir6 family members are inhibited by intracellular nucleotides, particularly ATP. In general, the cytoplasmic domain provides a critical interface for the interactions of Kir channels with their ligands, although specific details vary between different channel subfamilies.

In Kir3 channels, much effort has been devoted to determining the structural basis of channel interactions with G-proteins. Segments in both the N- and C-termini have been shown to interact directly with $G_{\beta\gamma}$ subunits. In addition, binding of $G_{\beta\gamma}$ appears to be enhanced when both the N- and C-terminal fragments of the channel are present together. This finding probably reflects the close physical proximity of these channel segments in crystal structures (Figure 1(b)) and suggests that $G_{\beta\gamma}$ interactions involve multiple contacts with the cytoplasmic domains of Kir3 channels. Also consistent with this hypothesis is the identification of multiple segments of $G_{\beta\gamma}$ subunits required for functional interactions with channels. Among the most pressing questions regarding physiological regulation of GIRK channels is the determination of mechanisms underlying receptor specificity. It is now well known that Kir3 family channels can be activated by the cytoplasmic application of recombinant $G_{\beta\gamma}$ with little specificity. However, the activation of GIRK channels in native tissues by the stimulation of cell-surface receptors can only occur if the receptors couple to pertussis toxin-sensitive G-proteins ($G_{i/o}$). One proposed means by which this specificity is achieved is that there are direct interactions between the channel and G_α subunits. This proposal diverges from the now widely accepted view of GIRK channel activation, in which the activation of a GPCR results in the dissociation of G_α and $G_{\beta\gamma}$ subunits, allowing $G_{\beta\gamma}$ to diffuse and bind/activate GIRK channels.

Binding of ATP to Kir6 subunits similarly involves residues in both the N- and C-termini. Several residues contributing directly to an ATP-binding pocket have been identified by mutagenesis studies, including N-terminal residues R50 and Q52 and C-terminal residues G334, R201, K185, E179, and R301. These amino acids map to nearby locations in a molecular model of the cytoplasmic domain of Kir6.2, generating four ATP-binding sites in an intact channel. Each ATP-binding site comprises N-terminal residues of one subunit and C-terminal residues of an adjacent subunit. Binding of ATP is coupled to the closure of a ligand-operated gate that occludes K^+ flux through the channel.

Significantly, K_{ATP} channels exhibit additional complex regulation by other nucleotides, adenosine diphosphate (ADP) in particular, which governs the activity of these channels in the face of various cellular metabolic conditions. ADP (in the presence of Mg^{2+}) actually counters the effects of ATP and exerts a stimulatory action on K_{ATP} channels. This requires interaction with the SUR auxiliary subunit of Kir6 channels rather than the direct interaction of a nucleotide with the channel. K_{ATP} channels are present in all muscle cell types and in the brain, although the physiological role of the dueling influence of ATP and ADP is probably best understood in β-cells of the pancreas. In these cells, K_{ATP} channels are tonically active under resting conditions and contribute significantly to the maintenance of a stable negative resting-membrane potential. However, when blood glucose is elevated and intracellular ATP levels are increased, the ATP/ADP ratio is increased, leading to the inhibition of K_{ATP} channels, depolarization of the membrane, opening of Ca^{2+} channels, and release of insulin.

Overall, there is a general theme of ligand gating in which ligands bind to the cytoplasmic domain of Kir channels and influence the conformational state of a gate located along the permeation pathway. Depending on the channel and the ligand, interactions may cause the gate to open (as with GIRK channels and $G_{\beta\gamma}$ subunits) or to close (as with K_{ATP} channels and ATP). The conformational changes involved in ligand-dependent gating have been studied in multiple channel types. Although considerable insights have been gained, there remain uncertainties regarding the nature of the gate itself and the molecular details of opening and closing. It has been suggested that several structural motifs play a role in channel gating, including the selectivity filter and the crossing point of the M2 helices (the bundle crossing; Figure 3(a)). At present, there is a general consensus that rapid conformational changes around the selectivity filter underlie the brief flickering openings and closings that characterize the intra-burst behavior apparent in single-channel recordings of Kir channels. In contrast to intra-burst flickering, the burst duration depends very strongly on ligand interactions and probably depends on the conformation of the bundle crossing. In the crystal structure of KirBac1.1, the M2 helices form a constriction in the bundle-crossing region, with the narrowest point formed by the bulky hydrophobic side chains of residue F146. Hinged movements of the M2 helix are thought to allow the widening of this aperture and the opening of the permeation pathway (Figure 3(b)). By analogy to Kv channels, in which a constriction near the base of S6 (equivalent to M2 in Kir channels) constitutes a steric gate to ion entry into the channel pore, the constriction of M2 at the bundle crossing probably acts as the ligand-operated gate in Kir channels (Figure 3(b)). Considerable evidence supports this hypothesis because the accessibility of cysteine residues substituted in the inner cavity of Kir6.2 and Kir2.1 can be impeded by ligand-mediated channel closure.

Most recently, multiple structures of Kir channels or isolated domains also revealed considerable structural variability of the G-loop region in the cytoplasmic domain (Figure 3(a)). It has been speculated that the G-loop may constitute an additional gating structure in Kir channels because, in certain crystal structures, the G-loop forms a narrow constriction near the top of the cytoplasmic domain. Mutations in the G-loop of Kir2.1 have been shown to disrupt channel function, although at present there is little experimental evidence demonstrating that conformational changes in the G-loop can regulate K^+ permeation in an intact channel. The G-loop does appear to exhibit considerable structural flexibility, and future work will probably determine whether this structure behaves as a gate or, rather, is involved in the coupling

Figure 3 Ligand-dependent gating mechanisms of Kir channels: (a) structural motifs proposed to be involved in ligand-dependent gating of Kir channels; (b) sketches of structural changes involved in Kir channel opening and closing. In (a), the structural motifs have been highlighted using the KirBac1.1 crystal structure as a template. It is likely that conformational changes in the selectivity filter (green) or at the crossing point of the M2 helices (bundle crossing, red) can result in channel closure, with the bundle crossing being the primary mediator of ligand-dependent channel gating and the selectivity filter being involved in stochastic ligand-independent opening and closing. Recent work suggested that the G-loop structure (yellow) in the cytoplasmic domain is also involved in ligand-dependent gating. As shown in (b), similar to Kv channels, channel opening is thought to involve hinged motions of the M2 helix (gray) that widen the pore in the bundle-crossing region.

of ligand binding to conformational changes elsewhere in the channel.

Kir Channel Regulation by Membrane Phospholipids

A final critically important regulator of Kir channel function is the lipid composition of the plasma membrane. Although the various Kir channel subfamilies each exhibit unique ligand-dependent gating properties, a universal feature of eukaryotic Kir channels is activation by anionic membrane phospholipids such as phosphatidyl-inositide-4,5-bisphosphate (PIP2). In most cases, PIP2 or another anionic phospholipids appear to be important cofactors for channel function because experimental depletion by various measures can significantly run down channel activity; the application of exogenous PIP2 can rescue activity. Several studies have identified residues in both the N- and C-termini of Kir channels that are critical for interactions with PIP2 and other anionic lipids. Prominent are a number of basic amino acids that are critical for channel stimulation by PIP2, probably through electrostatic interaction between positively charged side chains and the negatively charged lipid head group.

Physiologically, PIP2 interactions with Kir channels modulate the apparent efficacy or potency of other ligands. In Kir6.2 channels, for example, the addition of PIP2 to the channel membrane can dramatically decrease the apparent ATP sensitivity. In this particular example, the molecular basis for this effect of PIP2 appears to be due to partial spatial overlap between the residues involved in PIP2 interactions and the ATP-binding residues. Similarly, PIP2 application or depletion can alter the Kir3 channel response to $G_{\beta\gamma}$ subunits. In Kir1.1, the introduction of positive charges at specific locations in the N-terminus can enhance PIP2 interactions and allow PIP2 application to modulate the channel response to changes in pH. Although experiments to date have demonstrated that the manipulation of PIP2 levels can dramatically alter channel function and channel interactions with other ligands, the impact of physiological variation of lipid content on Kir-channel activity in living organisms has been incompletely explored, and may provide a rich topic for future study.

Ion Channel Localization in Cell Bodies and Dendrites

R Westenbroek, University of Washington, Seattle, WA, USA

Introduction

Neurons are highly polarized cells made up of a soma, a large dendritic tree, and an axonal region. They have the ability to receive, process, and transmit information due to the structural and molecular uniqueness of each of these compartments. The unique complement of ion channels in the somatodendritic and axonal region is one of the important factors determining the functioning of an individual neuron. Most neurons possess dendrites that are the recipients of thousands of synaptic inputs, and the integration of these numerous inputs is required for the generation of an action potential threshold in a neuron. With the hippocampal pyramidal neuron as a model (Figure 1), this article discusses the localization of voltage-gated sodium (Na_V), calcium (Ca_V), and potassium (K_V) channels, the most clearly understood members of the voltage-gated ion channel family, and describes their role in the integration of signals in the somatodendritic region.

Subcellular Localization of Na_v Channels; Na_V1 Family

Na_V channels are specialized for electrical signaling and are responsible for the initiation and propagation of action potentials in nerve, muscle, and endocrine cells due to the rapid and transient influx of sodium ions through their pore region. Depending on their dendritic localization (Figure 1(a)), Na_V channels may be key components of excitatory postsynaptic potential amplification, dendritic spike initiation, or action potential propagation.

Within the central nervous system (CNS), investigators using immunocytochemical techniques have identified the localization of the pore-forming α subunit of $Na_V1.1$, $Na_V1.2$, $Na_V1.3$, $Na_V1.5$, and $Na_V1.6$ channel protein within distinct subcellular domains of adult rat and human neurons. $Na_V1.4$, $Na_V1.7$, $Na_V1.8$, $Na_V1.9$, and Na_X do not appear to be expressed in the CNS. $Na_V1.1$ channels are localized mainly in the cell bodies and dendrites of neurons in both rats and humans. $Na_V1.1$ channel staining is dense in the soma and proximal dendrites of pyramidal neurons in the hippocampus. Recent reports suggest $Na_V1.1$ may also be localized in axons. In contrast, $Na_V1.2$ channels are localized mainly in axons. Dense staining of axon-rich regions or layers has been observed in the hippocampus and cerebellum. $Na_V1.2$ densely stains the stratum radiatum, where the axons and terminals of Schaffer collaterals reside in CA1 and in the mossy fibers in the CA3 region. There is also dense staining of the stratum oriens in the CA1 region, where axons of the commissural/association pathway reside. These anatomical findings suggest that $Na_V1.1$ channels participate in propagating signals from the dendrites to the cell body and are presumably involved in the integration of electrical signals over the soma surface and that $Na_V1.2$ channels are important in action potential conductance along the axon. $Na_V1.3$ has a somatodendritic localization in the adult human brain. In rats a somatic, sometimes dendritic staining pattern in limited regions of the cerebral cortex, hippocampal formation, and cerebellar granule cells is observed, along with axonal staining in fiber tracts like the corpus callosum and anterior commissure. The expression of $Na_V1.3$ channels is high in embryonic brain and low in adult animals.

$Na_V1.6$ is localized predominantly in the soma and proximal dendrites of output neurons, such as the hippocampal pyramidal and granular neurons, the Purkinje cells of the cerebellum, and the pyramidal neurons of the dorsal cortex, where they are involved in the integration of synaptic input. In addition, $Na_V1.6$ channels are localized to the axon initial segment and are very dense at both central and peripheral nodes of Ranvier in adult rodents, sites known to be important for the initiation and propagation of action potentials. Human studies identified a predominantly somatodendritic distribution of $Na_V1.6$ in the projection neurons of the hippocampus, cerebral cortex, and cerebellum.

$Na_V1.5$, $Na_V1.8$, and $Na_V1.9$, the tetrodotoxin-insensitive members of Na_V channels, have not been detected in the brain by electrophysiological techniques. $Na_V1.5$ is mainly expressed in cardiac myocytes, with limited expression in the brain. In contrast, $Na_V1.7$, $Na_V1.8$, and $Na_V1.9$ are mainly expressed in dorsal root ganglion neurons located in the peripheral nervous system.

Subcellular Localization of Ca_V Channels

Ca_V channels play a pivotal role in electrical signaling. They act as signal transducers by converting depolarization of the cell membrane into an influx of calcium ions through their pore. These calcium ions in turn initiate neurotransmission, contraction, secretion, and other intracellular regulatory events. Ten human genes encode the pore-forming Ca_V α1

Figure 1 Schematic diagram illustrating the expression of sodium channels and calcium channels on the soma, dendrites, initial axon segment (IAS), nodes of Ranvier (Nodes) and/or local axon/terminal (axon-term) of a representative hippocampal pyramidal neuron. (a) Distribution of Na_V channels and (b) distribution of Ca_V channels.

subunits. These genes fall into three subfamilies with relatively distinct patterns of localization and function (Figure 1(b)).

Physiological studies suggest that members of the Ca_V1 and Ca_V2 subfamilies make up the high-voltage-activated (HVA) calcium channels observed in electrophysiological studies. These same electrophysiological studies provide evidence for HVA channels in dendrites of various neurons with roles in amplification of synaptic responses, generation of action potential bursts, dendritic spikes, or calcium-dependent dendritic transmitter release. In addition, entry of Ca^{2+} through dendritic Ca_V channels can serve as a second messenger in a variety of intracellular signaling pathways that may ultimately affect synaptic plasticity. Hence, HVA dendritic Ca_V channels can play important roles in synaptic integration and synaptic plasticity.

Ca_V1 Subfamily

The Ca_V1 subfamily has four members, with only $Ca_V1.2$ and $Ca_V1.3$ present in brain neurons. $Ca_V1.2$ staining is punctate while $Ca_V1.3$ channels have a smooth pattern of localization on the soma of neurons located in the hippocampus, cortex, and cerebellum. $Ca_V1.2$ channels are concentrated on the proximal dendrites while $Ca_V1.3$ is also present in more-distal dendrites in clusters at or near axosomatic and axodendritic synapses, suggesting different functional roles for each of these channels in both soma and dendrites of most neurons.

Ca_V2 Subfamily

Localization studies of the three neuronal members of the Ca_V2 subfamily of channels have revealed both synaptic and somatodendritic patterns of subcellular localization. In rat brain, $Ca_V2.1$ channel staining is prominent in regions of synaptic terminals, such as in the molecular layer of the cerebellum and in the mossy fiber region of the hippocampus, and distinct molecular isoforms are differentially localized on dendrites. Since $Ca_V2.1$ channels are known to regulate transmitter release, the prominent staining of terminals by both isoforms is most consistent with known channel function. Limited studies in human brain tissue reveal $Ca_V2.1$ protein is present in the synapse-rich molecular layer of the cerebellum and on the soma and dendrites of hippocampal pyramidal neurons.

$Ca_V2.2$ α subunits are most prevalent in synaptic structures in rat brain, such as the mossy fiber terminals and along dendrites of cortical neurons, which correlates with their physiological role in neurotransmitter release in central neurons. There is a less intense but smooth pattern of staining along the dendrites of cortical neurons in layers II/III and V and on the dendrites of pyramidal neurons in the CA1–CA3 regions of the hippocampus. From alternative splicing

at the C-terminus of $Ca_V2.2$ messenger RNA (mRNA), a long and a short isoform have been identified. Immunocytochemical studies in hippocampal cultures indicate that the short isoform is targeted to the somal and dendritic regions and the long isoform is present in the presynaptic terminals of axons. Low levels of $Ca_V2.2$ staining are present on the cell bodies of cortical pyramidal neurons, hippocampal pyramidal neurons, and Purkinje neurons. In limited human studies, $Ca_V2.2$ protein was less intense at the mossy fiber terminals, expressed at low levels in the cell bodies of the hippocampus, and stronger in synapse-rich layers (stratum lucidum and stratum radiatum) of the CA regions.

$Ca_V2.3$ channels are present throughout the rat brain and are localized mainly to the cell soma, with clear dendritic staining in some populations of cells. Staining of $Ca_V2.3$ on the cell soma has been observed in projection neurons of the hippocampus and the neocortex, and in both the cell bodies and dendrites of Purkinje neurons. The most prominent cell body and dendritic staining was in the midbrain and hindbrain structures. In human tissue, $Ca_V2.3$ is strong in the cell body and dendrites of Purkinje neurons but weaker in the cell bodies of principal neurons in the hippocampus, and relatively strong staining has been observed in the region of mossy fiber terminals. These channels have been associated with multiple physiological functions, including neurotransmitter release and repetitive firing.

Ca_V3 Subfamily

Physiological studies classify this family of Ca_V channels as the low-voltage-activated calcium channels (T-type). These studies also suggest that low voltage-activated calcium channels are expressed in the dendrites of hippocampal pyramidal neurons, thalamocortical relay neurons, and Purkinje cells, where they play important roles in burst firing and/or amplification of synaptic responses.

The subcellular distribution of $Ca_V3.2$ is still unknown; however, $Ca_V3.1$ protein is widely distributed throughout the brain, and this protein is localized in both the soma and the dendrites of large neurons in rats and mice, with some staining of the neuropil. There is a low to moderate level of $Ca_V3.1$ protein in the soma and dendrites of pyramidal neurons of the CA1–CA3 regions of the hippocampus, low levels in the Purkinje cells, and moderate levels of staining in many cortical cell types, with the strongest staining typically in the cortical pyramidal neurons. These channels are important in thalamic oscillations.

$Ca_V3.3$ immunoreactivity is localized to both the soma of neurons and their processes. In the cortex, $Ca_V3.3$ immunoreactivity has been found in all regions and in all layers. In the hippocampus, scattered interneurons have been labeled in the stratum lucidum of the dentate gyrus and in the CA3 and CA2 fields, with the highest being in the CA2 region. $Ca_V3.3$ staining of terminals is supported by dense staining of the inner and outer thirds of the molecular layer of the dentate gyrus. Dense staining is also present in the cerebellar molecular layer, where parallel fibers and their terminals reside. Similar to $Ca_V3.1$ channels, these channels have important physiological roles in thalamic oscillations.

Subcellular Localization of K_V Channels

The largest ion channel family of the VGL-chanome are the K_V channels, which are products of 40 genes in 12 subfamilies. The K_V1–9 subfamilies are the most closely related and are responsible mainly for setting the resting membrane potential, repolarization of cells during the falling phase of action potentials, termination of trains of action potentials, and hyperpolarization of cells between bursts of action potentials. Besides the K_V family, potassium channels also include the Ca^{2+}-activated (K_{Ca}), the inwardly rectifying (K_{ir}), and two-pore (K_{2P}) families (Figure 2).

In contrast to dendritic Na_V and Ca_V channels, whose presence can amplify synaptic signals, dendritic K_V channels in general tend to decrease the influence of synaptic inputs and decrease dendritic excitability. Since there are numerous subtypes of K_V channels that can occur in dendrites, these channels have been grouped electrophysiologically as either transient or sustained K^+ currents, both of which can be influenced by multiple second messengers that ultimately alter the influence of dendritic K_V channels on dendritic excitability.

K_V1 Subfamily

$K_V1.1$, $K_V1.2$, and $K_V1.4$ are the three most highly expressed subunits of the K_V1 ($K_V1.1$–1.8) family in rat brain (Figure 2(a)). $K_V1.1$ and $K_V1.2$ maintain membrane potential and modulate electrical excitability, and $K_V1.4$ participates in neuronal afterhyperpolarization. Expression of $K_V1.1$, $K_V1.2$, or $K_V1.4$ protein is mainly in axons and at or near the axon terminals. $K_V1.1$, $K_V1.2$, and $K_V1.4$ have been shown to associate in different combinations across the brain. Only $K_V1.1$ and $K_V1.4$ are present in the mossy fiber axons. There is a high density of $K_V1.1$ and $K_V1.2$ and a much lower density of $K_V1.4$ and $K_V1.$ 6 in the cerebellum. There is extremely dense labeling of

Figure 2 Schematic diagram demonstrating the localization of various potassium-selective channels on the soma, dendrites, and/or local axon/terminal (axon-term) of a representative hippocampal pyramidal neuron. (a) K_V channels and (b) K_{Ca}, K_{ir}, and K_{2P} channels: their known sites of expression.

$K_V1.1$ and $K_V1.2$ in the axon terminal plexuses of cerebellar granule cells that surround the initial segment of Purkinje cell axons. $K_V1.1$ is densely expressed in the molecular layer of the cerebellum, where afferent inputs to the cerebellar cortex are situated. $K_V1.4$ and $K_V1.6$ antibodies also weakly stain the molecular layer. There is low expression of $K_V1.1$ on the cell bodies and proximal dendrites of pyramidal neurons in the cortex, the pontine reticular nucleus, and the principal sensory trigeminal nucleus and low levels of protein staining for $K_V1.1$ and $K_V1.2$ in hippocampal neurons. One region where there is a high density of staining on the cell soma and proximal dendrites is on the mitral cells in the olfactory bulb with anti-$K_V1.2$ antibodies. $K_V1.1$ is expressed in the cell bodies of neurons in some discrete regions of the brain, including the neocortex, the pontine reticular nucleus, and the principal sensory trigeminal nucleus. However, the main staining for the K_V1 family is in axons. The majority of $K_V1.3$ staining in the brain is localized to the parallel fibers of the granule cells in the cerebellum, suggesting that $K_V1.1$ and $K_V1.3$ can form heteromeric channels in these axons.

The staining of $K_V1.6$, a regulator of membrane potential in neurons in rodent brain, is mainly in interneurons, with some staining of dendrites of principal neurons. Many of the medium to large interneurons in the CA1–CA3 fields are immunoreactive for $K_V1.6$. $K_V1.5$ has low expression in the brain and may be mainly located in glial cells; however, there are high levels of expression of $K_V1.5$ on the soma and dendrites of Purkinje neurons. $K_V1.7$ is not present in the brain but is expressed in skeletal muscle, heart, and pancreatic islets, and $K_V1.8$ is expressed in the brain; detailed subcellular localization is still lacking.

K_V2 Subfamily

In contrast to the K_V1 subfamily of potassium channels that are localized predominantly to axons, the K_V2 family is expressed in the somatodendritic compartments of neurons in the brain. $K_V2.1$ channels are localized to the majority of neurons in the brain. At the subcellular level, they are present only on the soma and proximal dendritic membranes. $K_V2.1$ channels form large clusters in these regions. Neurons with especially high levels of $K_V2.1$ expression include cortical pyramidal neurons in layers II/III and V and interneurons and neurons in the hippocampus in general. The highest expression in the hippocampus is found in the dentate granule cells and in the CA1 pyramidal neurons. $K_V2.2$ channels are localized in a smooth pattern along the length of the dendrite and are not found in clustered pattern in the proximal dendritic membranes, as is observed for $K_V2.1$ channels. $K_V2.2$ channels are found in many of the same neurons and interneurons that

contain $K_V2.1$ channels; however, the highest levels of $K_V2.2$ expression are observed in olfactory bulb neurons and in cortical pyramidal neurons.

K_V3 Subfamily

K_V3 mRNA has extensive alternative splicing that results in numerous splice variants that differ at their C-terminus. $K_V3.1a$ proteins are expressed mainly in the axons of parvalbumin-positive interneurons in the neocortex, the hippocampus, and the caudate-putamen and in neurons of the cochlear nucleus. In contrast, $K_V3.1b$ is localized to the soma and proximal dendrites of some of the same neurons as $K_V3.1a$. $K_V3.1b$ is expressed in many parvalbumin-containing basket cells but is not present in hippocampal or neocortical pyramidal neurons. Instead, these pyramidal neurons are surrounded by $K_V3.1b$-labeled presynaptic terminals from interneuron axons.

$K_V3.2$ channels are in a different population of interneurons that are characterized as nonfast-spiking, somatostatin-containing, and calbindin-containing interneurons. $K_V3.2$ proteins are prominently expressed in patches in somatic and proximal dendritic membrane, as well as in axons and presynaptic terminals of these γ-aminobutyricacidergic interneurons. To date, the precise localization of the individual splice variants of $K_V3.2$ ($K_V3.2a$, $K_V3.2b$, and $K_V3.2c$) has not been determined.

Limited immunofluorescence studies have revealed staining in the cell soma and dendrites of Purkinje neurons with $K_V3.3$ channel antibodies. $K_V3.4$ is localized to the axons and terminals of principal cells located in the hippocampus and neocortex. For example, $K_V3.4$ appears to be present in the mossy fiber axons and/or terminals, in terminals of the perforant path, and in cerebellar basket cell terminals.

K_V4 Subfamily

$K_V4.1$ is expressed minimally in the brain while the levels of mRNA expression for $K_V4.2$ and $K_V4.3$ is widespread throughout the brain. $K_V4.2$ channels are mainly in dendrites of principal cells, and $K_V4.3$ mainly in interneurons and a smaller population of principal neurons. $K_V4.2$ and $K_V4.3$ staining is present in the distal dendrites of hippocampal granule cells and the distal portion of both the basal and apical dendrites of CA3 pyramidal neurons, while only $K_V4.2$ is expressed on the soma of CA3 pyramidal neurons. $K_V4.3$ is localized to the majority of interneurons in the hippocampus. There is a distinct separation of $K_V4.2$ and $K_V4.3$ staining in the dorsal cortex, with $K_V4.2$ staining predominating in the pyramidal neurons in layer V and $K_V4.3$ mainly in the pyramidal neurons of layer II. A population of interneurons in layers II–VI of the cortex stains for $K_V4.3$.

K_V5, 6, 8, and 9 Subfamilies

The K_V5, 6, 8, and 9 subfamilies of the K_V family do not produce functional channels on their own. Instead, these subunits form heterotetramers with K_V2 family subunits. As a result, they function as modifiers and/or silencers of the K_V2 family channel and increase functional diversity within the K_V2 family.

K_V7 Subfamily

There are five known members of this subfamily, collectively known as the delayed rectifier potassium channels, or voltage-dependent potassium channels that activate slowly but show no inactivation. The $K_V7.1$ channels are not found on neurons in the CNS, whereas $K_V7.2$–$K_V7.5$ exhibit a variable distribution in the brain and are known also as the M channels that exert crucial influence over neuronal excitability. Studies of protein expression show overlapping $K_V7.2$ and $K_V7.3$ expression on both the somata and the dendrites of pyramidal neurons in the hippocampus and cerebral cortex. This staining in the somata and dendrites is low compared with axonal staining in these regions. $K_V7.2$ staining is also present in the initial segment of neurons in the hippocampus, neocortex, brain stem, and striatum and is often co-localized with $K_V7.3$ staining. There is dense expression for $K_V7.2$ on the mossy fibers in the hippocampus. $K_V7.4$ channels have been localized to brain stem auditory nuclei, outer hair cells of the cochlea, and type 1 hair cells of vestibular organs and are known to mediate efflux of potassium from outer hair cells. $K_V7.5$ channel mRNA is broadly expressed in the brain and functions to determine subthreshold excitability of neurons.

K_V10 Subfamily

In rat both $K_V10.1$ and $K_V10.2$ staining is localized to the cell somas of pyramidal neurons in the hippocampus and granule cells in the dentate gyrus. $K_V10.1$ was also detected in the surrounding neuropil, suggesting its presence along the dendrites of these neurons.

K_V11 Subfamily

By means of antibodies, high levels of protein expression for $K_V11.1$ and $K_V11.3$ were observed in the somas of hippocampal pyramidal neurons in CA1–CA3. In contrast, $K_V11.2$ localization is absent from the pyramidal neurons of the CA2 region but present in the CA1 and CA3 regions. In the cortex, $K_V11.1$ and $K_V11.3$ stain the cell bodies of neurons throughout layers II–VI, with $K_V11.3$ also staining dendrites of pyramidal neurons. $K_V11.2$ displays weak somal reactivity in the cortex except for layer V neurons. There is intense staining of the cell bodies of Purkinje

neurons with $K_V11.1$, $K_V11.2$, and $K_V11.3$ antibodies. $K_V11.2$ antibodies also stain the proximal dendrites of the Purkinje neurons.

K_V12 Subfamily

The mRNA for $K_V12.1$, $K_V12.2$, and $K_V12.3$ is abundant in many regions of the brain. Patterns of subcellular localization and physiological functions are unknown.

Subcellular Localization of K_{Ca} Channels

K_{Ca} channels are important in many cellular processes involving calcium-dependent signaling in both electrically excitable and nonexcitable cells. In addition to voltage-dependent gating, K_{Ca} channels sense other intracellular signals (i.e., Ca^{2+}, Na^+, and H^+) that mediate their function.

$K_{Ca}1$ Subfamily

In rats, high levels of $K_{Ca}1.1$ protein are targeted to regions rich in terminals and axons, such as the mossy fibers and perforant pathway of the hippocampal formation, and to terminal areas of fiber tracts in the substantia nigra pars reticulata, globus pallidum, and olfactory system (Figure 2(b)). Unlike most other brain regions, $K_{Ca}1.1$ expression is found on the cell body and proximal dendrites of Purkinje neurons. In mouse brain, $K_{Ca}1.1$ channels were found on cell bodies, dendrites, axons, and synaptic terminals. Their physiological functions in the brain include presynaptic regulation of neurotransmitter release and, when selectively coupled to with $Ca_V2.2$ channels, mediation of fast afterhyperpolarization in neurons.

$K_{Ca}2$ Subfamily

This subfamily of ion channels is made up of three members, $K_{Ca}2.1$, $K_{Ca}2.2$, and $K_{Ca}2.3$, whose mRNA patterns of distribution are both overlapping and complementary in the rat brain. The reported pattern of protein expression is somewhat variable depending on the species. In mouse, $K_{Ca}2.1$ and $K_{Ca}2.2$ staining was mainly localized to somatic and dendritic structures while $K_{Ca}2.3$ was mainly associated with varicose fibers. All three channels are present in the soma of Purkinje neurons, while only $K_{Ca}2.2$ is observed in hippocampal pyramidal neurons and layer V pyramidal neurons of the cerebral cortex. In rat, $K_{Ca}2.1$ and $K_{Ca}2.2$ staining in cell bodies was quite variable while dendritic staining was similar to that observed in the mouse. As in the mouse, staining for $K_{Ca}2.3$ was observed mainly in varicose fibers and axonal-rich regions such as the mossy fibers. Collectively, this group of channels is involved in the afterhyperpolarization in vertebrate neurons.

$K_{CA}3$ and 5 Subfamilies

These two subfamilies have one member ($K_{Ca}3.1$ and $K_{Ca}5.1$) each, and they have not been detected in the brain.

$K_{Ca}4$ Subfamily

The physiological function of this subfamily has not been identified yet. $K_{Ca}4.1$ protein staining was found mainly in the brain stem, with limited expression in the cortex and hippocampus. In the hippocampus, $K_{Ca}4.1$ immunocytochemical staining was limited to the soma and axonal projections of interneurons located in the CA3 region. $K_{Ca}4.1$ was also limited to the frontal cortex and was associated with the cell somas and axons. In the brain stem, $K_{Ca}4.1$ was localized to the cell bodies and axons. Like $K_{Ca}4.1$, $K_{Ca}4.2$ is widely distributed in the rat brain, with strong hybridization signals and immunoreactivity in the brain stem. However, protein and mRNA for $K_{Ca}4.2$ were observed in regions that did not contain $K_{Ca}4.1$ expression. These include the CA1–CA3 regions of the hippocampus, the dentate gyrus, and cortical layers II, III, and V, which suggest $K_{Ca}4.2$ functioning independent of $K_{Ca}4.1$ in some of these regions. Unlike $K_{Ca}4.1$, $K_{Ca}4.2$ is observed mainly in somatosensory cortex and visual cortex, with staining mainly on cell bodies and in fiber tracts within layer VI. Within the hippocampus, $K_{Ca}4.2$ was localized to the dendrites, with little staining of the soma. Very low levels of $K_{Ca}4.2$ staining have been associated with Purkinje neurons. In the brain stem, $K_{Ca}4.2$ staining was present mainly on cell somas or axons.

Subcellular Localization of K_{ir} Channels

K_{ir} channels have a variety of tasks, including control of the resting membrane potential, regulation of cardiac and neuronal electrical activity, and control of electrolyte balance by conduction of large inward currents at membrane voltages negative to the K^+ equilibrium potential. The mRNA for $K_{ir}1.1$, $K_{ir}3.3$, $K_{ir}4.1$, $K_{ir}4.2$, and $K_{ir}5.1$ has been detected in the brain, but studies of protein localization are still lacking.

$K_{ir}2$ Subfamily

In general, $K_{ir}2$ channels are localized in the soma and dendrites of many neurons in the CNS and are involved in maintenance of a resting membrane potential and modulation of cell excitability (Figure 2(b)). In the hippocampus there is variable expression of $K_{ir}2$ channels. $K_{ir}2.1$ protein expression is high in the granule cells, weak in the CA3 region except for the mossy fiber tract, and moderate in the pyramidal cells of the CA1–CA2 regions. $K_{ir}2.2$ is expressed mainly in

the dendritic fields of granule cells and the pyramidal neurons of CA1–CA3. The $K_{ir}2.3$ channels have moderate staining in the CA1–CA2 regions, weak staining in CA3, and weak staining of the mossy fibers. In contrast, the $K_{ir}2.4$ channels exhibit moderate immunoreactivity in the cell bodies of the CA1–CA3 pyramidal neurons and in dentate granule cells. In the cortex, $K_{ir}2.1$–2.4 channels are strongly localized to the cell soma of neurons in all cortical layers, with weaker staining in the dendritic processes. In the cerebellum, $K_{ir}2.1$ channels are weakly expressed in the soma of neurons in the molecular layer, $K_{ir}2.2$ channels have a strong pattern of staining in the soma of granule cells, and $K_{ir}2.3$ protein is intensely expressed in soma and dendrites of Purkinje neurons, but $K_{ir}2.4$ expression is extremely low, if present. In general, $K_{ir}2.1$ is localized in particular subsets of neurons throughout the whole brain, with highest density of staining in the olfactory bulb and superior colliculus. $K_{ir}2.2$ staining is highest in the cerebellum, hypothalamus, and spinal cord while $K_{ir}2.3$ is predominately expressed in the cortex, Purkinje cells, basal ganglia, and olfactory bulb. $K_{ir}2.4$ is expressed at low levels in most neurons.

$K_{ir}3$ Subfamily

This subfamily is distinquished by being G-protein-coupled members of the K_{ir} group of channels. $K_{ir}3.1$ immunoreactivity is located in selected regions of the rat brain, including cerebral cortex, cerebellum, hippocampus, thalamus, and the olfactory system. There is staining of $K_{ir}3.1$ in the soma and dendrites of granule cells in the cerebellum, and it is absent from Purkinje neurons. In the cerebral cortex, $K_{ir}3.1$ staining is complex, with labeling of the neuropil in layer IV, labeling in the soma and apical dendrites of layer V pyramidal neurons, and labeling of dendritic terminals in layer I which originate from the pyramidal cells of layers II, III, and V. In the hippocampus, $K_{ir}3.1$ staining is present in the soma and apical dendrites of pyramidal neurons and the granule cells of the dentate gyrus. These channels are responsible for receptor-dependent hyperpolarization of membrane potential. $K_{ir}3.2$ immunoreactivity is observed in many regions of the brain and is mainly in the somatodendritic subcellular compartment and sometimes in axonlike fibers and they participate in the formation of the slow inhibitory postsynaptic potential and probably in presynaptic inhibition. Highest density of staining was observed in the hippocampus, septum, granule cell layer of the cerebellum, amygdala, and substantia nigra pars compacta. In the cortex there is weak staining of $K_{ir}3.2$ neuronal cell bodies, with stronger staining in the large cell bodies and apical dendrites of layer V pyramidal neurons within the sensorimotor cortex and in layer V cell bodies adjacent to the white matter. Intense staining of the neuropil was evident in the hippocampal formation, along with labeling of the cell bodies and proximal dendrites of the CA1–CA3 pyramidal neurons and dentate granule cells. In the cerebellum there are low levels of staining of the granule cells and Purkinje cells and strong staining of the cerebellar glomeruli.

With $K_{ir}3.4$ antibodies, there is mainly staining of cell bodies and dendrites. In the cortex, $K_{ir}3.4$ was observed only in cells in the deepest portion of layer VI, in cells located in the medial habenula, posterior hypothalamus, superior colliculus, and restricted nuclei of the forebrain. The cell bodies and proximal dendrites of Purkinje neurons also stain positive for $K_{ir}3.4$. mRNA studies suggest the presence of $K_{ir}3.4$ in rat and human hippocampal neurons while protein studies have found a lack of expression in the hippocampus.

$K_{ir}6$ Subfamily

$K_{ir}6.1$ channels are present in astrocytes in most regions of the brain and are expressed in the cell soma of only a few distinct nuclei or neuronal populations at significant levels in cholinergic interneurons in the striatum, the dorsal medial and paraventricular hypothalamic nuclei, the zona incerta, and the substantia nigra pars compacta. In the hippocampus, cortex, and cerebellum, $K_{ir}6.1$ staining is weak to negligible in the soma of neurons. $K_{ir}6.2$ is broadly distributed in the brain and is mainly observed in the soma of neurons and their main dendrites. These channels are thought to act as an oxygen and glucose sensor in the brain and are involved in cytoprotection during cardiac and brain ischemia. $K_{ir}6.2$ is present in layer V pyramidal cells and their dendrites, the cell soma and dendrites of dentate granule cells, CA1–CA3 pyramidal cells of the hippocampus, and Purkinje neurons of the cerebellum. Some regions of the brain also show strong staining of the neuropil, suggestive of axonal staining.

$K_{ir}7$ Subfamily

There is only one known member of this family, and limited studies of the protein distribution of this channel have determined it to be localized to the soma and dendrites of cerebellar Purkinje neurons and pyramidal cells of the hippocampus, where it contributes to resting membrane potential.

Subcellular Localization of K_{2P} Channels

In general, mammalian K_{2P} channels are thought to be responsible for the background or leak potassium currents in neurons and function in a highly regulated process that controls cellular excitability by stabilizing membrane potential below firing threshold and

expediting repolarization. The physiological function of most of these channels is still poorly understood. *In situ* studies have demonstrated the presence of mRNA in the CNS for $K_{2P}1.1$, K_{2P} 6.1, $K_{2P}7.1$, $K_{2P}12.1$, $K_{2P}13.1$, and $K_{2P}15.1$, but their precise subcellular distribution is still unknown. $K_{2P}10.1$, $K_{2P}16.1$, and $K_{2P}17.1$ channels are not present in the CNS.

$K_{2P}2.1$ Channels

Immunocytochemical studies suggest $K_{2P}2.1$ protein is localized to the soma and dendrites of both projection neurons and interneurons that are mainly γ-aminobutyric acid positive. Immunoreactivity is widespread in the CNS, with staining observed in such regions as cerebral cortex (concentrated in layers III and VI), basal ganglia, hippocampus (CA2–CA3 and granule cells in dentate gyrus), and cerebellum (both Purkinje cells and Golgi cells in the granular layer).

$K_{2P}3.1$ Channels

Immunocytochemical studies in rat suggest that $K_{2P}3.1$ staining is mainly in the somas of cerebellar granule cells and the Purkinje neurons. Neuropil staining was also present in the cerebral cortex, basal ganglion, thalamic nuclei, and amygdala, suggesting expression in axons or dendritic processes.

$K_{2P}4.1$ Channels

Immunocytochemical studies using anti-$K_{2P}4.1$ antibodies in mouse brain revealed a broad pattern of staining throughout the brain, with highest levels of staining in the cells located in the cerebellum, neocortex, hippocampus, dentate gyrus, thalamus, hypothalamus, caudate, putamen, and olfactory bulb. The $K_{2P}4.1$ staining was observed mainly in the soma of neurons and to a lesser degree in the axons and/or dendrites of most neurons.

$K_{2P}5.1$ Channels

In studies using anti-$K_{2P}5.1$ antibodies, staining was mostly localized to cell bodies and was most prominent in the pyramidal cells of the hippocampus, granule cells of the dentate gyrus, most neurons in the cortex, and the soma and proximal dendrites of Purkinje neurons.

$K_{2P}9.1$ Channels

In human tissue, immunocytochemical studies suggest strong cell body staining of Purkinje neurons and less-intense staining in the granule cells of the cerebellum. In rats, antibody staining has revealed $K_{2P}9.1$ expression in the cell bodies of neurons located in the hypoglossal motor nucleus, locus coeruleus, anterodorsal thalamic nucleus, dorsal raphe nucleus, and striatum of the rat. Others report expression of $K_{2P}9.1$ protein in the soma of neurons located in the rat hypothalamus, hippocampus, and a subset of cortical neurons.

Types of Axonal Ion Channels

Ion Channel Overview

Voltage-gated ion channels are multisubunit protein complexes that respond to changes in membrane potential with conformational changes that lead to gating, or opening and closing, of an ion-selective transmembrane pore. Voltage-gated ion channels selective for sodium (Na_v channels) and potassium (K_v channels) ions are the major determinants of axonal electrical transmission, although other ion channels play additional roles in axonal physiology. The past 20 years has seen major advances in our understanding of the structure and function of the Na_v and K_v channels that are important to the function of mammalian axons. Also, regulatory motifs on Na_v and K_v channel proteins involved in mediating interactions with a diverse set of axonal proteins have been identified. These axonal proteins in turn participate in macromolecular complexes that in certain cases may also mediate intercellular interactions crucial to the generation and maintenance of cell–cell interactions.

Axonal Na_v Channels

Axonal Na_v channels provide all of the inward depolarizing current that initiates and propagates the orthodromic action potential. As reviewed elsewhere in this encyclopedia, Na_v channels comprise principal α subunits and auxiliary β subunits. There exist in the mammalian genome genes encoding nine different principal α subunits, $Na_v1.1$–$Na_v1.9$. Of these, $Na_v1.4$ and $Na_v1.5$ are predominantly expressed in skeletal muscle and heart, respectively. All of the remaining Na_v1 α subunits have been described on axons. $Na_v1.1$, $Na_v1.2$, $Na_v1.3$, and $Na_v1.6$ are the predominant Na_v channel α subunits expressed in central neurons, with $Na_v1.3$ being found at higher levels in neonates than in adult. $Na_v1.7$, $Na_v1.8$, and $Na_v1.9$ are the predominant Na_v channel α subunits expressed in specific classes of sensory peripheral neurons. However, $Na_v1.6$ also makes a significant contribution in adult peripheral neurons, and $Na_v1.2$ and $Na_v1.3$ make a significant contribution in younger animals.

The subcellular localization of Na_v channel α subunits differs between neuronal types and in different compartments of the same neurons. $Na_v1.2$ is expressed at high levels in unmyelinated axons in many brain regions, such as mossy fiber axons arising from hippocampal dentate granule cells and the parallel fibers of cerebellar granule cells. $Na_v1.6$ is found in myelinated fibers, being the predominant Na_v channel α subunit present at nodes of Ranvier of adult myelinated axons (Figure 1, green). $Na_v1.6$ is also present at terminal heminodes (the last segment of the axon prior to the nerve terminal proper) and at the axon initial segment (AIS; Figure 2, green). As such, $Na_v1.6$ is crucial to the first, last, and intermediate steps of axonal action potential conduction. In certain central neurons, there exists a subcompartmentalization of the AIS, with $Na_v1.1$ present in a small region more proximal to the soma, and $Na_v1.6$ more distal and over the bulk of the initial segment. $Na_v1.1$ is also expressed in somatodendritic domains, although most dendritic staining is associated with proximal and not distal dendrites. A small percentage of nodes of Ranvier in adult myelinated axons contain $Na_v1.2$. The situation is reversed in early development and/or in the absence of intact myelin, when $Na_v1.2$ is present at the majority of nodes of Ranvier. $Na_v1.2$ is also found in high levels at the AIS of developing neurons, but unlike the situation at the node of Ranvier, it is developmentally replaced by $Na_v1.6$ independent of myelination.

Axonal K_v Channels

K_v channels are critical to regulating the excitability of the axon, by setting the resting membrane potential, and in action potential repolarization. K_v channels are also important in suppressing rebound back-propagating or antidromic action potentials by their presence at initial and terminal segments of axons. The mammalian genome contains genes encoding 32 different K_v channel α subunits that have been grouped into 12 different subfamilies (K_v1–K_v12). K_v channel complexes generally contain homotetrameric or heterotetrameric assemblies of α subunits from within the same K_v channel subfamily. The exception may be so-called 'electrically silent' α subunits from the K_v5, K_v6, K_v8, and K_v9 subfamilies, which in heterologous cells do not form functional channels in themselves but assemble promiscuously with functional α subunits from other K_v families to impact the function of the resultant complexes. K_v channel complexes can also contain cytoplasmic or transmembrane auxiliary subunits. The precise

Figure 1 Rat optic nerve triple immunofluorescence stained for $Na_v1.6$ (green), $K_v1.2$ (blue), and contactin-associated protein (Caspr) (red). Scale bar = 20 μM.

stoichiometry of K_v channel principal and auxiliary subunits determines the intracellular trafficking and localization, biophysical properties, and pharmacology of the resultant channel complexes.

Of these 12 subfamilies of K_v channels, it is clear that K_v1, K_v3, and K_v7 family members are expressed on axons. The seven members of the K_v1 channel α subunit subfamily, of which $K_v1.1$–$K_v1.6$ are expressed in neurons, form low-voltage activated channels that are present in virtually all mammalian axons. K_v1 channels are predominantly found as heterotetramers assembled from more than one K_v1 α subunit (e.g., $K_v1.1 + K_v1.4$). K_v1 channel complexes commonly contain cytoplasmic $K_v\beta$ subunits. $K_v1.1$, $K_v1.2$, and $K_v\beta2$ are a prominent combination and found at juxtaparanodes of myelinated axons (Figure 1, blue), along unmyelinated axons, in nerve terminals or preterminal axon segments, and at AISs. Based on this subunit composition, these K_v1 α and $K_v\beta$ subunits would be expected to form low-voltage-activated, non- or slowly inactivating channels sensitive to the mamba snake neurotoxin α-dendrotoxin. Complexes of $K_v1.1$, $K_v1.4$, $K_v\beta1$, and $K_v\beta2$ predominate in unmyelinated axons, nerve terminals, and preterminal axon segments in many brain areas. These subunits would be expected to form low-voltage-activated, somewhat rapidly inactivating channels also sensitive to α-dendrotoxin. These channels would be expected to exhibit use-dependent suppression due to the rapid onset of and slow recovery from inactivation; this process may be important in the frequency-dependent facilitation of neuronal firing. More complex mixtures of subunits (e.g., $K_v1.1$, $K_v1.2$, $K_v1.4$, and $K_v\beta2$) are also present on certain axons. All of these axonal K_v1 channels are targets of neuromodulation by a diverse array of neurotransmitters.

The four members of the K_v3 channel α subunit subfamily ($K_v3.1$–$K_v3.4$) are all expressed in mammalian brain, with $K_v3.1$–$K_v3.3$ most prominent. Transcripts from each of the K_v3 channel α subunit genes are subjected to alternative splicing to generate K_v3 channel α subunits with alternative C-termini. Such splicing can impact subcellular localization and sensitivity to neuromodulation. K_v3 channel α subunits form homomeric and heteromeric high-voltage activated channels that, given their high threshold for voltage-dependent activation, are probably only activated in response to action potentials. Somatodendritic K_v3 channels are critical to setting neuronal

Figure 2 Cultured hippocampal neurons triple immunofluorescence stained for MAP2 (blue), Na_v channels (green), and βIV spectrin (red). Scale bar = 10 mM.

firing rates; in fact, virtually all fast-spiking cells in brain express somatodendritic K_v3 channels. The $K_v3.1b$ isoform is found predominantly on axons and in terminal fields. $K_v3.2$ and $K_v3.4$ are also present in certain axons and terminal fields, most prominently in basket cell terminal pinceau. Unlike K_v1 channels, which are generally found at the base of presynaptic terminals and not in the terminals, K_v3 channels are found in the nonrelease face of the nerve terminal. $K_v3.1b$ is also found at a subset of central nervous system nodes of Ranvier. Interestingly, $K_v3.1b$ can also be found at peripheral nervous system (PNS) nodes in an animal model of Charcot–Marie–Tooth disease type IA, a demyelinating neuropathy, suggesting that myelination may regulate the localization and/or expression of these channels.

There are five members of the K_v7 subfamily of K_v α subunits, of which four ($K_v7.2$, $K_v7.3$, $K_v7.4$, and $K_v7.5$) are expressed in neurons (these are referred to as KCNQ2, KCNQ3, KCNQ4, and KCNQ5, respectively, in many reports). K_v7 α subunits are expressed in both the somatodendritic and the axonal compartments, with especially prominent expression of $K_v7.2$ and $K_v7.3$ observed in axons. Within the axon, K_v7 α subunits exhibit a restricted distribution, with robust expression of $K_v7.2$ and $K_v7.3$ at AISs and at nodes of Ranvier, coinciding with that for Na_v channels. K_v7 channels are especially sensitive to neuromodulation, which is achieved through a wide variety of mechanisms.

Other Axonal Ion Channels

Large conductance calcium and voltage-activated potassium, BK, or $K_{Ca}1.1$ channels are formed as tetramers of principal α subunits encoded by a single mammalian gene, Slo1. However, Slo1 transcripts are subjected to extensive alternative splicing that generates distinct C-termini that influence diverse aspects of $K_{Ca}1.1$ channels, including subcellular localization. $K_{Ca}1.1$ channels also contain transmembrane β subunits that modulate expression, localization, and function. $K_{Ca}1.1$ α subunits are found robustly expressed on axons and within nerve terminals, where they co-localize with voltage-gated calcium or Ca_v channels in the active zone. There is no evidence

to suggest that $K_{Ca}1.1$ channels are enriched at other axonal sites (e.g., initial segment and nodes of Ranvier).

Small conductance calcium and voltage-activated potassium, SK, or $K_{Ca}2$ channels are formed as tetramers of three different principal α subunits – $K_{Ca}2.1$ (SK1), $K_{Ca}2.2$ (SK2), and $K_{Ca}2.3$ (SK3) – each encoded by different genes. Robust $K_{Ca}2.3$ expression is present in mossy fiber and recurrent hilar axons and/or presynaptic terminals of hippocampal dentate granule cells. No other SK3 protein is detected in hippocampus. $K_{Ca}2.1$ is expressed in mossy fiber axons/terminals but is also present at high levels on the dendrites of many mammalian brain neurons. $K_{Ca}2.2$ is predominantly somatodendritic.

Slack, Slo2.2, or $K_{Ca}4.1$ α subunits form tetrameric pH-activated potassium channels and are strongly localized to axons and nerve terminals of expressing central neurons. $K_{Ca}4.1$ is expressed at high levels in brain stem neurons, such as in trigeminal and auditory nuclei, where it is expressed in axons and in large Calyx of Held terminals of the ventral cochlear nucleus globular bushy cells. Slick, Slo2.1, or $K_{Ca}4.2$ α subunits form tetrameric sodium-activated potassium channels that are found in a variety of neuronal axons, although robust staining is also observed in somatodendritic compartments.

Inwardly rectifying potassium or K_{ir} channels have not been described at the immunohistochemical level as being prominent on axons, nor have cyclic nucleotide gated or CNG channels. Some transient receptor potential (Trp) channels have been localized to axons. For example, TrpV1 is highly enriched in nociceptive C-fibers, and TrpC5 is involved in axon guidance through effects on calcium influx into growth cones.

There are four distinct mammalian hyperpolarization activated cation or HCN channels, HCN1–HCN4. These form homotetrameric channels, and they may also form heterotetramers. Of the HCN channels, only HCN1 has been reported in axons and terminals. The best example is in cerebellar basket cell terminals that contain high levels of HCN1, although there also exists prominent somatodendritic staining in certain neurons. Other HCN channels exhibit prominent somatodendritic staining.

Voltage-gated calcium or Ca_v channels also exhibit pronounced targeting to nerve terminals where they are integral components of release machinery and mediate calcium influx triggering vesicle fusion and transmitter release. The role of Ca_v channels in the axon proper is less clear.

Figure 3 provides a summary of the various axonal ion channels and their localization as described previously.

Figure 3 Schematic summary of the types and localization of axonal ion channels. CNS, central nervous system; PNS, peripheral nervous system.

Determinants of Ion Channel Localization

Intrinsic Determinants for Polarized Targeting of Ion Channels to Axons

A number of potential mechanisms exist to achieve localization of ion channels in axons, including direct targeting of channel-containing transport vesicles exclusively to the axon, general transport with selective insertion at axonal sites, and general transport and insertion with selective retention on axons and/or selective retrieval from dendrites. Which of these mechanisms is used for determining the axonal localization of the diverse ion channels cataloged previously is not clear. Work has begun to provide insights into molecular mechanisms leading to trafficking of ion channels to axons. Studies of Na_v channels by Dargent and colleagues have identified a motif that is in some contexts sufficient for ion channel targeting to axons. These workers made chimeric type I membrane proteins by appending different cytoplasmic fragments of axonal $Na_v1.2$ to the extracellular and transmembrane domains of CD4. They also made similar constructs using the analogous regions of a type II membrane protein, the transferrin receptor (TfR). Wild-type CD4 and TfR have nonpolarized distributions on both axons and dendrites. Cytoplasmic fragments of $Na_v1.2$, derived from the linkers between internally repeated domains I–II and

II–III, did not support the axonal localization of the resultant chimeras. However, inclusion of the cytoplasmic C-terminus of $Na_v1.2$ led to axonal localization of chimeras built on both CD4 and TfR backbones, due to the presence of a nine-amino-acid motif (CLDILFAFT) that contained a dileucine-like (IL) motif. Interestingly, even though this motif is 100% conserved in all neuronal Na_v channels (including $Na_v1.1$ and $Na_v1.6$), appending the C-terminus of $Na_v1.1$ and $Na_v1.6$ to CD4 did not yield a polarized expression on the axon. This suggests that other motifs found on the C-terminus of $Na_v1.2$, but not $Na_v1.1$ or $Na_v1.6$, are necessary for axonal localization of the reporter chimeras (although native $Na_v1.1$ and $Na_v1.6$ are both localized on axons). The role of the dileucine-like motif in axonal localization is in directing the selective endocytosis of the chimeras from the somatodendritic but not axonal plasma membrane. A second motif, in the cytoplasmic linker between internally repeated pseudosubunit II–III, also appears to mediate preferential somatodendritic endocytosis.

Two different C-terminal motifs can lead to axonal expression of CD4–K_v7 chimeras. As such, they are somewhat analogous in function to the C-terminal domains that direct axonal localization of Na_v channels. Interestingly, the K_v7 C-terminal domains have previously been shown to be required for subunit assembly, a requisite step for intracellular trafficking of multisubunit proteins. The mechanism (directed targeting or selective axonal retention/dendritic retrieval) has not been defined.

Axonal targeting of K_v1 channels has also been studies using a chimeric approach. In this case, the N-terminal T1 domain, which is highly conserved among K_v1 α subunits and directs subfamily-specific assembly, is also sufficient to direct axonal localization of CD4 and TfR chimeras. Unlike the case for Na_v and K_v7 motifs, the structure of the T1 domain has been solved by X-ray crystallography. Mutation of certain residues along a face of the domain that mediate the interaction with cytoplasmic auxiliary $K_v\beta$ subunits leads to loss of axonal localization of CD4 chimeras, consistent with a previous report that showed that $K_v\beta$ subunit coexpression was required for efficient axonal localization of exogenous K_v1 α subunits. The mechanism for T1-mediated localization of the chimeras to axons appears to at least in part be based on selective trafficking to axons because transport vesicles containing TfR are exclusively targeted to dendrites, whereas those containing the TfR–T1 chimera are found in both axons and dendrites. It is intriguing that the domains on K_v1 and K_v7 channels that can confer axonal localization to CD4 and TfR are unrelated at the level of primary structure but are both involved in assembly of these tetrameric K_v channel complexes.

Intrinsic Determinants for Clustering of Ion Channels at Precise Sites

Axonal ion channels can exhibit highly specific localizations within the axon (**Figures 1** and **2**). This suggests that subsequent to the mechanisms that lead to a biosynthetic enrichment of newly synthesized ion channels in the axonal plasma membrane, mechanisms must exist to selectively insert channel-containing vesicles at specific axonal sites and/or to capture plasma membrane ion channels at preferred axonal sites or selectively retrieve them from nonpreferred axonal sites. One of the best studied examples of the motifs that direct ion channels to specific axonal membrane domains is for the AIS because unlike other domains that require specific and complex cell–cell interactions (e.g., nodes of Ranvier), this structure forms spontaneously in pure cultures of neurons. Using the chimera approach described previously for defining axonal localization signals, a second motif on Na_v α subunits, located in the interdomain II–III linker, was identified that directed the enhanced targeting of $Na_v1.2$-containing chimeras to the AIS and its interaction with the scaffolding protein ankyrin-G (ankG). This motif (VPIALGESD) is highly conserved in all Na_v channels, and although not all axonal Na_v channels are restricted to sites enriched in ankG, they all bind to ankG *in vitro*. As such, we are left with a situation similar to the C-terminal dileucine-like motif; it is sufficient to direct a specific localization in certain contexts but it must be acting in conjunction with other unidentified determinants to yield the patterns of localization observed *in vivo*. Subsequently, an ankyrin-binding motif similar to that described in Na_v channels was identified on K_v7 channels, where it also directs localization to the initial segment. The importance of ankG for Nav and K_v7 channel clustering is further highlighted by the observation that Purkinje neurons lacking ankG fail to cluster these ion channels at the AIS.

Intrinsic determinants for localization of ion channels at specific sites outside of the initial segment are less well defined. K_v1 α subunits have at their C-termini active binding motifs (S/TXV) for class I PDZ domains, such as are present on membrane-associated guanylate kinases (MAGUKs) including PSD-95 and SAP97. PSD95 co-localizes with clustered $K_v1.1$, $K_v1.2$, and $K_v\beta$ subunits at juxtaparanodes of nodes of Ranvier of myelinated axons, as well as in cerebellar basket cell terminals. Thus, it seems likely that PSD95 plays some role in localization of K_v1 channels at these sites. However, genetic elimination of detectable PSD95 expression in transgenic mice does not affect K_v1

channel localization at these sites. Although there is no obvious upregulation of other MAGUKs at juxtaparanodes, it may be that other PDZ-containing proteins, or other less obvious compensatory mechanisms, are brought into play in these animals.

Extrinsic Determinants for Clustering of Ion Channels at Precise Sites

Rapid action potential propagation in mammals is a consequence of myelin. The traditional view has been that myelin passively alters the electrical properties of the axon by increasing the transverse membrane resistance and decreasing the membrane capacitance. Together, these properties limit the current necessary to depolarize the axonal membrane. However, it is now clear that myelin also actively regulates and promotes action potential propagation by directing a complex set of interactions (neuron–glia interactions) that ultimately result in the clustering of ion channels at and near nodes of Ranvier. Thus, in addition to the various intrinsic mechanisms described previously, the node of Ranvier is an outstanding example illustrating how complex intercellular interactions can modulate or even direct the localization of axonal ion channels. Most important, the active regulation of ion channel localization has profound effects on the biophysical and electrical properties of the axon.

As at the AIS, nodes of Ranvier have high densities of Na_v (primarily $Na_v1.6$) and K_v7 channels. Furthermore, both the AIS and the nodes contain a set of cell adhesion molecules (CAMs), including a neuronal splice variant of neurofascin (NF) called NF-186, and a set of cytoskeletal and scaffolding proteins, including ankG and βIV spectrin. Thus, nodes of Ranvier and initial segments share a common molecular organization. Despite these common constituents, one major difference between the nodes and the AIS is that the clustering of Na_v and K_v7 channels at the AIS only requires interaction with ankG, but clustering of these same proteins at nodes of Ranvier depends on the extrinsic influence of myelinating Schwann cells or oligodendrocytes in the peripheral and central nervous systems, respectively. How are ion channels clustered at nodes of Ranvier, and what is the role of myelinating glia in the formation of nodes?

Studies have shown that in the PNS, node formation is initiated by the recruitment and clustering of axonal NF-186 by a glial CAM called gliomedin. Axonal NF-186 binds to gliomedin, which is located at the tips of myelinating Schwann cells on small finger-like processes called microvilli. Binding to gliomedin causes NF-186 to accumulate in the axonal membrane beneath the microvilli. NF-186 then functions as a membrane attachment site for the recruitment of ankG; ankG binds to a C-terminal FIGQY motif conserved in all L1 CAMs. After ankG is correctly positioned along the axon, the process of ion channel clustering is thought to proceed in a manner similar to that for AISs: ankG functions as a scaffold, interacting with and anchoring Na_v and K_v7 channels to nascent nodal membrane domains, as well as the cytoskeletal protein βIV spectrin. βIV spectrin links the entire ion channel complex to the actin-based cytoskeleton. Ablation of either gliomedin or NF-186 results in failure to cluster ankG, βIV spectrin, and Na_v channels, emphasizing the crucial role that neuron–glia interactions play in defining sites of ion channel clustering in axons.

Nodes of Ranvier are flanked by the paranodal or axoglial junctions and are the locations where the myelin sheath attaches to the axon (**Figure 1**, red). These domains are composed of a tripartite CAM complex comprising axonal contactin and contactin associated protein (Caspr), as well as a glial splice variant of NF called NF-155. Together, this protein complex is thought to function as an adhesive attachment site for the myelin membrane. The paranodal junctions also contribute to ion channel function and localization by acting as both a membrane protein diffusion barrier and a paracellular ion diffusion barrier. Disruption of paranodal junctions results in mislocalization of nodal and juxtaparanodal ion channels.

Immediately adjacent to the paranodal junctions and beneath the myelin sheath is a domain called the juxtaparanode (**Figure 1**, blue). This region of the axon extends for 10–20 μm toward the internode and is characterized by a high density of K_v1 channels, including $K_v1.1$, $K_v1.2$ and, rarely, $K_v1.4$. The functions of these channels are not entirely clear, although data suggest they may play important roles during development in limiting repetitive firing of nodes due to re-entrant excitation of the nodal membrane. During disease, however, it is clear that these channels are functional since uncovering or redistribution of these channels from beneath the myelin sheath dramatically limits axonal excitability. Indeed, K_v1 channel blockers are currently in use to restore conduction in multiple sclerosis and spinal cord injury. Regarding the Na_v and K_v7 channels, juxtaparanodal K_v1 channel localization depends on neuron–glia interactions mediated by CAMs. Furthermore, the formation of this domain depends on a tripartite CAM complex similar to that found at the paranodal junction. In the axon, a heterodimer consisting of Caspr2 (a homolog of Caspr) and TAG-1 (a homologue of contactin) binds in trans with glial TAG-1. Caspr2 interacts indirectly with K_v1 channels, most likely through an unidentified PDZ domain-containing protein since both K_v1 channels and Caspr2 contain consensus PDZ binding motifs, and mutation of these

PDZ binding motifs blocks their association. Mice that lack either TAG-1 or Caspr2 have normal levels of K_v1 channels in the axon, but K_v1 channels fail to accumulate at the juxtaparanodes. Finally, Caspr2 interacts with the cytoskeletal linker protein 4.1B. This protein links the Caspr2/TAG-1/K_v1 channel protein complex to αII and βII spectrin and the underlying axonal cytoskeleton.

Together, these examples demonstrate that common molecular mechanisms are utilized to organize ion channels into discrete domains in myelinated axons. In general, ion channel clustering depends on interactions between glial and axonal CAMs which function as attachment points for scaffolding proteins to cluster and anchor ion channels in the membrane. Finally, these ion channel/scaffold/CAM protein complexes are stabilized through interactions with the axonal cytoskeleton.

Ionic Channels in Glia

Introduction

Kuffler and colleagues performed the first series of physiological studies investigating the biophysical properties of glial cells in the early 1960s. Using sharp microelectrodes, they demonstrated that glial cells from the mud puppy, leech, and salamander shared several biophysical properties. One common feature of glia was a hyperpolarized resting membrane potential (RMP), more negative than that of a typical neuron. A second common feature was an absence of electrical excitability. Injection of a depolarizing current (up to 200 mV) caused a linear change in the RMP, and current did not pass from the glia to a neuron or vice versa. However, glial cells did depolarize following neuronal stimulation, and it was discovered that this depolarization was due to an accumulation of external K^+ ions released from neurons after an action potential. Indeed, Kuffler and colleagues showed that glial membranes are selectively permeable for K^+ ions and suggested that glia may serve to regulate the extracellular K^+ concentration.

With the introduction of the patch–clamp technique in the early 1980s, it became possible to examine glial membrane properties more rigorously, and numerous studies have investigated glial cells from different species and preparations. These studies show quite universally that although passive, glial cells express many of the same ion channels and respond to most of the same ligands and neurotransmitters as their excitable neighbor, the neuron. However, because glial cells do not experience large voltage fluctuations necessary for many of these channels to activate, nor do they have the ability to fire action potentials, it has been difficult to assign putative functions for many of these channels. Indeed the ubiquitous expression of ion channels in all cell types (excitable or not) alludes to crucial functions in cellular biology distinct from conferring excitability. This article highlights the major findings of the past 25 years regarding ion channel expression and function in macroglial cells.

Potassium Channels

Inwardly Rectifying Potassium Channels

Inward rectifier potassium channels (Kir) are unique among K^+ channels expressed in glial cells in that they show their highest open probability close to the normal RMP values for most differentiated glial cells (~ -80 mV). Unlike the 'classic' gating of voltage-activated ion channels, the pore of the Kir channel is blocked from the intracellular side by polyamines and Mg^{2+}. This block is released at negative potentials, allowing K^+ influx. Because more channels are open at rest, they are capable of conferring the high potassium permeability typical of astrocytes and are hence ideally suited to establish and maintain the hyperpolarized glial RMP. Initial whole-cell patch–clamp experiments in glial cells demonstrated currents mediated by Kir channels in cultured rat astrocytes. To date, as many as eight of the 16 cloned Kir channels have been identified at the protein level in glial cells, while gene transcripts for all Kir genes have been identified (Table 1). It is believed that Kir4.1 is a particularly important member of the Kir channel family in glial cells.

The functions of Kir channels were directly inferred from the first biophysical studies. As mentioned above, most differentiated glia maintain a hyperpolarized RMP, close to the potassium equilibrium potential (E_K). This potential is required for the normal function of many of the transporters found in astrocytes. Opening of Kir channels will serve to pull the membrane potential toward E_K. Furthermore, Kir channel conductance increases with increasing concentrations of external potassium ions (Figure 1(a)). Therefore, when extracellular potassium rises, as it does following neuronal activity, channel conductance increases accordingly. Hence this channel is ideally suited to take up K^+ in response to neural activity by a process called potassium buffering. The polarized distribution of Kir channels (Figure 1(b)), which tend to localize preferentially to processes in the vicinity of neurons on the one hand and blood vessels on the other, allows astrocytes to remove potassium ions at their site of release during neuronal activity and subsequently redistribute these ions to blood vessels or areas where the extracellular potassium concentration is lower. Such a model of K^+ redistribution is supported by data from Müller cells, astrocyte-like cells in the retina which demonstrate co-localization of a specific Kir channel subunit, Kir4.1, at the subvitreal and perivascular spaces with the water channel aquaporin 4. Together these two channels allow for the uptake of K^+ and water in areas where concentrations are high and redistribute them to areas where concentrations are lower.

It is interesting that Kir channel expression appears to be developmentally regulated, with immature proliferating cells expressing fewer, if any, Kir channels

Table 1 Molecularly identified ion channels in glial cells

Channel and Subunit	*Preparation*	*Detection method*	*Putative function*
K^+-channels			
$K_{ir}4.1$	Müller cells	Immunogold-EM	Ion homeostasis

than do differentiated astrocytes. As expected, the higher density of Kir channels correlates with more-negative RMPs. In the context of disease, a lower Kir channel density is also observed in areas of gliosis, in brain regions associated with epileptic seizures, and in highly proliferative astrocytic tumors. Here the homeostatic roles of astrocytes which require a hyperpolarized RMP, as well as the inability to clear excess potassium, may no longer function, and hence this glial dysfunction may exacerbate neuronal hyperexcitability and cell death.

Voltage-Activated K^+ Ion Channels

Voltage-dependent potassium channels were the first voltage-activated channels to be described in glial cells. These channels form the largest and most diverse family of ion channels. Collectively they efflux potassium ions in response to membrane depolarization. Classically they are divided into three families: the fast-inactivating potassium channels (Ka), delayed-rectifying potassium channels (Kd), and calcium-activated potassium channels (KCa). The expression of each channel subtype in glia and possible functions are discussed below.

Ka and Kd Ka and Kd channels comprise the voltage-activated potassium channel subfamily (Kv), which, to date, comprises 40 identified members (Kv1.x–Kv12.x). In excitable cells, each of these channels has a specific role in shaping the action potential or its propagation. Currents mediated by classic Ka and Kd channels are easily distinguished from one another on the basis of their activation properties. Ka channel activation occurs rapidly, and currents typically inactivate quickly (Figure 2) whereas currents mediated by Kd channels activate with a delay and rarely inactivate, even with sustained depolarizations. These two channel types can be readily distinguished pharmacologically. Ka channels are sensitive to low millimole concentrations of 4-aminopyridine while Kd channels are inhibited by low millimole concentrations of tetraethylammonium. It is interesting that neither Ka nor Kd channels are open at typical RMPs of glial cells but instead begin to activate at approximately −40 mV.

Biophysical studies have demonstrated some Kd channel activity in nearly all glial cells, although higher channel activity is associated with developing glia. When induced to proliferate following brain injury or in the context of disease processes such as epilepsy, channel activity is increased relative to normal surrounding tissue. The RMP of proliferating or immature glia is depolarized relative to differentiated astrocytes, increasing the likelihood of Kd channel. It has been demonstrated that Kd channel inhibition or protein knockdown is sufficient to decrease cell proliferation rates suggesting a role for this channel in cell division. However, the underlying mechanism linking Kd channel activity and cell proliferation is unknown.

It is interesting that in the 25 years since these two channel types were first described in astrocytes, very

Figure 1 Inwardly rectifying potassium currents are robustly expressed in spinal cord astrocytes. (a) Typical voltage step response (protocol depicted in inset) in 5 mmol l^{-1} K^{+o} (top), 20 mmol l^{-1} K^{+o} (middle), and 5 mmol l^{-1} K^{+o} + 100 mmol l^{-1} Ba^{2+} (a nonspecific inward rectifier potassium (Kir) channel inhbitor; bottom). (b) Double immunogold labeling of Kir4.1 (10 nm particles) and aquaporin 4 (AQP4; 20 nm particles) in vitreal (A, B), perisynaptic (C), and perivascular (D) Müller cell (M) membranes. C and D are from the outer plexiform layer. (A, B) Note, in A, that the M end foot (M) is selectively labeled at its vitreal aspect (both aspects indicated by double arrow). The vitreal plasma membrane (between dashed lines in B) is obliquely cut, allowing labeling at the two sides of the section to be distinguished. Small arrows indicate Kir4.1 labeling. Asterisks indicate corresponding points at the vitreal surface (part of A is enlarged in B). C: Weak Kir4.1 (arrows) and AQP4 labeling is found in the thin M processes that surround photoreceptor terminals (Pt). D: Perivascular endfeet (M) show a polarized distribution of gold particles (double arrow; compare with A). End, endothelial cell; P, pericyte. E: Kir4.1 immunolabeling of an M microvillus (asterisk). The gold particles (arrows) are restricted to its basal part, which is devoid of large particles signaling AQP4. IS, inner segment of photoreceptors. Error bar = SEM (standard error of the mean). Graph shows linear densities of gold particles in different membrane domains of M. Note different scales for AQP4 (top) and Kir4.1 (bottom). Vitreal and perivascular endfeet membranes are coenriched in AQP4 and Kir4.1. Only in the microvilli is there a segregation between immunoreactivities for the two membrane molecules. Scale bars = 0.5 μm (a), 0.1 μm (b, e), 0.25 μm (c, d). (a) Reprinted from Olsen ML, Higashimori H, Campbell SL, Hablitz JJ, and Sontheimer H (2005) Functional expression of K_{ir} 4.1 channels in spinal cord astrocytes. *Glia* 53(5): 516–528, with permission of Willey–Liss, Inc., a subsidiary of John Wiley & Sons, Inc. (b) Reproduced from Nagelhus EA, Mathiisen TM, and Ottersen OP (2004) Aquaporin-4 in the central nervous system: Cellular and subcellular distribution and coexpression with KIR4.1. *Neuroscience* 129(4): 905–913, with permission from Elsevier.

little information has become available regarding possible functions. Conditions which depolarize the membrane sufficiently for channel activation are poorly understood. Although there is significant biophysical evidence to suggest that these channel types contribute to membrane conductance, possibly in the context of efflux during potassium buffering and/or maintenance of a hyperpolarized RMP, more-definitive functional studies are lacking. However, ubiquitous expression in nearly every glial preparation studied alludes to the importance of both Ka and Kd channels in glial cell biology.

Ca^{2+}-activated potassium channels Distantly related to the voltage-activated potassium channels are the calcium-activated potassium (KCa) channels. KCa channels can be grouped into three distinct subfamilies, large-conductance (BK), intermediate conductance (IK), and small conductance (SK) channels. As implied by their name, these channels differ in their unitary conductance. Unlike Kv channels, which activate solely in response to membrane depolarizations, all KCa channels require increases in intracellular calcium for their activation. BK channels also demonstrate voltage dependence not seen in

Figure 2 Pharmacological properties of K^+ currents observed in $BrdU^+$ spinal cord astrocytes. The isolated transient and sustained outwardly rectifying potassium currents from a typical scar-associated cell (6 h postinjury) recorded before and after the application of potassium channel blockers, as indicated. (a) In normal recording solution, large transient (left) and sustained currents (right) are recorded. (b) Application of 40 mmol l^{-1} TEA inhibited the sustained K^+ current by ~50% but had no effect on the transient current. (c) The addition of 4-aminopyridine (4AP; 2 mmol l^{-1}) completely inhibited the transient potassium currents and also inhibited the residual sustained K^+ current that was not inhibited by TEA. Ka, fast-inactivating potassium channels; Kd, delayed-rectifying potassium channels. Reproduced from MacFarlane SN and Sontheimer H (1997) Electrophysiological changes that accompany reactive gliosis *in vitro*. *Journal of Neuroscience* 17(19): 7316–7329, with permission from Elsevier.

either IK or SK channels and hence can be activated by $[Ca^{2+}]_i$, voltage, or both. Specific pharmacological channel inhibitors for each channel type are available, allowing for identification of currents mediated by each channel. BK and SK channels have been described biophysically in astrocytes, oligodendrocyte precursor cells, and Müller cells. Only a few studies have identified BK and SK channels *in situ* (Table 1).

Although glial cells rarely see depolarizations large enough to activate voltage-gated channels, there are numerous circumstances which raise $[Ca^{2+}]_i$ sufficiently to activate KCa channels. These include, but are not limited to, activation of purinergic receptors, G-protein-coupled receptors, transient receptor potential (TRP) channels, and mitogen signaling. It has been suggested that KCa channels may facilitate potassium efflux from glial cells. This interpretation would explain the localization of channels on glial endfeet that contact blood vessels. Furthermore, KCa channels may contribute to astrocyte–astrocyte signaling in response to $[Ca^{2+}]_i$ increases in the form of glial calcium waves. Depolarizations of the membrane activate calcium channels, and the combination of the calcium signal and membrane depolarization may activate either BK or SK channels. The resulting increase in extracellular potassium would serve to depolarize neighboring cells, thus further propagating the signal.

In some glial cells, BK channels display developmental regulation, with higher channel activity in proliferative cells. In fact, glioblastoma cells, or tumor cells thought to derive from glia, demonstrate robust BK channel activity. BK channels expressed in these cells demonstrate classic BK channel properties, including sensitivity to the specific BK channel inhibitor (Figure 3(a)) as well as a dependence on intracellular Ca^{2+} (Figure 3(b)). In general, proliferative cells maintain a more depolarized RMP than that of quiescent cells. The opening of any potassium channel will pull the RMP toward the potassium equilibrium potential or hyperpolarize the cell, suggesting that rather then remaining open, these channels open briefly in response to increases in intracellular calcium. This suggests that other channels mediate the resting conductance in proliferative cells. However, higher potassium channel activity in proliferative cells is commonly observed. Indeed, potassium channel activation has long been linked to cell cycle progression for nearly every cell type studied. However, whether glial potassium channels simply provide a permissive ionic environment for cell division or whether regulation of the RMP has a more instructive role remains to be seen.

Voltage-Activated Chloride Channels

Chloride channels are ubiquitously expressed in all cells and are typically involved in vital cellular functions that include cell volume regulation, cell proliferation, and salt secretion. As the chief physiological anion, chloride ions provide the counter ion for many cellular transport systems. Astrocytes and oligodendrocytes differ markedly in their chloride permeability, resting conductance, and resting chloride concentrations. Astrocytes have relatively low chloride permeability but actively accumulate chloride as their intracellular Cl^- concentration is much higher than predicted by the RMP. Consequently, the opening of astrocytic chloride channels results in chloride efflux. Oligodendrocytes demonstrate a higher permeability to Cl^- and have intracellular chloride concentrations favoring passive distribution.

Biophysical studies have described Cl^- channels in many glial cell preparations, yet the majority of these

Figure 3 Ca-activated potassium channels are expressed in glial cells. (a) Co-localization of rat large-conductance (BK) channels and glial fibrillary acidic protein (GFAP) in the rat cerebellum and hippocampus. Confocal images of BK (in red) and GFAP (in green) immunolabeling of the cerebellar granule cell layer (GCL), white matter (WM) ((a) and (b)), and the deep cerebellar white matter (c). Note that most cerebellar astrocytic GFAP labeling has little BK labeling associated with it (arrows); however, GFAP and BK co-localization, when it occurs, is frequently found surrounding blood vessels (broad arrowheads). (d) Confocal image of BK (red) and GFAP (green) immunolabeling within hippocampal CA1 region. Hippocampal GFAP labeling overlaps with BK along astrocytic processes (arrows), with high densities of overlap occurring at perivascular end-foot regions (arrowheads). (a), (c), and (d) are single optical sections, and (b) is a maximum projection reconstructed from a z-series ($n = 16$). Scale bars = 20 μm (a–c), 10 μm (d). (e) Whole cell voltage-dependent currents in human glioma cells were inhibited by the indicated concentration of scorpion-venom peptide iberiotoxin. (f) BK channels in glioma cells are particularly calcium sensitive to elevated intracellular calcium. (a–d) Reproduced from Price DL, Ludwig JW, Mi H, Schwarz TL, and Ellisman MH (2002) Distribution of rSlo Ca^{2+}-activated K^+ channels in rat astrocyte perivascular endfeet. *Brain Research* 956(2): 183–193, with permission from Elsevier. (e,f) Reproduced from Ransom CB and Sontheimer H (2001) BK channels in human glioma cells. *Journal of Neurophysiology* 85(2): 790–803, used with permission from The American Physiological Society.

studies have been carried out on cultured astrocytes. Collectively, they demonstrate that chloride channel activation requires an osmotic challenge or a change in cell morphology. In contrast, gliotic astrocytes or astrocytes which have undergone neoplastic transformation have an elevated resting chloride conductance, and in these cells chloride currents can be recorded in the absence of an osmotic challenge.

Several biophysical studies have identified an inwardly rectifying chloride current (mediating an efflux of chloride ions) which has the electrophysiological signature of ClC-2. ClC-2 belongs to the family of voltage-gated chloride channels (ClC1–ClC-9). Consistent with this finding, a comparison of astrocytes in ClC-2 knockout mice and wild-type littermates suggests that astrocytes normally express functional ClC-2 channels. ClC-2 immunoreactivity has been identified in astrocytic endfeet or processes which localize with γ-aminobutyric acid (GABA)ergic axon terminals. Here, ClC-2 may facilitate GABAergic transmission by presenting chloride ions to axons involved in GABAergic transmission. It is interesting that mutations in the ClC-2 gene have been linked to several of the most common types of idiopathic generalized epilepsy. It is thought that two such mutations would lower the transmembrane chloride gradient essential for GABAergic inhibition.

The majority of studies examining chloride channel function have done so in the context of cell volume regulation (Figure 4). Astrocytic volume changes have been demonstrated to occur in response to physiological events, such as potassium buffering and in pathophysiological conditions such as brain edema. In the former, the movement of K^+ and Cl^- ions enters the cells along with water in regions of elevated potassium. There does not appear to be any long-term net gain in cell volume; rather K^+ and Cl^- and water would also be released at a distant site. In edematous brain, astrocytic swelling dramatically decreases the size of the extracellular space and in turn increases the concentration of ions and molecules in this space. In culture, swelling of astrocytes by a hypotonic challenge results in activation of chloride channels that subsequently mediate regulatory volume decrease. Application of chloride channel inhibitors prevents the swelling-induced regulatory volume decrease. Unfortunately, the absence of specific chloride channel inhibitors makes the identification of the underlying channels difficult, but many possible gene candidates have been identified (Table 1). There remains a controversy as to whether the volume-activated Cl^- channel, often called ICl_{swell}, belongs to the ClC family or has yet to be molecularly identified.

Voltage-Gated Calcium Channels

Intracellular calcium concentrations are maintained at least four orders of magnitude lower than that of extracellular calcium. This gradient makes calcium an exceptionally effective intracellular signaling molecule. Plasma membrane voltage-gated calcium channels constitute a significant mechanism for calcium signaling. Five types of voltage-gated calcium channels (L, T, P, N, and Q) can be distinguished on the basis of biophysical and pharmacological properties. Molecularly, the alpha subunits that comprise the main channel structure are grouped into three families. These are Ca_v1, which include L-type channels; Ca_v2, composed of L, T, R, N, and P/Q channel subunits; and Ca_v3, or T-type channels. These channels can be distinguished pharmacologically (Figure 5). Auxiliary subunits often associate with the alpha subunit, altering its properties. Regardless of the channel subtype, Ca_v channels always require a depolarization for their activation. Physiological activation of

Figure 4 Hypotonic challenge activates whole-cell chloride currents in cultured cortical astrocytes. these channels in glial cells may be achieved by increases in extracellular potassium or by activation of other ligand-gated channels, which allows nonspecific cation influx to depolarize the membrane. In addition, glial cells respond to neurotransmitters such as glutamate, which results in calcium influx and membrane depolarization.

Voltage-activated calcium channels were first demonstrated in cultured astrocytes and oligodendrocytes. These initial investigations demonstrated that either coculture with neurons or exposure to agents that increase intracellular cyclic adenosine monophosphate is required to detect channel activity in cultured cells. Subsequently, several studies examined the expression of these channels in slices or acutely dissociated cells using calcium imaging techniques as well as whole-cell voltage clamp experiments. These investigations revealed that intracellular calcium increase caused by K^+-induced depolarizations was dependent on influx of calcium (independent of release from intracellular stores) and was inhibited with different Ca_v channel inhibitors. Although channel subtypes seem to vary in different preparations, the prevailing consensus is that glial cells express these channels *in situ*. Indeed, several Ca_v channel subunits have been molecularly identified in astrocytes, oligodendrocytes, and Müller cells (Table 1).

Under pathological conditions, plasma membrane depolarizations would likely be significant because of increases in extracellular K^+ and influx of calcium through other mechanisms. Indeed, many of the studies examining the functional role of Ca_v channels are in this context. Biophysical and molecular investigations have revealed that calcium influx through voltage-gated channels following injury or ischemia was detrimental and potentially contributed to glial injury. Furthermore, Ca_v channel immunoreactivity increased following injury. It is interesting that the regulatory volume decrease is severely impaired when astrocytic voltage-gated calcium channels are inhibited. Yet another curiosity pertains to Ca_v expression in the context of seizures. It has been shown that $[Ca^{2+}]_o$ (where 'o' denotes extracellular) levels are reduced below normal levels at seizure focal sites, and indeed, depletion of $[Ca^{2+}]_o$ is sufficient to produce seizurelike activity experimentally. This activity can be blocked with inhibitors of voltage-gated Ca^{2+} channels, suggesting that calcium channels present on neurons as well as glia may be involved in calcium uptake from the extracellular space. If true, glial

voltage-gated calcium channels may have a role in extracellular calcium homeostasis.

Voltage-Gated Sodium Channels

Voltage-gated sodium channels mediate the upstroke of the action potential in excitable cells. They are defined by an alpha subunit derived from one of nine genes ($Na_v1.1$–1.9). Auxiliary beta subunits typically associate with the alpha subunit and modify channel properties. The initiation and propagation of the action potential appears to be the only capacity in which these channels function. Yet glial cells do not fire action potentials. Not surprisingly, the first description of Na^+ channels in glia was greeted with suspicion. To date, glial cells from culture, acutely dissociated and in the acute slice, have been shown unequivocally to express voltage-gated sodium channels, albeit often at low density, insufficient to generate an action potential. Indeed, sodium currents reminiscent of those seen in neurons, which activate at approximately 60 mV, inactivate quickly, and are sensitive to low (10 nmol l^{-1}) tetrodotoxin, have been described in astrocytes (Figure 6(a)). A second type of current unique to glial cells has been described that demonstrates tetrodotoxin insensitivity (1000 nmol l^{-1}; Figure 6(b)). Sodium currents which display low tetrodotoxin sensitivity have been described in protoplasmic astrocytes as well as injured astrocytes *in vitro* (Figure 6). Studies from cultured spinal cord

Figure 6 Spinal cord astrocytes display altered tetrodotoxin (TTX) sensitivity on injury *in vitro*. (a) Photomicrograph of control culture and representative Na^+ current traces for control cells. In the presence of normal bath solution, Na^+ currents are evoked in response to a voltage protocol that hyperpolarized the cell to 110 mV for 200 ms and then depolarized the cell for 8 ms to potentials ranging from 70 to 80 mV. Sodium currents in control cells are inhibited largely by 10 nmol l^{-1} TTX. (b) Photomicrograph of scar-associated cells and their representative current recordings. In response to the same voltage protocol (above), scar-associated cells exhibit Na^+ currents with twofold greater conductance than those of control cells. These currents are largely resistant to 10 and 100 nmol l^{-1} TTX. (c) Dose-dependent current inhibition for control vs. Scar-associated Na^+ currents. Apparent IC50 for scar-associated cells was 314 nmol l^{-1}, which is ~40-fold less sensitive than control cells (IC50 = 8 nmol l^{-1}). Scale bar = 100 μm. Error bars = SEM (standard error of the mean). Reproduced from Macfarlane SN and Sontheimer H (1998) Spinal cord astrocytes display a switch from TTX-sensitive to TTX-resistant sodium currents after injury-induced gliosis in vitro. *Journal of Neurophysiology* 79: 2222–2226, used with permission from The American Physiological Society.

astrocytes, A2B5$^+$ progenitor cells, and astrocytes from acute hippocampal slices have demonstrated that channel activity is dynamic and heterogeneous. These data are supported by immunocytochemical studies which demonstrate regional variations and suggest channel expression may be developmentally regulated. Additional data from reactive glia, which express ionic currents reminiscent of immature glia, in tissue associated with epilepsy and low-grade astrocytic tumors demonstrate these cells display higher-than-normal sodium channel activity.

As stated above, the identification of Na_v channels in glial cells prompted many investigators to search for some type of excitability in these cells. And in some cell types under specific conditions, large or suprathreshold stimulations resulted in an action potential-like response. However, even in cultured spinal cord astrocytes, which display a relatively high sodium channel density, several factors, including a high potassium resting conductance and low input resistance, preclude them from becoming excitable. Putative functions for sodium channels in glia are scarce. However, blockade of sodium channels in astrocytes reduced Na^+K^+ adenosine triphosphatase (Na^+K^+ATPase) activity, depolarized the RMP, and reduced intracellular sodium concentrations, suggesting glial sodium channels may provide a pathway for sodium influx necessary to maintain Na^+K^+ATPase activity. Conversely, inhibition of sodium channel inactivation in astrocytes from hippocampal slice led to a marked increase in intracellular sodium, suggesting these channels function in some biological capacity.

TRP Channels

TRP channels are a large family of sensory transduction ion channels that are activated in response to a number of stimuli, including mechanical stimuli, chemical messengers, heat, osmotic stress, and odorants, among others. By and large, these channels are voltage-independent, nonselective cation channels, and their activation causes membrane depolarization due to movement of positively charged ions into the cell. However, because of the disproportionate driving force for calcium ions to enter the cell, this particular ion garners much of the attention. TRPC (C = canonical) channels comprise a subfamily of this large group of proteins; they influx Ca^{2+} in response to activation of membrane receptors linked to phospholipase C. Of the near 30 distinct genes encoding mammalian TRP channels, there are seven TRPCs, and all but one (TRPC7) have been molecularly identified in astrocytes (Table 1). Although controversial, several TRPC channels have been suggested to be the store-operated channels involved in capacitative calcium entry (CCE) whereby depletion of endoplasmic reticulum calcium stores activates influx from the plasma membrane. CCE in turn is important in intracellular calcium regulation. It is in this capacity that TRPC channels have been most studied in astrocytes. Supporting the idea that TRPC channels promote CCE, several TRPC channels are found on the plasma membrane of cultured astrocytes, and knockdown of TRPC1 in mouse cortical astrocytes decreases extracellular calcium influx in response to depletion of intracellular stores. In contrast, it has been shown that two TRPC-permeable ions, Ba^{2+} and Sr^{2+}, do not enter astrocytes during CCE, arguing that TRPC channels are not involved. A second line of investigation has suggested that TRPC channels may be involved in astrocytic calcium oscillations. Although they are likely involved in intracellular calcium regulation, further study is needed to elucidate the role of TRPC channels in astrocytes and their possible role in CCE.

ATP-Gated Channels

ATP is a primary signaling molecule in astrocytes under physiological as well as pathological conditions. Ligand-gated channels that bind ATP and its metabolites are termed purinergic receptors. These can be further classified into purinergic ion channel receptors (P2X) and G-protein-coupled receptors. This article focuses on P2X receptors, or receptors that allow influx of sodium and calcium and efflux of potassium in response to extracellular binding of ATP. Activation of P2X receptors results in large increases in intracellular calcium because of the huge driving force to move calcium ions into the cell. These changes in intracellular calcium culminate in a primary form of signaling between adjacent and neighboring astrocytes as well as astrocytes and neurons. Furthermore, the increases in intracellular calcium on astrocytic P2X receptor activation have been associated with increased cell proliferation, ion channel activation, and countless other downstream signaling events.

Purinergic receptors were first described in astrocytes more than 10 years ago, when perforated patch–clamp experiments demonstrated that application of 100 μmol l^{-1} ATP induced an inward current that desensitized rapidly. This current was dependent on external sodium ions, and measurements with potassium-sensitive microelectrodes demonstrated a decrease in intracellular K^+. Furthermore, calcium imaging demonstrated a transient increase in intracellular calcium that appeared dependent on both internal and external calcium sources. Since these

initial studies, all seven P2X receptors (1–7) have been molecularly identified in astrocytes in many preparations (Table 1).

Data from multiple laboratories suggest that astrocytes from injured or ischemic tissue respond differently to ATP. In addition, it has been suggested that increased ATP concentrations following brain injury may stimulate gliosis via stimulation of purinergic receptors. After injury, changes in P2X receptor subunit expression were demonstrated in reactive astrocytes; however, particular attention has focused on the P2X7 receptor, which shows postischemic upregulation both *in vivo* and *in vitro*. This subunit has the unique ability to form a pore permeable to relatively large molecules on prolonged exposure to agonist and in the presence of low divalent cations, conditions experienced during ischemic insults and seizures. Typically, activation of the P2X7 receptor subunit requires high concentrations of agonist seen after brain injury. It is interesting that P2X7 pore formation has been coupled to nonvesicular, calcium-independent glutamate release both *in vitro* and *in vivo*. Although not selectively permeable to glutamate, in astrocytes this anion maintains the largest concentration gradient. Because glutamate can induce ATP release, glutamate efflux may act to amplify purinergic receptor signaling, possibly leading to glutamate-induced cell death. This unique pore may also represent a unique pathway for astrocytic ATP release following brain injury.

Concluding Remarks

Biophysical studies of glial cells have challenged the notion that voltage-gated ion channels function exclusively or even primarily to generate an electrical signal. Instead, roles for ion channels in glia must be considered that pertain to ion homeostasis and general cellular biology. In many instances, the true importance of these channels remains elusive. Recent molecular genetic techniques are now making a more rigorous assessment of ion channel function a reality.

Joubert Syndrome

R J Ferland, Rensselaer Polytechnic Institute, Troy, NY, USA

Introduction

Mutations in basic developmental genes are frequently observed in a variety of human neurodevelopmental syndromes. Disorders affecting the cerebellum (and brain stem) comprise some of these developmental disorders, which often result in clumsiness (ataxia), developmental delays, learning disabilities, mental retardation, and autistic-like behaviors. Thus, identification and characterization of the genes responsible for these neurodevelopmental abnormalities will be critical in our understanding of the basic mechanisms of cerebellum and brain stem development in addition to understanding these neurological disorders. Joubert syndrome is one such neurodevelopmental disorder in which the development of the cerebellum and brain stem is greatly affected in addition to the presence of abnormalities in the crossing of axons in the posterior midline of the brain.

Clinical Presentation

Joubert syndrome was originally described by Dr. Marie Joubert in 1968 in a family presenting with hyperventilation, abnormal eye movements, ataxia, and mental retardation with agenesis of the cerebellar vermis. Joubert syndrome can be divided into various subclassification groups based on the clinical presentation and the neuropathological profile. The originally described syndrome is commonly referred to as classic Joubert syndrome and primarily consists exclusively of central nervous system (CNS) involvement. Patients with classic Joubert syndrome first present with weakness (hypotonia) and abnormal, irregular breathing (episodic hyperpnea and/or apnea) during the neonatal period. Later, atypical eye movements (oculomotor apraxia, nystagmus, and strabismus), ataxia, and mirror movements (behavior whereby the movements on one side of the body are 'mirrored' by the other) may become apparent. Patients with Joubert syndrome can have developmental delay and a spectrum of cognitive abilities ranging from normal intelligence to severe mental retardation. Another common feature of Joubert syndrome is the presence of autistic-like behaviors.

Non-CNS abnormalities also can occur in Joubert syndrome, including cystic kidney disease (renal disease whereby fluid-filled sacs develop in the kidney forming cysts), nephronophthisis (a progressive renal disease affecting the kidneys symmetrically, particularly the tubules and glomeruli), hepatic fibrosis (disease affecting the liver where fiber-like connective tissue develops throughout the liver), soft-tissue tongue tumors, and polydactyly (too many fingers or toes). These non-CNS features, when they occur with the more standard classical Joubert syndrome brain phenotype, are evidence for the clinical heterogeneity that is apparent in Joubert syndrome.

Neuroanatomical Abnormalities

Although Joubert syndrome was first identified in 1968, most of our understanding of the neuropathology of Joubert syndrome comes from magnetic resonance imaging (MRI) studies since there are few neuropathological studies of individuals with Joubert syndrome. The available neuropathological and neuroradiological data suggest that individuals with Joubert syndrome have two major brain abnormalities: (1) malformations of the cerebellum, and (2) an interesting, but complex, neuroanatomical abnormality called the molar tooth sign.

The cerebellum is divided into four major lobes, the flocculonodular lobe, the two cerebellar hemispheres, and the vermis, which lies between the two cerebellar hemispheres. Individuals with Joubert syndrome specifically have abnormalities of the cerebellar vermis including absence (aplasia), reduced size (hypoplasia), or a disorganized structure (dysplasia) (compare Figure 1(b) to Figures 1(d), 1(f), and 1(h)). These abnormalities can be observed *in utero*, in the developing fetus with Joubert syndrome. With aplasia of the vermis, the two cerebellar hemispheres appose one another, but do not appear fused. On MRI, the cerebellar hemispheres and flocculonodular lobe seem relatively unaffected in Joubert syndrome; however, there have been neurohistological reports of Purkinje cell loss and proliferation of Bergmann glia in the cerebellum. Overall, these neuropathological findings suggest that individuals with Joubert syndrome have abnormalities in the patterning of the cerebellar vermis, the major midline structure in the cerebellum.

There are four deep nuclei in the cerebellum, the dentate, emboliform, globose, and fastigial nuclei. The most severely affected of the four cerebellar nuclei, in individuals with Joubert syndrome, are the dentate nuclei which give rise to the superior cerebellar peduncles. In Joubert syndrome, the dentate nuclei are poorly defined and are separated into small

Figure 1 MRI of a normal brain (a, b) and the brains of individuals with *AHI1* mutations (c–h). MRIs are presented in an axial plane (a, c, e, g showing the cerebellum and upper pons) and in a sagittal plane (b, d, f, h showing a mid-sagittal section through the brain displaying the cerebral cortex, cerebellum, midbrain, and pons). Axial T1-weighted (a) and mid-sagittal T1-weighted (b) images of an unaffected child with a normal brain stem (a) and a normal cerebellar vermis (b). Axial T2-weighted (c) and mid-sagittal T1-weighted (d) MRI images of a male child at 6 years of age with *AHI1* mutations demonstrating the molar tooth sign ((c) black arrowhead) and the absence of the cerebellar vermis ((d) white arrow). Axial T1-weighted (e) and mid-sagittal T2-weighted (f) images of a male child with *AHI1* mutations at 4 years of age showing the molar tooth sign ((e) black arrowhead) and the absence of the cerebellar vermis ((f) white arrow). Axial T1-weighted (g) and mid-sagittal T1-weighted (h) images of a 2-year-old male child with *AHI1* mutations also noting the presence of the molar tooth sign ((g) black arrowhead) and a lack of a cerebellar vermis ((h) white arrow). In all of the axial images from affected individuals (c, e, g), the failure of the superior cerebellar peduncles to decussate can be appreciated by the presence of the peduncles traveling horizontal to the brain stem and not crossing the midline. Note that the brain structure that is present in the mid-sagittal sections (d, f, h) at the level of the cerebellum in individuals with Joubert syndrome is not the vermis but in fact is the right lobe of the cerebellum that is now in the plane of the mid-sagittal section because of the absence of the vermis. Scale bar = 5 cm. Adapted from Ferland RJ, Eyaid W, Collura RV, et al. (2004) Abnormal cerebellar development and axonal decussation due to mutations in *AHI1* in Joubert syndrome. *Nature Genetics* 36: 1008–1013, with permission.

islands; however, the dentate nuclei do appear to send out their axons forming the superior cerebellar peduncle.

The superior cerebellar peduncles are the major output (efferent) pathway of the cerebellum projecting to various thalamic, midbrain, and medullary structures. In normal brains, the superior cerebellar peduncle projections will cross the midline (or decussate) and project to the contralateral thalamus and midbrain. However, in Joubert syndrome, the superior cerebellar peduncle projections do not decussate in the dorsal midbrain, but remain ipsilateral to the dentate nuclei of origin. Moreover, the superior cerebellar peduncles are much more thickened, and run horizontally between the cerebellum and midbrain as compared to normal (compare **Figure 1(a)** to **Figures 1(c), 1(e), and 1(g)**). In addition to the absence of a decussation of the superior cerebellar peduncles, individuals with Joubert syndrome also lack the decussation of the central pontine tracts and the corticospinal tracts. These findings suggest that, in Joubert syndrome, there are defects in either axonal guidance or axonal crossing in the posterior midline of the brain.

The abnormally projecting superior cerebellar peduncles also are part of a complex brain stem malformation referred to as the molar tooth sign. The molar tooth sign, visible on radiographic imaging, consists of dysgenesis of the isthmic portion of the brain stem at the mesencephalon–metencephalon (pontomesencephalic) junction, enlargement of the 4th ventricle, vermic clefting, and the abnormally thickened and reoriented superior cerebellar peduncles (**Figures 1(c), 1(e), and 1(g)**). The molar tooth sign is one of the hallmark radiological features for the diagnosis of Joubert syndrome.

Other major neuroanatomical abnormalities that have been observed in Joubert syndrome are dysplasia/hypoplasia of the inferior olives, accessory olives, the solitary nuclei and tracts, and the nucleus and spinal tracts of cranial nerve V. In addition, elongation of the locus coeruleus has been consistently observed. Anomalies have been reported in the dorsal column nuclei, the descending trigeminal tract, the basis pontis, and the reticular formation in individuals with Joubert syndrome. Marked dysplasia of the caudal medulla has been noted specifically with neuronal swelling and aberrant axonal spheres (immunoreactive for neurofilaments) in the malformed nuclei gracilis and cuneatus. The posterior median sulcus also has been reported to be missing in individuals with Joubert syndrome.

Other less frequent neuroanatomical abnormalities in Joubert syndrome include retinal dystrophy, Leber

congenital amaurosis (retinal degenerative disorder), and ocular colobomas (defects in the lens, iris, retina, or optic disc). There are reported cases of individuals with Joubert syndrome that have focal regions of cortical dysplasia or polymicrogyria (a neuronal migration disorder characterized by many small folds on the surface of the cerebral cortex), but the incidences of these cortical findings in Joubert syndrome are currently unknown. However, these findings are mostly based on MRI, and subtle alterations in the cerebral cortex might be missed and need to be examined at the microscopic level. Moreover, it is important to note that many of the major abnormalities of the cerebellum, superior cerebellar peduncles, and corticospinal tract, discussed above, are primarily based on MRI imaging; however, there have been a few cases of Joubert syndrome that were analyzed histologically which verified these MRI findings. However, more neuropathological studies are needed in order to determine whether there are more subtle abnormalities in Joubert syndrome in other regions of the brain beyond the detection/resolution limits of MRI. As a whole, these neuroanatomical findings suggest that Joubert syndrome is primarily a disorder of the posterior midline of the brain involving defective patterning and axonal guidance in these regions.

Clinicopathologic Correlations in Joubert Syndrome

Given the knowledge of some of the brain anomalies and behavioral deficits in Joubert syndrome, we can begin to explain the neuroanatomic underpinnings of some of the abnormal behaviors associated with Joubert syndrome. The most obvious behavioral correlate for the cerebellar malformations in Joubert syndrome would be clumsiness (ataxia), since the cerebellum is critical for mediating the ability to maintain posture and movement. However, hypotonia is also observed in individuals with Joubert syndrome and the cerebellar malformations in Joubert syndrome could explain the hypotonia; however, it also might be explained by cerebral cortical malformations. The cognitive difficulty, ranging from mild to severe mental retardation, that is present in Joubert syndrome, could be explained by the cerebellar malformations given the role of the cerebellum in motor learning and the more newly evolving research demonstrating the importance of the cerebellum in cognition. Alternatively, the cognitive difficulty also might be explained by the presence of cerebral cortical abnormalities. The abnormal eye movements indicative of Joubert syndrome could result from the absence of the vermis since the anterior vermis is one of the brain structures important in eye movements; however, the extensive brain stem malformations in patients are an alternative explanation for the aberrant eye movements. That is because the tectoparapontine reticular formation pathway and the basis pontis nuclei, which are disrupted in Joubert syndrome, are important for the proper movement of the eyes. The nuclei gracilis and cuneatus in the brain stem are important structures in mediating normal breathing patterns. The irregular breathing (hyperpnea) that is found, especially in young children with Joubert syndrome, may be the result of malformations in these nuclei. Lastly, one other major behavioral manifestation that occurs in individuals with Joubert syndrome is mirror movements. The corticospinal fibers that normally decussate in the medulla are one of the main neuroanatomical substrates responsible for producing alternating movement of the arms and legs. Since the corticospinal tract fails to properly decussate in Joubert syndrome, this lack of midline crossing may be responsible for the mirror movements. However, higher cortical functioning also is important in mediating alternating motor behavior, so cerebral cortical involvement also has to be considered. Overall, the neuroanatomical abnormalities associated with Joubert syndrome can explain the behavioral manifestations present in this disorder.

Joubert Syndrome Is a Clinically Heterogeneous Syndrome

It is now becoming increasingly clear that certain clinical and neuropathological characteristics of Joubert syndrome can be observed in subclasses of Joubert syndrome in addition to other disorders that also involve the cerebellum and brain stem. As mentioned earlier, classic Joubert syndrome is characterized by mainly the molar tooth sign and varying degrees of cerebellar vermis hypoplasia/aplasia. In addition, there are at least three distinct subclasses of classic Joubert syndrome that include the hindbrain malformations and either (1) retinal dystrophy, (2) polymicrogyria, or (3) renal dysfunction (all discussed in the next section). These multiple subclasses of Joubert syndrome demonstrate that this syndrome is clinically heterogeneous.

However, the molar tooth sign is not only found in Joubert syndrome. It can also be observed in patients with COACH syndrome (Cerebellar vermis hypoplasia/aplasia, Oligophrenia (type of congenital mental retardation), Ataxia, ocular Coloboma, and Hepatic fibrosis); Dekaban–Arima syndrome (agenesis of the cerebellar vermis, ocular abnormalities (Leber

congenital amaurosis and colobomas), renal cysts, and liver disease); Malta syndrome (cerebellar vermis abnormalities, hydrocephalus, encephalocele (protusion of the brain through a fissure in the skull), Leber congenital amaurosis, and renal cysts); Senior–Loken syndrome (cerebellar vermis hypoplasia/aplasia, Leber congenital amaurosis, and nephronophthisis); and Varadi–Papp syndrome (or orofaciodigital syndrome VI: disorder comprised of cerebellar vermis abnormalities, psychomotor retardation, polydactyly, and cleft lip/palate). Whether these syndromes should be considered as additional subclasses of Joubert syndrome remains to be determined. However, as researchers continue to search for genes that can cause these disorders, defining the clinical and neuropathological sequelae in individuals with these various syndromes will be critically important so as to be confident in the pooling of various individuals for genetic mapping studies.

The Genetics of Joubert Syndrome: A Genetically Heterogeneous Syndrome

Genetic research has demonstrated that Joubert syndrome is genetically heterogeneous. The early studies of Joubert syndrome defined the mode of inheritance for this disorder as autosomal recessive. The incidence of Joubert syndrome is not definitively known, but best estimates range from 1:50 000 to 100 000 births. Most of the genetic research that aimed at identifying causative genes for Joubert syndrome utilized linkage analysis and positional cloning. These studies relied mostly on homozygosity mapping in consanguineous families (where first and second cousins produce offspring). The use of consanguineous pedigrees greatly increases the power of homozygosity mapping. Homozygosity mapping is based on the fact that recessive diseases, such as Joubert syndrome, require two mutant copies of a gene (allele) for the disease to become manifest. Because of linkage disequilibrium, genetic regions surrounding a disease locus will be homozygous in individuals with the disease. By identifying genomic regions that are homozygous in individuals with disease, one can begin to locate regions of the genome that may contain a mutated, causative gene for the disease.

The JBTS1 Locus

The first genetic loci that was linked to Joubert syndrome was identified on chromosome 9q34.3 in 1999 and is now referred to as JBTS1. The JBTS1 locus appears to correspond to classic Joubert syndrome involving the pure CNS phenotype of cerebellum and brain stem malformations. To date, no causative gene has been identified for this locus.

The JBTS2 Locus

The second genetic locus for Joubert syndrome (JBTS2) was found in 2003 on chromosome 11p12-q13.3. Individuals with Joubert syndrome that are linked to the JBTS2 locus have the characteristic brain features of classic Joubert syndrome, but also have renal, liver, and retinal involvement. No gene has yet been found for the JBTS2 locus.

The JBTS3 Locus

In 2004, the third locus for Joubert syndrome was identified on chromosome 6q23 and was called JBTS3. JBTS3 appears to represent classic Joubert syndrome with cerebellum and brain stem abnormalities is sometimes associated with cerebral cortical malformations, most commonly polymicrogyria. Reports of kidney disease (nephronophthisis) and retinal dystrophy have also been noted. In the JBTS3 loci, mutations were identified in the *Abelson helper integration site 1* gene (*AHI1*) in individuals with Joubert syndrome. Based on sequence analysis, AHI1 appears to be a cytoplasmic phosphoprotein with multiple protein-binding domains including an N-terminal coiled-coil domain, WD40 repeats, and a C-terminal SH3 domain. To date, mutations have been identified throughout the *AHI1* gene including the WD40 repeats and the SH3 domain; however, no mutations have been identified in the coiled-coil domain. Remarkably, even though these mutations occur in very different regions of *AHI1*, there do not appear to be any obvious genotype–phenotype relationships.

Human *AHI1* mRNA is highly expressed in the developing fetal brain and kidney. In adult human brain, *AHI1* mRNA is highly expressed in cerebellum and cerebral cortex, with weaker expression in the putamen. Murine *Ahi1* mRNA is found in the developing embryo as early as embryonic day 10.5 (E10.5) and continuing into adulthood; however, the expression level decreases significantly following the first week after birth. Mouse *Ahi1* mRNA expression is most pronounced in the developing and mature hindbrain and spinal cord (**Figures 2(a)–2(f)**). *Ahi1* expression is found in the cerebellar primordium at E12.5 to E16.5, peaking around E14.5 (**Figures 2(a) and 2(a′)**). The deep cerebellar nuclei, especially the dentate nuclei, have particularly high levels of *Ahi1* expression with the cerebellar hemispheres having proportionately weaker expression (**Figures 2(f) and 2(f′)**). The *Ahi1* expression patterns in the cerebellum remarkably parallel the cerebellar malformations seen in individuals with Joubert syndrome, specifically the severe abnormalities of the midline structures (cerebellar vermis and deep cerebellar nuclei). The

Figure 2 Continued.

low-level expression of *Ahi1* in the cerebellar hemispheres also parallels the Joubert syndrome pathology since the cerebellar hemispheres are largely spared. These developmental expression patterns suggest that *Ahi1* may be an important mediator in the patterning of the cerebellum, particularly the cerebellar vermis.

The cell bodies giving rise to the axonal tracts that fail to decussate at the midline in Joubert syndrome express *Ahi1* mRNA. Specifically, *Ahi1* mRNA expression is found in the layer V cell bodies of the cerebral cortex that give rise to the corticospinal tract (**Figures 2(e) and 2(e′)**). In Joubert syndrome, it is the corticospinal tract that fails to decussate and cross the midline in the medullary pyramids. In addition, *Ahi1* expression is also found in the cell bodies of the dentate nucleus of the cerebellum (**Figures 2(f) and 2(f′)**). These are the cells that give rise to the superior cerebellar peduncles whose axons fail to cross the midline in Joubert syndrome. Overall, these results suggest that *Ahi1* may be a critical cell autonomous modulator of axonal decussation, given its expression in the neurons which give rise to midline crossing, and since human *AHI1* mutations result in a lack of decussation in Joubert syndrome.

Expression of *Ahi1* mRNA also is observed in many other brain structures not always associated with Joubert syndrome, such as the hippocampus, basal ganglia, hypothalamus, and thalamus (**Figures 2(a)–2(f)**). Assuming that the human expression pattern parallels the mouse descriptions of *Ahi1* expression, it is then plausible that some of the behavioral features of Joubert syndrome might be mediated by structures that are not usually malformed in patients.

Another potential glimpse into the role of *AHI1* in brain development comes from work suggesting that *AHI1* may have been a target of evolutionary selection. Differences in the structure of the nervous system rely heavily on genes that control its development. Evolution allows for changes in such genes that specify the nervous system resulting in mutations occurring in genes that can alter the structure of the nervous system in either an advantageous or disadvantageous manner. Advantageous mutations presumably would result in a better functioning nervous system whereas disadvantageous mutations might result in poorer functioning nervous system. It is through the accumulation of these advantageous mutations in developmental control genes that our nervous systems have attained their current level of higher-order functioning. The *AHI1* gene is one such developmental control gene that has changed through evolution and may be involved in the evolution of human higher-order functioning, although there are many other genes that are also involved.

Comparisons of primate *AHI1* and rodent *Ahi1* resulted in the observation that whereas the primate protein contained a 140-amino acid N-terminal coiled-coil domain, the mouse protein was lacking this functional domain. Moreover, there does not appear to be a homologous protein similar to AHI1 in lower species such as *Caenorhabditis elegans* or *Drosophila*. As a whole, this analysis suggested that the N-terminal coiled-coil domain might be particularly dynamic evolutionarily.

Further analyses in which *AHI1* was sequenced and compared in various nonhuman primates and humans suggested that the full-length *AHI1* gene was under positive evolutionary selection in humans, with the 5′-half of the *AHI1* gene, which includes the coiled-coil domain, giving an evolutionary signature that was particularly suggestive of positive evolutionary selection along the human lineage. Positive evolutionary selection is when natural selection favors a single mutation and therefore continuously propagates this mutation in a species, presumably because it is adaptive. Overall, these studies suggest that given the aberrant axonal patterns and associated motor abnormalities in individuals with Joubert syndrome, combined with the molecular evolutionary pattern of selection, *AHI1* may be involved in some aspect of the evolution of the distinctive motor programs that characterize humans.

Figure 2 Spatial expression of murine *Ahi1* during brain development and postnatal development. *In situ* hybridizations for *Ahi1* mRNA in sagittal sections of mouse brain at E14.5 (a), E16.5 (b), P0 (c), P6 (d), and P21 (e). *Ahi1* mRNA is widely expressed throughout the entire brain with the greatest level of expression occurring in the hindbrain. Weaker expression also occurs in the developing cerebellar primordium (E12.5–E16.5) with the highest expression occurring at E14.5. *Ahi1* expression is also present in the olfactory bulb, hippocampus (dentate gyrus, CA1–3), neocortex, basal ganglia, and spinal cord. (f) *Ahi1* mRNA expression in sequential sections through the cerebellum of a P6 mouse brain demonstrating the relative weak expression of this gene in the cerebellar hemispheres following embryogenesis. However, *Ahi1* expression is high in the cerebellar dentate nuclei, the output nucleus of the cerebellum that forms the superior cerebellar peduncle (f, f′), and the deep layer cortical neurons (layer 5) that form the corticospinal tract (b–e, e′). Scale bar 6 = 1 mm (a–e), 500 μm (f), and 100 μm (a′, e′, and f′). The JBTS4 Locus

Since individuals with Joubert syndrome can also have nephronophthisis, mutational analysis was performed on one of the major nephronophthisis genes, *nephrocystin 1* (*NPHP1*), on chromosome 2q13. Homozygous deletions of *NPHP1* were identified in individuals with a mild form of Joubert syndrome with nephronophthisis. However, this deletion mutation in *NPHP1* is considered a relatively rare occurrence, but demonstrates the potential for the co-expression of both Joubert syndrome and nephronophthisis having a singular genetic cause. NPHP1 has been localized close to cell–cell junctions and can form complexes with proteins involved in focal adhesion formation and adherens junctions suggesting possible roles in cell proliferation and cell signaling. It will be important to establish the role of *NPHP1* in brain development, particularly in hindbrain development, and to determine whether there is an interaction between *AHI1* and *NPHP1*.

The JBTS5/6 Locus

Most recently, a new genetic locus for Joubert syndrome was identified on chromosome 12q21.32–12q21.33 called JBTS5/6. Individuals with Joubert syndrome that demonstrate linkage to JBTS5/6 have the brain phenotype consistent with classic Joubert syndrome, but also have severe retinal and renal abnormalities. Mutational analysis revealed multiple mutations in the *CEP290* gene encoding the centrosomal protein of 290kD. The *CEP290* gene is also called *NPHP6*. The CEP290 protein is composed of 13 putative coiled-coil domains, a region of homology to SMC (structural maintenance of chromosome) chromosome segregation ATPases, a bipartite nuclear localization signal, six RepA/Rep+ protein KID motifs (involved in chromosome segregation and cell cycle regulation), three tropomyosin homology domains (possible interactions with actin filaments), and an ATP/GTP binding site motif A with a P-loop (possibly involved in active transport).

Murine *Cep290* mRNA is expressed as early as E7 and persists into adulthood. Expression of *Cep290* mRNA appears to be widely expressed in the body, but is most prominent in the kidney and brain, particularly in the retina and hindbrain. *Cep290* mRNA *in situ* hybridization studies on the developing cerebellum demonstrates expression in both the external and internal granule cells. Since the external granule cells are one of the main proliferative cell types in the cerebellum, this suggests a role for *Cep290* in cerebellar neurogenesis. In further support of this role, *Cep290* mRNA is also present in the dividing cells of the telencephalon. Since the internal granule cell layer is one of the final resting places for cells that have migrated from the external granule cell layer, expression of *Cep290* mRNA in the internal granule cell layer might suggest a role of *Cep290* in granule cell migration.

As the name of the *CEP290* gene implies, it encodes a centrosomal protein. Experimental evidence suggests that *CEP290* is localized to the area surrounding the centrioles and colocalized with the centrosomal protein, γ-tubulin, all consistent with its presumptive role in centrosome function. Moreover, CEP290 localization to centrosomes is not only dynamic during the cell cycle, given that it redistributes to the cytosol in prometaphase, but its localization also appears to occur independently of microtubules and dyneins. These results suggest that CEP290 is a component of the centrosome, and therefore has at present an undetermined role in the microtubule-organizing center of the cell and in the progression of the cell cycle.

Phylogenetic analysis of *CEP290* determined that this gene was present in both zebra fish (*Danio rerio*) and sea squirts (*Ciona intestinalis*). Knockdown of *cep290* expression in zebra fish, by injection of *cep290* antisense morphilinos into the developing zebra fish embryos, resulted in defects in retinal, cerebellar, optic cavity, and renal (cyst formation) development. These abnormalities were noted to be reminiscent of the malformations occurring in humans with *CEP290* mutations.

Joubert Syndrome: A Disease of Primary Cilia (Ciliopathy)?

Given the clinical and anatomical overlap between Joubert syndrome and other related diseases, and the identification of common genes that can cause these disorders, it is becoming increasingly clear that cilia may be important in brain and renal development. The role of cilia in the development and functioning of the kidney has been appreciated for some time given the involvement of multiple genes, which localize to the cilia, in nephronophthisis and polycystic kidney disease. However, only until recently have studies begun to address the role of cilia in the brain.

Cilia are organelles that are extensions of the plasma membrane of cells. They are approximately 5–10 μm in length. The microtubule-organizing center, called the basal body in cilia, is located at the base of the cilia. These basal bodies are composed of centrioles. Some cilia constantly beat (motile cilia) and others that do not beat are thought to act as sensors (nonmotile cilia). Nonmotile cilia are the predominant form in the CNS. Cilia have an outer membrane surrounding a core called the axoneme. The axoneme contains nine pairs of microtubule doublets. Motile cilia have this

configuration of the axoneme, but also contain two additional microtubule singlets attached to the outer microtubule doublets (referred to as the 9+2 structure). Nonmotile cells, such as neural cells, just have the nine pairs of microtubule doublets with no singlets (referred to as the 9+0 structure). This 9+0 cilia structure is found in the outer segment of the rod photoreceptor in the eye, in the terminal fibers containing the odorant receptors in olfactory neurons, and in the Purkinje cells and granule cells of the cerebellum. Motile cilia have been observed in the brain, particularly along the ependymal surface of the lateral ventricles where these beating cilia are required for normal cerebrospinal fluid flow through the ventricles, for controlling gradients of guidance molecules in the cerebrospinal fluid, and for directional migration of neural cells. Based on this information, it is apparent that cilia have important roles in the development and functioning of the brain.

One of the proteins known to cause both nephronophthisis and Joubert syndrome, NPHP1, has been shown to localize to primary cilia, particularly in the basal bodies, in renal epithelial cells. Likewise, CEP290 is also localized to the base of the cilia. However, morpholino antisense knockdown of *cep290* expression in zebra fish did not produce any observable changes in either cilia length or cilia motility in the pronephroi of zebra fish. This suggests that *cep290* may not have a critical structural or mechanical role in cilia function, but may have an important role in the signaling of the cilia. Whether AHI1 is localized to the basal bodies of the cilia remains to be determined. In fact, all of the Joubert genes identified to date, *AHI1*, *NPHP1*, and *CEP290*, appear to be cytoplasmic proteins and not membrane-spanning proteins, further suggesting that these genes may be involved in the signal transduction events that occur following membrane receptor activation. In fact, the sonic hedgehog and Wnt signaling pathways have been implicated in the formation and functioning of cilia leading to critical roles in the patterning of the body plan in vertebrates. Future studies are needed which specifically examine whether any of the Joubert syndrome genes have important roles in the development of the CNS and kidney through a role in primary cilia function.

Kainate Receptor Functions

J Lerma, Instituto de Neurociencias de Alicante Consejo Superior de Investigaciones Científicas-Universidad Miguel Hernandez, San Juan de Alicante, Spain

© 2009 Elsevier Ltd. All rights reserved.

After finding specific kainate receptors (KARs) in central neurons, physiologists suffered many problems trying to elucidate the role of these receptors in the nervous system, principally due to the lack of pharmacological tools to activate or antagonize KARs. Indeed, many of the pharmacological agonists and antagonists that activate KARs also interact with α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPARs). This lack of pharmacological specificity has hindered our understanding of KAR function for several years. Thus, the discovery that 2,3-benzodiazepines, and particularly GYKI 53655 (LY300168 or the active isomer LY303070), antagonize AMPARs but not KARs represented a significant breakthrough in the field. More recently, other compounds that specifically act on KAR subunits have been developed and mice deficient for KAR subunits have been generated, paving the way for the study of the synaptic physiology of KARs. As a result, KARs have been seen to play a role in synaptic transmission, influencing both neuronal excitability and information transfer in the brain. An interesting characteristic of KARs that has emerged is that they use two forms of signaling: a canonical pathway that involves ion flow and another, more unexpected noncanonical signaling pathway that links KAR activation to G-proteins and second-messenger cascades.

Elementary Properties of Kainate Receptor Channels

KARs are nonselective cation channels. Therefore, the single-channel conductance of some KAR assemblies has been determined. According to stationary noise analysis, the single-channel conductance of KARs lies in the picosiemen range with values of 2.9 and 5.4 for homomeric glutamate receptor (GluR)5(Q) or GluR6(Q), respectively. A more detailed study of channel openings revealed three subconductance levels that are approximately two or three times the size of the smallest current. Like AMPARs, the replacement of Q by R in the channel domain as the result of RNA editing reduces the single-channel conductance of KARs by more than one order of magnitude. Furthermore, the conductance is also altered by heteromerization. For instance, the elementary conductance of GluR5(R) channels is less than 200 fS, but it increases to 950 fS on co-assembly with KA2. Similarly, GluR6(R) homomers have a single-channel conductance between 230 and 260 fS, whereas the value for GluR6(R)/KA2 heteromers lies between 570 and 700 fS. The effect of KA2 on the conductance of unedited homomeric receptors is more subtle, with increases to 4.5 and 7.1 pS, for GluR5 and GluR6, respectively. Interestingly, native receptors display similar values, a conductance of 2–4 pS having been measured in dorsal root ganglion (DRG) cells and three subconductance levels, similar to those found for GluR5(Q) or GluR5(Q)/KA2, have been identified. These findings are in accordance with the abundant expression of GluR5 in DRG neurons. In addition, the conductance of KARs expressed in immature proliferating cerebellar granule neurons has been determined to be ~1 and ~4 pS, the channels spending most of their open time in the 4 pS state.

Desensitization of Kainate Receptor Currents

Rapid desensitization is one of the major characteristic features of KARs. The time course of current decay in the continued presence of an agonist follows a single or double exponential decay. The speed of desensitization is dependent on the receptor subtype and on the cell type being analyzed. GluR6 homomers and native hippocampal KARs have desensitization time constants of ~11–13 ms, a value similar to that found for recombinant channels in excised patches or lifted cells. However, KARs recover slowly from the desensitized state, and this recovery is dependent on the nature of the agonist. Indeed, whereas the recovery from desensitization by a pulse of kainate takes over 1 min, the receptor requires only 15 s when glutamate is the agonist. The subunit composition also affects recovery from desensitization; thus, whereas GluR5 homomeric receptors recover in about 1 min, the time constant for the recovery of GluR5/KA2 heteromers is just 12 s. These dramatic differences in the time scale of desensitization and recovery imply that the equilibrium between the two states is strongly displaced toward the inactive state. In other words, the receptors spend most of their time desensitized. This contradicts the fact that low concentrations of kainate and glutamate have a striking effect on native KARs, as seen in neurons in brain slices. There is still no clear explanation for this behavior, which is not predicted from rapid

activation and inactivation kinetics. However, it is possible that unknown proteins interact with native KARs, altering their gating properties, as seen for other receptors and channels.

Pharmacological Aspects

As already mentioned, a major difficulty in understanding KAR function has been the lack of a specific pharmacology for these receptors. For instance, kainate, albeit showing a clear preference for KARs, has a significant action on AMPARs at relatively low doses. Indeed, there is only a 5–30 times difference between the apparent affinity of these two receptors for kainate. There has also been some progress concerning selective KARs agonists. Some derivatives of willardiine have been developed as selective KAR agonists (Table 1). Among them, (*S*)-5-iodowillardiine shows a ~130-fold selectivity for KARs (median effective concentration (EC_{50}) = 140 nM). SYM 2081, the (2S-4R) diastereomer of 4-methylglutamate, displays a potency three orders of magnitude higher for KARs than for AMPARs, both in binding and in functional assays, but the selectivity of this molecule for kainate over *N*-methyl-D-aspartate receptors (NMDARs) is significantly lower. Although its pharmacological profile is incomplete, SYM 2081 does not seem to show the subunit specificity observed for ATPA and for (*S*)-5-iodowillardiine; it elicits rapidly desensitizing currents on GluR5 and GluR6 homomeric channels. Due to this property, this compound has also been used as a functional antagonist of the KARs because it efficiently desensitizes KARs at low concentrations (Table 2).

Similarly, the prototypic non-NMDAR antagonists, 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX), 6,7-dinitroquinoxaline-2,3-dione (DNQX) and 6-nitro-7-sulphamoylbenzo[f]quinoxaline-2,3-dione (NBQX), just show poor selectivity between AMPARs and KARs, although it has been shown that low concentrations of NBQX do not have any action on KARs. However, the separation of KAR-mediated responses from the AMPAR-mediated currents is possible by using 2,3-benzodiazepine GYKI 53655 (Lilly's code LY300168), which is selective for antagonizing AMPARs. Therefore, in the presence of GYKI53655, or its active isomer LY303070, CNQX could be used as a KAR antagonist (Table 2). Several other very useful compounds have been developed lately. In particular, LY382884 ((3S, 4aR, 6S, 8aR)-6-((4-carboxyphenyl) methyl-1,2,3,4,4a,5,6,7,8,8a-decahydro isoquinoline-3-carboxylic acid), seems to antagonize KARs at concentrations that do not affect AMPARs or NMDARs. Actually, LY382884 is a selective antagonist at neuronal KARs containing the GluR5 subunit (Table 2).

Table 1 Kainate receptor agonists

Compound	*Selectivity*
ATPA	GluR5-contaning; GluR6/KA2
S-5-iodowillardine	GluR5-containing; GluR6/KA2; GluR7/KA2
Kainate	All assemblies
Domoate	GluR5- and GluR6-containing.
AMPA	GluR5-containing; GluR6/KA2; GluR7/KA1
Me-Glutamate (SYM 2081)	GluR5- and GluR6-containing

AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; GluR, glutamate receptor.

Table 2 Kainate receptor antagonists

Compound	*Selectivity*	*Mechanism*
CNQX	All assemblies; more potent at AMPAR	Competitive
LY382884	GluR5-containing	Competitive
UBP296	GluR5-containing	Competitive
NS3763	Homomeric GluR5	Noncompetitive
LY377770	GluR5-containing	Competitive
Kynurenate	GluR5-containing and homomeric GluR6	Competitive
SYM2081	GluR5- and GluR6-containing	Desensitization

AMPAR, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor; CNQX, 6-cyano-7-nitroquinoxaline-2,3-dione; GluR, glutamate receptor.

Kainate Receptors Have a Fundamental Role in Controlling Synaptic Neurotransmitter Release

The discovery that GYKI 53655 (or LY303070, the active isomer) antagonizes AMPARs but not KARs paved the way for the study of the participation of KARs in synaptic responses. Nowadays, there is considerable evidence suggesting that KARs may be situated on both sides of the synapse. A considerable amount of effort has been devoted to determining the role of presynaptic KARs in controlling transmitter release, particularly in the hippocampus. In this structure, KARs are widely distributed in presynaptic buttons, and they can bidirectionally regulate the release of glutamate at the mossy fibers to CA3 synapses. The mild activation of KARs enhances the release of glutamate, whereas when they are more intensely activated glutamate release is inhibited. As such, a proportion of the high-frequency-dependent facilitation, a hallmark of the mossy fiber synapses, can be attributed to the activation of presynaptic KARs by synaptically released glutamate, as if low concentrations of exogenous kainate had been applied (Figure 1(b)). Therefore, the characteristic short-term plasticity of mossy

Figure 1 Proposed roles of kainate receptors (KARs) in synaptic transmission: (a) mossy fiber-CA3 synapses; (b) synaptic response of the mossy fibers to CA3 pyramidal cells; (c) presynaptic role; (d) postsynaptic current; (e) postsynaptic responses at the thalamo-cortical synapse. These can be isolated in the presence of APV (to block NMDA receptors) and GYKI53655 (to block AMPA receptors). In all cases, the KAR-mediated synaptic responses are much slower than those observed for AMPA receptors and usually present one-tenth their amplitude (in (d), both responses have been normalized). In (c), presynaptic KARs can enhance or inhibit glutamate release, depending of the degree of activation. The best-established example is the synapse made by mossy fibers on to CA3 pyramidal neurons, where KARs seem to be responsible of a part of the high-frequency facilitation, a characteristic of these synapses. KARs also mediate synaptic responses of Schaffer collateral to interneurons (not shown). In (e), EPSCs mediated exclusively by AMPA or KARs have been isolated by minimal stimulation. AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; EPSC, excitatory postsynaptic current; Glu, glutamate; NMDA, *N*-methyl-D-aspartate. (d) Adapted from Lerma J (2003) Roles and rules of kainate receptors in synaptic transmission. *Nature Reviews Neuroscience* 4: 481–495. (e) From Kidd FL and Isaac JT (1999) Developmental and activity-dependent regulation of kainate receptors at thalamocortical synapses. *Nature* 400: 569–573.

fiber–CA3 synapses is partly mediated by the long-lasting activation of a kainate autoreceptor. This mechanism has been shown to impose associative properties on mossy fiber long-term potentiation (LTP) because the activity in neighboring mossy fiber synapses, or even associational/commissural synapses, influences the threshold for inducing LTP. However, higher concentrations of kainate, instead of facilitating mossy fiber synaptic transmission, depress it. Interestingly, this phenomenon is reproduced by synaptic activity, such that a brief conditioning of tetanus on associational-commissural fibers enhances the mossy fiber responses, whereas prolonged tetanus depresses it. The exact mechanism involved in the presynaptic facilitation of glutamate release is unclear. One explanation for the facilitation of glutamate release is that presynaptic KARs depolarize synaptic terminals to a level at which further release is enhanced. Also, it has been claimed that a Ca^{2+}-induced Ca^{2+} release from the intracellular stores is required for this phenomenon to occur. Therefore, such a mechanism remains unclear. How the larger activation of KARs might lead to the inhibition of glutamate release in mossy fiber buttons also remains a matter of debate. It could be the case that the large depolarization of synaptic terminals inactivates

the generation of action potentials, leading to a failure in release. However, recent data show that inhibition (but not facilitation) of release by presynaptic KARs depends on a G-protein-dependent mechanism. This indicates that KARs act independent of their ion channel activity. Therefore, it is possible that the threshold for activating one or other KAR signaling pathway could determine the physiological response.

It is now widely accepted that presynaptic KARs also control the release of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). Although KAR stimulation may enhance the release of GABA at connections between the hippocampal interneurons, stimulation of these receptors inhibits GABA release at interneuron–pyramidal cell synapses. Thus, data indicate that the spillover of glutamate from adjacent terminals could activate KARs at presynaptic GABA terminals (Figure 2(b)). The specific role that the receptors controlling GABA release play in hippocampal synaptic networks remains unclear. However, the infusion of kainate *in vivo* reduces the efficiency of recurrent inhibition, producing a state of hyperexcitability that leads to the generation of recurrent epileptic spikes. Accordingly, KAR antagonists should be able to prevent and/or abolish epileptic

Figure 2 Role of kainate receptors (KARs) in neurotransmitter synaptic release: (a) CA1 pyramidal neurons receive excitatory inputs from the Schaffer collateral and inhibitory actions from interneurons; (b) illustration of an excitatory and an inhibitory synapse on a CA1 pyramidal cell dendrite; (c) a low concentration of kainate selectively reduces the GABA release, as evidenced by a reduction in the evoked IPSC, under pharmacological isolation of $GABA_A$-mediated responses; (d) glutamate could spill over to activate presynaptic KARs present in GABAergic terminals such that the IPSCs (induced by a single shocks to the stratum oriens) are reduced after a train of stimuli is applied on the Shaffer collateral pathway; (e–f) synaptically released glutamate could activate postsynaptic KARs. Synaptically released glutamate could also activate presynaptic (not shown) KARs. Although the activation of postsynaptic KARs does not induce any synaptic current ((e), +GYKI), the afterhyperpolarization current ((f), I_{AHP}) is depressed. KARs have been shown to exert all these actions by activating G-proteins. EPSC, excitatory postsynaptic current; GABA, γ-aminobutyric acid; Glu, glutamate; IPSC, inhibitory postsynaptic current. (d) Adapted from Min MY, Melyan Z, and Kullmann DM (1999) Synaptically released glutamate reduces gamma-aminobutyric acid (GABA)ergic inhibition in the hippocampus via kainate receptors, *Proceedings of the National Academy of Sciences of the United States of America* 96: 9932–9937. (f) From Lerma J (2006) Kainate receptor physiology. *Current Opinion in Pharmacology* 6: 89–97.

activity. This has indeed been demonstrated when epilepsy is induced in rats by a pilocarpine injection. In this model, KAR antagonists (e.g., LY377770, Table 2) not only abolish the established seizure activity but also prevent the development of seizures when they are applied beforehand. Therefore, these and other data indicate that the excitability of the network may be tightly controlled by the extracellular concentrations of glutamate through the transient and/or tonic activation of KARs.

One important issue that has remained a matter of intense debate over the last few years relates to the mechanism by which KARs affect release at these inhibitory synapses. There is evidence indicating that GABA release is inhibited by a G-protein- and protein kinase C (PKC)-dependent mechanism (Figure 2(b)). It is possible that the large barrage of inhibitory postsynaptic current (IPSC) received by pyramidal cells on kainate perfusion may cause some short circuiting, but it is now generally accepted that this is not sufficient to account for such inhibition. Indeed, it should be taken into account that KARs may regulate CA1 GABAergic circuits through two distinct and opposing mechanisms. Whereas the activation of somatodendritic KARs may increase the activity of GABA interneurons, presynaptic KARs may diminish inhibition. These two effects are mediated by receptor populations that are functionally, physically, and pharmacologically distinct, one of which is located in the somatodenritic and/or axonal compartments and the other at the presynaptic terminals directly inhibiting GABA release. Likewise, there is considerable data that point to a prominent role of KARs in the regulation of neuronal excitability through the modulation of the GABAergic system in a variety of brain nuclei, such as the amygdala, the neocortex, the striatum, and the cerebellum.

Kainate Receptors Mediate Part of the Postsynaptic Response at Certain Synapses

Synaptic release of glutamate can also activate postsynaptic KARs, as seen primarily in synapses established by mossy fibers on CA3 neurons. Subsequently, KAR-mediated synaptic responses were demonstrated in Schaffer collaterals–hippocampal CA1 interneurons, at the parallel fiber–Golgi cell synapses, in the basolateral amygdala, in Purkinje cells of the cerebellum, at thalamo-cortical connections on cortical interneurons (Figure 1(e)), in neocortical pyramidal neurons, and in the synapse established by cones on bipolar cells in the retina. Similarly, a synaptic component mediated by KARs has been found in the synapse between afferent sensory fibers and dorsal horn neurons in the spinal cord. With the exception of excitatory postsynaptic currents (EPSCs) in the retina, the KAR-mediated EPSCs all displayed common characteristics such as a low amplitude (approximately an order of magnitude lower than the component mediated by AMPA receptors) and a longer-lasting time course than the EPSC mediated by the AMPA receptor (Figure 1(d)).

What could be the functional significance of a small and long-lasting EPSC for neurons? Although it is not definitively determined, a slow small EPSC, such as that mediated by KARs, offers the possibility of integrating excitatory inputs over a wide time window. Thus, the relative contribution of KARs to synaptic drive could be significant. It has been calculated that KARs elicit sufficient charge transfer so as to exert a substantial impact on the activity of interneurons. Indeed, the kinetics of KAR-mediated EPSPs are sufficiently slow to allow substantial tonic depolarization even during modest presynaptic activity. Such tonic depolarization could account for the observation that single afferent inputs are very effective in driving interneuron spiking. Accordingly, KARs contribute to the ongoing ionotropic glutamatergic transmission in the hippocampus. Therefore, neurons may display unique integration properties in areas where KARs are expressed.

Why native and recombinant KARs present different kinetic properties has not been convincingly explained. However, KARs take direct part of the glutamatergic synapse because these receptors are activated by quantal release of glutamate at both mossy fibers–CA3 synapses and excitatory synapses on CA1 interneurons. In addition, there is evidence that AMPARs and KARs can be segregated at different synapses. This seems to be true at least in CA1 interneurons and at thalamo-cortical synapses, although not in individual mossy fiber synapses. These studies allowed the kinetics of elementary KAR-mediated EPSC in CA1 interneurons to be determined, revealing that they are still slower than the pure AMPAR-mediated EPSC. Therefore, there should be factors such as the dissimilar composition of the synaptic receptors or accessory proteins that may explain the difference between the response kinetics of the native and recombinant receptors studied so far.

The retina constitutes one of the systems in which KARs have been shown to display similar properties to those found in recombinant receptors, specifically at the synapse from cones to the off bipolar cells. In this system, the kinetics of the synaptic responses fits well with the activation and desensitization properties of KARs determined in recombinant systems. In these synapses, the slow kinetics of recovery from desensitization of KARs is exploited in processing the afferent signals rather than suffering the constrictions

of the faster time course of AMPARs. In the dark, a cone releases sufficient neurotransmitter to desensitize most postsynaptic KARs, leaving just a small persistent postsynaptic current. Because the postsynaptic KARs desensitize rapidly and recover from desensitization slowly, little recovery can occur during the brief hyperpolarizations that are produced in the cones by repetitive light stimuli. Therefore, the large increase in conductance that would saturate the membrane voltage if the rate of transmitter release by the cone was high is prevented. Actually, signaling between the cones and the three morphological types of off bipolar cells occurs through distinct postsynaptic receptors. Whereas two cell types use KARs with distinct properties, the other type uses AMPARs. Each receptor recovers from desensitization with a particular time course, and this property contributes to determining the temporal characteristics of synaptic transmission in the retina (Figure 3).

Recent studies have demonstrated that KARs are also involved in long-term synaptic plasticity (LTP). Indeed, mossy fiber LTP may be prevented by the GluR5 antagonist LY382884. This antagonist, however, is ineffective for preventing LTP induced by tetanic stimulation of associational/commissural fibers in the CA3 region or at CA1 synapses. Therefore, a role for KARs in the induction of LTP seems to be specific for the mossy fiber pathway, although pharmacological data are at odds with results obtained from knockout mice. The use of KAR subunit-deficient mice confirmed that KARs play a critical role in mossy fiber LTP. However, mossy fiber LTP was reduced, but not abolished, in GluR6-knockout mice, whereas GluR5-deficient mice exhibited normal LTP at these synapses. Clearly, more investigation is needed to understand the molecular mechanisms by which KARs may play a permissive role at mossy fibers to induce a permanent change in release properties. Also interesting is the fact that at thalamo-cortical synapses in the neonatal barrel cortex, LTP expression is associated with a reduction in the KAR-mediated component of the synaptic response. Thus, as recently confirmed, KAR-mediated synaptic transmission can undergo a form of long-term depression (LTD) that is mechanistically distinct from the LTD seen for AMPAR-mediated transmission.

Figure 3 Canonical and noncanonical signaling of kainate receptors (KARs). As ligand-gated ion channels, the activation of KARs evokes an inward current, through which they depolarize the membrane (1). However, they can also set in motion a noncanonical signaling pathway triggered by the activation of a pertussis toxin-sensitive G-protein (G). The signaling pathway involves phospholipase C (PLC), leading to the synthesis of diacylglycerol (DG) and inositol 1,4,5, triphosphate (IP3). Although IP3 could release Ca^{2+} from intracellular stores, as revealed by confocal Ca^{2+} imaging (2), DG activates protein kinase C (PKC), which in turn inhibits Ca^{2+} channels, as illustrated by the direct recording of Ca^{2+} currents (3). This pathway is also responsible for the inhibition of the Ca^{2+}-dependent K^+ current, accounting for the hyperpolarization of the membrane after repetitive firing (afterhyperpolarization). These effects of kainate do not seem to require ion channel receptor activity, providing evidence for the existence of a metabotropic KAR that inhibits Ca^{2+} and K^+ channels. Adapted from Rozas JL, Paternain AV, and Lerma J (2003) Noncanonical signaling by ionotropic kainate receptors. *Neuron* 39: 543–553.

Dual Signaling of Kainate Receptors

It was recently demonstrated that KARs and other ionotropic glutamate receptors may transmit signals both through ion flux and by receptor coupling to G-proteins, which in turn may regulate voltage-dependent Ca^{2+} channels (Figure 3). This was initially described in the hippocampus, and it was later confirmed in other tissues. Indeed, activation of KARs in cultured DRG cells, which almost exclusively express GluR5 and KA2 KAR subunits, induces the release of Ca^{2+} from intracellular stores in a G-protein-dependent manner (Figure 3). Interestingly, the concomitant activation of PKC inhibited voltage-dependent N-type calcium channels. This noncanonical signaling is independent of ion channel activity and provides insights into the dual signaling of KARs because both pathways depend on a common ionotropic subunit, GluR5. But the way in which an ion channel becomes coupled to a G-protein is still unclear, although it seems likely that intermediate or linker proteins may assist in the process. Unfortunately, none of the proteins that interacts with KARs identified to date seem to carry out this role, and thus, these intermediate elements remain to be identified. In addition, this property does not seem to be restricted to a given KAR subunit. Postsynaptic KARs can also inhibit hyperpolarizing currents through similar signaling mechanisms (Figure 2(f)), and this seems to involve KA2 subunits rather than GluR6 or GluR5 subunits. There is compelling evidence indicating that synaptically released glutamate could activate postosynaptic KARs in CA1 and CA3 pyramidal neurons that do not involve the generation of inward currents. Rather, these receptors reduce the typical afterhyperpolarization current seen after cell firing (I_{AHP}). Inhibition of after hyperpolarization has a great impact on the neuron excitability, such that the response to a given input is drastically altered. Afterhyperpolarization is induced by the activation of Ca^{2+}-dependent K^+ channels, curtailing repetitive firing. The reduction of such a current causes the neuron to generate large burst of spikes, largely increasing the neuronal output. Together with the inhibition of GABA release, this represents an example in which KARs may exert a striking effect on neuronal excitability by a noncanonical signaling. Therefore, temporal integration of neuronal inputs may be modulated by KARs not acting as ion channels, just by attenuating hyperpolarizing conductances such as I_{AHP} and GABA receptor-mediated current. Although exogenous kainate could facilitate or inhibit transmitter release, depending on the concentration and type of synapse, cumulative data indicate that the rule is that the inhibitory activity of KARs is linked to this noncanonical signaling. However, the variety of signals activated by these metabotropic KARs indicates a certain lack of predictability in the coupling of KARs to G-proteins. Hence, much work remains to be done to clarify when KARs may work through classical or noncanonical signaling pathways. Although not without their problems, the availability of specific drugs as well as of knockout mice for each of the KAR subunits allows us to clarify which subunit participates in specific KAR-mediated responses.

Involvement of Kainate Receptors in Neuropathology

The implications of KARs for nervous system pathology is being underscored but not without uncertainties. For instance, a contribution of KARs to pain is supported by pharmacological data because the GluR5-selective antagonist LY293558 has demonstrated preclinical and clinical efficacy in models of pain. Indeed, GluR5 subunits are essential for KAR-mediated responses in DRG neurons and for presynaptic regulation of transmitter release in the spinal dorsal horn. However, nociceptive thresholds are largely unaffected in GluR5- and GluR6-deficient mice. Only one report found decreased response to capsaicin and formalin in GluR5-deficient mice. Such a profile raises the possibility that KAR antagonists could be effective for the treatment of certain forms of pain and acute migraine. Similarly, excitotoxicity is triggered by the enhanced activation of GluRs. Although kainate was demonstrated to be a neurotoxin long ago, there is no compelling evidence for a direct role of KARs in this process. The most sensitive area in the brain to kainate-induced excitotoxicity is the hippocampal CA3, a region rich in high-affinity KARs. However, in GluR6-knockout mice, kainate-induced CA3 toxicity is attenuated but not eliminated. Recently, KARs activation has been linked to the activation of c-jun N-terminal kinase 3 (JNK) and mixed lineage kinase 3 (MLK3) that seem to link GluR6-containing KARs to the cell death pathway activated after ischemic insults.

The best-established brain disorder in which KARs are implicated is the excitatory imbalance linked to epilepsy. Certainly, kainate injections have provided an animal model for studying human temporal lobe epilepsy. The inhibition of GABA release leading to recurrent epileptic activity may account for the acute epileptogenic effect of kainate. Recently, it has been observed that the synaptic response mediated by KARs provides a substantial component of the excitatory transmission at functional aberrant synapses formed by sprouting of glutamatergic fibers, a hallmark of human temporal lobe epilepsy. Thus, these

results raise the possibility of designing antiepileptic therapies based on KAR antagonists.

A number of studies have examined the link between the expression of KARs genes and/or single-nucleotide polymorphisms (SNPs) to disorders with a genetic background with disparate results. No strong associations have been found between the expression of genes coding for KAR subunits (GluR6 and GluR7 (*GRIK2* and *GRIK3* in human nomenclature)) and obsessive–compulsive disorder patients. Only *GRIK2* SNP I867 was transmitted less readily than expected. Interestingly, this variant has also been associated with autism. An allele of the GluR6 gene is associated with the early age of onset of Huntington's disease; GluR6-mediated excitotoxicity has been implicated in the pathogenesis of Huntington's disease. Allelic variants of *GRIK1* (GluR5), but not *GRIK2* (GluR6), appear to contribute a major genetic determinant to the pathogenesis of juvenile absence epilepsy and related phenotypes. Interestingly, the GluR5 gene is located at chromosame 21q22.1, and physical mapping situates it near the familial amyotrophic lateral sclerosis APP and SOD1 regions, making it a possible candidate for familial amyotrophic lateral sclerosis and other diseases. Whether GluR5 influences the phenotypes associated with partial trisomy or monosomy of chromosome 21 remains to be determined. Other recent results have indicated that there is a disequilibrium of *GRIK2* (GluR6) transmission in autism and schizophrenia. However, no linkage has been established with GluR5 (*GRIK1*) SNPs and their haplotypes in schizophrenia. Whether the described SNPs may impact the function and/or trafficking of KARs is yet to be determined. Therefore, a definitive role of KARs in these disorders is possible but not demonstrated.

Kainate Receptors: Molecular and Cell Biology

J Lerma, Instituto de Neurociencias de Alicante Consejo Superior de Investigaciones Científicas – Universidad Miguel Hernandez, San Juan de Alicante, Spain

© 2009 Elsevier Ltd. All rights reserved.

It is now well established that there are three types of ionotropic glutamate receptors (GluRs), whose nomenclature reflects their preferred ligands: AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid) receptors, NMDA (*N*-methyl-D-aspartate) receptors, and kainate receptors (KARs). The cloning of many GluRs at the beginning of the 1990s and the discovery of their structural relationships confirmed the legitimacy of this pharmacological subdivision. Likewise, their cloning has enabled us to advance our understanding of the biophysical properties and the physiological role of each receptor subtype in the mammalian brain. Indeed, analyzing just a few of these GluR subunits emphasized that true KARs are ion channels with a stronger preference for this agonist rather than for AMPA and that they display rapidly desensitizing responses. Thus, defining the molecular biology of KAR subunits represents a real breakthrough in the study of these receptors, establishing the foundations for us to better understand their physiology.

The Diversity of Kainate Receptors

It is now accepted that all ionotropic GluRs share a conserved transmembrane topology and stoichiometry. Like the AMPA receptors (AMPARs) and NMDA receptors (NMDARs), KARs are tetrameric combinations of the GluR5, GluR6, GluR7, KA1, and KA2 subunits. Of these, GluR5/6/7 can form functional homomeric or heteromeric receptors, whereas KA1 and KA2 participate in functional receptors only when accompanied by GluR5/6/7 subunits. In the ionotropic GluRs, each monomer carries its own ligand binding site and it contributes with a specific amino acid stretch to the channel lumen. In addition to this hydrophobic sequence, each subunit has three transmembrane segments (M1, M3, and M4) arranged in such a manner that the N-terminal domain of each protein lies extracellularly and the C-terminal region lies within the cell. As in the case of AMPARs, the glutamate binding site of KARs is formed by residues that are distributed throughout the distal N-terminal domain (called S1) and the loop between M3 and M4 (called S2). Indeed, this latter segment contains specific residues that confer the receptor with high or low sensitivity to various agonists (AMPA and kainate), as well as to ions that participate in the channel gating.

According to the rules governing subunit assembly and the different arrangements that give rise to functional receptors, a wide diversity of KARs may be expressed in the brain. Of the five KAR subunits that have been cloned so far, some combinations do not render functional channels and others are not specific to kainate. For example, the GluR5 subunit forms receptors that can be activated not only by glutamate but also by kainate, domoate, and AMPA. When activated by kainate these receptor channels desensitize relatively slowly, whereas when they bind glutamate their desensitization is faster and almost complete. In contrast, GluR6 subunits form homomeric channels with fast-desensitizing kinetics when activated by either agonist. Unlike the GluR5 receptors, GluR6 homomeric channels are not sensitive to AMPA or to its derivative ((RS)-2-amino-3(3-hydroxy-5-*tert*-butylisoxazol-4-yl) propanoic acid (ATPA) (**Figure 1(b)**). Functional homomeric receptors can also be formed by GluR7 subunits, these displaying a very low affinity for glutamate and complete insensitivity to AMPA and domoate. Each of these three subunits also form heteromeric assemblies with KA1 or KA2, and the resulting heteromeric receptors present slightly different biophysical and pharmacological channel properties. Moreover, GluR5, GluR6, and GluR7 may also combine with one another to form functional receptors. The sequence alignment reveals a homology of 75–80% between GluR5, GluR6, and GluR7, whereas KA1 and KA2 present 68% of similarity. Homology, however, drops to 45% when these two subfamilies of KARs are considered. The homology of KAR subunits with AMPARs is also approximately 40%, although they are not able to form heteromeric receptors.

Kainate Receptor Subunits Are Subject to Alternative Splicing

In addition to the inherent variation in KARs, alternative splicing generates a number of different isoforms of KAR subunits (**Figure 1(a)**). Indeed, two different GluR5 variants have been found, one that contains an extra segment of 15 amino acids in the N-terminal region (GluR5-1) and another that lacks this insert (GluR5-2). Furthermore, the GluR5-2 subunit presents four different C-terminal domains. The C-terminus of the 2a variant is 49 amino acids shorter than the variant originally described (which was then renamed 2b) due to the introduction of a premature stop codon. Variant 2c contains an extra in-frame exon

Figure 1 Kainate receptor (KAR) subunits: (a) structure of subunits; (b) electrophysiological recordings of responses to different agonists of the corresponding homomeric receptors recombinantly expressed in HEK293 cells. In (a), the KAR subunits are all made of a chain of approximately 900 amino acids (~100 kDa) that spans the membrane three times (hydrophobic segments M1, M3, and M4). Thus, the N-terminal domain of the protein is extracellular and the C-terminal domain lies intracellularly. The M2 hydrophobic sequence does not cross the membrane, but it is thought to dip into the membrane forming a loop and forming the pore of the channel. Two isoforms of GluR6 subunits exist, -a and -b, differing in their C-terminal domain. The GluR5 can be found as two different variants: GluR5-1, which contains 15 extra amino acids in the N-terminal region, and GluR5-2, which lacks this insert. GluR5-2 presents three additional possibilities generated by a splice of the C-terminal domain. GluR5-2a is 49 amino acids shorter than the GluR5-2b because of the introduction of a premature stop codon. GluR5-2c contains an extra in-frame exon that makes it 29 amino acids longer than the 2b isoform. GluR7 can be present as two isoforms with different C-terminals due to a 13-amino-acid insertion (blue segment), which produces a new open reading frame and a completely different C-terminus (red segment). In contrast, no splice variants have been found for the KA1 and KA2 subunits. GluR5 and GluR6 subunits undergo mRNA editing at the M2 (Q/R site), generating a mixture of edited and nonedited subunits. GluR6 presents two additional editing sites in M1. In every case, a single receptor channel is believed to be composed of four subunits. In all KARs, the binding domain is formed by two peptide segments, S1 and S2, which are situated before the M1 (S1) and linking M3 and M4 (S2). In (b), responses of GluR6 are also shown when this subunit heteromerizes with KA2 subunits (bottom). GluR, glutamate receptor. ATPA, (RS)-2-amino-3(3-hydroxy-5-*tert*-butylisoxazol-4-yl) propanoic acid; Dom, domoic acid.

that makes it 29 amino acids longer than the 2b isoform. Finally, the last 15 amino acids of variant 2d (not shown), from Q824 onward, are completely unrelated to any other variant, and significantly this last isoform was isolated from human tissue. Two splice variants of the murine GluR6 have also been found and, again, these differ in their C-terminal domains. Furthermore, in the rats and humans two splice variants of the GluR7subunit have been discovered. In this case, the insertion of 40 nucleotides out-of-frame in the C-terminal sequence of GluR7a leads to the production of a shorter protein, GluR7b, which bears no significant homology in this region to any of the known ionotropic GluRs. In contrast, the KA1 and KA2 subunits do not seem to undergo alternative splicing. Despite the existence of this repertoire of isoforms, the role of the different KAR splice variants (e.g., in receptor trafficking) is just starting to be determined.

Some Kainate Receptor Subunits Undergo mRNA Editing

The structural repertoire of KAR subtypes is even larger because the pre-mRNA of the KAR subunits GluR5 and GluR6 can undergo editing at the so-called Q/R site of the second membrane domain (M2). As in AMPARs, the Q to R substitution in homomeric KARs assembled either from GluR5 or GluR6 decreases the permeability of the receptor to calcium. Furthermore, this substitution transforms the rectification properties of these receptors from inwardly rectifying to linear or slightly outwardly rectifying, and it reduces the unitary conductance of the channels. As in AMPARs, inward rectification arises from the blockade of the ion channel by internal polyamines, such that the presence of an arginine (R) residue not only drastically reduces calcium permeability but also abolishes ion channel block by polyamines. In addition, GluR6 alone presents two further sites in the first transmembrane domain (M1) that are susceptible to editing, where I567 and Y571 could be changed to V and C, respectively. Although the role of these M1 editing sites remains unclear, editing within the M2 domain of GluR6 KARs has recently been shown to exert a significant effect on synaptic physiology.

Kainate Receptors Are Widely Distributed throughout the Brain

Most of the studies defining the distribution of KARs in the brain come from *in situ* hybridization analysis of mRNA. KAR subunits are widely expressed throughout the nervous system, although there are a few known cell types that exclusively express a given subunit. For instance, GluR5 and KA2 are the only subunits that have been detected in the dorsal root ganglion (DRG) neurons. GluR5 transcripts are also abundant in the Purkinje cells of the cerebellum as well as in the subiculum, the piriform and cingulate cortices, and the hippocampal and cortical interneurons. On the other hand, GluR6 is the most abundant subunit in cerebellar granule cells, the striatum, the dentate gyrus, and the CA1 and CA3 regions of the hippocampus. The mRNA encoding GluR7 is expressed at low levels throughout the brain, but it is particularly prominent in the deep layers of the cerebral cortex, in the striatum, and in the inhibitory neurons of the molecular layer of the cerebellum. The KA1 subunit is present at low levels in the dentate gyrus, in the amygdala, and in the entorhinal cortex, being more abundant in the CA3 region. In contrast, KA2 mRNA can be found in virtually every part of the nervous system. Although the different KAR subunits are already present in the embryo, most of these expression patterns emerge during the early postnatal period. Thus, the amount of GluR5 mRNA peaks between P0 and P5, and it then begins to decline toward the levels found in adults by P12. Similarly, the patterns of GluR6 and KA1 expression observed within the hippocampal formation begins to change at around P0 (GluR6) and P12 (KA1).

We are still awaiting the development of specific antibodies against various KAR subunits. Although *in situ* hybridization is informative, it is not capable of revealing the subcellular distribution of a given subunit. Relatively specific antisera against the KAR subunits GluR6/7 and KA2 have been used to detect KARs, and to date, the most convincing studies have been carried out in the rat retina. In this tissue, the localization of these subunits at the synapse has been investigated by electron microscopy and the selective synaptic distribution of KARs in both plexiform layers of the retina has been observed. Whereas GluR6/7 could be found in horizontal cell processes postsynaptic to both rod spherules and cone pedicles, the KA2 subunit was found only in postsynaptic densities of the cone pedicles in the dendrites of off-bipolar cells.

Anti-GluR6/7 and less specific anti-GluR5/6/7 antibodies have also been used to study other neurons in the brain. Although the limitation of these antibodies, particularly the latter, must be taken into account when interpreting the data obtained, they appeared to map KARs to fibers and synaptic terminals, as well as to dendrites and postsynaptic membranes. Hence, it seems that KARs may be found in both pre- and postsynaptic locations. In particular, GluR5/6 and KA2 have been found on parallel fibers and GluR5/6 immunoreactivity has been identified in a large population of terminals that form axospinal and axodendritic asymmetric synapses in the monkey striatum.

Regulation of the Surface Expression of Kainate Receptors

Although more recent experiments have been directed toward understanding how KARs are targeted to specific membrane domains, the mechanisms controlling surface expression remain unclear. Retention in the endoplasmic reticulum (ER) plays a rate-limiting role in KAR trafficking. As in most GluRs, the residues important for ER retention or exit are proximal to Psd-95, Dlg, and ZO1 (PDZ) binding motifs present in the C-terminal domain. A number of proteins containing PDZ motifs have been shown to interact with KAR subunits, although most of these are promiscuous, also binding to AMPARs and, possibly,

NMDARs. These include postsynaptic density protein (PSD-)95/ synapse-associated protein (SAP-)90, CASK, glutamate receptor interacting protein (GRIP), protein interacting with C kinase 1 (PICK1), and syntenin. However, PDZ proteins such as PICK1, GRIP, and PSD-95 do not appear to play a significant role in the exit of GluR5 or GluR6 from the ER but, rather, they have been implicated in the insertion and/or maintenance of AMPARs and KARs at the synapse. Indeed, it was recently shown that the number of KARs in the membrane surface can rapidly be altered through protein–protein interactions.

These PDZ proteins appear to regulate kainate and AMPARs in a distinct manner. Disrupting the interaction with GRIP decreases synaptic responses through KARs while concomitantly increasing the AMPAR-mediated component. Similarly, interfering with the interaction of PICK1 with KARs and AMPARs depresses the KAR-mediated excitatory postsynaptic current (EPSC), leaving the current mediated by AMPARs unaltered. It is likely that the synaptic expression of KARs is tightly regulated through interactions with still unknown scaffolding proteins, as well as through proteins that influence the trafficking and targeting of KARs. For instance, the rules governing the polarized targeting of KARs to axons and dendrites remain unknown. The study of mice that fail to express different subunits has not demonstrated a link between subunit composition and the compartment to which KARs are targeted. Nevertheless, a variety of trafficking determinants in kainate receptors may promote either membrane expression or intracellular sequestration. The identification of the proteins involved (chaperones) should shed light on the mechanisms that regulate KAR signaling and function. Indeed, a recent study has identified the co-atomer protein complex I (COPI) vesicle coat as a critical mechanism for the retention of KA2 subunits in the ER, such that assembly of KA2 subunits with other KAR subunits to form heteromeric receptors reduces their association with COPI.

The Atomic Structure of Kainate Receptor Binding Domain Has Been Resolved

One of the most exciting advances in the structure–function relationships of KARs has been the achievement of high-resolution crystal structures for the ligand-binding core of some subunits. This has provided a detailed understanding of agonist recognition not only for KARs but also for other ligand-gated ion channels. Indeed, the crystal structure of the GluR5 and GluR6 KAR ligand binding cores complexed with glutamate and other agonists, such as kainate and

Figure 2 Atomic structure of glutamate-bound GluR6 and GluR5 binding domains: (a) ribbon representation of GluR6 and GluR5 crystal structures at resolution 1.65 and 2.1 Å, respectively; (b) suggested molecular architecture of glutamate ionotropic receptors. In (a), S1, S2, and loops 1 and 2 are colored blue, gold, and green, respectively. The linker shown in gray replaces the TM segments 1 and 2. The C-terminus of GluR5 appears partially disordered (discontinued line) in the crystal. The bound glutamate molecule is illustrated with ball and stick representations. The three ligand binding pocket side chains shown are conserved in all kainate receptors. Letters A through K name the different α-helical structures loops in the molecule. In (b), the architecture is composed of the crystal structures of the mGluR1 ligand-binding domain dimer (green), the GluR5 ligand-binding core dimer (S1, cyan; S2, orange), and two subunits from the KcsA potassium channel tetramer (gray). An intact glutamate receptor is believed to assemble as a dimer of dimers. GluR, glutamate receptor; mGluR, metabolic glutamate receptor. quisqualate, have been shown at a resolution of 1.65 (GluR6) and 2.1 Å (GluR5) (Figure 2(a)). As in the AMPARs and NMDARs, the structure of the KAR binding domain revealed a two-domain closed shell motif linked by β strands. Glutamate binds in a cavity that is isolated from the external solution. For example, agonist binding induces shell closure; this evokes a conformational rearrangement, leading to the opening of the channel. Interestingly, the cavity is smaller in GluR6 than in GluR5 but larger than that of the AMPAR subunit GluR2, due to the presence of unique side chains in KAR subunits. Nevertheless, the mechanism by which glutamate binds to GluR5, GluR6, and GluR2 is nearly identical. Like GluR2, the GluR6 domain associates as a dimer with many conserved interdimer contacts. Thus, an examination of the atomic structure explains why some residues are critical for GluR5-selective ligands (e.g., ATPA). Binding of these agonists to GluR6 is prevented by steric occlusion because the cavity in GluR6 is too small to accommodate the agonists that, like ATPA, bind to GluR5. In Figure 2(b), a recently suggested molecular structure for ionotropic glutamate receptors, including KARs, is presented. It seems that ionotropic GluRs are formed by the fusion of discrete segments, whose ancestors could be found as bacterial proteins. The structure has been built by taking the solved crystal structures of both the N-terminal domain of metabotropic GluRs and the agonist binding domain of KARs. So far, the structure of the GluR ion channel is unknown at the atomic resolution. However, based on the fact that the ion channel of ionotropic GluRs presents remarkable sequence homology with bacterial potassium channels, the crystal structures of a bacterial potassium channel, the KcsA potassium channel, has been incorporated as the channel domain. Although it is likely that a KAR presents a similar arrangement, much work remains to finally solve the structure of the GluR channel. It is expected that this rapidly developing area will soon provide the real structure at the atomic resolution.

Introduction

To behave adaptively under novel and changing circumstances, many animals extend and adapt their movement repertoire. Humans and other primates in particular have an extraordinary capacity for learning skilled arm and hand movements. Reaching and grasping are crucial components of the movement repertoire of all primates and the foundations of many sophisticated human skills. While these basic skills are learned early in life, changes in the motor apparatus due to growth or injury require continuously monitoring and recalibrating the neuronal control system for maintaining adequate performance. Moreover, using tools and performing sports often requires learning new reaching and grasping skills. Consider, for example, reaching with a cursor on a computer screen using a 'mouse,' grasping a small object with a forceps under a microscope, or hitting a ball with a racket. In this article, recent advances in the study of the characteristics and the neural basis of motor learning are reviewed. The focus is on learning and adaptation of reaching skills as a specific but very significant case of motor learning.

To control reaching, as for many other goal-directed movements, the central nervous system (CNS) has to map sensory input into motor output. Vision and audition provide information about the movement goal, that is, the spatial location to be reached. Vision and proprioception are used to determine the location of the hand and the arm joints configuration. The activations of shoulder and arm muscles constitute the motor output. This sensorimotor mapping involves both kinematic and dynamic transformations. Kinematics is the description of the motion of the limb joints or the motion of the limb endpoint, while dynamics is concerned with the forces acting on the limb segments and the segment masses that produce or affect those motions. The overall mapping can be decomposed into different transformations. First, proprioceptive information has to be aligned with visual information in a common reference frame. This alignment process is likely accomplished through transformation of proprioceptive information about the limb configuration into a vision-based coordinate frame and requires a direct kinematic transformation: the mapping of joint angles and muscle lengths into end-effector spatial location. Second, a motor error, formulated as a difference vector between the location of the target and the location of the hand, must be transformed into a motor plan, possibly expressed as the joint displacements necessary to zero the error and bring the hand to the target. This is an inverse kinematics transformation: from end-effector to joints. Finally, the motor plan must be mapped into muscle activations, an inverse dynamic transformation.

When learning a new reaching skill, such as moving a cursor on a computer screen by moving an object (a 'mouse') with the hand or reaching with a stick, a new kinematic mapping between the end-effector motor error and the motor plan must be acquired. For example, the motor error may be on a vertical plane (the computer screen) while the hand moves on a horizontal plane (the desk surface). In situations involving perturbations of the alignment of vision and proprioception, as when vision is distorted by prism glasses (see the section titled 'Adapting to prism glasses'), the existing kinematic mappings must be adjusted. Finally, when learning to reach while holding an object with unusual dynamic properties, a new dynamic mapping between motor plan and motor output must be acquired, or when adapting to novel dynamic behavior of the arm, the existing mapping must be modified.

Learning Kinematics

Adapting to Prism Glasses

The adaptation processes induced by a perturbation of the visual input has been investigated experimentally using prism glasses. When people wear glasses with wedge prisms in place of regular lenses, the path of light is deviated by a certain angle, and the visual field is rotated accordingly. Initially, participants are unable to reach a nearby target in front of them with their hand or to hit a more distant target by throwing a clay ball (Figure 1). For example, participants wearing prisms that bend the light path to their right, so that objects appear shifted to the left of their actual location, initially reach to the left of the target. With practice, participants progressively change the movement direction until they reach accurately in the direction of the target. When the prisms are removed, participants miss again the target by reaching to its right, a phenomenon called negative aftereffect. Within a few trials, this aftereffect disappears.

The existence of aftereffects indicates that some changes have occurred in the kinematic transformations used for controlling reaching movements in

Figure 1 Adaptation to prism glasses. In the adaptation study illustrated here, a participant wearing wedge prisms bending the light path to the left (a) initially throws a ball to the left of the target ((b), II, where the horizontal displacement of the impact points from the target are shown as a function of the trial number). With practice, the participant progressively adapts to the visual perturbation and hits the target with the same accuracy ((b), III) than before wearing the prisms ((b), I). In the first trial after the removal of the prisms, the participant misses the target by throwing to its right ((b), IV), that is, making an error in the opposite direction to the error observed in the first trial with the prisms (aftereffect). Within a few trials without the glasses, the participant hits the target accurately again ((b), V). (c) Gaze and throw directions in the different phases of the experiment schematized with arrows. Adapted from Martin TA, Keating JG, Goodkin HP, Bastian AJ, and Thach WT (1996) Throwing while looking through prisms. II. Specificity and storage of multiple gaze-throw calibrations. *Brain* 119: 1199–1211, with permission from Oxford University Press.

normal conditions. The adaptation is specific to the trained arm: participants who have adapted and reach correctly with one hand while wearing the prisms do not show aftereffects when reaching with the other hand after removing the prisms. Thus, the adaptation cannot be accounted for by a shift of the mapping of the visual input to the reference frame where a motor error is encoded. Instead, the specificity of adaptation is compatible with a shift in the kinematic transformations that map proprioceptive input into a visual reference frame. This proprioceptive shift can be interpreted as a shift in the 'felt' hand location in the visual field. However, while this proprioceptive shift allows the CNS to compute the correct motor error even when the hand is not in sight, accurate reaching with the prisms requires that the kinematic mapping between motor error and motor plan be adjusted as well. In fact, the original mapping of motor errors in visual coordinates into joint displacements would generate a correct motor plan only if the physical world were shifted along the visual field. Thus, the kinematic mapping between motor error and motor plan is adjusted during adaptation to compensate for the shift of the visual field.

Learning Visuomotor Transformations

In the experiments with prism glasses, the CNS interprets a mismatch between vision and proprioception and between motor error and motor plan as an error in the implementation of the normal sensorimotor transformations used for reaching and recalibrates those transformations. However, in other conditions the CNS may interpret a visuomotor mismatch as due to the kinematic characteristic of an object or tool being manipulated. In this case, a new visuomotor transformation is learned instead of adapting the existing transformation used for normal reaching. For example, learning to reach with a computer mouse does not affect normal reaching movements, and it is possible to switch from one transformation to the other instantaneously. Visuomotor recalibration, as in the case of prism adaptation, and visuomotor skill learning, as in the case of tool-specific skills, generalize differently to untrained conditions. Generalization has been studied in experiments using novel visuomotor transformation. In these experiments, visual feedback provided by either a computer screen or a virtual reality display allowed simulating either a novel tool whose end-effector movements did not coincide with the hand movements, as in the case of a computer mouse, or a precisely controlled prismlike perceptual distortion of the movement of a person's own hand. In both cases, by training study participants in a single reaching condition, such as reaching in one direction, and testing them on multiple conditions, it was possible

Figure 2 Visuomotor rotation learning. In this experiment, participants sat facing a computer monitor at eye level and controlled a screen cursor by moving a hand-held indicator in a horizontal digitizing tablet. Participants were required to move the cursor from one central location to different peripheral targets. After practicing without any visual perturbation, participants were trained to perform the task while the direction of cursor movement relative to the hand movement on the tablet was rotated counterclockwise by 30°. Training with a single target (a), the directional error was quickly reduced with practice. When generalization to other targets was tested, the amount of adaptation resulted very small except for directions very close to the trained direction ((b), where the curves representing the percent adaptation as a function of the angular difference between trained and tested targets, bottom, are shown with different symbols for different trained targets, top). Adapted from Krakauer JW, Pine ZM, Ghilardi MF, and Ghez C (2000) Learning of visuomotor transformations for vectorial planning of reaching trajectories. *Journal of Neuroscience* 20(23): 8916–8924, Copyright (2000) by the Society for Neuroscience.

to study how the learned visuomotor transformation generalizes to untrained conditions.

When the transformation between the hand movement on a horizontal plane, recorded by a mouse or a pen on a digitizing tablet, and the movement of a cursor on a vertically mounted computer display is altered by a rotation or a shift, with practice people learn the novel visuomotor transformation (Figure 2(a)). Learning this skill does not affect the accuracy of normal reaching movements, and if only one movement condition is trained, the generalization to other untrained conditions is modest (Figure 2(b)). In contrast, when a novel visuomotor transformation is introduced in a virtual reality display, where participants initially see a virtual representation of the position in space of their fingertip matching its actual location (Figure 3(a)), learning to reach in one movement condition generalizes to other conditions (Figures 3(b) and 3(c)). Moreover, immediately after the removal of the visual perturbation, normal reaching is affected and aftereffects are observed. Thus, the perception of the coincidence of the source of visual feedback and the end effector may be a crucial element in determining whether motor learning occurs through recalibration of an existing visuomotor mapping or by acquisition of a new mapping.

Learning Dynamics

When adapting to altered visual feedback or learning new visuomotor skills, the CNS needs to deal only with kinematic transformations. However, in many circumstances the forces necessary to generate a desired movement may change, and thus the CNS must recalibrate or acquire a new dynamic transformation that maps motor plans to muscle activations.

Adapting to Novel Inertial Forces

The dynamics of the arm change during trunk rotations. Moving the arm with respect to a rotating reference frame generates velocity-dependent inertial forces (Coriolis forces) that alter the hand trajectory generated by a given muscle activation pattern. This effect is fully compensated for when normal reaching movements are combined with active trunk rotations so that it is possible to reach accurately during whole-body turning. However, exposure to artificially generated Coriolis forces, during passive trunk rotations, causes reaching errors. The adaptation process required to compensate for these unusual inertial forces has been investigated in experiments in which participants performed reaching movements in a rotating room. If the heads of the participants are close to the rotation axis and the angular velocity is constant, participants do not perceive the effect rotation if they do not move. When a participant moves, Coriolis forces act on the whole arm without any external mechanical contact (Figure 4(a)). Initially, reaching toward a remembered location, without vision of the arm, is inaccurate (Figure 4(b)). The trajectory of the hand deviates from the straight line connecting start to target which would normally

Figure 3 Learning a local visuomotor transformation in a virtual reality environment. A three-dimensional virtual visual feedback setup ((a), constituted by a mirror, a rear projection screen, and shuttered glasses synchronized with the display for stereoscopic perception) was used in this experiment to overlay images onto the arm workspace. Participants could not see their arm but were shown a target location and their finger location as a 1 cm-edge cube. A computer-controlled discrepancy between the finger and the cube position could be introduced. After a familiarization phase, during which participants pointed to 36 different targets with continuous veridical feedback, pointing errors without visual feedback of the finger location were assessed in a preexposure phase. During the following exposure phase, participants pointed to one target only while the finger position was displaced, gradually across trials, up to 6 cm to the right of the average preexposure position, and the visual feedback of finger position was displayed only within 3 cm from the target. As a control condition, visual feedback was altered so that participants had to point to their average preexposure position to see their finger on the target. Changes in pointing due to the exposure of the visuomotor remapping were assessed in a postexposure phase by testing all targets without visual feedback. In the control condition (b), changes in pointing due to the exposure to the remapping when pointing to the target indicated by a square were not significant. In contrast, remapping of the visual feedback at one target ((c), exposure target indicated by a square) induced significant changes over the whole workspace. Adapted from Vetter P, Goodbody SJ, and Wolpert DM (1999) Evidence for an eye-centered spherical representation of the visuomotor map. *Journal of Neurophysiology* 81(2): 935–939, used with permission from the American Physiological Society.

be followed in reaching movements, and the hand does not reach the planned location. Within a few trials, accuracy increases, and the trajectories in the rotating room resemble those in a stationary environment (Figures 4(b) and 4(c)). However, the first reaching movement performed after the room rotation is terminated is inaccurate. The hand trajectory is deviated in a direction opposite to the direction of the deviation induced by Coriolis forces. Such aftereffects disappear after a few trials.

As for the experiments with prism glasses, the existence of aftereffects indicates that the dynamic transformation used for reaching movements in normal conditions is adapted during the exposure to novel velocity-dependent noncontacting forces. Since the adaptation occurs without visual or tactile feedback, proprioceptive input is sufficient to adjust the dynamic transformation. A mismatch between expected and actual signals from the muscle spindles conveys the information about an incorrect execution of the motor plan. The resulting changes in the generation of the muscle activations allow for implementing the normal motor plan, a straight hand trajectory from start to target, in the dynamically altered conditions. This dynamic mapping is specific to the arm exposed to the dynamic perturbation, as shown by

Figure 4 Adapting to novel inertial forces. (a) In this experiment, conducted in a dark room rotating counterclockwise (ω: angular velocity), Coriolis forces (F_{cor}) generated on the reaching arm (v: velocity relative to the torso; m: arm mass) are directed to the right. (b) The trajectory of the first movement to reach a visual target (extinguished at movement initiation) during rotation (10 rpm) was deviated in the direction of the Coriolis force (per-rotation, initial, average over 11 participants) and did not reach the target. However, at the 40th movement (per-rotation, final), the trajectory was not different from the trajectory in the stationary room (prerotation). The first movement after rotation (postrotation) showed mirror symmetric endpoint error and curvature to the first movement during rotation (aftereffect). (c) Summary of endpoint error and curvature before (trials 1–40), during (41–80), and after (81–120) rotation. Adapted from Dizio P and Lackner JR (1995) Motor adaptation to Coriolis force perturbations of reaching movements: Endpoint but not trajectory adaptation transfers to the nonexposed arm. *Journal of Neurophysiology* 74(4): 1787–1792, used with permission from the American Physiological Society.

the fact that the trajectory adaptation does not transfer to the other, unexposed arm.

Learning Novel Viscous Force Fields

The dynamics of the reaching arm is also altered when one is grasping an object or manipulating a tool. For objects and tools whose dynamic characteristics are well known, trajectory and endpoint accuracy of reaching while holding the object does not change with respect to reaching with the empty hand, indicating that the CNS is automatically selecting the dynamic mapping appropriate for each condition. The process of learning such tool-specific mappings has been studied experimentally by using a two-link planar robot manipulator (Figure 5(a)) that imposes novel velocity-dependent (viscous) forces on the arm (Figures 5(b) and 5(c)). In a velocity-dependent force field, as in the case of Coriolis forces, no perturbation is applied at the beginning and at the end of the movement, when the arm is stationary. In a typical experiment, participants make reaching movements while holding the end-effector of the manipulator. As for some of the visuomotor learning experiments described above, participants are first trained to move a cursor on a computer screen by moving the manipulator handle. Trajectories are approximately straight in this baseline condition. Next, a perturbing force is applied to the hand by the manipulator. This force has a magnitude proportional to the hand tangential velocity but a direction which is not always opposite to the movement direction, as is usual with viscous forces. The direction may be always perpendicular to the hand velocity (curl force field) or change as a function of the movement direction. When first exposed to the force field, participants make large errors. Without visual feedback, the trajectory is skewed and deviated from a straight line (Figure 5(d)). With practice, however, the trajectories become straight again, indicating that a dynamic mapping correctly implementing the motor plan has been acquired (Figure 5(e)). Finally, when the perturbing forces are removed, participants initially produce trajectories which are mirror images of the initial trajectories after force field exposure (Figure 5(f)). With practice these aftereffects also disappear.

Comparing the adaptation to viscous force fields delivered by a robot manipulator with the adaptation to the Coriolis forces, there are a number of differences. Full adaptation to the perturbation is accomplished after a few tens of repetitions with noncontacting Coriolis forces, but it requires hundreds of movements with the robot manipulator. Moreover, after the adaptation, normal reaching in free space is impaired in the case of Coriolis forces but not with the robot. Thus, the adaptation to noncontacting Coriolis forces and the adaptation to forces applied through mechanical contact appear as different processes. The former is more directly related to an internal calibration process of the dynamic transformation used for reaching with the free arm, whereas the latter is related to the acquisition of a new mapping useful to skillfully control a novel tool.

Neural Basis of Motor Learning

Neural plasticity is the likely physiological mechanism underlying the recalibration and acquisition of the kinematic and dynamic transformations involved in the control of reaching. Plasticity may be caused by unmasking of existing connections, synaptic changes, or growth of new connections. The areas of the CNS involved in motor learning are beginning to be identified through lesion and imaging studies. These studies

Figure 5 Learning novel velocity-dependent forces. Participants made reaching movements while grasping the handle of a two-link planar robot manipulator with their arm on a horizontal plane (a). The location of the handle on the plane was displayed on a monitor placed in front of the participants. The torque motors of the manipulator could be programmed to apply forces to the handle that depended on the handle velocity ((b), handle velocity and force in *x–y* Cartesian coordinates). Different from normal viscous forces, the applied force was not aligned with the movement direction but, instead, depended on it. This fact is illustrated by the forces acting on the hand during simulated center-out reaching movements from one central location to eight peripheral targets (c). Note that forces at the beginning and at the end of the movement vanish because the velocity is null. After practicing in the null field (torque motors off), participant performed reaching movements in the force field with randomly interspersed trials in the null field (catch trials). In all conditions, a fraction of the movements were performed without visual feedback. At the beginning of the exposure to the force field ((d), average and standard deviation of hand path without visual feedback recoded during the first block of 250 trials in the force field indicated by black dots and gray areas, respectively), the hand path deviated substantially from the null field straight-line trajectory, and there were corrections at the end of the movements. With practice, paths become progressively straighter ((e), average and standard deviation of hand path without visual feedback recoded during the fourth and last block of force field trials). However, during catch trials ((f), average and standard deviation of hand path without visual feedback in the null field recoded during the last block of trials), the hand paths showed aftereffects with deviations opposite to those observed during the initial force field exposure ((d)). Adapted from Shadmehr R and Mussa-Ivaldi FA (1994) Adaptive representation of dynamics during learning of a motor task. *Journal of Neuroscience* 14(5 Pt 2): 3208–3224, used with permission from Society for Neuroscience.

suggest that motor learning depends on multiple, interconnected cortical and subcortical systems, each contributing to specific aspects and different phases of the process. Moreover, the changes in the neural representation of movement parameters in some of the areas involved in motor learning have been investigated with single cell recordings in monkeys.

CNS Structures Involved in Motor Learning

Studies of patients with lesions of the CNS and imagining studies of normal participants have identified some of the cortical and subcortical areas involved in learning the kinematic and dynamic transformations involved in goal-directed arm movements. Cerebellar dysfunctions impair adaptation of both kinematic (prism) and dynamic (force field) transformations. Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) studies have also found an increase in cerebellar activation during early phases of visuomotor rotation and force-field learning. The cerebellar involvement during early phases might be related to its role in processing the large execution errors present before adaptation

is complete. Activation of the posterior parietal cortex has been observed with PET during adaptation to prism glasses and during learning visuomotor hand–cursor rotations. A parietal activation has also been observed with fMRI during early stages of visuomotor learning. This parietal activation might be related to the remapping of the proprioceptive representation of the hand position in a visual reference frame containing the representation of hand and target position. During the learning of a force field perturbation, significant activations have been observed with PET in the dorsolateral prefrontal cortex during early learning phases and in the posterior parietal cortex, premotor cortex, and cerebellum during recall of the learned dynamic transformation.

Neural Correlates of Kinematic and Dynamic Learning in the Motor Cortex

Recordings of the activity of single cells in the premotor and primary motor cortex of macaque monkeys during reaching have shown that these cortical areas encode both kinematic and dynamic parameters. The firing rate of most cells in these areas is modulated by the movement direction, with a directional dependence well captured by a cosine function. Thus, the firing rate of each cell is maximal for some direction of movement, the preferred direction. The population vector, a simple algorithm for decoding the direction of movement from the activity of a population of neurons on the basis of the linear combination of the preferred direction of individual cells, indicates that kinematic parameters are accurately encoded by populations of cortical cells. However, the activity of many cells is also modulated by dynamic parameters, such as the force applied by the hand against a load and the orientation of the arm during reaching. It is likely that different populations of cortical neurons, in parietal and frontal cortical areas, constitute a multilayer recurrent network capable of transforming a population representation of the target and the current limb position, derived from visual and proprioceptive sensory input, into a population representation of the motor output, the appropriate muscle patterns for reaching the target.

When learning a new visuomotor mapping, such as the one required to reach with prism glasses or after a rotation of the joystick–cursor transformation, the neural representation of the mapping must also

Figure 6 Amplitude modulation of the firing rate on neurons in the motor cortex during visuomotor learning. Macaque monkeys were trained to move a manipulandum on a horizontal plane to move a cursor on a vertical monitor from one central location to eight peripheral targets. In the default visuomotor mapping, a rightward (0°) hand movement (on the horizontal plane) corresponded to a rightward cursor movement (on the vertical plane) and a forward hand movement (90°) to an upward cursor movement. Monkeys were tested with this mapping before and after learning a novel visuomotor transformation. In the learning epoch, monkeys had to reach only the 90° target, but the direction of hand movement required to reach the target was changed on each experimental session (randomly chosen between 0°, 45°, 135°, and 180°, that is, requiring a rotation of −90°,−45°, 45°, or 90° between hand and cursor movement direction with respect to the default mapping). Neural activity in the default eight-target task was compared before and after learning. (a) Raster plots and peristimulus histograms of the activity of two cells for the eight directions of movements before learning (gray ticks in the raster plots, where each row represents a trial and each tick a spike; gray lines in the peristimulus histogram, showing the sum of the spikes across trials in each time bin after alignment with the onset of the target stimulus) and after learning (black ticks and lines). In the first cell (top row of raster plots and histograms), the learned movement direction necessary to reach the 90° target was 180° (indicated by an arrow) whereas in the second cell (bottom row), it was 45°. The firing rate during the preparatory period (after stimulus onset but before movement onset) is enhanced in the learned-movement direction. (b) Changes in the population averages of normalized firing rates during the preparatory activity before (gray) and after (black) learning. The abscissa shows the angular distance between the cells' preferred direction and the learned-movement direction; the number of cells in each bin is indicated. Only cells with a preferred direction close to the learned-movement direction showed a significant change in firing rate due to learning. Reprinted by permission from Macmillan Publishers Ltd. (Paz R, Boraud T, Natan C, Bergman H, and Vaadia E (2003) Preparatory activity in motor cortex reflects learning of local visuomotor skills. *Nature Neuroscience* 6(8): 882–890), copyright (2003).

change. Single unit recordings in the motor cortex during visuomotor learning have revealed a complex pattern of changes in the neuronal activity. A large fraction of the cells show a change in the magnitude of the activity modulation during adaptation, some increasing and others decreasing. When the visuomotor rotation to be learned is local, that is, in only one direction of movement, changes in the activity modulation are observed only in a subpopulation of cells with a preferred direction near the direction of the learned movement (Figure 6). Thus, it appears that the neural representation of the visuomotor transformation is accomplished by local elements, that is, subpopulations with a specific directional tuning, which can be adjusted independently to adapt to novel mappings. Moreover, the changes in neuronal activity in motor cortex during visuomotor learning occur during movement preparation and not during movement execution. This observation suggests that these changes involve the representation

Figure 7 Rotation of the preferred direction for different types of cells in the motor cortex during force field learning. Macaque monkeys were trained to move a manipulandum on a horizontal plane to move a cursor on a vertical monitor from one central location to eight peripheral targets. As in the experiment described in Figure 6, a rightward hand movement (0°) was mapped to a rightward cursor movement and a forward (90°) hand movement to an upward cursor movement. However, in this experiment two torque motors acting on the manipulandum, during the 'force field' epoch, generated a clockwise velocity-dependent curl field, imposing a force on the hand perpendicular to the movement direction. (a) An example of the tuning curves of the movement-related activity of a 'kinematic' cell before, during, and after adaptation to the force field. The preferred direction (indicated by a red segment in the polar plot) of this cell does not change across epochs. (b) An example of a 'dynamic' cell: Its preferred direction rotates in the direction of the force perturbation during the force field epoch but returns to the initial direction in the washout epoch. (c) An example of 'memory' cell: The preferred direction rotates during the force field exposure and does not change back after the force field has been removed. Adapted from Li CS, Padoa-Schioppa C, and Bizzi E (2001) Neuronal correlates of motor performance and motor learning in the primary motor cortex of monkeys adapting to an external force field. *Neuron* 30(2): 593–607, with permission from Elsevier.

of the kinematic transformation of motor error into movement plan rather than the dynamic transformation of movement plan into muscle activations.

During learning of novel forces applied by a robot manipulator, the neuronal activity of single cells in the motor cortex during movement execution also shows a complex pattern of changes. Macaque monkeys, like humans, learn with practice to reach accurately under a viscous force field, and they show aftereffects when the perturbation is removed. Some cells show no change in magnitude of activity modulation and its directional tuning after learning the force field (**Figure 7(a)**). These cells might contribute to a kinematic representation of the motor plan. Some cells change their modulation magnitude and directional tuning only during the presence of the force field (**Figure 7(b)**). This group of cells appears to be involved in the representation of the motor output. In fact, the preferred direction of these cells rotates, similar to the muscles, in the direction of the force perturbation. Finally, other cells change their tuning during the force field but maintain this change after the perturbation is removed (**Figure 7(c)**). This group of cells might be encoding the learned novel dynamic mapping required for reaching in the force field. At the population level, this persistent change in the directional tuning after the perturbation is removed is balanced by a change in the tuning, in the opposite direction, of a fourth group of cells.

Kinship Signals in Animals

Introduction

Biologists have long been interested in the evolution of sociality and the factors promoting cooperation and competition among individuals. Social relationships mediate speciation, population dynamics, mating systems, and reproductive success, and theoretical work has focused on the advantages of helping kin (nepotism), avoiding inbreeding, and engaging in affiliative and agonistic relationships with conspecifics as a function of relatedness. WD Hamilton's seminal work on inclusive-fitness theory, arguably the most noteworthy advance in evolutionary biology since Darwin's theory of natural selection, posited that individuals could increase their genetic fitness directly by producing offspring, as well as indirectly by helping collateral kin produce their offspring. Thus behaviors which are costly to an individual can evolve if they help kin to survive and to pass on genes shared in common. Since Hamilton's work, significant advances have been made in understanding the functions of kin recognition in facilitating nepotism (a specific form of altruism in which costly behaviors directly benefit kin) and mate choice (minimizing costs of inbreeding and outbreeding). Hamilton also noted that selection would favor the evolution of mechanisms that permit accurate discrimination among kin. The discussion here will address kin recognition from both of Tinbergen's levels of analysis, including proximate explanations (the developmental, physiological, and cognitive aspects of recognition occurring within an individual's lifetime) and ultimate explanations (the phylogeny and adaptive significance of kin recognition across generations).

Kin recognition is an internal process of assessing genetic relatedness that can be inferred through kin discrimination – the observable, differential treatment of conspecifics based on cues that correlate with relatedness. The recognition process typically involves three components (Table 1): the expression of unique phenotypic cues, or labels (such as odors, plumage patterns, or vocalizations; referred to as the production component), the perception of these labels and their degree of correspondence with a recognition template (the perception component), and the action taken by the animal as a function of the perceived similarity between its template and an encountered phenotype (the action component). The particular action taken, if any, depends on the degree of relatedness between individuals and the costs or benefits of the action. Production and perception components make up the mechanism of recognition, both of which are necessary for discrimination of conspecifics. That is, the action component requires this mechanism before any differential treatment of conspecifics can occur (e.g., nepotism, inbreeding avoidance, aggression, avoidance, cooperation).

Thus recognition labels and perceptual-matching abilities provide proximate or mechanistic explanations for kin recognition. The action component provides a functional or adaptive explanation for recognition because it involves behaviors with fitness costs or benefits (such as agonism or avoidance of inbreeding). As a consequence, recognition may not lead to discrimination; likewise, a lack of discrimination does not necessarily indicate a lack of recognition ability. It is important to note that each component of recognition is subjected independently to natural selection (and perhaps sexual selection), such that if kin labels and perceptual abilities have not both evolved, differential treatment of individuals cannot be selected, regardless of how favorable it might be. For example, in species in which there is little philopatry or overlap of generations, selection may not favor the evolution of a production or perception component to identify kin, because there is little risk of mating with kin. Similarly, nepotistic behaviors might be evident in one species but not in a closely related species if those animals do not live near kin or if the costs of such favoritism are not outweighed by the inclusive-fitness benefits.

The Production Component

Any phenotypic trait that correlates reliably with relatedness can serve as a kin label. In many taxa, recognition of conspecifics is mediated through chemical cues, including insects, amphibians, mammals, fish, and, perhaps, birds. Depending on the species, recognition odors can include urine and feces, cuticular hydrocarbons, glandular secretions, or secretions from unspecialized skin cells. Odors, or other kin labels, can have multiple functions, particularly in mammals, when odors are complex mixtures of several to hundreds of compounds. Not only can odors indicate an animal's individual identity, sex, or relatedness, they can also reveal its genetic quality, its reproductive status, its age, or even its location.

Although it is widely recognized that odors can mediate kin recognition, it is still unclear how odors

Table 1 The components of kin recognition

Component	*Description*
Production component	
Phenotypic trait which reliably correlates with relatedness ('kin label')	Chemical, visual, acoustic, tactile, behavioral, spatial, or mating cues
Perception component	
Prior association	Familiar individuals recognized as kin
Phenotype matching	Cues of unfamiliar individuals are matched to a recognition template and recognized as kin if match is close
Context based	Spatial location, mating exclusivity, or cohort sharing used as contexts for recognizing individuals as kin
Recognition alleles	Alleles control production of kin label, perception of label, and resulting cooperation
Action component	
Nepotism	Costly behaviors which benefit kin
Mate choice	Avoidance of extreme inbreeding and outbreeding

convey information about genetic relatedness. Assessment of relatedness via odors may be facilitated by the major histocompatibility complex (MHC), a large group of genes involved in vertebrate immune function, which also influences odor production. These highly variable genes, some having over 100 alleles per locus, regulate recognition of self versus non-self tissues and pathogens. Because of the large number of alleles involved, the likelihood of two random conspecifics having the same MHC haplotypes is very low, but since relatives, by definition, share many genes in common, the MHC can serve as an accurate proxy of relatedness. Further, the extreme variability of the MHC likely facilitates an individual's ability to resist a broad range of rapidly evolving parasites and pathogens, and therefore could be used in mate-choice contexts, not only to reduce inbreeding but also to promote heterozygosity in offspring if adults prefer MHC-dissimilar mates. In addition to coding for glycoproteins, the MHC also influences odor production, probably through an interaction between MHC by-products and bacteria on gland surfaces (leading to unique secretions) or in gastrointestinal tracts (creating unique urine and fecal odors). Thus families share both similar MHCs and similar odors; MHC-derived odors could serve as kin labels that are learned from family members during early development (see later, discussion of perception component).

Laboratory rodents (rats and mice) can discriminate between the odors produced by highly inbred animals that are genetically identical except for a single MHC allele. They also often prefer to mate with MHC-dissimilar individuals, although the strength of this preference varies with the sex of the choosing individual and the experimental methods. Little is known about whether MHC-derived odors mediate mate choice and nepotism in free-living outbred animals, although mate preferences are influenced by the MHC in some salmonids, lizards, jumping rats, pheasants, and, perhaps, humans. Further, because diet and health status can influence MHC-based odors of inbred laboratory rodents, it is important to determine if foraging habits and parasite loads affect perception of genetic differences among odors in free-living animals as well.

Much of the research on the production component in rodent kin recognition has emphasized MHC-based odors, but recent work has identified another compound that may be involved in social recognition. In house mice, major urinary proteins (MUPs) are large, nonvolatile compounds that bind and carry the more volatile odor molecules that are traditionally thought to mediate recognition. Each male excretes urine with 10–12 different genetically encoded MUPs, and the resulting distinct odors are sufficient for individual recognition.

Production Cues from Other Modalities

Because odors can vary with genetic relatedness and provide evolutionarily reliable cues to assess kinship, most studies of kin recognition have focused on this modality. However, relatedness could potentially be assessed through other modalities, such as vocalizations or visual markers. If the production of such cues is stable across time, then young animals could become familiar with them and use them for discriminating among kin classes. Nonolfactory kin labels might be important if chemical differences were inaccurate indicators of relatedness, such as when nests of social insects contain multiple matrilines but all workers acquire similar odors from the nest material upon eclosion. Yet if cues are to accurately mediate kin recognition of previously unfamiliar kin (via phenotype matching; see later), then differences among cues must be heritable. That is, behavioral cues such as vocalizations or visual displays may differ among families, but if these behaviors are plastic (whether

during early development or throughout the life span), then they are subject to drift and may not reliably co-vary with relatedness. For example, nestling long-tailed tits learn the contact calls of their adult caretakers, many of whom are kin. These calls can serve as kin labels for recognition of familiar family members, but since calls are learned, they unlikely to mediate recognition of unfamiliar kin, such as cousins or half-siblings.

Mechanisms of Kin Recognition: Perception Component

As noted previously, the evolution of kin-biased behaviors requires the evolution of mechanisms that permit recognition of kin. Several mechanisms for kin recognition have been described, and the use of particular mechanisms varies across and within species as a function of ecological factors, demographic patterns, and life-history variables. These mechanisms are not mutually exclusive or necessarily exhaustive, and individuals might use several mechanisms, depending on their age or the recognition context. Two of the mechanisms, prior association and phenotype matching, have been the focus of most empirical research and are described in detail in the following sections.

Prior-Association Mechanism

Recognition can be based on familiarity via prior association, when animals learn the phenotypes of individuals (often during early development) and later discriminate these familiar relatives from unfamiliar animals. For instance, animals might learn the traits of their parent(s) and same-aged siblings, as well as their older or younger siblings if dispersal is delayed, and recognize these individuals later, regardless of when or where they are encountered. Learning can occur through habituation, imprinting, or associative learning, although the actual type of learning involved is usually unknown. Prior association can also mediate recognition through with a third individual, such as when siblings born in different years both interact with their parent or when a parent's behavior toward the younger offspring promotes similar behavior by the older offspring (e.g., helpers at the nest). Note that with prior association, animals can recognize familiar individuals, but unfamiliar kin such as paternal half-siblings or cousins would be identified as non-kin.

As a proxy for relatedness, prior association or familiarization can be adequate for accurate recognition of kin when relatives reliably interact in the absence of non-kin during early learning, such as at nest sites or in exclusive home ranges. If young animals are precocial and mix with non-kin shortly after hatching or birth, learning should occur rapidly, to restrict establishment of familiarity with kin only.

Parent–offspring recognition and sibling–sibling recognition are often achieved through prior association when litter, brood, or clutch size is >1 or when young remain with their natal group. This mechanism also operates when there is little selection pressure to favor discrimination among equally familiar individuals (e.g., full maternal and half-maternal siblings) or equally unfamiliar individuals (kin and non-kin), such as when animals are short-lived with little overlap of generations or when there are few opportunities for social interactions with other kin. However, prior association will lead to recognition mistakes if non-kin are encountered during the learning phase (e.g., communal nesters; parasitized nests with eggs of other females), or if close kin are not encountered until some time later (e.g., young born in different years).

Phenotype-Matching Mechanism

Through a generalization from prior association, animals can learn their own phenotypes or those of their familiar kin, store these memories in a recognition template, and later compare or match the phenotypes of unknown animals to this template. Phenotype matching requires a correlation between phenotypic and genotypic similarity so that individuals with traits that most closely match an animal's template are its closest kin; that is, kin labels must be heritable. Unlike prior association, phenotype matching permits discrimination among unfamiliar kin and non-kin. That is, unfamiliar relatives are 'recognized' as belonging to a particular kin class. This recognition occurs through generalization from recognition templates, with the degree of match between an encountered phenotype and an individual's template indicating the degree of relatedness between the two animals.

Phenotype matching is favored when animals typically encounter unfamiliar kin, because it allows discrimination among kin and non-kin without prior direct contact with them. It is expected when males mate multiply (for recognition of paternal half-siblings), when females nest communally (so females can discriminate against familiar young that are not their own), when individuals disperse as juveniles or after successful breeding (allowing them to recognize their dispersed siblings or parents that they had not previously encountered), or when there is overlap of generations, particularly in long-lived species (allowing recognition of aunts, cousins, etc.). Self-referential phenotype matching, using one's own cues as a referent for recognizing kin, should be favored in species with multiple paternity or maternity to discriminate

among full siblings and half-siblings or when individuals commonly encounter older (or younger) siblings after dispersal. It would also be favored in brood parasitism or communal nesting, when individuals encountered early in life might not be kin and thus would be poor referents. It would be especially advantageous when highly accurate estimates of relatedness are required, because an individual's own cues most reliably reflect its genotype.

Phenotype-matching abilities can be demonstrated empirically by cross-fostering young at birth or hatching and later testing their ability to recognize unfamiliar siblings (this assumes that kin cues are not learned prenatally), or by testing the ability of normally reared individuals to recognize unfamiliar kin, such as older full siblings or paternal half-siblings. A more robust demonstration of phenotype matching would involve manipulation of recognition templates with subsequent changes in patterns of social interactions.

Context-Based Recognition

Some types of discrimination are based on contextual cues rather than on cues borne by individuals. First, animals may be recognized indirectly based on spatial cues, with individuals encountered in a particular area treated as kin regardless of true relatedness (e.g., parent–offspring recognition in nests). Spatial cues may correlate reliably with relatedness, such as when females lay their eggs or give birth in a nest to which other individuals do not have access, and when communal nesting and brood parasitism do not occur. A second contextual cue that can reliably correlate with kinship is mating effort (assuming internal fertilization). Here, recognition of offspring is based on the amount of time a male had exclusive mating access to a female, as a rule-of-thumb for estimating paternal certainty, rather than based on traits of offspring. This mating-effort mechanism of discrimination will be favored if it reliably leads to increased investment in own kin (albeit not exclusive), or in avoidance of or aggression toward non-kin. A third contextual cue, referred to as 'cohort sharing,' can allow young to recognize their paternal half-siblings (and perhaps other classes of unfamiliar kin), and can allow for adults to identify likely paternal half-siblings and perhaps even to assess paternity. If breeding in a social group is seasonal and is dominated by one or a few males, then most young born into a cohort are likely to be offspring of that one male or those few males. However, if cohort sharing is to be a reliable mechanism for recognition, the timing of births must be episodic enough for distinctions between separate cohorts to be clear to all in the group.

Recognition-Allele Mechanism

Finally, recognition could be mediated by so-called recognition alleles that cause expression of a phenotypic cue, recognition of that cue in others, and preferential treatment of individuals bearing the cue. This recognition mechanism has not been the focus of much research because, conceptually, it would lead to cooperation with non-kin who also express that cue, thereby selecting against such a single-allele cue-based cooperation system (Dawkins' green-beard effect). For example, planktonic larval ascidians (*Botryllus schlosseri*) settle near and eventually fuse with kin, more than with non-kin, and these kin-biased aggregations are beneficial because colonies composed of kin grow and reproduce faster than do aggregations of distant or non-kin. Larval settlement patterns are mediated by cellular recognition, as larvae fuse with other individuals if they share a histocompatibility allele but reject those with a different allele, even if those larvae are kin. Thus in this system the expression, perception, and action components all appear to be influenced by histocompatibility alleles.

As previously discussed, the vertebrate MHC, a large and highly polymorphic set of genes involved in immune functioning, influences the production of kinship-correlated odors. In addition, olfactory-receptor genes are found in the MHC (although it is currently unknown whether these genes are functional), which suggests that the MHC could serve as recognition alleles. To date there is no evidence that the MHC also causes preferential treatment of individuals with similar MHCs, so, although the MHC influences the production of genetically distinct odors, these odors were likely co-opted for kin-recognition purposes independently.

Action Component

Once an animal assesses its degree of genetic relatedness to another individual (kin recognition), it can then interact with that individual accordingly (kin discrimination); however, as noted earlier, recognition does not always lead to differential treatment. The action component generally takes two forms: nepotism (kin favoritism) and mate choice. Nepotistic behaviors include coalitions with kin, parental care of offspring, warning kin of predators, reducing or sacrificing reproduction in favor of kin, and selective withholding of aggression against kin. Nepotism is typically seen in group-living animals, particularly among the philopatric sex, such that animals live near and frequently encounter kin.

According to kin-selection theory, nepotism results in increased reproductive success of recipients; that is,

there are fitness costs to the nepotist and fitness benefits to the receiver. Specifically, nepotism is favored when Hamilton's rule, $rb - c > 0$, is satisfied, where r is the coefficient of relationship between two individuals, b is the fitness benefit to the recipient, and c is the fitness cost to the actor. This may result in a net inclusive-fitness benefit to the nepotist, if the action helps the receiver to reproduce and pass on genes the two individuals share in common. Because the benefits to the recipient are devalued by r, nepotism is typically directed toward close kin only.

Accurate kin recognition is favored in mate-choice contexts because inbreeding depression can be a potent selective force, according to theory and the available empirical data from both captive and free-living populations. The deleterious effects of inbreeding can be minimized through a variety of processes, such as multiple mating or extra-pair matings, postcopulatory mate choice, sex-biased breeding or natal dispersal, and, importantly, kin recognition with active avoidance of kin. Kin recognition might also facilitate mating preferences to optimize gene combinations. Although there is ample evidence that relatedness influences mate choice and reproductive success in captive animals, less is known about choice in free-living animals that must make trade-offs between kinship, mate quality, and search time. It has been argued that the kin-recognition mechanisms for nepotism and mate choice are organized similarly, but for most animals it is unknown whether there are indeed commonalities in the mechanisms used.

Issues in Kin Recognition

Evolution of Recognition Components

Kin labels can evolve specifically for recognition purposes, or they can be artifacts of some other unrelated mechanism(s). For example, sexually selected traits in male birds, such as song repertoires, which are learned from male parents, might also serve as patrilineal markers. Oral- and dorsal-gland odors of Belding's ground squirrels (Figure 1) are both individually distinct and kin distinct, suggesting a generalized mechanism by which secretions reflect genetic variation among individuals as well as among kin classes. (The production of multiple, unique odors, or other cues, can facilitate accurate discrimination of conspecifics.) Although songs and odor cues probably did not evolve for recognition purposes, use of them to discriminate individuals and kin classes would provide a parsimonious mechanism for social recognition.

Kin-selection theory predicts that recognition components (production, perception, and action) will evolve with sociality, depending in part on species' social systems, the nature of interactions with kin, and costs and benefits of nepotism. For example, despite the wide range of social systems among voles in the genus *Microtus*, including group size, patterns of natal dispersal, and frequency of multiple mating, social interactions and reproductive behaviors of most species examined to date appear to be influenced by prior association rather than by relatedness (although there have been few empirical studies of their recognition abilities). Similarly, depending on the social system, kin-recognition abilities may not lead to differential treatment. Like Belding's ground squirrels, golden-mantled ground squirrels also produce kin-distinct oral odors and can discriminate among kin classes, even though this species shows no evidence of nepotistic behaviors except between mothers and their dependent young. However, these recognition abilities might be used in mate-choice contexts, to avoid mating with close kin.

Given the predominance of sex-biased dispersal among most vertebrates, some have claimed that there is no need for other inbreeding-avoidance mechanisms, such as kin recognition, yet few data are available to support this prediction. Dispersal does not

eliminate the risk of mating with half-siblings or cousins, In addition, adults may remain where they mate year after year and thus risk mating with their reproductively mature offspring which have not dispersed. Finally, if kin recognition can be used to avoid mating with, for example, cousins or half-siblings, it is parsimonious to expect that a similar mechanism is used to avoid very close inbreeding.

Model System for the Study of Recognition Components

Belding's ground squirrels are one of a few species for which all three recognition components have been investigated. In this species females are philopatric and can survive up to 12 years; the resulting kin clusters have favored the evolution of nepotism. Females with close kin (e.g., mothers, daughters, sisters) are more likely to give potentially fatal alarm calls than are females without close kin. During gestation and lactation, when females defend natal burrows against potential infanticide, they are less agonistic toward and more cooperative with close kin than are non-kin or distant kin (e.g., aunt, cousin; Figure 2). Maternal half-sisters are more agonistic than are full sisters, suggesting discrimination of equally familiar littermates that vary in relatedness. Males, which disperse as juveniles and rarely live near kin, are not nepotistic nor do they behave nepotistically. Mothers use spatial cues to discriminate among young, caring for any pup in their underground nests, until just before young leave the nest (Figure 3). After young emerge from the nest at about a month of age, spatial cues no longer reliably correlate with relatedness, because young can mix with litters in other territories. However, at this age offspring are beginning to produce unique recognition odors, and this corresponds with when mothers are able to use a prior-association mechanism for discriminating among own and unfamiliar young. Odors from both oral and dorsal glands are kin distinct, being more similar among close kin than among distant kin, which in turn are more similar than are those of non-kin (Figure 4(a)). Juveniles

Figure 2 Nepotism among adult female Belding's ground squirrels. Proportion (mean and standard deviation) of times females chased (left) or assisted in chases with (right) various kin and non-kin classes from their territory during gestation and lactation. Asterisks indicate that close kin were tolerated and cooperated with more often than were distant or non-kin. Figure 3 Proportion of young *Spermophilus beldingi* accepted by unrelated adult females in a field cross-fostering experiment. Free-living *S. beldingi* mothers readily retrieved into their natal burrow unrelated young placed at their burrow entrance, but only until their own young reached about 25 days of age, which coincides with when mothers' own young emerge aboveground from their natal burrow. Reproduced from Holmes WG and Sherman PW (1982) The ontogeny of kin recognition in two species of ground squirrels. *American Zoologist* 22: 491–517, copyright by American Society of Zoologists, 1982, with permission.

Figure 4 Tests of the production and perception components of kin recognition in Belding's ground squirrels. (a) Duration of investigation (mean second + SE) of dorsal-gland odors by 13 individuals in habituation–discrimination tasks designed to test whether odors vary with genetic relatedness. Solid bars represent investigation of the referent odor (three habituation trials) and open bars represent investigation of test odors (discrimination phase), collected from a referent's mother, maternal grandmother, half-aunt (mother's half-sister), and non-kin. Investigation of test odors increased as relatedness to the referent decreased, demonstrating that odors vary linearly with relatedness. (b, c) Duration of investigation (mean second + SE) of odors collected from unfamiliar relatives of seven individuals during preference tasks designed to determine whether the animals can spontaneously discriminate among odors of their unfamiliar kin. (b) Investigation of oral-gland odors of unfamiliar kin, collected from the individual's three-quarter sibling (offspring of two sisters mated with the same male), cousin (offspring of the individual's mother's brother), and non-kin. (c) Investigation of oral odors collected from individual's grandmother and aunt. An increase in investigation as relatedness of the odor donor to the individual decreases indicates that odors of distant kin are perceived as less familiar to individuals than are odors of close kin. Significant differences in investigation of odors from various kin classes indicate discrimination of those odors, and thus that the individual can recognize the difference between, for example, its distant kin and non-kin. Numbers inside bars are estimated coefficients of relationship between individuals and odor donors. Horizontal bars and asterisks represent significant differences in investigation of odors (*, $p < 0.05$; **, $p < 0.01$) based on repeated measures (ANOVAs or paired *t*-tests). Adapted from Mateo JM (2002) Kin-recognition abilities and nepotism as a function of sociality. *Proceedings of the Royal Society of London. Series B* 269: 721–727.

Figure 5 Mean frequencies (+ 95% CI) of (a) play and (b) nasal investigations between pairs of juveniles as a function of relatedness (three-quarter siblings are offspring of two sisters who mated with the same male). Horizontal bars and asterisks represent differences in behavior frequencies (*, $p < 0.05$; **, $p < 0.01$) based on Poisson regression analyses. Mean frequencies are adjusted statistically by the regression model for effects of sex of each juvenile in a pair and the weight difference between juveniles in each pair. Reproduced from Mateo JM (2003) Kin recognition in ground squirrels and other rodents. *Journal of Mammalogy* 84: 1163–1181, by permission of Alliance Communications Group, a division of Allen Press, Inc.; copyright by American Society of Mammalogists, 2003.

and adults can also use phenotype matching to discriminate among unfamiliar individuals based on genetic relatedness (Figures 4(b) and 4(c)). This recognition ability influences social behaviors, including nasal investigations (allowing perception of kin-distinct oral-gland odors) and play-partner preferences among juveniles (thought to influence the development of adult kin preferences; Figure 5). Discrimination among unfamiliar kin and non-kin, as evidenced by differential nasal investigation, therefore leads to preferential social interactions with kin. Both sexes are able to recognize their distant kin, indicating that the limited action component (nepotism among close female kin only) cannot be explained proximately by deficits in recognition ability. The importance of these kin recognition abilities in mate choice is currently under study.

Recognition Errors

Evolutionary theory predicts that animals will discriminate on the basis of relatedness if the benefits

outweigh the costs, such as preferential investment in own offspring. Yet in some instances adults appear to treat young indiscriminately, caring for their own young as well as so-called alien young. These parent–offspring recognition 'failures' should be explained at the ultimate level of analysis (e.g., evolutionary costs and benefits of recognition) as well as at the proximate level. That is, what recognition cues are produced and what perceptual mechanisms might be employed? There has been much theoretical and empirical interest in why cuckolded male birds invest in unrelated young, yet few studies investigate whether young birds even produce kin labels or whether males have the ability to discriminate among these labels. This recognition mechanism must evolve before preferential investment in one's own young (the action component) can be expressed. Further, if young animals benefit from kin-biased behaviors at an early age, then it follows that kin labels must develop early. For example, prairie vole mothers interact differentially with weanlings, but not with newborns, as a function of relatedness, and this result has been interpreted as a function of costs of investment in young across development. Yet a proximate explanation should be considered as well, such as whether newborns produce recognition cues.

The Meaning of 'Template'

The word 'template' is used to refer to memories of familiar kin, which are probably learned during early development. Here, a template is not thought of as a neural structure, such as face-recognition cells or song-nuclei circuits. Instead, it is typically used as a heuristic for conceptualizing recognition mechanisms, although it is still unclear how kin labels are remembered. That is, do templates consist of exemplars (specific memories of individuals' phenotypes) or prototypes (a single amalgam or gestalt of several individuals' phenotypes)? Many species can discriminate among specific kin, such as sibling A and sibling B, suggesting that templates contain some specific representation of these individuals. When an unfamiliar relative is encountered, such as a half-sibling, animals could refer to these separate representations for recognition (necessitating multiple comparisons between each representation and the stranger's phenotype), or they could use a gestalt template composed of those representations (requiring just one global comparison). Functionally, the outcome would be the same whether exemplars or prototypes are used, but these possibilities pose interesting neurobiological questions. Templates may be both exemplar based and prototype based, since some animals can both recognize individual kin (via prior association) and 'recognize' unfamiliar kin (via phenotype matching).

Neural Correlates of Perception

In most taxonomic groups, unfamiliar stimuli receive more attention than do familiar stimuli. This includes a higher frequency or duration of tactile inspection, odor investigation, or visual attention toward unfamiliar individuals or most distantly related kin, compared with familiar individuals or close kin, respectively (e.g., Figures 4(b) and 4(c)). These investigatory behaviors suggest that it takes longer to identify or recognize unfamiliar individuals, compared to familiar ones, as if additional time is needed for unknown cues to be compared or matched to templates. However, recent perceptual studies with laboratory rodents suggest otherwise, because trained animals take the same amount of time to discriminate simple odors, regardless of the similarity of the odor stimuli and thus the difficulty of the task. If these findings apply to other species, then why do animals attend to unfamiliar cues longer? It is possible that an unknown phenotype is perceived and characterized quickly (e.g., in the olfactory bulb or antennal lobe) by an animal, but it needs additional time to match it to the recognition template and accurately determine its degree of relatedness to the new individual. Familiar individuals would match the template, producing a threshold response (match or not match), whereas unfamiliar individuals would have to be evaluated against the template, with some decision algorithm used to produce a graded response according to relatedness.

Future Directions

In the four decades since Hamilton's seminal work on kin selection, most of the research on kin recognition has focused on the perception component, determining how animals use familiarity and relatedness to discriminate among conspecifics. More work is needed on the production component, determining the extent to which phenotypic traits vary with kinship and thus can potentially be used as kin labels. As labels are identified, our understanding of how they evolved would be enhanced by a quantitative assessment of the correlation between genetic similarity and cue similarity. For example, gas chromatography and mass spectrometry have revealed that beavers' (*Castor canadensis*) anal-gland secretions are more similar among kin than among non-kin, and can be used for phenotype matching; their castoreum is largely diet derived and does not co-vary with relatedness, and thus is not a reliable kin label. Finally, for a complete understanding of kin recognition, we need to determine whether discrimination and resulting kin-biased behaviors are indeed adaptive. That is, do individuals in fact increase their fitness by performing nepotistic

behaviors or by rejecting kin as mates? Evidence of a kin bias alone is insufficient to posit a function for kin-recognition abilities.

Kisspeptins and their Receptors

Introduction

Reproductive function is sustained by a complex neurohormonal system, which conforms the gonadotropic or hypothalamic–pituitary–gonadal (HPG) axis. The main hierarchical element of this axis is the hypothalamic decapeptide, gonadotropin-releasing hormone (GnRH), which is secreted by a discrete neuronal population of the forebrain (the GnRH neurons) and operates as driving signal for the pulsatile release of the pituitary gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). These are, in turn, responsible for the development and trophic maintenance of different gonadal functions, such as spermatogenesis, folliculogenesis, and ovulation. In addition, secretion of gonadal steroids and peptides is elicited by gonadotropins, thereby contributing to the dynamic regulation of this neuroendocrine axis via negative and positive feedback loops. Moreover, multiple central and peripheral regulators participate in the tuning of reproductive function, mostly acting primarily on hypothalamic GnRH neurons, which operate as integrators and a common output pathway for a wide diversity of modulatory factors. However, the mechanisms and neuronal networks projecting on to GnRH neurons and mediating such regulatory actions at different developmental and physiological conditions are far from being completely deciphered.

The KiSS-1/GPR54 System: Identification, Structural Features, and Initial Functions

The KiSS-1/GPR54 is a ligand–receptor system whose elements were sequentially identified between 1996 and 2001. First, by the use of subtractive hybridization in melanoma cell lines with different metastatic capacity, KiSS-1 was identified and originally cataloged as metastasis-suppressor gene, given that its expression was significantly attenuated in tumor cells with high invasiveness. Independently, in 1999, GPR54 was cloned in the rat as an orphan receptor with a partial sequence similarity (>40%) with the transmembrane regions of galanin receptors; the human ortholog of GPR54 was subsequently cloned and termed AXOR12 or hOT7T175. Finally, in 2001, the structural characterization of the peptide products of the KiSS-1 gene was completed. These turned out to be a family of structurally related peptides, globally termed kisspeptins, which result from the differential proteolytic processing of a common precursor. All kisspeptins were found capable of binding and activating GPR54, which was then deorphanized and cataloged as the cognate receptor of KiSS-1 peptides.

In the human, the KiSS-1 precursor is a 145-amino-acid protein, which contains a putative 19-amino-acid signal sequence, two potential dibasic cleavage sites (at amino acids 57 and 67), and one putative site for terminal cleavage and amidation (at amino acids 121–124). Its major proteolytic product appears to be a 54-amino-acid peptide, largely secreted by the placenta, termed metastin or kisspeptin-54. In addition, other peptide fragments of the KiSS-1 precursor have been identified, such as kisspeptin-14, kisspeptin-13, and kisspeptin-10. All kisspeptins share the C-terminal region of the metastin molecule, where they present an Arg-Phe-NH_2 motif distinctive of the RF-amide peptide family. The shorter 10-amino-acid fragment at the C-terminus (kisspeptin-10) retains maximal activity at the receptor level.

The biological functions initially assigned to the KiSS-1 system were restricted to its role in the control of tumor progression. Thus, the initial observations that loss of KiSS-1 expression is linked to increased invasiveness of melanoma cells were followed by a number of studies assessing the expression of KiSS-1 gene and/or the biological actions of kisspeptins in different tumors cell lines. In brief, those studies demonstrated that metastin and other kisspeptins are provided with antimetastasis activity in several tumors, and the loss of KiSS-1 gene expression was suggested as potential index for tumor progression and metastasis in different types of cancer. In any event, the actual relevance of this system in the control of cancer progression remains to be fully clarified.

In parallel to the characterization of their potential role in tumor progression, expression analyses of KiSS-1 and GPR54 genes in normal tissues from humans and rodents strongly suggested that the KiSS-1/GPR54 system is probably involved in additional biological functions. Thus, KiSS-1 gene expression was detected in human placenta, testis, small intestine, and brain, where KiSS-1 mRNA showed scattered distribution throughout the central nervous system. Similarly, GPR54 gene expression was demonstrated in a number of central and peripheral tissues, with maximal mRNA levels in the placenta, pancreas, pituitary, spinal cord, and various brain areas. Indeed, based on their patterns of distribution

in the central nervous system, it was suggested that kisspeptins and their receptor play a role in nociception, visceral regulation, and/or neuroendocrine control. Yet the functional evidence to support these assumptions was very limited, and in the case of neuroendocrine control, it was initially restricted to the demonstration of the ability of kisspeptin-10 to stimulate oxytocin release. At peripheral tissues, the observation that KiSS-1 gene expression is maximal in human placenta, together with the dramatic increase in serum metastin levels observed during pregnancy, led to the hypothesis that kisspeptins may participate in the control of key aspects of placental physiology. In this sense, kisspeptin-10 has been demonstrated to inhibit trophoblast invasion *in vitro*, although the physiological relevance of this function is still a matter of debate. Other potential peripheral functions of the KiSS-1/GPR54 system, in tissues such as the pancreas and gonads where expression of this system has been reported, remain mostly unexplored.

Distribution of KiSS-1 mRNA/Protein in the Brain

In this article, we focus on the analysis of the role of kisspeptins in the neuroendocrine control of the reproductive axis. As an introduction, it is considered relevant to provide a map of the known patterns of distribution of KiSS-1 expression (at the mRNA and peptide levels) in the central nervous system, with special attention to the hypothalamus. However, results from different studies do not totally overlap, and the mRNA and peptide data are not completely analogous.

Concerning KiSS-1 gene expression, initial analyses were conducted by means of reverse transcription polymerase chain reaction (RT-PCR) of isolated brain regions in humans. Those studies demonstrated a scattered pattern of expression, with moderate levels of KiSS-1 mRNA being detected throughout the central nervous system, including the basal ganglia and the hypothalamus. Likewise, KiSS-1 gene expression was also demonstrated in the rat brain, specifically in the hypothalamic area. These expression data have been recently refined by *in situ* hybridization analyses that demonstrated the presence of KiSS-1-expressing neurons at different sites along the rostral–caudal extent of the hypothalamus in the mouse, including the arcuate nucleus (Arc) and the anteroventral region of the periventricular nucleus (AVPV). In addition, KiSS-1 mRNA-expressing cells have been also detected in the anterodorsal preoptic nucleus, medial amygdala, and bed nucleus of the stria terminalis. In primates, expression of KiSS-1 mRNA has been also observed in the Arc.

Regarding distribution of KiSS-1 peptides, an exhaustive immunohistochemical study on the rat brain was initially reported, showing that metastin-like immunoreactivity (irMT) is widely detected throughout the central nervous system. Thus, irMT was observed in the dorsomedial hypothalamic nucleus, ventromedial nucleus, and Arc within the hypothalamus; nucleus of the solitary tract; and caudal ventrolateral medulla. In addition, fibers with different levels of intensity of irMT were detected in different areas of the telencephalon (amygdala, bed nucleus of stria terminalis, septal nuclei, nucleus accumbens, and basal ganglia), diencephalon (several hypothalamic regions, thalamus, and zona incerta), mesencephalon (periaqueductal gray and raphe nuclei), metencephalon, and myelencephalon (lateral parabrachial nuclei, locus coeruleus, spinal trigeminal tract, and medullary reticular nucleus). However, these immunohistochemical analyses were conducted using a polyclonal antiserum against human kisspeptin-10, which might cross-react with other peptides showing the terminal RF-amide motif. More recently, an additional study, using a different antibody raised against mouse kisspeptin-10, identified three major populations of hypothalamic neurons expressing kisspeptins located at the anteroventral and preoptic periventricular regions (AVPV/PeN), dorsomedial hypothalamus, and Arc. In addition, the latter study provided the first morphological demonstration of the close apposition between kisspeptin fibers and GnRH neuron cell bodies within the hypothalamus.

Finally, our knowledge of the pattern of expression of GPR54 in the central nervous system remains somewhat limited. Thus, although RT-PCR assays initially demonstrated that GPR54 mRNA is present in the spinal cord and various brain areas, including the hypothalamus, basal ganglia, amygdala, substantia nigra, and hippocampus, no immunohistochemical analysis of the distribution of GPR54 protein within the brain has so far been reported. Likewise, precise location analyses of GPR54 mRNA across the central nervous system are still pending. Yet the expression of GPR54 mRNA has been demonstrated in rat GnRH neurons by means of *in situ* hybridization.

Disclosure of the Reproductive Facet of KiSS-1/GPR54

Identification of the connection between the KiSS-1/GPR54 system and the neuroendocrine control of reproductive function did not take place until late

2003, when two research groups independently reported the presence of deletions and inactivating mutations of GPR54 gene in patients suffering familial or sporadic forms of idiopathic hypogonadotropic hypogonadotropism (HH). Since then, a limited number of additional loss-of-function mutations of the GPR54 gene have been described in humans affected by hypogonadism of central origin. Moreover, simultaneous with the description of the first cases of hypogonadotropism in humans bearing mutations in GPR54, mice engineered to lack functional GPR54 were reported to be a complete phenocopy of affected patients. Altogether, these data evidenced an indispensable, highly conserved role of GPR54 and its ligands in the control of reproduction in mammals.

Although from an epidemiological perspective the number of cases of HH caused by GPR54 mutations appears to be low, disclosure of the essential role of the KiSS-1/GPR54 system in the control of reproduction drew considerable attention from a physiological standpoint. Indeed, initial hormonal studies conducted in humans and mice with genetic inactivation of GPR54 strongly suggested that the KiSS-1 system is fundamental in the control of GnRH secretion at the hypothalamus. This assumption was based on the observation that GPR54 mutation did not disrupt the capacity of the pituitary to respond to GnRH. Similarly, lack of GPR54 signaling did not prevent normal migration of GnRH neurons from the olfactory placode at early stages of development, nor did it impair GnRH synthesis, as indirectly suggested by the demonstration of preserved GnRH content at the hypothalamus of GPR54 knockout mice. Obviously, the hypothesis that the KiSS-1 system operates as major regulator of GnRH secretion needed to be experimentally validated. Compelling evidence from molecular, physiological, and pharmacological studies, gathered during the last 3 years, has now substantiated that kisspeptins and their receptor are probably (one of) the most important gatekeepers of the function of GnRH neurons and, hence, of the gonadotropic axis. The most salient roles of KiSS-1 and GPR54 in the control of reproduction are reviewed in the following sections.

KiSS-1 System and the Control of Gonadotropin Secretion: Negative Feedback

In the context of reproduction, one of the facets of the KiSS-1 system that initially attracted more attention was its potential role in gonadotropin secretion. Thus, between 2004 and early 2005, pharmacological studies conducted in different species, such as the rat, mouse, sheep, and macaque, demonstrated that kisspeptins are very potent stimulators of LH and FSH release. More recently, the ability of metastin to stimulate LH secretion has been also shown in humans. Interestingly, some differences have been noticed in the patterns of LH and FSH responses to kisspeptins, such as their relative magnitude (higher for LH) and time course (faster for LH), as well as in the threshold and mean effective doses (two orders of magnitude lower for LH). In any event, it is becoming evident that kisspeptins are probably the most potent elicitors of the GnRH–gonadotropin axis known so far (see Figure 1). A particular feature of the gonadotropin-releasing effect of kisspeptins is that it is detectable even after the systemic administration of low doses of metastin or kisspeptin-10. This is in contrast with most of the neuropeptides involved in the central control of gonadotropin secretion, which are ineffective when administered systemically.

The mechanism whereby the KiSS-1 system activates the reproductive axis and stimulates gonadotropin secretion involves a primary action at the hypothalamus, where kisspeptins seem to operate as major synaptic excitatory signals for GnRH neurons. This contention was initially suggested (indirectly) by the demonstration that blockade of GnRH actions (by means of a specific antagonist) completely blunted the ability of kisspeptins to stimulate gonadotropin secretion *in vivo*. Thereafter, double-labeled *in situ* hybridization studies in the rat showed that >75% of GnRH neurons co-express GPR54 mRNA and that kisspeptin-52 (equivalent to metastin in the rat) is able to induce c-fos expression in >85% of GnRH neurons. Moreover, hormonal analyses

Figure 1 Potent LH releasing activity of kisspeptin after intracerebral administration. A range of doses of kisspeptin-10 (5 nmol, 1 nmol, 500 pmol, 100 pmol, 10 pmol, 1 pmol, and 100 fmol) were tested. Nonlinear regression allowed to estimate an ED_{50} of ~2 pmol for LH responses to central injection of kisspeptin. ED_{50}, mean effective dose; LH, luteinizing hormone.

demonstrated the ability of kisspeptins to stimulate GnRH secretion by rat hypothalamic explants *ex vivo*, as well as to induce the release of GnRH into the cerebrospinal fluid in the sheep after *in vivo* administration. In sum, these data are evidence that kisspeptins act primarily on hypothalamic GnRH neurons to elicit GnRH secretion, which in turn stimulates LH and FSH release from the pituitary.

Further evidence for the relevance of the KiSS-1 system in the physiological control of gonadotropin secretion came from expression analyses in the hypothalamus in models of gonadectomy in the rat. Thus, bilateral orchidectomy and ovariectomy induced a significant increase in KiSS-1 (and, to a lower extent, GPR54) mRNA expression in whole hypothalamic fragments. Such changes in mRNA levels closely paralleled the expected rise in circulating LH concentrations following gonadectomy. Moreover, sex steroid replacement fully prevented both hormonal and gene expression responses. These observations strongly suggested that the hypothalamic KiSS-1 system plays an essential role in relaying the negative feedback input of sex steroids to GnRH neurons. Indeed, location analyses by means of *in situ* hybridization fully confirmed these original observations and demonstrated that the subset of KiSS-1 neurons in the Arc, where the expression of KiSS-1 mRNA is enhanced after gonadectomy and decreased following androgen or estrogen supplementation, is responsible for conveying the negative feedback actions of sex steroids on gonadotropin secretion.

KiSS-1 System and the Female Gonadotropic Axis: Positive Feedback

In situ hybridization analyses of KiSS-1 mRNA expression at the hypothalamus of ovariectomized rats also provided experimental evidence for a higher degree of complexity of the KiSS-1 system and its regulation by sex steroids. Whereas KiSS-1 mRNA levels in the Arc appeared to be repressed by estrogen, KiSS-1 gene expression in the AVPV was suppressed by ovariectomy and enhanced by estrogen replacement. Considering that the AVPV had been previously identified as an hypothalamic area involved in the positive feedback control of gonadotropins, those observations raised the intriguing possibility that the population of KiSS-1 neurons at this hypothalamic site might be involved in the positive feedback effect of estradiol on gonadotropin secretion during the preovulatory phase. This hypothesis has been recently supported by the demonstration that KiSS-1 mRNA levels in the AVPV, but not in the Arc, significantly increase in the rat during the evening of proestrus (i.e., coinciding with the preovulatory surge of gonadotropins). Altogether, these data evidence that KiSS-1 neurons in the AVPV participate in the network responsible for the generation of the positive feedback effect of estradiol on gonadotropin secretion in the female, thus playing a pivotal function in the generation of the hormonal signal triggering ovulation. This is in good agreement with previous evidence showing that immunoneutralization of central metastin prevents the preovulatory surge of gonadotropins in the cyclic rat. Note that, although the existence of the positive feedback effects of estradiol on gonadotropin secretion had been known for decades, the actual neuronal circuitry responsible for such a phenomenon remained largely unknown. The contribution of KiSS-1 neurons in the AVPV and Arc in mediating the positive and negative feedback effects of estradiol is tentatively depicted in Figure 2.

KiSS-1 System and Onset of Puberty

In keeping with the ability of kisspeptins to stimulate gonadotropin secretion, the hypothalamic KiSS-1 system is also involved in the physiological mechanisms of the onset of puberty, as indirectly suggested initially by the demonstration of a state of impuberism in humans and mice with inactivating mutations of GPR54. Thus, expression analyses in hypothalamic

Figure 2 Tentative model for the differential role of KiSS-1 neurons at the arcuate nucleus (Arc) and the anteroventral periventricular nucleus (AVPV) of the hypothalamus in relaying the negative and positive feedback effects of sex steroids (estradiol) on GnRH neurons. +, positive feedback; −, negative feedback; EP, estradiol; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; Kp, kisspeptin; LH, luteinizing hormone.

samples from male and female rats at different stages of postnatal development demonstrated a significant increase in KiSS-1 and GPR54 mRNA levels at the time of puberty onset, which was preceded by low expression levels during the prepubertal period. Likewise, hypothalamic levels of KiSS-1 and GPR54 mRNAs significantly increased during the transition from the juvenile to the mid-pubertal stage in monkeys. Moreover, repeated injections of kisspeptin-10 in immature female rats induced the precocious activation of the gonadotropic axis (with earlier vaginal opening, increased LH and estradiol levels, and elevated uterus weights). Similarly, chronic administration of kisspeptin-10 at the end of the juvenile phase evoked a sustained train of GnRH discharges, similar to that found at puberty, in primates.

More recently, functional and expression analyses have suggested that activation of the hypothalamic KiSS-1 system is not merely derived from the enhancement of KiSS-1 gene expression at the time of puberty. Thus, *in vivo* and *in vitro* studies, testing the effects of different doses of kisspeptin on LH secretion and its ability to activate GnRH neurons, have demonstrated that a significant increase in the sensitivity of GnRH system to kisspeptin activation takes place in rodents during puberty; a phenomenon which might involve the enhanced expression of GPR54 and increased efficiency in its coupling to intracellular effector systems. In addition, the maturational activation of the KiSS-1 system at puberty probably involves plastic changes in fiber projections and synaptic density (especially for KiSS-1 neurons at the AVPV) because a significant increase in the number of appositions between kisspeptin fibers and GnRH cell bodies has been demonstrated in the mouse along pubertal transition. Altogether, these observations demonstrate that the activation of the KiSS-1 system at the time of puberty is a complex phenomenon that involves changes in KiSS-1 and GPR54 gene/peptide expression, receptor signaling efficiency, and physical interactions between KiSS-1 and GnRH neurons. Such a sophisticated, multistep regulatory process clearly illustrates the fundamental role of the KiSS-1/GPR54 system in the activation of the reproductive axis at puberty.

KiSS-1 System and the Metabolic Control of Reproduction: Modulation by Leptin

In addition to its role in puberty onset and feedback regulation of gonadotropin secretion, the hypothalamic KiSS-1 system also has been involved in the neuroendocrine circuitries responsible for the metabolic control of reproductive function. This contention was originally proposed based on the observed changes in KiSS-1 gene expression in models of energy insufficiency linked to hypogonadotropic hypogonadism. Thus, short-term fasting, which induced the expected reduction in basal gonadotropin levels, also decreased KiSS-1 mRNA expression in the hypothalamus of male and female rats, 60 h after food deprivation. Similarly, in another model of metabolic alteration associated to hypogonadotropism, such as streptozotocin (STZ)-induced diabetes, decreased expression of KiSS-1 gene was observed in male and female rats, both in intact condition and after gonadectomy. Such changes in hypothalamic KiSS-1 expression closely paralleled the reduction of serum LH levels detected in STZ-injected animals. Altogether, these data suggest that the suppression of hypothalamic KiSS-1 system in states of energy deficit and metabolic disturbance is mechanistically relevant for the observed inhibition of the gonadotropic axis in those conditions.

Further evidence for the relevance of the KiSS-1 system in the metabolic regulation of reproduction came from functional studies analyzing the effects of administration of kisspeptins on different parameters of the gonadotropic axis in conditions of energy insufficiency. Thus, repeated administration of kisspeptin-10 to immature female rats subjected to a regimen of undernutrition (30% caloric restriction), which was able to prevent puberty onset, was sufficient to restore vaginal opening (as an external index of puberty) in a significant number of animals (60%) and to induce robust gonadotropin and estrogen responses. Likewise, despite the prevailing reduction in basal gonadotropin levels, kisspeptin administration in diabetic rats was capable of acutely eliciting maximal LH responses and to ameliorating several indices of reproductive dysfunction (such as reduced prostate and testis weight, as well as decreased LH and testosterone levels) after repeated administration. In sum, results from expression analyses and functional tests strongly suggest that the body energy status has an influence on the hypothalamic KiSS-1 system and that replacement with kisspeptin can rescue (at least partially) the hypogonadotropic state observed in conditions of undernutrition and metabolic alteration. In this context, the hypothalamic KiSS-1 neurons might be considered sensors for the energy status of the organism, thus contributing to the coupling of the state of energy reserves and the function of the reproductive axis in different physiologic and pathologic conditions.

The nature of the signal(s) responsible for conveying metabolic information to KiSS-1 neurons is being actively investigated. In this context, the adipocyte-derived hormone, leptin, has recently emerged as a major regulator of hypothalamic KiSS-1 expression.

Of note, leptin had been long known to operate as a key neuroendocrine integrator signaling the magnitude of body energy (fat) stores to multiple hormonal axes, including the reproductive system, on which leptin has been reported to play mostly a permissive/stimulatory role. Supporting the possibility of the direct modulatory effects of leptin, a substantial proportion of KiSS-1 neurons in the Arc have been recently shown to express leptin receptors in the mouse. In addition, leptin-deficient *ob/ob* mice were reported to have a lower expression of KiSS-1 gene in the hypothalamus, a phenomenon which could be rescued by exogenous leptin administration. Moreover, chronic intracerebral infusion of leptin was sufficient to normalize hypothalamic KiSS-1 mRNA levels, as well as LH and testosterone concentrations, in hypogonadotropic diabetic male rats, which are also severely hypoleptinemic. Altogether, these data suggest that circulating leptin modulates the functioning of the reproductive axis (and, specifically, of GnRH neurons), at least partially, via regulation of the hypothalamic KiSS-1 system. This indirect mode of action on GnRH neurons helps to explain the paradoxical observation that, although it is sensitive to the actions of leptin, this neuronal population does not apparently express leptin receptors.

Proposed Model: The KiSS-1 Neuron as Novel Gatekeeper of the GnRH System

The identification of the prominent reproductive roles of kisspeptins and their receptor has been defined as the most important finding in the field of neuroendocrinology of reproduction since the isolation of GnRH in early 1970s. These fundamental functions of kisspeptins involve key roles in the full activation of the gonadotropic axis at puberty, the regulation of gonadotropin secretion by sex steroids, the generation of the preovulatory surge of LH (as hormonal trigger for ovulation), and the metabolic control of reproductive maturation and fertility. In addition, environmental cues with prominent

Figure 3 Tentative model for the central role of hypothalamic KiSS-1 neurons in the neuroendocrine control of reproduction. According to this model, KiSS-1 neurons are the target for the modulatory actions (stimulatory, +; inhibitory, −) of different regulators of the gonadotropic axis, such as sex steroids, leptin, and environmental signals, on which this information converges and integrates. In turn, KiSS-1 neurons operate as major regulators of GnRH neurons, which respond to changes in kisspeptin input with activation or, eventually, inactivation (if kisspeptin tone decreases); GnRH is the ultimate effector for kisspeptin actions on the gonadotropic axis. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

modulatory actions on the HPG axis, such as dark–light rhythms, have been recently suggested to operate via the hypothalamic KiSS-1 system. Considering the short time that has elapsed since the first discovery of the reproductive dimension of kisspeptins, it is understandable that several aspects of these functions remain to be fully characterized. In any event, the experimental evidence gathered in the last 2 years allows us to propose a tentative model for the integration of KiSS-1 neurons in the central networks governing reproductive function, as depicted in Figure 3. Thus, whereas it was conventionally assumed that GnRH neurons operate both as integrators and final output pathway for the array of regulatory signals of the gonadotropic axis, in this hypothetical model the KiSS-1 neuron functions as the center for the dynamic integration of the information conveyed by different central and peripheral modulators of the HPG system. In contrast, the GnRH neuron might play a more passive role, acting as the final transducer of the information relayed by the KiSS-1 system. This hypothetical model does not exclude the potential integration of additional excitatory and inhibitory inputs at the level of GnRH neurons. Notwithstanding, the KiSS-1 system can be now defined as a novel, essential gatekeeper of the reproductive axis. Further progress in our knowledge of the physiological roles of this system in the control of reproduction will require the complete characterization of the afferents to and projections of KiSS-1 neurons in the hypothalamus, as well as the identification of the major central and peripheral regulators of hypothalamic KiSS-1 expression and function, in what promises to be a very active area of research in neuroscience in the near future.

Lamina-Specific Neuronal Connections

M Yamagata, Harvard University, Cambridge, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Neurons are connected with a remarkable degree of synaptic specificity in neuronal circuits. One prominent feature of neuronal wiring is regional specificity, such as topographic maps, in which the spatial order of neurons maps systematically onto their axonal target. Similarly striking is laminar specificity of neuronal wiring in the orthogonal orientation. Many areas of the nervous system in both vertebrates and invertebrates consist of multiple neuronal cell layers, each forming lamina-specific connections with entering afferents and intrinsic interneurons. Thus, lamina-specific synaptic connectivity appears to be a major organizational principle of the central nervous system.

In vertebrates, clearly stratified parts include the cerebral cortex, olfactory bulb, hippocampus, lateral geniculate nucleus, superior colliculus (optic tectum), cerebellum, retina, and spinal cord. In these areas, each lamina bears a distinct series of neuronal subtypes, distinguishable by morphology, neurochemistry, and synaptic projections. The dendrites of such neurons span multiple laminae, but specific populations of input axons make arbors and synapses confined to particular laminae. Here, axons synapse onto neurons that are themselves restricted to particular laminae (**Figure 1(a)** also see later, **Figure 3(b)**). This specificity is seen in the cerebellum where climbing and pontine afferents synapse on Purkinje and granule neurons, respectively, which populate discrete layers. In other cases, inputs synapse on somata or lamina-confined segments of dendrites that span several laminae (**Figure 1(b);** also see later, **Figure 3(g)**). This class of subcellular domain specificity is spectacularly observed in the hippocampus, where different types of input fibers lay an array of synapses on distinct subdivisions of pyramidal and granule cell dendrites in a lamina-specific fashion. The concept of cellular and subcellular specificities can be also applied for lamina-specific connections between neurons wiring intrinsically in laminated structures. In many systems, however, lamina-specific synaptic connections involve a combination of both cellular and subcellular specificities.

During development, incoming axons form specific synaptic connections in the correct target laminae. Several mechanisms can be proposed that might explain how lamina-specific targeting, branching, and synapses are established (**Figure 2**). One possible scenario could be that the time of arrival of the distinct class of axons into developing laminae influences their lamina-specific pattern of innervation. However, recent studies have demonstrated a plethora of molecular and cellular mechanisms. These include (1) the diffusible and immobilized lamina-specific cues that attract or repel axons to target laminae (**Figure 2(a)**), (2) cell surface determinants displayed on lamina-specific postsynaptic neurons or their subcellular domain (**Figure 2(b)**), (3) nonneuronal cues associated with glial cells and/or extracellular matrix (**Figure 2(c)**), (4) guidepost cells that help navigate connections without directly participating in functional wiring (**Figure 2(d)**), and (5) activity-dependent mechanisms that sculpt initially diffuse projections (**Figure 2(e)**). Although accumulating evidence suggests that lamina-specific connections develop in different manners in different areas, it is likely that multiple mechanisms cooperate to generate lamina-specific synaptic connections in each system. In this article, these basic mechanisms are discussed in detail by citing some examples.

Lamina-Specific Signals

Growing axons arrive at the appropriate region after their journey. The growth cones still need to encounter a series of cellular and molecular cues until they are in the correct lamina at the apposition of synaptic targets: development of lamina-specific connections relies on a precisely organized spatiotemporal network of a panoply of lamina-restricted cues expressed along the axonal pathway (**Figure 2(a)**). These cues could be signals permitting or inducing axonal extension, nonpermissive or repulsive signals from inappropriate laminae, or branching or synaptogenic signals from target neurons to enable arborization or presynaptic differentiation in the target lamina. In recent years, much progress has been made in identifying molecules that play crucial roles in axon guidance. These molecules include the attractants and repellants that act in a long-range or in a contact-dependent manner. The similar molecular mechanisms can be envisioned to regulate lamina-specific responses of axons while passing through nontarget laminae, as well as after contacting the target lamina.

Several cues can be observed using organotypic cultures *in vitro*. In the chick retinotectal system, retinal ganglion cell axons enter the optic tectum through a superficial lamina, then turn into discrete deeper target laminae (**Figure 3(a)**). Using an

Figure 1 Lamina-specific neuronal connections. Entering inputs establish synaptic connections with specific types of neurons populating distinct laminae (a). In other cases, inputs terminate on discrete subdivisions of the target neuron's surface (b).

Figure 2 Developmental principles of lamina-specific neuronal connections. (a) Lamina-specific signals. Incoming axons outgrow, turn into the laminated structure, then extend orthogonally along several laminae until they contact the target lamina. The cues support a series of axonal behaviors, including axon outgrowth, turning into deeper laminae, intralaminar extension by contact guidance, chemoattraction mediated by diffusible factors, inhibition or collapse of outgrowth on inappropriate laminae, and chemorepulsion by nontarget laminae. Target-lamina-derived signals stop axonal growth, cause branching axon terminals, and induce synaptogenesis. (b) Target recognition. Cellular recognition involves direct choice of a correct target neuron populating the target lamina, whereas subcellular recognition involves selection of the particular subcellular domain of a target neuron (pink). (c) Nonneuronal cues. Glial cells and extracellular matrix can also regulate a mode of axon behavior, such as repulsion, attraction, and synapse formation. (d) Guidepost cells (green) are specific cellular cues used by axonal growth cones in axon pathfinding and targeting decisions. During development, incoming axons transiently contact guidepost cells, which help deliver the axons to final synaptic partners (pink). (e) Activity-dependent refinement. An initially diffuse pattern of connectivity is elaborated to establish a precise projection pattern by neural activity.

organotypic culture system, outgrowth, branching, and arborization patterns of retinal axons were recapitulated in the lamina-selective manner. The similar behavior of axons was essentially observed on chemically fixed tectal slices. Thus, each tectal lamina bears distinct immobilized cues that change lamina-selective behavior of retinal axons. In the cerebellum, cultured granule neurons arrested the outgrowth of their pontine mossy fiber afferents *in vitro*, suggesting that the cerebellar granule cell layer could halt growth of their afferents as a stop signal (Figure 3(b)). Although the molecular nature of these cues has not been fully characterized, these studies demonstrate that a panel of unique cues arranged in a lamina-restricted manner modulate a series of behavior of incoming axons.

In other systems, some of the lamina-specific cues have been molecularly identified. For instance, a role of lamina-specific expression of the cell surface ephrin/Eph family has been fairly well studied during early postnatal development of the mammalian cerebral cortex. In the six-layered cortex, thalamic axons make lamina-specific synaptic connections in the layer 4 (Figure 3(c)). Ephrin-A5 is strongly expressed in layers 4 and 6 when the thalamic afferents form synapses. *In vitro*, ephrin-A5 acts as a branch-promoting factor for thalamic axons: thalamic axons encountered on membrane substrates of layer 4 or ephrin-A5 develop more branches than when on layer 5 or on control substrate. Furthermore, *in vivo*, thalamic afferents from ephrin-A5-deleted mice stop normally in layer 4, but make less complex arbors. Thus, it appears that ephrin-A5 controls the arborization of thalamic axons in the target lamina. Neurotrophin-3 together with ephrin-A5 promote axonal branching of layer 6 neuronal axons, which target layer 4 expressing ephrin-A5. Importantly, ephrin-A5 inhibits branching of layers 2 and 3 neuronal axons, which normally avoid layer 4. Many other members of the Eph/ephrin family show a lamina-specific expression in other laminated structures as well as in the cortex, suggesting that the Eph/ephrin system plays a universal role in formation of lamina-specific connections.

Semaphorins comprise a large family of membrane-associated and secreted proteins that signal axon repulsion and/or attraction. Sema3A, one of the best characterized members in this family, is a diffusible molecule that induces growth cone collapse and axon repulsion of a variety of neuronal populations, through interaction with a receptor complex containing neuropilin-1/plexin-A1. One of its functions during development is thought to be the establishment of an appropriate pattern of lamina-specific axonal innervation within the dorsal horn of the spinal cord (Figure 3(d)). Sema3A functions to selectively repel axons from a subset of dorsal root ganglion neurons that are of small size, are nerve growth factor sensitive, and are responsible for nociception and thermoreception. Lamina-specific expression of Sema3A in the ventral horn during development is believed to restrict the growth of these axons to laminae I and II of the dorsal horn.

Target Recognition Molecules

The *sine qua non* of lamina-specific connections is to establish functional wiring by apposing two membranes of synaptic partners (Figure 2(b)). To give an explanation for development of specific neuronal wiring, in 1963, Roger Sperry formulated the 'chemoaffinity theory' in which complementary tags or adhesion molecules determine specificity of the 'lock' and 'key' kind. Consistent with this classic hypothesis, several cell surface molecules have been identified as potential recognition determinants in vertebrates and invertebrates.

Sidekicks (SDKs) have been considered as essential for the formation of lamina-specific synaptic connections in the retina. The vertebrate SDK molecules were identified in the course of a screen for genes expressed by subsets of chick retinal ganglion cells. Vertebrates have two SDKs, whereas insects and nematodes have only one SDK (rig-4 in *Caenorhabditis elegans*). From N- to C-terminus, each SDK protein contains a signal peptide sequence, six immunoglobulin C2 motifs, 13 fibronectin type III motifs, a single type II transmembrane domain, and an approximately 200-amino-acid cytoplasmic domain. In the chick retina, *SDK1* and *SDK2* genes are expressed by nonoverlapping subsets of the retinal ganglion cells, with each expressed in nearly a quarter of the cells there. The inner plexiform layer (IPL) of the retina is made from layers of axons and dendrites from the retinal ganglion cells, amacrine cells, and bipolar cells (Figure 3(e)). Distinct subsets of retinal ganglion cells confine their dendritic arbors to certain layers of the IPL, displaying distinct laminar specificity. In the IPL, a complementary localization of SDKs is also found in the synaptic regions. Dividing the IPL into five sublaminae (S1–S5), each occupying 20% of the IPL, showed that SDK1 is concentrated in S4 with lower levels in S2, whereas the converse is the case for SDK2. Surprisingly, ectopic expression of SDKs by in ovo electroporation of early chick embryos diverted projections of neurons from their normal position in SDK-negative sublaminae to SDK-positive sublaminae. Together with the homophilic adhesive interactions between each SDK, the gain-of-function experiment suggests that SDKs could function to target specific

Figure 3 Examples of lamina-specific neuronal connections. (a) Retinotectal system: retinal ganglion cell axons project to only four retinorecipient laminae of the optic tectum, which contains >15 laminae. Experiments using an organotypic culture identified a series of lamina-selective cues which can control lines of axonal behavior. Distinct subsets of ganglion cells (red, blue) terminate in different laminae, although molecular and cellular mechanisms that underlie this fine laminar selection have not been elucidated. (b) Cerebellum: mossy fibers from the pons innervate granule cells in the granule cell layer, whereas climbing fibers from the inferior olive innervate onto dendrites of Purkinje cells in the molecular layer. This wiring pattern is thought to depend on the stop signal on granule cells. Basket interneurons make GABAergic ponceau synapses exclusively on the axonal initial segment (green) of Purkinje cells. (c) Cortex: thalamic inputs terminate in layer 4 of the six-layered cortex. This lamina-specific connection appears to be regulated by ephrin-A5 expressed in layers 4 and 6. By contrast, neurons in layers 2 and 3 develop their arbors on the outside of the ephrin-A5-expressing layers. (d) Spinal cord: distinct subpopulations of sensory neurons in the dorsal root ganglion project to different laminae of the spinal cord. Inputs from

neurites to certain sublaminae. SDKs are localized at the synapses and contain a postsynaptic density/disc/zonula occludens-1 (PDZ) domain binding motif in their cytoplasmic domains. It is likely that these molecules not only mediate the recognition events in synaptic specificity but also send a signal for inducing synapses, including presynaptic and/or postsynaptic differentiation. In addition to SDKs, a panel of synaptic adhesion molecules has been recently described in synapses. However, the combinatory roles of these molecules in synaptic specificity and formation remain still elusive.

The color-sensitive photoreceptors of the *Drosophila* visual system provide a genetically amenable, stereotyped, simple system in which to study layer-specific axon targeting (Figure 3(f)). The adult *Drosophila* visual system develops at the end of larval life. Each class of photoreceptor neuron (R1–R6, R7, and R8 cells) projects to a different synaptic layer in the brain. Several genes are known to contribute to the establishment of the layer-specific projection pattern of photoreceptors. Endogenous expression of the leucine-rich repeat cell adhesion molecule Capricious in R8 or its ectopic expression in R7 directs these photoreceptors to innervate the Capricious-positive layer. The interaction mediated by Capricious is homophilic, whereby the proteins interacting on the two opposing membranes are also homophilic, being reminiscent of SDKs in the vertebrate retina. In addition, the seven-pass transmembrane cadherin Flamingo is required for R8 targeting, whereas loss of either *Drosophila* neuronal (DN)-cadherin or the immunoglobulin superfamily (IgSF) receptor-type protein tyrosine phosphatases alters R7 to mistarget to the R8 layer. Thus, an array of these cell surface molecules and their ligands are candidates that directly drive the layer-specific assortment of distinct photoreceptor projections.

In addition to choice between correct and incorrect target neurons, lamina-specific connectivity involves subcellular specificity. One intriguing observation in the cerebellum clearly demonstrates a molecular mechanism that underlies this specificity. Basket neurons establish a distinct type of γ-aminobutyric acid (GABA)ergic synapse only on the axon initial segment of Purkinje neurons (Figure 3(b)). This subcellular specificity of synapse formation is mediated by a subcellular gradient of the IgSF molecule neurofascin 186 along the proximal–distal axis of Purkinje cells. This gradient is established by the cytoskelton protein ankyrin G, which binds neurofascin 186. Thus, the cytoskeleton-based recruitment of crucial adhesion molecules determines the subcellular or lamina-specific location of synapses.

Nonneuronal Cues

In addition to neurons, the nervous system contains numerous glial cells. Moreover, an extracellular matrix (ECM) produced by glial cells and/or neurons occupies the space between cells. Thus, the lamina-specific signals that affect axonal behavior can be associated with glial cells and the ECM (Figure 2(c)).

The importance of glial cells in lamina-specific innervations can be demonstrated by ablating glial cells. In the *Drosophila* visual system, when R cell axons enter the 'lamina' (note that 'lamina' is a nomenclature for the particular layer in this system), they encounter both glial cells and neuronal plexus (Figure 3(f)). R1–R6 axons stop in the flat lamina layer structure,' while R7 and R8 axons pass through this lamina layer and terminate in the medulla. The cellular requirement for R1–R6 axonal projection was determined using loss-of-function mutations affecting different cell types in the lamina layer. Deletion of glial cells but not neurons disrupts R1–R6 targeting. Thus, glial cells in this system provide the initial stop signal, promoting growth cone termination for R1–R6 axons in the lamina layer.

In the mammalian hippocampus, the commissural/associational (CA) fibers, which originate from the mossy cells, innervate the inner molecular layer. By contrast, entorhinal afferents, which originate from the entorhinal cortex, innervate the outer molecular

small-size sensory neurons specifically terminate in lamina I and lamina II, presumably by the repellant action of Sema3A. (e) Retina: the inner plexiform layer (IPL) of retina composed of an array of synapses formed between neurites of retinal ganglion cells and amacrine/bipolar cells. Homophilic sidekick adhesion molecules are expressed by specific subsets of retinal neurons which are making synaptic contacts in a subset of sublaminae. Overexpression of this adhesion molecule in a cell which does not normally express sidekicks diverts its neurite to sidekick-positive sublaminae. (f) Fly visual system: distinct types of photoreceptors project to distinct layers in either the lamina layer or the medulla layer. R1–R6 axons project to the lamina layer whereas R7 and R8 axons pass through the this layer and project to the medulla layer. R7 and R8 innervate the different layers of the medulla. (g) Hippocampus: entorhinal (red) and commissural/associational (CA) inputs (blue) terminate in the different laminae. In the hippocampus, the pattern of lamina-specific innervations is divergent, depending on the area. In the dentate gyrus, granule cells receive inputs on their different subdivision of dendrites, providing a good means to study subcellular specificity in lamina-specific neuronal connections. (h) Retinogeniculate system: axons from retinal ganglion cells in mammals terminate in different laminae of the lateral geniculate nucleus. Two inputs of the ipsilateral and contralateral eyes project to discrete laminae in adults as shown in this schematic. This eye-specific, lamina-specific connection is initially diffuse during development, and later is refined through a neural activity-dependent mechanism.

layer (Figure 3(g)). These lamina-specific axonal projections show a subcellular specificity of inputs: CA fibers synapse on proximal dendritic segments, whereas entorhinal fibers innervate only the distal dendritic segments of the same target neurons. In an adhesion assay using live hippocampal slices, dissociated entorhinal neurons selectively adhere to the outer molecular layer, raising the possibility that the laminar adhesive cue controls the laminar specificity. This lamina-specific adhesion was abolished by treating the slices with hyaluronidase, which degrades glycosaminoglycans. Furthermore, laminar specificity of entorhinal fiber ingrowth to the right target lamina was disturbed by treatment with *Streptomyces* hyaluronidase, which specifically degrades hyaluronan (hyaluronic acid). Interestingly, hyaluronidase treatment did not affect the laminar specificity of other afferent projections, such as the CA projection to the dentate inner molecular layer or the mossy fiber projection. Taken together, these data suggest that laminar specificity of entorhinal fibers that project to the correct target lamina requires hyaluronan or hyaluronan-associated ECM molecules. Major hyaluronan-associated molecules in the ECM are a lectican family of chondroitin sulfate proteoglycans such as aggrecan, neurocan, brevican, and versican. In this system, however, it is not known what types of neurons and glial cells express these proteoglycans. In the chick optic tectum, versican is expressed by lamina-specific neurons and deposited in a lamina-specific manner. In this system, versican appears to regulate maturation of synapses in the versican-positive laminae.

The other large ECM molecule, reelin, is expressed and secreted by Cajal–Retzius cells in the marginal zone of the hippocampus. Besides its role in neuronal migration, reelin has been shown to influence the branching pattern of entorhinal fibers projecting to the outer molecular layer. In the reeler mouse, entorhinal afferents are less branched than they are in wild-type mice, which suggests that reelin acts on entorhinal axons and influences their branching pattern. However, reelin is not required for the laminar specificity of entorhinal fibers *per se*, because in reeler mutants entorhinal fibers still innervate the correct target lamina. Instead, both ephrin/Eph and semaphorin/plexin systems play an important role in selection of this lamina-specific termination. Thus, this is an example of cooperation of multiple cues.

Guidepost Cells

Guidepost cells are specific cellular cues used by axonal growth cones in pathfinding and targeting choices (Figure 2(d)). For example, it has been experimentally demonstrated in insects that pioneer axons follow pathways marked by specific nonadjacent guidepost cells. In the developing mammalian cortex, pioneer neurons provide a transient scaffold for ingrowing axonal projections. A similar mechanism is also suggested for a synaptic target specificity in *C. elegans* which requires a heterophilic binding between two IgSF adhesion molecules, Syg-1 and Syg-2. Thus, it can be surmised that 'guidepost cells' are involved in formation of lamina-specific connections.

One example is seen in the hippocampus: transient Cajal–Retzius cells in the marginal zone were suggested to serve as intermediate targets for incoming entorhinal fibers. Transient synapses between entorhinal afferents and Cajal–Retzius cells were detected before the establishment of synaptic contacts between entorhinal fibers and their final targets, the granule cell dendrites. Furthermore, Cajal–Retzius cells were shown to make an early axonal projection to the entorhinal cortex, suggesting a role for these axons as a scaffold for the first incoming entorhinal axons that are seeking their correct target lamina. In fact, after ablation of Cajal–Retzius cells in organotypic slice cultures, entorhinal fibers no longer terminated in the target lamina, indicating that Cajal–Retzius cells play an indispensable role in development of this lamina-specific axonal connection.

Activity-Dependent Refinement

The last mechanism is based on a gamut of observations in which some precise lamina-specific connections arise from an inaccurate projection (Figure 2(e)). The most examined preparation is the retinogenicular projection. Retinal ganglion cells, particularly in higher mammals, send their axons to target neurons in the lateral geniculate nucleus in such a way that axons originating from the two eyes terminate in adjacent but nonoverlapping eye-specific laminae (Figure 3(h)). During development, initial projections from the ipsilateral and contralateral eyes are intermixed, and the adult precise pattern appears gradually, as axons from the two eyes mutually sort out into different laminae, making a lamina-specific termination. Several lines of evidence indicate that the segregation process, even though it occurs before vision develops in higher mammals, requires firing of ganglion cells, thereby neural activity plays a pivotal role in the lamina-specific segregation. The first compelling observation is that blocking ganglion cell action potentials with a voltage-dependent sodium-channel blocker inhibits the segregation of laminae. These action potentials are generated by the ganglion cells, which fire spontaneously and synchronously with each other, exhibiting waves that spread across the retina. A calcium imaging

study has shown that amacrine cells also participate in the correlated activity patterns, suggesting that a synaptic circuit within the developing retina is responsible for producing the retinal waves. Thus, it appears that, before the photoreceptors are functional, the spontaneous and synchronous activity produced in the retina is transmitted across central target synapses. Since spontaneously generated activity is present not only in the developing visual system but also widely in the developing nervous system, this process of activity-dependent neural circuit formation could be used to help elaborate other sets of lamina-specific neural connections.

Finally, even for activity-dependent refinement in the retinogeniculate system, recognition-molecule-mediated interaction also appears necessary. Class I major histocompatibility complex (MHC) molecules, known to be essential for immune recognition of antigen, are also expressed by neurons in an activity-dependent manner. In mice lacking class I MHC, lamina-specific connections in the retinogeniculate system are not perfect during development. These results demonstrate a potential role for class I MHC in the activity-dependent tuning of neuronal wiring.

Landau Kleffner Syndrome

M A Mikati, R M Kurdi, and A N Shamseddine, American University of Beirut, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Definition and Epidemiology

Landau–Kleffner Syndrome (LKS), which was first described in 1957, is a childhood disorder manifesting two main symptoms: an acquired aphasia and a paroxysmal electroencephalogram (EEG) with spikes and spike slow waves that are often multifocal, most commonly seen in the temporal or temporo-parieto-occipital regions, and that are enhanced during sleep. This syndrome is also often associated with two other symptoms: behavioral problems and epileptic seizures. The International League Against Epilepsy (ILAE) defines this syndrome as "a childhood disorder in which an acquired aphasia, multifocal spikes, and spike and wave discharges are associated." Onset of LKS ranges from 3 to 8 years following a normal cognitive and language development. To date, the prevalence of LKS has not been determined. Eighty-one cases were reported between 1957 and 1980, and 117 cases between 1981 and 1991. It is worth noting that there are definitely many more cases than reported. During the past two decades, there has been increasing interest in LKS course, its pathogenesis, and treatment. Patry et al. in 1971 were the first to coin the term 'subclinical status epilepticus induced by sleep,' which was later referred to as 'electrical status epilepticus during slow-wave sleep' (ESES). Now it is known as epilepsy with 'continuous spikes and waves during slow-wave sleep' (CSWS). CSWS often occurs in LKS. The sex (male to female) ratio in LKS is 2:1. Family and medical history are usually, otherwise, negative, and there are usually no additional coexisting neurological symptoms other than those mentioned above (see Table 1).

Clinical Manifestations

Patients present with loss of expressive speech and auditory verbal agnosia. Behavioral and psychiatric disturbances are common. These include motor hyperactivity, impulsivity, and aggressive behavior. Anxiety can occur as a reaction to the sudden loss of understanding of spoken language that these patients experience. Language problems typically start as word deafness or auditory agnosia. Children do not respond to their parents' commands even with loud voices. The auditory agnosia may exacerbate to a stage that those children are unable to recognize even familiar sounds like bells or ringing phones. These patients are usually suspected to have hearing impairment. No abnormalities are found in audiograms or brain stem auditory evoked responses (BAERs). There are delays in long-latency cortical evoked responses which implicate posterior temporal regions' involvement. Permanent extinction of one ear contralateral to the involved temporal cortex is shown with dichotic listening tasks. Word deafness can extend to complete lack of response. Problems in expression such as frequent or even continuous misarticulations, use of telegraphic speech and flowing jargon, or even complete mutism often occur. The language problems of LKS resemble in many aspects those of the autism spectrum disorder. However, there are clear and well-defined differences. Autism patients suffer from problems in the development of spoken language and in the capability of starting a conversation. The language that the autistic child uses is stereotyped, repetitive, and characteristic. Confusion sometimes also arises from the fact that autistic patients can have seizures with frequent EEG discharges. In addition, at minimum, one-third of the autistic cases suffer from neurodevelopmental deterioration involving language, sociability, playing, and thinking skills. However, the language regression in autism occurs before 3 years of age, whereas the age of onset of LKS is typically 5–7 years. Autistic children suffer from early regression that involves losing single words, whereas children with LKS, who are older, suffer from more dramatic changes as they have acquired more vocabulary and language. Problems in reciprocal social relatedness and limited stereotypical forms of interests and behaviors that are associated with autism are not manifested in LKS patients. Patients who fulfill the criteria of LKS, but who also have the behavioral problems of autism, are known as patients with the Landau–Kleffner variant.

Epileptic Manifestations

Seventy percent of patients with LKS have seizures. One-third of them have one seizure or a single status epilepticus event, usually at the onset of the syndrome. The other patients usually have occasional seizures between 5 and 10 years of age. Sporadic seizures persist in one-fifth of the patients after the age of 10 years. Seizures rarely occur by the time patients reach the age of 15 years. Seizures in LKS are mostly nocturnal simple partial motor seizures. Complex-partial seizures occur infrequently. Atonic seizures are common. The occurrence of generalized

Table 1 Characteristic features of Landau–Kleffner syndrome, epilepsy with CSWS, and CSWS as an EEG finding

Characteristics	*LKS*	*ESES or epilepsy with CSWS*	*CSWS as an EEG finding*[a]
Age of onset	3–8 years	The first seizure occurs between the ages of 1 and 10 years, with a peak at 4–5 years	Usually in children
Symptoms	Auditory verbal agnosia and loss of expressive speech with behavioral psychiatric disturbances	Atypical absence seizures, seizures with falls, and sometimes absence status. Other seizure types commonly occur. Neuropsychological dysfunction as a rule is present	Depending on the epilepsy syndrome: LKS (in 80% of cases), ESES (in all cases), or BECTS (in occasional cases)
EEG features	Focal or multifocal epileptic discharges that occur most commonly in the temporal areas and that are consistently enhanced during sleep. EEG may also show CSWS (i.e., >85% of sleep dominated by continuous electrographic seizure activity) in 80% of cases.	In the waking state, focal and/or multifocal, and/or generalized diffuse spike wave activity. During sleep, the EEG shows continuous bilateral and diffuse slow spike wave activity persisting through all or most (>85%) the slow sleep stages (i.e., CSWS)	Spike wave activity constitutes more than 85% of slow-wave sleep time
Etiology	It is unknown in most cases (cryptogenic). Multiple etiologies: encephalitis, autoimmune mechanisms, and others	Posthemorhagic, postinfectious, hydrocephalus, focal cortical dysplasia, periventricular leukomalacia, perinatal occlusion of middle cerebral artery, arachoid cyst, congenital biopercular syndrome, and other etiologies	Depending on the epilepsy syndrome
Therapy	Anticonvulsants, corticosteroids, adrenocorticotropic hormone (ACTH), intravenous immunoglobulin, and surgical	Anticonvulsants, corticosteroids	Depending on the epilepsy syndrome
Prognosis	50% of the patients recover partially or suffer from permanent aphasia	In adulthood, 50% of patients suffer from speech abnormalities and behavioral problems	Depending on the epilepsy syndrome

[a]Can be seen in multiple epilepsy syndromes including BECTS, epilepsy with CSWS and LKS.

tonic-clonic seizures, atypical absences, and myoclonic-astatic seizures is noted less frequently. The prognosis is not dependent on the frequency and type of seizures. Seizures, but not aphasia, are usually controlled by the use of anticonvulsants.

EEG Findings

Focal or multifocal epileptic discharges commonly occur in the temporal areas. Paroxysmal activity is rarely precipitated by hyperventilation or photic stimulation, but is consistently enhanced during sleep, often leading to CSWS. Though common, the presence of CSWS is not essential to diagnose LKS as studies have shown that CSWS occurs in 80%, but not in all patients fulfilling the criteria of LKS. CSWS as an EEG finding is determined to be present when the spike wave activity constitutes more than 85% of slow-wave sleep time. The ILAE defines the epilepsy syndrome of "epilepsy with CSWS" as a condition that "results from the association of various seizure types, partial or generalized, occurring during sleep, and atypical absences when awake" and "despite the usually benign evolutions of seizures, prognosis is guarded because of the appearance of neuropsychologic disorders." The spike slow-wave activity is characterized by being bilateral and mainly generalized. In that respect, one should distinguish between epilepsy with CSWS as an epilepsy syndrome (as defined above) and CSWS as an EEG finding (also as defined above). The epilepsy syndrome of CSWS resembles LKS clinically, but the difference between them arises from the EEG (which may not show CSWS in LKS), from the general mental deficiency in epilepsy with CSWS, and the serious comprehension problems (auditory agnosia) in LKS. Also, the two syndromes can be differentiated by their clinical profile when patients reach adulthood, whereby patients with epilepsy with CSWS suffer from global cognitive abnormalities, and those with LKS have these deficits restricted to speech abnormalities and behavioral problems.

Etiology and Pathogenesis

It is probable that LKS is a syndrome of multiple etiologies which are yet to be fully elucidated. This

syndrome was initially assumed to be secondary to encephalitis because an initial report indicated the presence of encephalitic changes in a biopsy taken from the cortex of a case of LKS. Subsequent studies could not confirm the presence of encephalitic changes in pathological specimens taken from other patients. Autoimmune mechanisms have been reported to be potentially important, at least in some patients. Autoantibodies against each of the following – brain-derived neurotrophic factor, neuronal antigens, myelin, and brain endothelial cells – were found in the sera of some patients with LKS. Other possible etiologies have been implicated in different case reports. These include genetic predisposition, cerebral arteritis, toxoplasmosis, neurocysticercosis, temporal astrocytoma, temporal ganglioglioma, hemophilus influenzae meningitis, subacute sclerosing panencephalitis, inflammatory demyelinating disease, and abnormal zinc metabolism. The neurologic deficit in LKS is thought to be secondary to the frequent and at times continuous electroencephalographic discharges that inhibit the function of the speech centers. The pathophysiology of this electroencephalographic seizure activity is believed to be that thalamic-related neural generators of synchronous sleep-related EEG oscillations combine to promote electrographic seizure propagation during nonrapid eye movement sleep and drowsiness.

Laboratory and Radiological Studies

Cerebrospinal fluid (CSF), computed tomography (CT), and magnetic resonance imaging (MRI) usually show no abnormalities. In rare cases, there may be an elevation in CSF protein, changes in white matter, or structural lesions on CT or MRI scans. Occasionally, some enlargement or asymmetry of temporal horns may be present, and this is suspected to be due to the effects of long-term epileptic activity. Various studies using single photon emission computed tomography (SPECT) and positron emission tomography (PET) on LKS patients have demonstrated the presence of abnormalities in the temporal lobe in brain perfusion and in glucose metabolism. These include hypometabolism in middle temporal gyri on fluoro-deoxy glucose (FDG)-PET. Also, decreased temporoparietal perfusion was detected by SPECT. The exact relationship between LKS aphasia and hypometabolism or hypoperfusion of the temporal lobe is not known because these features are also seen in epileptic patients who do not manifest aphasia.

Diagnosis and Differential Diagnosis

Essentials for the diagnosis of LKS include (1) auditory agnosia with language regression and (2) epileptiform EEG abnormalities that exacerbate during sleep. The workup to define the underlying etiology, if one can be found, usually includes an MRI scan. On rare occasions, functional imaging, CSF studies, or arteriograms may be needed. These tests are, however, not essential for making the diagnosis of this syndrome. It is crucial to differentiate LKS and Landau–Kleffner variant from CSWS (see the earlier section 'EEG findings'), autism (see the earlier section 'Clinical manifestations'), and from benign rolandic epilepsy with centrotemporal spikes (BECTS) with exacerbation in sleep. In rare cases of BECTS, the strong activation during sleep of the centrotemporal EEG spike and wave activity results in cognitive decline and attention disorders. In the usual BECTS cases, the EEG shows normal background rhythms; spike foci can be unilateral or bilateral. It also shows typical morphology of high amplitude and diphasic waveforms. BECTS seizures are typically simple partial seizures that include speech arrest, excessive drooling, twitching of the face, stiffening of the tongue, or other sensomotor phenomena of the orofacial region and the regression is not verbal auditory agnosia. Their seizures can also, less frequently, be complex-partial, generalized, or partial with secondary generalization. Most patients keep a normal global intellectual efficiency and good long-term outcome. However, some, as mentioned above, may suffer from oromotor dysfunction, neuropsychological deficits, or attention deficits with learning disorders. This may be more common in BECTS with atypical features. Atypical BECTS features include leg jerking, unilateral body sensations, ictal blindness, epigastric pain, lateral body torsion, diurnal seizures only, status epilepticus, developmental delay, and attention-deficit disorder (ADD). Some patients can have additional neuropsychological problems such as cognitive dysfunction, auditory–verbal and visuospatial memory problems, and behavioral disturbances. BECTS can be aggravated by the administration of some antiepileptic drugs (AEDS) leading to the development of CSWS. Some patients presenting with typical BECTS may present later with atypical features. Moreover, a small number of patients with BECTS develop LKS years later. Landau–Kleffner variant patients manifest LKS features, but also have the behavioral problems of autism (see the earlier section 'Clinical manifestations'). These patients are managed predominantly as LKS patients and less as autism patients.

Therapy

General Principles

Therapy of LKS still has many controversial issues due to the complete lack of controlled clinical trials in

this syndrome. The therapeutic approaches that are used are based on open label data usually collected from case reports involving small numbers of patients. There are essentially two main lines of therapy. Pharmacological treatment which includes anticonvulsants, corticosteroids, adrenocorticotropic hormone (ACTH), or intravenous immunoglobulin (IVIG), and surgical treatment. Surgical therapy is still largely controversial. In addition, while treating LKS, one should treat all its aspects including seizures, speech, and behavior. Controlling seizures is usually easy. Sometimes, improvement in EEG is associated with language restoration. Due to the fluctuating profile of LKS and its unpredicted remissions, it is difficult to assess the effectiveness of any treatment.

Antiepileptic Drugs

The conventional AEDs are effective in controlling seizures of LKS patients; however, their effect on aphasia is not consistent. Valproate (10–50 mg $kg^{-1}day^{-1}$), clobazam (1–1.6 mg $kg^{-1}day^{-1}$), and ethosuximide (20 mg $kg^{-1}day^{-1}$) were reported to be efficient in stopping seizures and in reducing language problems in about half of the patients that received them. Valproate at a dose of 20 mg $kg^{-1}day^{-1}$ was reported to be effective in ameliorating the speech problems, especially in patients whose aphasia started earlier. High dosage of oral diazepam (0.75 mg $kg^{-1}day^{-1}$ with a blood level of 100–400 ng ml^{-1}) given for six short cycles (3–4 weeks) was successful in treating ESES patients including one with LKS. Riviello from Children's Hospital, Boston, reported administering 1 mg kg^{-1}per dose of rectal or oral diazepam (up to a maximum of 40 mg) for patients with LKS or ESES on two consecutive nights with continuous video EEG monitoring for 2 days and pulse oximeter monitors for 4 h after the diazepam dose. The patients were administered 0.5 mg $kg^{-1}day^{-1}$ (up to a maximum of 20 mg) for 3–4 weeks, then the dose was tapered (2.5 mg per month). Eleven out of 13 patients responded to treatment and they had their language and EEG improved within a month. The use of ethosuximide (20 mg $kg^{-1}day^{-1}$) combined with either valproic acid, phenobarbital, carbamazepine, or a benzodiazepine, and that of vigabatrin combined with ethosuximide, carbamazepine, or clonazepam were also reported to be effective in some LKS patients. Also, lamotrigine monotherapy improved cognitive functions and language in some patients. Nicardipine (0.5–2 mg $kg^{-1}day^{-1}$) combined with conventional AEDs was reported to be effective in LKS patients. Felbamate given as polytherapy or monotherapy (60 mg $kg^{-1}day^{-1}$) was able to dramatically improve language skills and EEG in some patients. Sulthiame and levetiracetam (35–60 mg $kg^{-1}day^{-1}$) were reported to be effective in helping some LKS patients. The 4:1 ketogenic diet (4 parts saturated fats, 1 part proteins and carbohydrates) was reported to be an effective treatment of acquired epileptic aphasia patients. It is not recommended to use carbamazepine for LKS patients since it was found to often worsen this condition.

Corticosteroids and Adrenocorticotrophin Hormone

Corticosteroids and ACTH (50–80 μg day^{-1} given for 4 weeks to 3 months) have been reported to be useful in improving language, cognitive, and behavioral problems. It is not known which regimen is the most effective. Prednisone is given orally (2–3 mg kg^{-1} for 1–2 months, then tapered according to response) or given at a dose that ranges from 30 to 60 mg day^{-1}. Dexamethasone is often given in a dose of 4 mg day^{-1} for 2 weeks before being tapered off. Intravenous methyl prednisolone given as 20 mg kg^{-1} daily for 3 days, then every 4 days, followed by oral prednisolone 2 mg kg^{-1} daily for 1 month or given as 500 mg over 3 h daily for 5 days, followed by 250 mg infusion over 2 h once per month was reported to be effective in a few patients resistant to other therapies. Treatment with steroids usually needs to be prolonged for several months or for more than a year to avoid relapses. This prolonged steroid therapy may cause several side effects such as avascular necrosis of hip, hypertension, behavioral abnormalities, gastric ulcers, hyperglycemia, and immunosuppression. These side effects can be minimized by using every other day dosing or weekend pulse dosing.

Intravenous Immunoglobulin

Occasional cases of LKS respond to IVIG; usually given as 2 g kg^{-1} for 4–5 days). The response to IVIG, in those that do respond (and those are a small minority), is usually quick and dramatic starting by day 3 of the infusion and resulting in remission of speech within a few days to a few weeks. However, this at times usually lasts for 3–4 months, after which a second or a third course is needed to result in similar responses and eventually in a permanent remission.

Surgery

The surgical procedure that has been reported to improve the profile of LKS patients that have failed medical therapy is multiple subpial transection (MST). This procedure involves sectioning the horizontal interneurons, which is hoped to lead to a decrease in epileptic discharges originating from the speech cortex while maintaining the area's physiologic functions. MST was reported to result in eradication of continuous spike waves during sleep and in

ameliorating the language functions in many of the above patients. However, MST is still viewed as an experimental procedure by many experts. In fact, it is usually required, before proceeding with MST, that the patient should fulfill several restrictive criteria. These include having normal developmental history of language and cognition before starting to lose language skills, normal nonverbal cognitive functions, unilateral intra- and perisylvian epileptogenic zone, and CSWS duration of less than 3 years. Vagal nerve stimulation (VNS) has recently been introduced as another type of surgery that could help LKS patients with refractory seizure. It was reported to decrease seizure frequency by half in three out of six children. Its effects on the aphasia still need to be determined.

Speech Therapy and Behavioral Intervention

Several interventions such as sign language, a daily diary of consecutive pictures of the classroom routine, auditory training starting with environmental sounds, and 'graphic conversation' technique have been found to be useful intervention tools. Even after LKS patients receive the appropriate treatment, they can still have problems related to processing oral language. Thus, even if they respond, there is still a need to use different methods to bypass the auditory channel of processing. Moreover, patients may need some behavioral modification techniques to deal with their behavioral problems. Medications to control hyperactivity and behavioral problems are also occasionally needed.

Evolution and Prognosis

Children with LKS may show complete recovery from aphasia months or years after the onset of LKS. Others, constituting around 50% of the patients, recover partially or suffer from permanent aphasia. Some cases are characterized by periods of fluctuating remissions and relapses. Prognosis is affected by many factors such as age of onset, type of language deficit, frequency and topography of EEG abnormalities, epilepsy duration, and effectiveness and side effects of AEDs. Outcomes can be as good as complete recovery and as bad as permanent aphasia. Most patients improve with some remaining moderate language problems. Moreover, one can expect better prognosis when the onset of language deficits takes place after the age of 6, and when speech therapy is started at an early stage. The relationship between the age of onset of language deficits and the end result is contrary to the situation of childhood aphasia after structural injury. The older the LKS patients, the greater their chance of language improvement. In aphasia that is associated with a lesion, the older the age at which the lesion appears, the lower the probability of language improvement. Improvement in EEG often precedes improvement in LKS-associated language disorders, but it does not guarantee the most favorable end point. In fact, some have found a strong relationship between the manifestation of language problems and EEG changes whereby improvement in both speech and EEG occurred at the same time, whereas others did not find such a relationship.

Introduction

The ability of human children to acquire a language is one of the hallmarks of the species. Within 24 h of being born, infants already show evidence of having learned aspects of the broad rhythmic structure of their mother tongue, most likely from hearing speech *in utero* during gestation. Infants continue to attend to the patterns in their language and start to learn a considerable amount about its structure well before they start combining words in their own speech. After just a few years, children will have mastered many of the complex grammatical structures in their language, and persistent systematic errors become rare as children approach their tenth birthday. Children exposed early on to additional languages will learn them without any significant added difficulty compared with monolingual acquisition, provided they have sufficient exposure to each language.

Language development in children is remarkable for its regularity across individuals and different languages, even when the languages are quite diverse. Children universally progress through many of the same stages, mastering certain components of the grammar before others and making characteristic errors in production and comprehension at each stage. Despite individual differences in intelligence and other abilities, and despite normal differences in language exposure, all children end up able to speak and understand their native language(s) fluently. This is in marked contrast to adult learners, who show much greater variability in learning processes and ultimate outcomes. Indeed, differences between children and adult learners in ultimate outcome, in the kinds of errors made, and in the stages of acquisition have led many researchers to conclude that there is a critical or sensitive period for language development. As in other developmental domains with critical periods, learning that takes place outside this period is more variable and less robust, leading to a greater range of outcomes and more idiosyncratic patterns of acquisition.

In addition to the uniform patterns of acquisition across languages, there are some aspects of language development that are tied more closely to structural properties of the particular language being learned. Comparing components that are more or less language dependent can lead to insights about the learning mechanisms involved in language development and the properties of the linguistic input to which learners attend.

This article gives an overview of early language development, discussing some key phenomena in acquisition and some major theoretical issues. Other articles offer more-detailed discussions of specific areas within language development.

Overview of Early Language Development

First Words

Linguistic structure When acquiring a vocabulary, learners associate word forms with concepts related to their meanings. In addition, they store information about how words combine with other words to makes sentences. The combinatorial patterns in language are governed primarily by the categories of words rather than by words themselves; thus learners must represent category information. While all languages have categories for nouns and verbs, languages vary as to what other categories are differentiated grammatically, such as adjectives, adverbs, determiners, and so forth. For example, many languages have classifiers – words or morphemes (see the section titled 'Morphology') that occur obligatorily and specify general properties of objects (e.g., animate, long thin object) – but English does not have a classifier system. The presence or absence of a grammatical class in a language should not be confused with the language's ability to express related concepts. For example, in English one can talk about attributes generally designated by classifiers in other languages, but English uses phrases involving adjectives and nouns instead of a unique class of markers.

Production Children produce their first words at approximately 1 year of age, although there is considerable variability in the onset of lexical production. These words are distinct from babbles in that they have referential content, although phonetically they may only approximate the target word form. Semantically as well, a word may only approximate the adult target. Thus, [dɔ] ('daw'), might be a 1-year-old's word for dog, but also for horses and other four-legged animals.

Children's productive vocabulary increases relatively slowly as the first 50–100 words are acquired. The initial cohort of words is primarily nouns. The early dominance of nouns appears to be a universal phenomenon and is attributed to the relative ease

of determining a noun's referent (often a concrete object) versus a verb's referent (complex relationships between objects, internal mental states, etc.).

Perception Although children generally do not produce their first words until they are approximately 1 year old, they segment the stream of continuous speech sounds into wordlike units much earlier. By 4.5 months, infants can recognize their own names embedded in fluent speech, and by approximately 7.5 months, their ability to segment words is much more fully developed. Thus, many months before producing their first words, infants become aware of the sound sequences that correspond to words in their language.

Morphology

Many words are made from smaller parts – sublexical meaning-bearing units called bound morphemes. Bound morphemes cannot exist alone as words but combine in systematic ways with stems to create words. For example, in English the morpheme *-ed* signifies past tense and affixes to the ends of verbal stems to produce past tense forms: *talk* + *-ed* → *talked*; the morpheme *–er* affixes to the end of verbal stems to produce related nouns: *talk* + *-er* → *talker*.

Although there is a relatively restricted range of functions or meanings associated with bound morphemes, individual languages differ as to what grammatical functions are marked morphologically. For example, many languages mark grammatical case – subject, object, possessor, and so forth – on nouns morphologically, but in English, case marking appears only on pronouns (e.g., *he* is in nominative case for subjects, *him* is in accusative case for objects), and case roles are determined structurally, using word order. Thus, in learning a language, children must learn what the bound morphemes are in their language, as well as the way in which these morphemes combine.

Production The timing of children's first productive uses of grammatical morphemes depends on the language being learned. For example, while a typical 18-month-old learning English is unlikely to systematically vary tense or agreement marking on verbs – such as always saying *walk* instead of *walked*, *walks*, or *will walk*, and so forth – a Turkish-learning child will use past tense morphology by as young as 15 months. Cross-linguistic differences in children's mastery of grammatical components is unlikely to arise from differences in children's conceptual development or general manner of conceiving of events and relations across language. Rather, many such differences can be explained by formal differences in the morphological systems. Turkish has a richer inflectional system that morphologically marks case and number on nouns and tense, mood, aspect, and agreement on verbs. Moreover, in Turkish each marker is a unique morpheme, unlike in English. For example, the English morpheme *-s* marks both third person and singular, whereas in Turkish, one morpheme marks third person and another marks singular. Overall, then, there is a greater prevalence of bound morphemes in Turkish than in English. In addition, inflections in Turkish are phonetically more salient than in English: they are syllabic, containing unreduced vowels, and usually receiving stress. Finally, the near-perfect one-to-one mapping of morpheme to grammatical function in Turkish makes the morphological system less ambiguous than in languages like English (where, for example, *-s* marks both third-person singular on verbs and plural on nouns), which could make learning faster. Thus, language-specific factors such as the regularity of form, the uniqueness of form-to-meaning mappings, and the acoustic/phonetic salience of morphemes all influence the time course of morphological development.

Perception Before children use morphology productively, they must identify the phonological forms that correspond to bound morphemes in their language. As discussed above, in languages in which grammatical morphemes are acoustically salient, regular, and unambiguous, detection of the forms and mastery of the form–meaning mappings proceed more rapidly than in languages that do not have these properties. Nevertheless, perception of morphological forms and dependencies of forms occurs well before the forms are used productively. In English, 18-month-old infants have been shown to be aware of the dependency between the auxiliary verb *is* and the main-verb ending,*-ing*, in present progressive sentences: they differentiate grammatical sentences such as *The baker is baking bread* from ungrammatical sentences such as *The baker can baking bread*, in which *can* and *-ing* are incompatible.

First Word Combinations

During the period of early vocabulary growth, children's utterances consist almost entirely of isolated words. Children between 18 and 24 months of age start to combine words, producing both one- and two-word utterances. During that time, children's vocabulary growth rate increases as well, with an increase in the ratio of verbs to nouns compared with prior periods. Early word combinations often combine nouns with verbs, as well as nouns with

other nouns and sometimes adjectives. These multiword combinations show consistent ordering patterns that generally reflect the basic word order patterns of the exposure language. For example, the basic word order pattern in English transitive sentences is subject–verb–object (SVO). At the stage when English-learning children combine at maximum two words per utterance, they sequence verbs before nouns to express action–patient, action–theme, action–goal, and action–location relations, and they sequence nouns before verbs to express agent–action relations. For example, a child in this stage might produce 'kick ball' to indicate an action performed on a ball (action–patient), and 'baby kick' to refer to an agent performing an action. Noun–noun combinations also respect the basic word-order relations, so that in the example above, expressing both agent and patient would be accomplished by the utterance 'baby ball', in which the correct ordering relation between the two arguments is maintained but the verb is missing. The last example points to potential ambiguity in interpreting early child productions as there are also situations in which the same sequence of words ('baby ball') might express a possession relationship, that is, 'baby's ball,' without the possessive morpheme. Many analyses of children's speech thus consider the context of an utterance in determining its meaning and underlying structure. The researcher Lois Bloom pioneered this method of analysis, coined 'rich interpretation,' in the early 1970s. After carefully analyzing the situational contexts under which children's early utterances are produced, Bloom argued that children's two-word utterances express the same kinds of basic semantic and syntactic relations as adult sentences express – possessor, thing possessed, subject, direct object, indirect object, and so forth. While there was (and still is) disagreement about the particular categories and grammatical structure underlying children's early utterances, many researchers followed Bloom's lead in using context to infer structuring principles that would not be evident from analyzing the sequence of words alone.

Even languages that place few syntactic constraints on word order (marking subject, object, and direct object by case marking on nouns) have canonical word-order patterns that are governed by pragmatic and discourse constraints. For example, Turkish allows all possible orders of subject, verb, and object in transitive sentences; however, there is a statistical predominance of subject–object–verb (SOV) sequences, with SVO sequences being the second most frequent (and, indeed, Turkish is usually considered an SOV language, the most common type cross-linguistically). Children learning Turkish reflect these patterns in their own multiword utterances. Thus, word-order patterns are one of the first structural properties that young children attend to and master. Their representation of these patterns includes knowledge of how structural positions correspond to semantic roles, such as agent, patient, theme, goal, and location.

Gradual Development of Grammatical Constructions Involving Phrases

Most grammatical formalisms include categories for word sequences, or phrases, as well as for individual words, and many grammatical operations involve phrase-level constituents. For example, *the red dog* is a noun phrase (NP) in English, and it takes its category type from the phrase head (the noun, *dog*). Grammatical operations, such as question formation, operate on elements at this level: for example, the declarative *John sees the red dog* becomes *Who does John see?* in the interrogative, with the entire NP replaced by *who* (which is subsequently moved).

While phrases are an important structuring component in language, they are abstract entities, in that phrases – the boundaries between phrases, the category of phrases, and the hierarchical organization of phrases – are not explicitly marked in speech. Thus, part of what children must learn in acquiring a language is the internal organization of phrases and the sequencing of phrases within sentences. Children must also learn how grammatical operations manipulate phrases. In some cases, mastery develops in stages and suggests processes of reorganization in language development. Several examples are given in the next sections.

Question Formation

English-learning children go through several distinct stages in forming interrogative sentences, producing ungrammatical questions early on. For example, they produce sentence-initial *wh*-words without required auxiliaries: "what doing?" or "what you doing?" Next, they produce the auxiliary verbs but without the required inversion with the subject: "what you are doing?" Finally, they perform the required inversion of subject and auxiliary verb: "what are you doing?" Although there is individual variation across children in this general pattern, it is striking how predictable the development of question formation in English is. The stable pattern of errors has been used to argue for highly constrained mechanisms guiding learning, but the facts are also consistent with theories of language development that posit more general mechanisms that are sensitive to the statistical properties of the input. The acquisition of questions is also an example of the incremental development of linguistic capabilities.

In Chinese and Japanese (among other languages), forming questions does not involve moving words or inserting auxiliary verbs like *do*. Children learning such languages consistently produce well-formed questions before English-learners do. Comparing the course of development for similar syntactic functions across typologically different languages can give insights into the nature of the mechanisms and representations involved in acquisition because it provides evidence about the ease or difficulty with which different surface features are mastered to achieve similar linguistic functions.

Verb Complement Clauses

A phrase can have another phrase embedded within it. Examples are sentences with sentential complements, for example, *Mary saw (that) [Sam was sad]*, in which the embedded verb is tensed, and *Mary wanted [Sam to be happy]*, in which the embedded verb is infinitival. The function words *that* and *to* serve to mark embedded clauses, and their consistent use by children would be suggestive evidence that they have the adult complement structures in place. However, early productions of tensed complements occur without *that*, for example, *I know he sits here*. Although this appears to be a grammatical complement construction, some accounts of these early constructions propose that they involve two hierarchically adjacent phrases rather than one phrase embedded within a larger sentence. The structure of the last example would be similar to *He sits here, and I know this*. On that account, early utterances like those do not involve embedded clauses.

Similarly, children initially produce utterances such as "I want open it" or "I gonna get it" without the obligatory infinitival marker, *to*. The marker emerges gradually, first restricted only to a small set of matrix verbs (e.g., ... *want to* ...). But even in those constructions, it is rare for subjects to intervene between the main verb and *to*, with the result that the subject of the embedded clause is identical to the subject of the main clause (e.g., *I want (to) open it* vs. *I want Sam (to) open it*). These restricted aspects have led some researchers to claim that these utterances do not contain embedded complement clauses at all; they analyze the main verb as a modal verb that modifies the second verb (which would be analyzed as the main verb). In this view, *I want open it* is parallel structurally to *I can open it*. These accounts of early complement-like constructions claim that early utterances do not, in fact, involve embedded clauses.

In summary, mastery of complement phrases appears to be gradual and depends, in part, on the identity of the main verb. Even when children correctly produce and comprehend most complement constructions, some still cause difficulty. In particular, some main verbs are special, in that the embedded subject is not the subject of the embedded clause. Compare *Sam wanted Mary to set the table* with *Sam promised Mary to set the table*. In the first sentence, the embedded subject is the subject of the embedded complement, and this is the normal situation. However, in the second sentence, the matrix subject *Sam* is also the subject of the embedded clause. Children routinely interpret such sentences as though *Mary* is setting the table, and these errors can persist until about age 9.

Relative Clauses

Relative clauses are another kind of embedded clause that adds complexity to basic sentences, here within NPs. For example, the material after *that* in *the man that I know*, is a sentence embedded within an NP; the relativizers (*that*, *who*, etc.) are often optional. As with complement clauses, development of these structures in production is gradual. At first, children omit relativizers and generally modify only the last noun in a sentence, resulting in the modifying material occurring at the end of the utterance, which modifies the sentential object: "I see the car has the stripes." Later, they also produce relative clauses in subject position and are more likely to include *that* or other relative pronouns (e.g., *who*): "Man that I saw is leaving." Thus, as with complement clauses, the development of relative clauses in production is incremental.

Overregularization

There are regularities in the way a given language carries out grammatical functions. For example, in English, the past tense is formed by suffixing *-ed* onto a verb stem: *walk* → *walked*. In addition, there are exceptions to the regular patterns: the past tense of *go* is not *goed* but the irregular *went*. A universal phenomenon in language development is the overregularization of irregulars by children. When children initially produce an irregular, they may do so correctly, but as they start to learn more and more regular forms, and learn the generalized pattern, they sometimes apply the pattern to irregular forms – either to the stem (e.g., *goed*) or the irregular form itself (e.g., *wented*). These overgeneralization errors can persist in individuals for several years.

The phenomenon of overregularization has played an important role in the theorizing about language acquisition. Patterns of overregularization have been used as evidence in support of a variety

of different architectures for lexical memory and related storage and access mechanisms, from general pattern associators that treat all stems and derivations equally, to specialized mechanisms that explicitly distinguish regular and irregular forms.

Nativism and Domain Specificity

One of the core questions in language acquisition research is the nature of the mechanisms and representations that make learning a first language possible. Central issues are nativism – the degree to which acquisition relies on innate mechanisms and representations – and domain specificity – the degree to which learning mechanisms are specific to language development. Although these issues are often conflated, they are two distinct theoretical claims.

It is clear that human language involves, to some degree, innate or biologically determined components that are present in humans but absent in other species. Inherent differences in cognitive architecture across species, in part, make human language qualitatively different from the natural communication systems of other species. (Clearly there are nonneurological biological differences between species that are relevant for language learning and use. Spoken language as we know it is not possible without a vocal tract capable of producing the necessary range of phonetic material, and a species without hands or the appropriate visual system would be unable to communicate using a signed language. But the crucial formal characteristics of human language are modality independent and in principle could be implemented in a variety of physical systems. It is these properties that arguably have an innate component in the cognitive architecture of humans.)

These innate components contribute to the highly systematic and uniform pattern of development cross-linguistically and to the inability of nonhuman species to achieve the same degree of mastery. What is generally debated is the content of the innate components: is there specialized functional machinery that is dedicated to the acquisition and/or use of language, or does language have the structure it does, and do children learn language the way they do, because of more-general properties of human cognition and/or human social interaction?

One of the most influential theories about the innate component was proposed in the 1960s by Noam Chomsky. Chomsky proposed that humans possess an innate, universal grammar (UG). In its standard conception, UG specifies the structural properties that all human languages share (and thus that putatively do not have to be learned), for example, that words are organized into phrases and phrases are organized into sentences, the kind of syntactic operations that words in certain phrasal positions can undergo, and so forth. UG also contains specialized mechanisms for learning the nonuniversal idiosyncrasies of the language to which the child is exposed (e.g., whether question formation involves inversion of the subject and auxiliary verb). The motivation for the theory is often referred to as the 'poverty of the stimulus' (POS) argument. The core of the argument states that the data from which children learn language – the utterances that they hear – are too variable and too underspecified to guarantee that all learners would converge on the correct grammar without specialized constraints and linguistic knowledge guiding learning. UG provided a description of these constraints.

Within this general theoretical framework, different theories were proposed for learning mechanisms that could determine the language-specific properties that were specified in (but also highly constrained by) UG. The content of UG and the associated learning mechanisms were described in the vocabulary of formal linguistic theory and were traditionally viewed as specific to language. But in a broader sense, UG could be construed as a set of constraints on possible inferences that can be made from linguistic input. Viewed in this way, it becomes reasonable to investigate alternative sources or descriptions of these constraints. For example, some constraints on learning and generalization could emerge from constraints in substrate learning components such as working memory, sequential processing, and so forth, and constraints governing their interaction. Some universal constraints on linguistic structure could arise from social and cultural phenomena, as opposed to specific cognitive structures for language. The computational problem of linking linguistic forms to meanings, sequencing these forms when producing utterances, and comprehending these sequences when listening to speech could lead to specific kinds of structures, in order to be carried out in real time by a human brain.

Nevertheless, many constraints on linguistic structure seem difficult to motivate from these other sources. For example, from sentence (2a), question (2b) is possible, but (2c) is ungrammatical. What could account for this difference?

(2a) Sam knows a man who likes wine.
(2b) Who does Sam know who likes wine?
(2c) What does Sam know a man who likes?

Grammatical theories account for this difference by positing constraints on grammatical operations and defined on the basis of syntactic structures; in other words, domain-specific constraints. It is not immediately obvious how the alternative sources of

constraints just discussed could account for such phenomena, but a number of research programs are currently addressing just these questions.

Recovery from Errors and Negative Evidence

Part of the POS argument is the observation that a learner who was not adhering to the right structural constraints could posit grammars that overgenerate sentences. That is, the grammars would account for the utterances the child heard, but also ungrammatical utterances. This is not, in principle, an insurmountable problem. Having such a grammar, a child would be expected to make errors and produce ungrammatical sentences. But if the child received a corrective signal that the utterance was ill-formed – negative evidence – then the learner could update the grammar to rule out the ungrammatical utterance. This alternative has two essential components: (1) there must be reliable sources of feedback available to children when they make errors, and (2) the feedback should change the pattern of errors a child makes. If either of these points is not satisfied, then an alternative to a highly constrained learning mechanism becomes more difficult to maintain.

In fact, there is considerable evidence that none of these conditions are satisfied by the empirical data. A number of possible sources of negative evidence have been proposed, primarily involving the types of replies adults give in response to children's ungrammatical utterances (e.g., repeating the utterance with errors repaired, expanding the utterance, etc.), but caretakers vary widely in the kinds of responses they give to children's ungrammatical utterances, and so far no type of feedback has been shown to be reliable enough to be universally informative. Moreover, even in cases when children's errors are explicitly corrected, children very rarely alter their behavior, and the errors persist. When errors do cease, they do so without corrective feedback from adults.

Taken together, the reliability across children in the kinds of errors they make and their recovery from errors in the absence of negative evidence points to learning mechanisms that follow an internally constrained program. However, these facts are neutral as to the nature of the constraints and whether they are special to language or derive from more-general principles and properties of learning.

Cues to Structure

An important aspect of the POS argument is that utterances do not come marked with their structural description. For example, words are not inherently marked as noun, verb, adjective, and so forth, and phrasal constituency in utterances is not explicitly marked. If structure were transparent in the input, then the nature of the learning problem would be very different, as learners could simply 'read off' the structure from the utterance.

Researchers are examining the degree to which cues that correlate with important structural distinctions are available to infants and children acquiring a language. In many languages, there are bound morphemes that correlate strongly with lexical category (noun, verb, adjective, etc.). For example, case markers occur on nouns but not on verbs, and tense markers appear on verbs but not on nouns. Even though the correspondence between overt marker and lexical category may be many-to-one (e.g., because there are multiple nominal cases), as opposed to one-to-one (the simplest kind of cue), morphological markers could nevertheless be extremely useful cues to category membership.

However, not all languages have robust marking; as discussed earlier, languages like English have case marking only on pronouns, and verbal morphology is relatively impoverished. In addition, in some languages, morphemes that occur with different lexical categories are homophonous, and therefore ambiguous cues; in English, for example, *-s* is a plural marker on nouns (e.g., *cats*) and a third-person-singular agreement marker on verbs (e.g., *grows*). Therefore, while bound morphemes might provide useful category cues in some languages (e.g., Turkish), their usefulness might be limited in others. However, other cues, such as the co-occurrence patterns of words and phonological cues, have been shown to be informative for determining lexical categories.

Studies have also investigated whether prosodic information – information involving pitch, syllable duration, pause duration between words, and amplitude – could cue major phrase boundaries, such as boundaries separating subject NPs from the verb phrase. There is cross-linguistic evidence that combinations of cues involved in prosody are probabilistic indicators of phrase boundaries and could thus be used by children to aid in assigning structure to an utterance.

Another cue to phrase-level constituency that is available in some languages is inflectional marking, in particular, case marking within NPs. In German, for example, case is marked on articles and adjectives (both within an NP), and the case morpheme often (although not always) takes the same form on the article and adjective. For example, in the masculine declension, the definite article is *der* in the nominative case, and the corresponding ending on a following adjective would be *-er*; however, in the accusative case, the definite article is *den*, and the corresponding case marker on the adjective is *-en*. The phonological

similarity of endings within a phrase (the article and adjective) could be used by learners as a cue to identify phrasal constituency. Even when within-constituent endings are not as similar phonologically, the endings covary within a phrasal constituent to a significant degree, and the patterns of dependency within phrases could be a more general cue to phrasal constituents.

Investigations into possible cues to structure are uncovering a variety of probabilistic cues inherent in the structure of utterances and in statistical patterns across utterances that learners could use to recover some aspects of the structural description of an utterance. To learn successfully using these cues, learners must attend to the relevant perceptual dimensions and process their input in specific ways. Experiments with infants and young children demonstrate that learners are indeed sensitive to many of the requisite properties and perform the necessary types of analysis on the basis of those properties. These lines of research are helping to specify the nature of the innate mechanisms involved in language learning. In some cases, the sensitivities and constraints are not clearly specific to language but rather could be viewed as more-general constraints on sequential processing, auditory perception, and categorization.

Introduction

Language is often referred to as one of the hallmarks of our species. However, the emergence of language may be more than simply an important event in human evolution; it may be one of only eight 'major transitions' in the evolution of life, as listed by the two eminent evolutionary biologists John Maynard Smith and Eörs Szathmáry. Each major transition denotes a key event in the history of our planet, signaling radical changes in the way evolution works, starting with a change in the way molecules replicate in the very earliest stages of the origins of life, through the emergence of DNA, to larger scale subsequent phenomena such as the evolution of colonies where once there were only solitary individuals and including, as the most recent evolutionary transition, the emergence of language (Figure 1).

Why is the emergence of language such a significant event? What does it have in common with the other major evolutionary transitions? One of Maynard Smith and Szathmáry's interesting observations is that, despite their diversity, these transitions have some features in common. In particular, many of the transitions give rise to a new mechanism for the transmission of information. Language, they argue, provides just such a novel mechanism – essentially enabling a system of cultural transmission with unlimited heredity. As such, language enables the transmission and storage of very complex cultural information. But how did we, as human beings, evolve this powerful ability? Before discussing the possible answers to this question, we briefly survey the structural features of language that support this powerful information transmission system.

The Structure of Language

One way of thinking about language (although by no means the only way) is as a coding system that maps between two spaces: the space of concepts and intentions, on the one hand, and the space of articulation and perception, on the other hand (Figure 2). Traditionally, the study of the structure of language has been divided into a number of subdisciplines, each of which concerns a different aspect of this mapping system:

- *Phonetics*. The production and perception of sounds/manual gestures.
- *Phonology*. The systematic behavior of the sounds of language.
- *Morphosyntax*. The system for combining the basic meaningful units of language into words and sentences.
- *Semantics*. The meaning of words and sentences in isolation.
- *Pragmatics*. The system for relating word/sentence meaning to communicative intention in the context of communication.

The first and last two subdisciplines on this list deal mainly with the two ends of the mapping in Figure 2, whereas morphosyntax is most clearly the study of the aspects of language that govern how these two are connected, using words recruited from a mental lexicon.

What is extraordinary about this system, and what makes it particularly important for Maynard Smith and Szathmáry, is that it is constructed in such a way as to allow unbounded yet faithful transmission of information (sometimes termed 'digital infinity'). This combination of an infinite range of messages with a high-fidelity mechanism for transmitting those messages is almost unique in nature. Arguably, the only other example is the genetic code.

It is easy to understand why human language is in principle unbounded. If we were to try to find the longest sentence of English, we would fail. This is because the syntactic system delivers mechanisms that will allow us to elaborate on sentences in an unlimited fashion (e.g., by adding subordinate clauses, adverbial phrases, and prepositional phrases). This kind of infinity is 'digital' because it does not rely on continuous changes in the signal to convey changes in meaning but, rather, the addition of discrete elements. In contrast, we could imagine a different signaling system in which the pitch of a signal conveyed differences in meaning (e.g., the severity of a particular threat). This system would be infinite because there are infinitely many different pitches, but it would not be digital.

Another unusual aspect of human language is that the lexicon is flexible. New words can be added, and the meanings of words can change. Although this feature of language is not discussed as much as digital infinity, it is actually the combination of these two that really sets human language apart as a uniquely powerful tool for the unbounded transmission of cultural information. In summary, language structure allows high-fidelity, unbounded, and flexible communication.

Figure 1 Maynard Smith and Szathmáry's eight major transitions in the evolution of life.

Figure 2 Language can be viewed as a system that maps between two different domains: concepts and intentions, on the one hand, and mechanisms for articulation and perception of speech (or gesture), on the other hand.

Questions surrounding the origins and evolution of language have, since the early 1990s, seen a major increase in interest in the scientific community, across a very wide range of disciplines. In the remainder of this article, we discuss major areas of consensus and current controversies. It is important to realize, however, that this is far from an exhaustive summary of a subject that draws on evidence from archeology to computer science, from genetics to philosophy.

Major Points of Consensus

Understanding language evolution poses many challenges for contemporary science, and the picture that is emerging is highly complex. Nonetheless, considerable progress has been made in the field of language evolution since it emerged as a legitimate area of scientific enquiry during the 1990s. Here, we first provide an overview of the major areas of consensus before discussing some of the current controversies.

Possible Preadaptations for Language

There is a general consensus that to understand language evolution, we need a good understanding of what language is. However, the field is divided over what the exact characterization of language should be, and in what terms it should be defined. Nonetheless, agreement appears to be in sight regarding some of the necessary steps toward language. Specifically, there seems to be agreement that prior to the emergence of language, some preadaptations occurred in the hominid lineage. There is less agreement about what these may have been, but one candidate that has been proposed by many is the ability to use symbols. In this context, symbol use is typically construed as a capacity for linking sounds or gestures arbitrarily to specific concepts and/or percepts – particularly for the purpose of communication. In addition, it has been suggested that the ability to relate these symbols to each other was a further necessary preadaptation for language. Although there is evidence that nonhuman primates have some capacity, albeit limited, for using sequences of arbitrary symbols in captivity, there is considerable debate regarding whether they use these symbols to refer things in nature. For example, the use of manual gestures for symbolic communication in the wild has been called into question. Thus, the use of complex sequences of symbols referring to objects and situations may be a uniquely human ability.

Several other possible candidates for language preadaptations have been put forward, of which we mention a few relating to changes in social or cognitive abilities. Joint attention – that is, the capacity to follow eye-gaze direction or direct the attention of another to a specific object – is important for successful communication, and it may have been a social precondition for language. Another potential social preadaptation for language is the capability of modern humans for sophisticated imitation of action sequences for the purpose of communication. Our ability to represent others as intentional beings with their own beliefs and desires, which can be manipulated by our actions, may also be a social prerequisite for language. At the cognitive level, an increase in the capacity for representing complex concepts and combinations thereof may have predated the emergence of language. Additional cognitive preadaptations that may have paved the way for language include the ability for complex hierarchical learning of sequentially presented information and increases in memory for sound sequences, both of which are important for

learning and processing of language. It should be noted, however, that many of the preadaptations mentioned previously are shared with other species, particularly other primates, and that differences in these skills may be more quantitative in nature than qualitative.

The Necessity of Interdisciplinary Collaborations

Perhaps the strongest point of consensus among language evolution researchers is a methodological one: to fully understand language evolution, it must be approached simultaneously from many disciplines. We must understand how our brains work; how language is structured and what it is used for; how early language and modern language differ from each other and from other communication systems; in what ways the biology of hominids has changed; how we manage to acquire language during development; and how learning, culture, and evolution interact.

Thus, language evolution research must necessarily be cross-disciplinary in order to provide sufficient constraints on theorizing to make it a legitimate scientific enquiry. Nevertheless, most researchers in language evolution only cover parts of the relevant data, perhaps for the reason that it is nearly impossible to be a specialist in all the relevant fields. Still, as a whole, the field appears to be moving in the direction of becoming more interdisciplinary. Collaborations between researchers in different fields with a stake in language evolution are likely to become increasingly more important.

The Importance of Modeling

Another emergent area of consensus is the growing interest in using computational modeling to explore issues relevant for understanding the origin and evolution of language. Many researchers across a variety of different disciplines now either conduct language evolution simulations or refer to such work as evidence for particular theoretical perspectives. For example, modeling work has been used to inform high-level theories about biological adaptations for grammar or the emergence of language structure through cultural transmission but also at a more detailed level, such as the evolution of phonetic gesture systems or a neural basis for grasping as a precondition language based on manual gesture. Models are useful because they allow researchers to test particular theories about the mechanisms underlying the evolution of language. Given the number of different factors that may potentially influence language evolution, our intuitions about their complex interactions are often limited. It is exactly in these circumstances, when multiple processes have to be considered together, that modeling becomes a useful, and perhaps even necessary, tool.

The role of computational modeling in language evolution research can be divided into three rough categories.

1. Evaluation: Computational models, like mathematical models, have the virtue that they enforce explicitness in the formulation of an explanation. As such, they can act as a rigorous check that a particular explanandum actually does follow from a particular explanans. In other words, they can help researchers to identify hidden problems. In some sense, they allow us to create novel experiments to test under which conditions language evolves.
2. Exploration: Computational simulations can be used (with caution) to explore the general ways in which explanatory mechanisms or theoretical constructs interact. In this mode, simulations can help direct us to new theories.
3. Exemplification: Computational simulations can be a valuable tool for demonstrating how an explanation works. They can augment verbal and mathematical theorizing to provide working models for pedagogical purposes.

Computational modeling thus provides a powerful new tool for the study of language evolution. However, it cannot stand on its own. It must take its place alongside theoretical considerations, mathematical modeling, experimentation, and data collection (e.g., linguistic and archaeological). For example, some computational models may eventually lead to mathematical models, or vice versa. Computational models may suggest novel psychological experiments and so on. We envisage that the interest in computational modeling is likely to increase, especially as it becomes more sophisticated in terms of both psychological mechanisms and linguistic complexity.

The Usefulness of Comparative Approaches

An additional type of evidence that is becoming increasingly important is data from studies that directly compare the learning and processing abilities of nonhuman primates with those of humans (either adults or children) using the same experimental paradigms. For example, comparisons of 8-month-old human infants and cotton-top tamarins on a simple artificial language learning task using the same preferential head-turn methodology indicate that both species may have similar abilities for basic statistical learning. Such work may allow us to better determine which components of language may be unique to humans and which may be shared with other species. As a case in point, comparative evidence regarding sequential learning suggests that an important

difference between human and nonhuman primates is our superior ability for learning and processing hierarchically organized temporal sequences. When combined with further corroborating evidence from neuropsychology and neurophysiology, computational simulations, and linguistic considerations, this human ability becomes a compelling candidate for a possible hominid biological adaptation that may eventually have led to the evolution of complex language. Future comparative research may reveal additional differences that can inform our understanding of language evolution.

Insights from Genetics

Advances in genetics are now figuring prominently in discussions of language evolution. As we obtain a better understanding of the genetic bases of language and cognition, as well as their interaction with the environment during development, genetic information promises to provide new constraints on language evolution theories, particularly with respect to issues related to the origin of language. However, the relationship between language and genes is extremely complex, and the relationship between genes, language, and evolution perhaps even more so. Consequently, current evidence provides few constraints on evolutionary theorizing. For example, data regarding the *FOXP2* gene have been cited in support for very different theories of language evolution, ranging from a gesture-based perspective to a speech-based perspective, from accounts involving large endowments of innate linguistic knowledge to accounts eschewing such innate knowledge. Nonetheless, there seems to be agreement that the FOXP2 data may suggest a late evolution of speech. In this way, the genetic data may be particularly useful in informing our understanding of the timeline for language evolution.

Current Controversies

Although much progress has been made and several areas of consensus have emerged, a number of major points of disagreement remain, of which we highlight the more current ones here.

Biological versus Cultural Evolution

Although there is considerable agreement about a possible symbolic preadaptation among our hominid ancestors prior to the emergence of language, opinions differ considerably about the subsequent evolution of grammatical structure.

One line of theorizing suggests that grammatical structure is a consequence of an evolved innate grammar. There are several different proposals regarding how and why a biological adaptation for grammar may have evolved in the hominid lineage by way of natural selection. One suggestion is that language evolved gradually as an innate specialization to code increasingly complex propositional information (e.g., who did what to whom, when, where, and why). This may have been for the purpose of social information gathering and exchange within a distinct 'cognitive niche' or for a kind of social 'grooming' at a distance in groups of hominids too large for establishing social cohesion through physical grooming. Another perspective suggests that grammar emerged more rapidly with the speciation event that produced modern humans approximately 120 000 years ago. Common to most of these proposals is the suggestion that language syntax shows evidence of complex design – similar to, for example, our visual system – and that biological adaptation is the only way to explain the appearance of such design.

A different line of theorizing views grammatical structure not as a product of biological adaptation but, rather, as emerging through cultural transmission of language across hundreds (or perhaps thousands) of generations of learners. Essentially, in this view language is an evolutionary system in its own right – but one driven by cultural rather than genetic evolution. This has interesting implications for Maynard Smith and Szathmáry's view of evolutionary transitions. They focus on language as a mechanism through which the transmission of cultural information is possible. The cultural approach to language evolution highlights the additional fact that knowledge of language itself is passed on culturally through the process of language learning by children.

Aspects of linguistic structure might therefore be viewed as adaptations by language to the cultural evolutionary 'problem' of being transmitted faithfully from generation to generation of language learners. In this approach, language is seen as adapting to the narrow transmission bottleneck imposed by children's learning mechanisms. Evidence in favor of this perspective has come from computer modeling of cultural transmission, the development of indigenous sign languages, and the archeological record of artifacts. Many proponents of this viewpoint on language evolution argue for a 'culture-first' perspective in which language evolved only after basic competences for relatively complex social culture had emerged in the hominid lineage. However, additional constraints would seem to be needed if the appearance of design in language is to be explained. Such constraints may be found in the limitations on our ability for sequential learning of hierarchical structure, in the learning bottleneck created by forcing languages through the limited channel of children's

Figure 3 The complex adaptive systems view of language. Language arises from the interactions of three dynamical adaptive systems that operate on differing timescales: Biological evolution through natural selection shapes our mechanisms for learning language. Language emerges from the interaction of many individual learners through a process of cultural transmission and evolution. The structure of the language that emerges will partly determine the biological fitness of the possessors of that language, thus completing the cycle of interactions.

learning mechanisms, or in the complexities of our conceptual apparatus. Alone or in combination, these constraints have been suggested to explain the elements of language that give the appearance of design, such as linguistic universals.

It is likely, however, that biological adaptation and cultural transmission may have interacted in the evolution of language. Language arises from the interaction of three different adaptive systems: individual learning during development, cultural transmission across generations of learners, and biological evolution of the learners (Figure 3). Our understanding of such interaction is complicated by the fact that the three adaptive systems interact on three different timescales: the lifetime of the individual (tens of years), the language (thousands of years), and the species (hundreds of thousands of years). Determining the exact weighting of these three components with respect to each other and the nature of their contribution is thus an important issue for future research in the evolution of language.

Vocal versus Manual Origin of Language

Another strongly debated issue in language evolution research is whether language originated as a system of manual gestures or evolved exclusively in the vocal domain. On the one hand, it has been proposed that because vocal communication in primates is largely affective in nature, with little voluntary control, language is likely to have emerged from manual gestures rather than primate calls. In some versions of this account, the emergence of gestural language was predated by the evolution of a unique human ability for complex imitation. The subsequent change from a gestural to a primarily vocal language has been argued to be due to either increased tool use coming into conflict with the use of the hands for linguistic gestures or the 'recruitment' of vocalization through associations between gesture and sound. The close relationship between manual gesture and a subsequently evolved sophisticated ability for vocalization (in the form of speech) is furthermore suggested to have left us with the uniquely human characteristic of right-handedness.

One the other hand, critics of the gestural theory of language origin have argued that manual gestures suffer from two major disadvantages in comparison with spoken language: they require direct line of sight and they cannot be used at night. Instead, several proposals have been put forward to support the possible origin of language in the vocal domain. One suggestion is that the basic structures of syllables derive from the succession of constrictions and openings of the mouth involved in chewing, sucking, and swallowing – eventually evolving into phonetic gestures. It has also been contended that this evolutionary process may subsequently have resulted in the major syntactic distinctions between noun phrases and sentences. An alternative perspective suggests that natural selection for brain structures necessary for the motor activities involved in walking on two legs may have laid the groundwork for the evolution of the neural substrate necessary for speech production and perception, which in turn provided the basis for the emergence of syntax.

Although mathematical and computational modeling may help inform the discussions about the relationship between biological adaptation and cultural transmission in language evolution, such modeling is less likely to be able to address issues related to the origins of language. However, evidence from other disciplines, such as archeology, comparative neuroanatomy, primatology, psycholinguistics, and cognitive neuroscience, may provide clues to an answer, although it is unclear whether this debate can ever be settled completely.

The Nature of Protolanguage

Setting aside the possibility of sharing some or many of the systems underpinning language with other species, it is clear that there is a huge gulf in complexity between the language spoken by any human and the communication used by our nearest primate relatives. For many researchers, this gulf is a problem for any evolutionary account of language. It leads us naturally to wonder whether it is possible to have something that was less than a full human language but more than an animal communication system – an evolutionary 'protolanguage.'

Broadly speaking, there are two different views of what the nature of protolanguage may have been. One approach suggests that protolanguage was 'compositional,' involving simple combinations of meaningful words but with little or no syntactic structure. Alternatively, it has been proposed that protolanguage was 'holistic' in nature, with unanalyzed wholes expressing complex meanings that we today would express using multiword combinations. In both cases, however, it has been suggested that there exist a number of 'living fossils' of protolanguage that we can observe today.

Evidence in favor of compositional protolanguage comes from pidgin communication (the communication system sometimes formed in communities of adults that lack a shared language), child language at particular stages of development, and the language of trained apes. Analyses of these diverse forms of behavior suggest the possibility of an evolutionarily prior form of language that may have shared some features of fully modern language but lacked others. In particular, whereas all three use individual meaningful words, their combination to form utterance meanings involves little or no syntactic structure (e.g., there is no recursive embedding, obligatory propositional structure, or purely structural grammatical elements).

Support for holistic protolanguage can be found in the form of formulaic language, which consists of utterances or parts of utterances in normal language use that appear to be processed completely holistically as unanalyzed chunks rather than syntactic combinations of individual meaningful words. These formulas include idiomatic expressions, such as 'bought the farm' (whose meaning, 'died,' appears to be completely unrelated to its form); certain standard situational utterances, such as 'was there anything else'; and other expressions, such as 'by and large,' whose semantic opacity suggests they are holistically processed. (It is important to note that although the examples of formulas appear to be strings of words, this is simply because they exist within a language that is already syntactic.) Such formulaic use appears to be rampant in normal language use and may thus be seen as a potential key element of protolanguage.

Further differences between these two perspectives on protolanguage derive from different ideas about how full human language may have evolved from its proto-form. Whereas the compositional approach suggests that the change was a biological one, the holistic approach suggests it was driven by cultural transmission. The plausibility of the latter claim has been given some support by computational models that have demonstrated the spontaneous emergence of syntactic structure in populations initially speaking a holistic protolanguage.

Independent of the outcome of this debate, the protolanguage evidence demonstrates the logical possibility of a system of communication that is like language but with some components missing, and it furthermore points to real instances of such a system in the world that are at least partially functional. Theoretically, this points to a possible smooth adaptive pathway from an alingual state to a linguistic one. Moreover, the notion of protolanguage is interesting because it opens up the possibility of 'major transitions' within the evolutionary trajectory of language. It may thus be useful to return to Maynard Smith and Szathmáry's work and seek parallels with other evolutionary transitions to help illuminate the debate.

Conclusion

Since the 1990s, research on the evolution of language has seen rapid growth. This increased research activity is warranted given that an understanding of language evolution may shed much light on human evolutionary history. However, if Maynard Smith and Szathmáry are correct, then language evolution research may also provide important insights into the evolution of life. Thus, the evolution of language constitutes an important challenge for contemporary science. In this article, we provided a brief survey of some of the work being undertaken to answer this challenge, focusing on current trends and controversies. It is conceivable that there will be questions to which we may never find definitive answers. However, it is clear that we will only be able to address the many questions surrounding the evolution of language by taking into account the various systems that underlie it, making this scientific endeavor an interdisciplinary enterprise by necessity.

Language Following Congenital Disorders (not SLI)

R Leech, University of London, London, UK
F Dick, University of London, London, UK; and University of California at San Diego, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Congenital developmental disorders can result in a wide range of language outcomes. At one extreme, children with some disorders never master complex language use. At the other extreme, after an initial period of delay, some children may achieve a language outcome indistinguishable from that of typically developing peers. Congenital disorders affecting language also vary considerably in terms of the underlying etiology; indeed, etiology of a congenital disorder is one of the most important determinants of the course of language development and eventual outcome. However, the relationship between the degree and location of frank neurological abnormality and the degree of corresponding language deficit is anything but straightforward.

In this article, we contrast the effects of two general classes of congenital disorder on language development: 'neurodevelopmental' disorders, such as Williams and Down syndromes and autistic spectrum disorder, and 'acquired' disorders, such as focal brain lesions (FLs) acquired in the pre- or perinatal period. The neurological sequelae of neurodevelopmental disorders often tend to be subtle, relatively widespread, and heterogeneous, at least on a gross anatomical level. For instance, people with autistic spectrum disorders (ASD) tend to have reduced volume in the cerebellar vermis but increased volume of the cerebral and possibly cerebellar white and gray matter. People with Williams syndrome (WS) appear to have particular cortical abnormalities in occipital and parietal regions but relatively preserved cortical structure in the superior temporal lobe, whereas people with Down syndrome (DS) appear to have dysmorphology in the medial temporal lobe. In addition, a number of postmortem studies suggest that ASD, WS, and DS may be associated with aberrant neuronal morphology, packing density, and columnar architecture, albeit in somewhat different forms. In contrast, children with perinatal FLs are assumed to have a typical neurodevelopmental trajectory and cerebral architecture except for the lesion immediately affected by the infarct (with potential longer-term quantitative changes in connecting white matter tracts and homologous gray matter regions).

A comparison of these two types of developmental disorders allows for an examination of the relationship between neural development, cerebral functional differentiation, and language acquisition across the first two decades of life. Importantly, the relative strengths and weaknesses that characterize the language profiles tend to change from infancy through toddlerhood and into late childhood, and they differ according to the etiology of the language disorder. In this article, we first trace the development (and possible neural and social underpinnings) of the linguistic strengths and weaknesses associated with three neurodevelopmental disorders (ASD, WS, and DS). We then discuss language acquisition in children with FLs, focusing not only on eventual outcome but also on the transient relationships between lesion side and site, and linguistic and nonlinguistic abilities over development.

Neurodevelopmental Disorders

As noted previously, the changes to brain structure and function that result from neurodevelopmental disorders tend to begin very early in development and to become more pervasive and more enigmatic. For instance, unlike FLs, it is not possible to diagnose developmental disorders from brain imaging because of high interindividual variability in the neural manifestation of the disorders. Children with neurodevelopmental disorders all tend to show atypical performance in many different social and cognitive skills including language. However, what makes the study of developmental disorders particularly informative is that different disorders have divergent profiles of strengths and weaknesses, not only in language processing but also in aspects of social and cognitive development that appear to be necessary for the early stages of language development. We highlight some of these early appearing social and cognitive deficits, and link them to possible linguistic deficits further 'downstream' in childhood. The following sections are roughly chronological, highlighting the diverging developmental paths in WS, DS, and ASD first in infancy and toddlerhood and later in school-age years and adolescence.

Language Learning in Infancy and Toddlerhood

Language is heavily dependent on social cognition in order to start developing. Early social skills, such as the ability of the infant to share attention with caregivers, are thought to play a substantial role in developing language and nonlinguistic communicative skills. Even in the first months of life, important social precursors to language already distinguish

between infants with neurodevelopmental disorders and typically developing (TD) infants. For example, TD infants show a preference for their mother's speech, whereas infants with ASD show no such preference and seem to have very little interest in people and social interaction. These infants show poor levels of eye contact and gaze following, and they may even attempt to avoid the gaze of a caregiver. This early lack of social motivation and attention sharing, and later lack of social conventions such as turn-taking, provides a plausible explanation for the inability of approximately half of children with ASD to develop any kind of complex language. There is some speculation that low-level attentional switching deficits in ASD may contribute to the higher-level social deficits noted here, and that these may be linked to the cerebellar abnormalities characteristic of this syndrome.

In contrast, infants with WS are typified by their strong desire for social interaction and keen interest in faces. However, this preference also leads to poor gaze-following behavior because infants with WS prefer to look at the face of the caregiver as opposed to following the direction of gaze. Such atypical use of referential information by children with WS may in part explain their delays, relative to TD children, in early language comprehension and production. Infants with DS also enjoy interacting socially, although there is a delay in mutual eye contact, which may have an impact on subsequent dyadic interactions between infant and caregiver. Moreover, once these initial problems resolve, infants with DS seem to prefer to focus on the eyes as opposed to visually exploring the facial features of the caregiver, as TD infants do. Deviations in early interactive behavior can also be seen in more complicated triadic interactions between infant, caregiver, and object. For example, infants with WS struggle to switch their attention from the caregiver to an object. This problem with triadic interactions is thought to hinder the acquisition of conceptual knowledge of objects, contributing to a subsequent delay in vocabulary development. In general, ASD, WS, and DS are all characterized to varying degrees by some form of deficit in social skills, which are very important for structuring the early word and grammar learning of infants and young children.

Precursors of Expressive Language in Developmental Disorders

As for social cognition, infants with neurodevelopmental disorders diverge from TD infants in terms of their prelinguistic 'productive' abilities, such as babbling and gesturing. As before, the exact patterns and the mechanisms underlying these delays tend to vary with the type of disorder. For instance, for infants with DS, there is an average delay in the onset of babbling of 2 months, with subsequent delays in phonological development. These may be due to the articulatory difficulties, which frequently occur in conjunction with the disorder (because of differences in palate shape and tongue position), as well as to DS children's frequent problems with hearing loss due to chronic and severe otitis media (probably due to deformations of the eustachian tube).

Unlike their profile with babbling, young children with DS produce far more communicative gestures than those seen in TD, a behavior that may serve as a compensatory mechanism for delayed and error-prone phonological production. In contrast, young children with ASD and WS gesture very little. Use of referential pointing in WS does not appear until after the naming explosion, demonstrating that children with WS do not follow the typical language development trajectory and may be using atypical mechanisms for early referential language use.

Despite the differences between DS and WS, children with DS and WS show a similar delay in the onset of babbling. Furthermore, children with WS show early problems with speech segmentation, which is surprising given the relatively strong phonological abilities of older children with WS. This highlights the fact that the pattern of deficits and relative strengths in the adult does not imply that these same deficits and strengths are present earlier in development.

Word Comprehension and Production and Early Grammatical Development

Just as prelinguistic expressive skills in developmental disorders are delayed, so is the onset of first word comprehension and production. Both WS and DS children are severely delayed in word production, obtaining a vocabulary size of approximately 50 words approximately 2 years later than a TD child, who would produce this many words at approximately 16 months. After reaching this critical vocabulary size, the language profiles of DS and WS diverge. TD children demonstrate an almost lawful relationship between the size of their vocabularies and their productive grammatical complexity, implying that a certain level of vocabulary is necessary for complex language to get started. Similarly, children with WS follow the same relationship between vocabulary size and grammatical complexity as TD children (Figure 1), albeit one that is considerably delayed (i.e., young children

Figure 1 Vocabulary size vs. grammatical complexity. Children with WS show the same developmental trajectory as TD children (albeit one that is markedly delayed), whereas children with DS diverge from the typical trajectory, with less grammatical complexity thanwould be expected given their vocabulary size. The lines mark the 50th, 10th, and 90th percentiles for TD children. Redrawn from Bates and Goodman (1997).

with WS demonstrate similar complex language abilities as younger TD children with the same vocabulary level). In contrast, children with DS show an atypical relationship, with their grammatical complexity worse than would be predicted by their vocabulary size (Figure 1). For children with DS, syntactic development is slow and does not generally result in these children consistently producing and understanding more complex forms. However, despite the differences in the rate of grammatical development between disorders, it has been suggested that, in general, children with developmental disorders acquire grammatical knowledge in approximately the same sequence as TD children.

Perhaps not surprisingly, there are profound differences in the ways that children with these neurodevelopmental disorders use language to communicate. For example, both children with DS and children with WS generally enjoy the opportunity to interact within a social environment, and their use of language is motivated through social exchanges in conversation. By contrast, language in many children with ASD, even when fluent and social, appears to lack a sense of reciprocity in conversational norms. Such a language profile is often linked to a significant discrepancy between verbal and nonverbal IQ. Overall, early communicative styles differ as substantially between disorders as do their social and grammatical abilities.

Later Language Learning

The profiles of strengths and weaknesses seen in different developmental disorders are not constant throughout the child's life. Instead, the relative strengths and weaknesses of early and late language abilities can be quite different as the multiple interacting linguistic and social factors underlying language acquisition unfold.

Williams Syndrome

The main feature of later language development in WS is delay. Despite this, relative to mental age-matched (MA) controls, school-age and adolescent children with WS may develop good semantic knowledge, an extensive vocabulary, and complex syntax, although their vocabulary skills generally exceed their syntactic ability relative to MA controls. In this regard, when narrating a picture book story, children with WS show a very similar profile of slowed morphosyntactic development as children with a seemingly very different developmental disorder, language impairment (LI). However, by age 10–12 years, children with WS (unlike those with LI) produce the same proportion of complex syntactic structures as typically developing controls, although there are subtle differences from TD children in their discourse structure. For instance, children with WS fail to establish ties between the protagonist's goals

and his or her actions. Finally, as might be expected given their hypersocial nature, children with WS far surpass even typically developing children in their use of socially engaging cues when telling a story. Thus, part of the language profile of children with WS might be accounted for by nonlinguistic characteristics of the disorder, such as a strong desire for social interaction.

Down Syndrome

In general, older children with DS show the same sequence of developmental 'events' as do TD children but are generally very delayed. For example, children with DS usually produce the same pattern of phonological errors produced by younger TD children. However, when WS and DS children are compared across early and later childhood, there is a divergence of DS and WS developmental trajectories in different language domains. For instance, in early language development, children with WS and DS have a similar level of vocabulary, but by adolescence the vocabulary of children with WS exceeds that of those with DS. Thus, the performance of children with DS appears to asymptote at a lower level.

Autistic Spectrum Disorders

In contrast to DS, children with ASD exhibit severe pragmatic difficulties in comparison to MA controls, although there is major individual variability in language outcome. Whereas children with ASD will use language to manipulate their environment, their use of language to engage in conversation or express thoughts and emotional states is often limited. It has been suggested that autistic children may actually use their language knowledge to bootstrap their understanding of others' mental states. In terms of pragmatic ability, children with ASD struggle to understand figurative speech, such as 'It's raining cats and dogs', taking literal meanings from such sentences. Other characteristics of autistic speech include a flat pattern of intonation and echolalia (in which children repeat the verbal utterances of others). These may occur when the child is required to respond to a question or in the form of preconstructed speech during conversation.

Neurodevelopmental Disorders versus Acquired Disorders

Whereas the different neurodevelopmental disorders vary considerably in the profiles of relative strengths and weaknesses of language skills, almost all affected children fail to achieve the functional language outcome of TD children. This contrasts strikingly with children with pre- and perinatal FLs who generally fall within the normal range of language use despite the severity of their neurological damage. However, as with all such developmental disorders, a 'normal' language outcome may mask previous language delays and atypical trajectories in different aspects of language development. Thus, in the following sections we consider first the general language outcome of older children with FLs before discussing the more subtle lesion site-specific language problems observed during infancy and early childhood.

Acquired Language Disorders: Learning Language after Early Brain Injury

Pre- and perinatal focal lesions are typically the result of vascular insult (e.g., congenital arteriovenous malformation or pre- or perinatal stroke) and are exceedingly rare events, observed in approximately 1 or 2 of every 10 000 births. Of particular neuroscientific and clinical interest are cases of children with unilateral focal lesions because they generally occur without concomitant global neurological malformation (e.g., cortical dysplasias) and thus allow direct comparisons with results from adult neuropsychological patients with similar lesions.

Comparisons of children and adults with FLs have provided a unique perspective on the fundamental questions of neural development, plasticity, and domain specificity, particularly how these play out in the establishment of language function in the brain. Although the inherent variability in lesion site and size makes children with FLs far from a homogeneous group, results from 30 years of research paint a fairly consistent picture. In particular, the impressive but delayed language outcomes of children with congenital focal lesions suggest that many of the neural biases needed for language to start developing are very coarse indeed.

Lesion Location and Language Outcome

Based on the adult model, the language outcome of children with FLs should depend to a large degree on whether the injury is located in the left or the right hemisphere because left hemisphere injury in adults frequently leads to severe and lasting language problems. However, the overall picture from the literature on children with early focal lesions tends not to show consistent differences between early left and right hemisphere in terms of language processing. When sample sizes are large, and direct statistical comparisons between lesion groups are made, (i.e., right hemisphere damage (RHD) vs. left hemisphere damage (LHD), controlling for seizure history

and lesion onset time), lesion side and site generally do not predict language proficiency. If differences are observed, they are noted only for a few language subscales and are considerably smaller than those observed in adults with commensurate injuries.

For instance, language studies on adult patients with focal lesions reveal a classic double dissociation, with RHD patients showing impaired comprehension of familiar phrases and idioms (e.g., 'It's like talking to a brick wall') with relatively preserved comprehension of novel literal phrases (e.g., 'She's looking down at her black cat'), whereas LHD patients show the opposite pattern of deficits. In stark contrast, not only is there no difference between children with LHD and children with RHD on either measure but also both groups perform within the low-normal range for their age-matched controls, whereas their adult aphasic counterparts are massively impaired relative to healthy age-matched controls (Figure 2). This striking difference has been observed across a range of language tasks, such as narrating brief biographical sketches and online complex syntactic comprehension. As would be expected, adults with LHD are significantly more impaired than their RHD counterparts. However, comparisons between children with RHD and those with LHD reveal no differences. Indeed, in narration tasks, children with FLs differ very little from typically developing children, performing in the normal to low-normal range on a variety of measures. The only significant (but small) delays observed in children with FLs involved the production of somewhat fewer words and more omission errors than age-matched controls. Similarly, the syntactic comprehension of children with FLs to either hemisphere appears to be somewhat delayed but not deviant from the language trajectory of typically developing children.

Figure 2 Accuracy in interpreting novel literal and idiomatic sentences, contrasting children and adults with left hemisphere damage (LHD) vs. right hemisphere damage (RHD). Redrawn from Kempler et al. (1999).

Lesion Location and Language Acquisition in Infants

Although there are few, if any, apparent differences between language outcomes for children with LHD and those with RHD by the time they begin primary school, it is possible that younger children and toddlers with FLs may demonstrate more subtle and transient language difficulties associated with hemisphere- and site-specific damage. Beginning at the start of language development, prospective cross-sectional and cross-linguistic studies of children with FLs allow a direct contrast between various 'stages' of brain organization for language. Several studies have investigated the early language abilities of infants from 10 to 40 months old, from first word comprehension to production, multiword utterances, and grammatical development. The results of these studies serve as *prima facie* evidence against the theoretical notion that the developing brain is a conglomeration of inexorably maturing modules devoted to different processing needs.

Early in the development of language skills (10–18 months), some children with perinatal focal lesions show a delay in language comprehension as well as gestural communication. However, this delay is only observed in children with right hemisphere injury; those with LHD (even with left temporal damage) are within the normal range on word comprehension. Not only is this the opposite of what one would expect from an adult model of language comprehension, in which left temporal damage tends to correlate with comprehension disorders, but also this finding goes against the usual lesion correlate of deficits in gesture production and comprehension, which in adults are strongly associated with LHD.

For early single-word production in the same cohort of children (10–18 months), lesions to either hemisphere provoke delays in development but are particularly severe in children with left temporal damage. This again contrasts with the adult model, in which language production deficits tend to correlate with left frontal damage. Similarly, results from multiple studies show that left temporal damage continues to be a predictor of delayed language production somewhat later in development (e.g., 19–31 months). Toddlers with left temporal damage show impaired lexical production, with commensurate delays in grammatical development. In contrast to the left temporal findings, frontal damage to either hemisphere was also implicated in production delays – again unlike the adult

model of left-lateralized frontal damage leading to production difficulties.

Neural Plasticity in Response to Focal Lesions

The low-normal language outcome of children with early onset FLs as well as the changing and distinctly non-adult-like profile of lesion site-to-language mappings over early development provide compelling evidence for the plasticity of the developing brain. These results also suggest that the usual pattern of brain organization for language (i.e., left hemisphere dominance) is neither inevitable nor even necessary for successful language processing. These findings suggest that there is considerable change in how the brain processes language, even well into the school-age years.

Clearly, these children's brains are organizing themselves differently than they would in typical development. Does this indicate that the brain is equipotential for language (i.e., any brain region can be equally co-opted into language processing), or are there early forming connections and architectures that make some developing brain regions more hospitable to language than others? More concretely, if left frontal and temporal regions are damaged early in development, will the brain regions enabling language function emerge throughout the brain (as one might predict given strict equipotentiality), or will contralateral regions homologous to those characteristically associated with language be recruited for language tasks?

This question has been investigated using positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) on patients with early onset lesions. In a PET study, activation profiles for children with perinatal left and right focal lesions were compared on sentence listening and repetition tasks. Children and adolescents with early left hemisphere lesions showed extensive right lateralization of activation in both traditional perisylvian 'language' areas as well as much of the right temporal lobe (particularly the anterior temporal lobe), the angular gyrus, the precuneus, and the anterior cingulate. Roughly the opposite pattern was seen for the group with right hemisphere lesions. An fMRI study of five children with left periventricular lesions (causing hemiplegia but no epilepsy) showed a similar mirroring of typical left lateralized activation in a covert verb generation task.

Similarly, studies have directly compared typical adult language-related activation in children and adults with early and late-onset left hemisphere focal lesions, respectively. The expectation was that earlier injuries would allow greater potential for reorganization of function. Neurologically intact adults showed the usual left-lateralized perisylvian activation profile for sentence comprehension, whereas patients with early onset focal lesions showed a mirrored and right-lateralized profile, and late-onset patients show highly symmetrical perisylvian activation. The dramatic lateralization difference between the early and late-lesion groups suggests that at least some of the remarkable capacity of the early lesion group to acquire normal language may be due to development of these (or closely related) functions in the right hemisphere. These findings argue against the notion that language functions are inexorably hard-wired within specific left hemisphere regions; rather, they indicate that the brain has some flexibility to reorganize such cognitive functions, if necessary.

Interestingly, this early lesion-induced shift in interhemispheric activation is not seen in all domains, even in the face of early cerebral insult. One study comparing sentence listening with a basic motor task (finger tapping) in patients with relatively early onset left hemisphere lesions found strong rightward activation asymmetries for the language task (a pattern opposite that of healthy controls). However, the same participants showed strong leftward activation asymmetries in the motor task – a pattern very similar to controls. These results suggest that the development and commitment of neural resources for language is a protracted process – one that might be more flexible than the development of more developmentally and evolutionarily entrenched capacities such as the motor system. However, it is worth emphasizing that lesion-induced reorganization of language function appears to recruit roughly homologous regions in the right hemisphere rather than, for instance, co-opting left hemisphere visual and somatosensory regions to accomplish language tasks. This suggests that regions with certain patterns of cortical and subcortical connections may be more amenable than others to co-option or 'shared use' by language.

Conclusions

There are clear differences between 'acquired' and 'neurodevelopmental' congenital disorders, as well as considerable differences between the different neurodevelopmental disorders. The impressive language outcome in FLs is testament to remarkable abilities of an otherwise typically developing brain to adapt in the face of substantial neurological insult. This stands in stark contrast to the more complex and more pervasive language problems associated with children with ASD, WS, and DS, whose brains are following multiple and distinct atypical developmental pathways.

Language in Aged Persons

E A L Stine-Morrow and M C Shake, University of Illinois at Urbana–Champaign, Champaign, IL, USA

Introduction

Communicative competence is essential for effective functioning through adulthood. The ability to understand and remember language depends on a coordinated array of processing components that translate an orthographic or acoustic signal (i.e., printed symbols and speech sounds, respectively) into a representation of the meaning of written text or speech that changes dynamically as the signal unfolds in real time. Language production can be thought of as a reverse process, requiring message formulation from which a surface form is generated. Aging brings both growth (e.g., knowledge) and decline (e.g., speed of processing). As a result, there are a variety of changes in how language is processed, both normatively and in what is required for successful performance. In this article, we consider the nature of these changes. We first review prominent theories of cognitive aging and then present a conceptual model of language processing. We then consider how language comprehension, memory, and production change with age, taking into account data from behavioral paradigms, event-related potentials, and imaging.

Theories of Cognitive Aging

Although there are a number of competing theories for cognitive and brain mechanisms that underlie age-related changes in cognition, there is broad agreement that at a coarse level, age effects on cognition can be characterized as a result of two competing forces. On the one hand, senescence drives a decline in mental mechanics, the speed and accuracy with which elementary information processing components can be completed. On the other hand, there is accumulating evidence that the brain has immense potential for plasticity into late life so that experience-based growth in knowledge systems, skill, and expertise offers potential for growth. Language processing can potentially depend on both of these systems.

There are a variety of cognitive theories characterizing the specific nature of declines in mechanics with age, all of which have influenced both behavioral and neuroscience approaches to the study of language. The slowing hypothesis suggests that aging brings a systematic decrease in the speed with which mental operations can be performed. The working memory (WM) hypothesis posits that aging is associated with a decline in the capacity to perform basic processing operations and store their products (as might be required, for example, as one listens to a lecture and tries to construct an understanding of what is currently being discussed and integrate it with what has come before). The inhibition deficit (ID) hypothesis focuses on the important role that inhibitory function plays in effective language processing by suppressing irrelevant environmental input, inappropriate (or no longer appropriate) features of meaning, and incorrect interpretations. According to the ID account, inhibitory function is reduced with age, thus compromising comprehension by allowing irrelevant (or incorrect) information to be incorporated into the language representation – and consuming working memory capacity that might otherwise be used for effective processing. Finally, drawing on the WM hypothesis, the effortfulness hypothesis identifies sensory loss as critical to understanding the aging language system, not simply as a direct influence on the quality of signal, but as an influence on central resources that are strained by the attempt to interpret the muddy signal.

At the same time, aging may bring growth in vocabulary and some aspects of verbal ability, with evidence suggesting that such growth depends on habitual engagement with literacy-based activities. Particularized knowledge systems and expertise develop differentially as a consequence of occupational and leisure pursuits. Well-developed procedural skills, such as reading, can be well maintained into late life. Evidence suggests that language processing may impact the trajectory of mental mechanics as well, with several demonstrations of enhanced executive function among fluent bilinguals, who habitually manage two language systems.

Patterns of growth and decline are also evident in the aging brain, with selective changes in both brain structure and function. Consistent with the notion of age-related declines in controlled attention, as suggested by WM and ID accounts, the prefrontal cortex is the brain region most vulnerable to deterioration. Both evoked potential and imaging data very often show more diffuse activation in the aging brain, a pattern that has been explained alternately in terms of dedifferentiation (effectively, inhibition failure) and as compensatory recruitment.

The Nature of Language Processing

In both reading and speech understanding, the signal unfolds linearly in time. However, the structure of thought arising from this process is not linear and certainly represents information beyond the verbatim input. The task faced by theories of language comprehension, then, is to explain how this mental representation is constructed and updated over time during comprehension, as well as later when certain tasks require retrieval or use of the text representation. Contemporary models of language comprehension distinguish among distinct processes that operate in concert to construct different facets of the language representation. At the surface level, individual lexical items (words) are encoded from the orthographic or acoustic signal, and their meanings are activated. The stream is parsed into syntactically coherent segments (e.g., clauses and sentences) that establish the thematic roles (functions such as agent and object) for the constituents of the sentence. The semantic representation can be described in terms of integrated ideas (or propositions) that establish relationships among concepts given by the text, a representation called the textbase. Knowledge plays a role in facilitating integration, enabling elaborative inference, and evoking a simulation of the situation suggested by the text. Production can be described as the reverse of this process. To express a thought, a syntactic structure has to be formulated, particular lexical items must be selected to fill thematic roles (a process called lemma selection), and the phonology must be assembled (phonological encoding).

Age-Related Change in Language Processing

Language Comprehension and Memory

Consistent with the divergent age trajectories of mechanics and knowledge-based processes, aging appears to have the strongest impact on resource-consuming aspects of language processing.

Word processing Vocabulary often shows an increase with age, particularly among those who read regularly. Word recognition appears to be highly resilient through late life. For example, word frequency effects (i.e., faster processing for more familiar words) in reading and word naming are typically at least as large for older adults as they are for young. Sublexical features (e.g., neighborhood density), however, may have a smaller effect on processing time on older readers, suggesting that accumulated experience with literacy may increase the efficiency of orthographic decoding.

By contrast, declines in auditory processing can make spoken word recognition more demanding so that more acoustic information is needed to isolate the lexical item. Such effects may not merely disrupt encoding of the surface form but also tax working memory resources that would otherwise be used to construct a representation of the text's meaning. For example, when elders with normal or impaired hearing listen to a word list and are interrupted periodically to report the last word heard, they may show negligible differences. However, if asked to report the last three words, hearing-impaired elders will likely show deficits. The explanation for such a provocative finding is that the hearing-impaired elders overcome a sensory loss at some attentional cost so as to exert a toll on semantic and elaborative processes that enhance memory. Presumably, the same mechanisms would operate in ordinary language processing.

At the same time, there is evidence that older adults can take differential advantage of context in the recognition of both spoken and written words, especially in noisy environments. Semantic processes at the lexical level also appear to be largely preserved. Semantic priming effects (i.e., facilitation in word processing by prior exposure to a related word) are typically at least as large among older adults as among the young. Also, in the arena of neurocognitive function, evoked potentials show similar lexical effects for young and old – a reduced N400 component for related words relative to unrelated controls. One area of difficulty that older adults may have in word processing is in deriving the meaning of novel lexical items from context, with research showing that older adults are likely to infer more generalized and imprecise meanings relative to the young – a difference that can be largely accounted for in terms of working memory deficits.

Syntactic processing Syntax, or the set of rules directing appropriate formation of grammatical sentences, guides the near instantaneous and incremental processing of words into coherent chunks as we encounter them, a phenomenon often termed 'parsing.' Paradigms in neuroscience have shed some light on the influence of aging on brain activity during syntactic parsing. Most of this research indicates that initial parsing processes are fundamentally preserved with aging. Studies using functional magnetic resonance imaging (fMRI), for example, show that for simple sentences, the left peri-sylvian areas responsible for sentence processing produce similar patterns of activation for young and old. Also, attempts to understand ungrammatical sentences produce similar effects among young and old in evoked potentials – for example, exaggerated left anterior negativity to number violations or an exaggerated P600 to phrase

structure violations. Other research with evoked potentials suggests a qualitative shift in brain region recruitment, with brain potentials to syntactic violations becoming less asymmetric and more frontal with age. Despite substantial preservation of certain aspects of syntactic processing, complex syntax can especially compromise the older adult's ability to interpret a sentence's meaning and remember it, a finding often attributed to processes downstream from the initial parse. Such effects may be due to cognitive constraints imposed by age-related declines in the working memory resources needed to retain the products of parsing in memory. For example, behavioral and imaging studies comparing the effects of syntactically simpler subject-relative sentences (e.g., 'The dog that chased the boy is friendly') to more complex object-relative sentences (e.g., 'The dog that the boy chased is friendly') suggest that age differences emerge primarily for more complex constructions. As syntactic structure becomes more complex, older adults are more likely to show comprehension errors (e.g., was it the boy who chased the dog or vice versa?) than younger adults and may show relatively less activation in the left peri-sylvian sentence processing region. However, variability among older adults is high, so there is typically a subset of elders who perform at least as well as the young. These high-comprehension older adults appear to achieve good performance in part by upregulating additional brain regions associated with verbal working memory (e.g., left dorsal portions of the inferior frontal cortex and right temporal–parietal regions).

Textbase processing Older adults typically show poorer memory for the content expressed directly by the text. Online measures of reading (e.g., reading time and probed recognition) suggest that the fundamental mechanisms of the system used to construct an integrated representation of ideas are preserved. However, processes used to construct the textbase (e.g., to instantiate and integrate concepts in the text) are among the most resource-consuming of those required in language understanding and are hence the most vulnerable to aging. When reading is self-paced, older adults require more time for effective propositional encoding (e.g., as indexed by effective reading time, the time allocated per idea unit recalled). In listening, when the pace is controlled by the speaker, older adults may have particular difficulty in understanding and retaining the information, especially as propositional density (ideas expressed per word) is increased or in noisy environments. Older adults appear to have no difficulty drawing anaphoric inference (i.e., correctly identifying the referent when the pronoun is used to refer to a noun that was introduced earlier) over short distances, but they may have difficulty when the pronoun and referent are separated by intervening text so that the referent must be retained in working memory. Similarly, older adults may have difficulty in reactivating nouns during sentence comprehension in the way that younger adults do, which may compromise the ability to represent a coherent meaning. For example, younger adults trying to understand an object-relative construction, as described previously (e.g., 'The dog_i that the boy chased t_i is friendly') will reactivate the object (e.g., dog) of the matrix clause following the verb (i.e., at t_i, the gap in the phrase structure that leaves a trace of the constituent moved in the relativized construction) and actually show facilitated processing of the object at the gap site. Older adults are less likely to reactivate the object as the noun-gap distance is increased (e.g., 'The dog_i wearing the blue bandana that the boy chased t_i is friendly').

The general impression from the behavioral data that the semantic (textbase) representation is more fragmented and less distinctive among older adults is reinforced by evidence from evoked potentials. Semantic anomaly (e.g., 'The dog wearing the blue bandana is a tree') exaggerates the N400 component of the evoked potential for the anomalous word (in this case, 'tree') for both younger and older adults; however, the brain response to this anomaly is less pronounced among older adults. Such findings suggest that the encoding of the sentence context up to the anomalous word was not as distinctive among the older adults so that the perception of anomaly was not as strong when the implausible word was encountered. Interestingly, there is no evidence of a delayed response to the anomaly with age; rather, the data are more consistent with a reduced level of response. Contrary to early claims in the literature that aging brings no semantic deficits, it appears that difficulty in integrating concepts can lead to an impoverished semantic representation.

Ironically, older adults may ordinarily allocate less attention to textbase processing. This is demonstrated in reading time for naturalistic text, in which regression analysis is used to isolate the effects of textbase processes. For example, with lexical properties such as length and frequency controlled, reading time increases when new concepts are introduced or at the ends of syntactic constituents, which are sites at which readers pause briefly to integrate concepts into a coherent meaning. These data show that older readers may allocate less time to these processes. However, analogous to fMRI findings with sentence processing, older adults who show high levels of language memory performance often overallocate attention to these processing components or, as

described later, may shift allocation to process more holistic features of the discourse. Some older adults do show very good language comprehension and memory, with data from behavioral studies and neuroimaging suggesting that compensatory recruitment of additional resources underlies their successful performance.

Less is known about the factors that engender this recruitment. However, age effects on language performance are often moderated by verbal ability: more verbal older adults are more likely to show event-related potential patterns similar to young, allocate resources to construct the textbase, and show relatively good textbase memory. To the extent that literacy activities are practiced across the life span, growth in knowledge-based systems may support language processing at different levels.

Situation model Aside from deriving ideas directly from the text, language understanding also involves elaboration on these ideas based on existing knowledge. Some theories focus on the perceptual quality of this level of representation, which gives rise to a perceptual simulation of the events described by the text. For example, in narrative understanding, readers track the goals and emotional reactions of characters, as well as their movement through space and time. Behavioral methods to study this level of representation include probe recognition for objects in the narrative as well as reading time, both of which show subtle effects of situation model processing. Readers are slower to verify the existence (in the narrative world) of objects that are spatially distant from the protagonist relative to those that are nearby. Readers also slow down when new characters are introduced or when there is a spatial discontinuity (e.g., the locus of narrative events shifts from the village to the castle) or a temporal discontinuity (e.g., 'The next day . . .'). When the text describes a goal to be achieved (e.g., Susan intends to buy her mother a purse for her birthday), the goal is activated in memory until it is achieved so that concepts related to the goal are more quickly verified as long as the goal is open (e.g., the purse will be more quickly verified if Susan cannot find the purse when she goes to the store relative to a condition in which she succeeds in securing the gift). To the extent that these paradigms have been used to explore adult age differences in situation model processing, there has been very little evidence of developmental differences in situation construction and updating.

Outside of narrative comprehension, it appears that older adults also show the perceptual symbols effect, suggesting that fundamental processes of perceptual simulation are preserved. For example, adults are faster to verify that a pictured object was described in a sentence if the picture of the object represents its shape implied from the sentence (e.g., in encountering, 'She watched the egg frying in the pan,' readers are faster at verifying that the sentence described an egg if the drawing depicts a cracked egg with yolk and white relative to a picture of an egg in its shell, with the reverse effect for 'She watched the egg boiling in the pot'). According to perceptual symbol theory, response time is faster when the picture matches the shape implied by the sentence because sentence processing evokes a perceptual simulation of the events described so that the implied shape is more available when the picture is presented. This perceptual symbols effect is at least as large in the elderly as it is among the young.

Older adults may particularly rely on the situation model to support textbase processing. For example, in ambiguous text (e.g., 'The strength and flexibility of this equipment is remarkable. Not everyone is capable of using it even though most try at one point or another . . .'), older readers take differential advantage of titles (e.g., Driving a Car) that disambiguate the meaning to facilitate processing. Because the title renders the situation instantly transparent, both younger and older adults are more efficient in reading when it is available; however, older adults show this effect to a larger degree.

To the extent that the hallmark of situation model processing is an integration of textbase content with knowledge, one might expect that older adults would be particularly adept at inferential processing; however, this is not always the case. Although older adults are more likely to draw elaborative inference (e.g., in recall, to annotate their recollections with personal experiences or related information learned in another context), if inference is constrained so that it requires retrieval of textbase content, age deficits are the norm.

Discourse structures and context Beyond sentence processing, different genres of text have characteristic forms. For example, narratives typically begin by introducing a setting and characters and proceed to describe a series of episodes in which goals or problems are introduced to be resolved, and so on. Expository texts have certain characteristic forms of argumentation (e.g., problem–solution and thesis–evidence). Older readers generally appear to track these larger discourse structures in the same way as the young. For example, scrambling a narrative so that the canonical form is disrupted will impair recall similarly for young and old. However, other research suggests that older readers may have more difficulty in remembering narratives relative to matched expository text, presumably because of the

demands of establishing and tracking complex plot structures. For example, older adults are more likely to have difficulty when two plots are interwoven.

Recap Collectively, these findings are generally consistent with what would be expected given declines in mechanics accompanied by experience-based growth in knowledge. The most resource-intensive aspects of language processing requiring the associationist connection of concepts in propositional encoding and storage in working memory show the largest age deficits. At the same time, sensory deficits may indirectly tax working memory by diverting resources to interpret muddy input. However, knowledge-based processes are largely preserved and may support these other processes.

Language Production

In contrast to comprehension, production shows more pronounced differences as a function of age at almost every level of analysis. In this domain, methodological approaches are almost exclusively behavioral, and even among behavioral measures, the focus has been on word production and on comparing global measures of spontaneous production (e.g., diaries) because of the problems associated with constraining production in a way that can be measured (although there are interesting recent innovations).

Word production stands in sharp contrast to receptive word processes in showing age differences. Picture naming is slower and likely to produce more errors among older adults. As do the young, older adults show effects of name agreement and word frequency on naming latency, suggesting that processes of lemma selection and phonological encoding are intact. Older adults may show relatively faster response time when name agreement is high, suggesting perhaps enhanced effects of knowledge on lemma selection. Aging is also likely to bring an increase in tip-of-the-tongue experiences, that feeling of knowing the word one wants to say (e.g., this experience is evoked among some people by asking them the name of a person who collects stamps) but not quite being able to come up with it (e.g., philatelist). Interestingly, spelling errors also increase with age. This asymmetry between comprehension and production has been explained in terms of transmission deficits between the phonological and semantic networks. It is assumed that connections among lexical and phonological units generally decrease with increased age and disuse. Although the semantic representation is rich in connections, phonological units are constrained (e.g., there are rich and variable ways to encode the concept of chocolate, but if one cannot activate /ch/, production is necessarily disrupted).

Cross-sectional studies of spontaneous production show that older adults generally produce shorter sentences with fewer complex syntactic constructions (e.g., embeddings and left-branching constructions). Diary studies have shown longitudinal change toward simpler syntactic forms and reduced information content as a function of normal aging, with declines exaggerated among those later diagnosed with Alzheimer's disease.

In constrained production (e.g., construct a novel sentence from a given set of target words), age differences may be negligible when the number of target words to be accommodated in the production is small; however, as the number of targets is increased, older adults are more likely to become dysfluent, presumably because of the greater demands on syntactic construction and proposition assembly. Another form of constrained production that has been explored with aging is to create a sentence to describe a picture. In this paradigm, too, older speakers are likely to produce dysfluencies. The monitoring of eye movements has been used to examine the extent to which older adults might plan their utterances ahead to enhance fluency, but evidence on this issue is not yet clear.

Finally, there have been several demonstrations in the contexts of laboratory tasks (e.g., text recall) that older speakers may be more likely to produce off-target speech. Whereas some have shown this to be related to independent estimates of inhibition and have labeled this phenomenon verbosity, other research has demonstrated that such age differences in such elaboration can be exaggerated for personal topics, suggesting that such patterns may be related to social demands rather than to individual differences in cognitive function. This issue remains to be resolved.

Conclusion

There appears to be a two-way street between the multidirectional change in adult cognition and language processing. Age-related declines in sensory processes and cognitive capacity impact the ability to derive meaning from text and spoken language, especially as syntactic structure becomes more complex or speech rate is increased. Age-related declines also impact name retrieval and the syntactic complexity of production. Knowledge-driven processes can offset these declines to a large degree so that in many arenas, aging individuals will show better performance than their younger counterparts. At the same time, language processing (e.g., habitual reading, or learning a second language) appears to exercise the cognitive system so as to contribute to cognitive vitality.

Aphasia is an acquired impairment in language due to a brain injury. To be considered aphasic, the impairment must affect a range of language functions, including speech, comprehension, reading, and writing. Aphasia usually follows from injury to the left hemisphere of the brain. In stroke, it is usually due to a disruption of blood flow in the middle cerebral artery, which provides blood supply to the lateral surface of the cortex. Aphasia can also occur following a traumatic brain injury or may emerge gradually due to progressive, degenerative brain disease. Traditionally, aphasia has been classified using subtypes that are characterized by specific patterns of impairment in spoken fluency, comprehension, naming, and repetition. These aphasia subtypes include Broca's aphasia, Wernicke's aphasia, conduction aphasia, global aphasia, anomic aphasia, and transcortical aphasia. This article reviews the behavioral characterization of these aphasia subtypes as well as discusses their anatomical basis.

Broca's Aphasia

Broca's aphasia was first described by the French neurologist, Paul Broca, in the 1860s. He described a patient who could say very few words and repeatedly uttered the sound, 'tan tan tan,' when trying to speak. Despite his poor speech output, this patient understood much of what was said to him. A second patient soon followed who showed a similar dissociation of reduced speech fluency and relatively preserved comprehension. This form of aphasia came to be known as Broca's aphasia, and it is sometimes referred to as motor aphasia or nonfluent aphasia.

The following is a speech sample of a patient with Broca's aphasia as he attempts to describe a drawing of a lakeside picnic from the Western Aphasia Battery (WAB):

> I see dog, boy, boy, sand, see book, people, boats, on boat . . . girl and man reading, man fishing . . .

Such telegraphic speech is typical of patients with Broca's aphasia. Despite its halting nature, such speech often contains important content words so that the main ideas are conveyed, but smaller functor words (e.g., 'a' and 'the') are omitted, resulting in agrammatic speech (e.g., "I see dog"). There is debate as to whether such agrammatic speech is due to the inability of these patients to use grammatical forms or whether it simply reflects a strategic choice due to a reduced processing capacity. One way in which this issue has been addressed has been to study agrammatic patients who speak different languages. In German, for example, it has been shown that patients with Broca's aphasia do not commonly omit functor words such as 'the' (as American Broca's aphasics might) because these words are critical to the meaning of the noun (whereas in English they are not). This cross-cultural difference would suggest that patients with Broca's aphasia can produce grammatical forms if necessary to communicate content but simply omit what is not essential in order to simplify production demands.

The most severe form of Broca's aphasia manifests as recurring utterances, where a patient repeatedly utters a single word or phrase (such as Broca's original patient). Interestingly, such patients can effectively use intonation to vary the pitch of such utterances and thus communicate in a limited fashion. This behavior illustrates the fact that patients with Broca's aphasia, despite their severely reduced speech output, have relatively good awareness of their communication deficit.

Comprehension in patients with Broca's aphasia is relatively preserved, as long as sentences are not complex. For example, sentences such as 'The boy was kissed by the girl' may be misunderstood as 'The boy kissed the girl,' the latter being the more canonical construction in English. Repetition and naming are also disrupted in Broca's aphasia due to the speech output disturbance. Similarly, reading and writing are affected; for example, patients often are unable to write complete phrases or sentences (parallel to their spoken output).

Commonly accompanying Broca's aphasia is apraxia of speech, a motor speech disorder characterized by a reduced ability to coordinate the articulators (lips, tongue, etc.) that results in groping and misarticulated speech. Another commonly coexisting motor speech disorder is dysarthria, which results in slurred and distorted speech due to muscular weakness. Although these motor speech disorders often accompany Broca's aphasia, they can also occur in the other aphasias described later.

Textbook descriptions of the neural correlates of Broca's aphasia most commonly associate it with Broca's area in the posterior, inferior frontal gyrus, as originally described by Broca. Current research

Figure 1 Average lesion map of 36 stroke patients with chronic Broca's aphasia showing the region of common overlap in the insula, rather than Broca's area.

data, however, suggest that for a chronic, persisting Broca's aphasia, the lesion is generally much larger, encompassing regions of inferior frontal and insular cortex, as well as deeper, white matter. Indeed, a recent three-dimensional magnetic resonance imaging (MRI) imaging study of Broca's two original patients' brains (Tan and Leborgne) revealed that the lesions of these historic cases actually extended quite medially, much deeper than Broca could have seen. Figure 1 shows an average lesion map of 36 stroke patients with chronic Broca's aphasia (poststroke > 12 months) from our research database. The color bar indicates the degree of lesion overlap across patients, from 0% (dark blue) to 100% overlap (dark red). As can be seen, the region of common overlap in patients with Broca's aphasia is in the insula (deep red), a region of neocortex that is buried beneath frontal and temporal cortices. We have previously shown this region to be critical for coordinating articulation, which is commonly impaired in patients with Broca's aphasia.

Wernicke's Aphasia

Karl Wernicke was a German neurologist and psychiatrist born in 1848. In 1874, at the age of just 26 years, he published a major work on aphasia that described patients with an inverse pattern of deficits from that observed by Broca, namely patients with fluent speech and a marked comprehension impairment. This form of aphasia came to be called Wernicke's aphasia but is also referred to as sensory aphasia or fluent aphasia. Unlike Broca's aphasia, Wernicke's aphasia is considered a fluent aphasia because patients with Wernicke's aphasia speak spontaneously with a normal to fast rate of speech, and their speech rhythm and prosody (melody) are normal. The following is a sample from a patient with Wernicke's aphasia describing the picnic scene:

> The/goll//dz/George. It isn't correct. He guess – he/hamilz/in the the one guy who/stamilz/in the – oh I can't say it. This girl who has her own rain. She can see this/goll/who has a ride. A picnic – he is/kain/a you see the mai tai.

Although their speech may be fluent, patients with Wernicke's aphasia are often unintelligible. This is in part due to the presence of numerous speech errors. Such errors sometimes take the form of literal paraphasias, which involve the swapping of sounds or syllables, or substituting one sound for another (e.g., saying 'pyramos' for 'pyramid'). Sometimes, these errors are so distorted that the target word is unclear (e.g., 'tiromon'). Such errors are referred to as neologisms. Patients with Wernicke's aphasia also make semantic errors, substituting a related word for an intended target (e.g., 'son' for 'brother'). Paraphasic errors occur during repetition and naming as well as spontaneous speech. Interestingly, despite the abundance of paraphasic errors in Wernicke's speech, many aspects of syntactic structure remain intact.

In addition to their paraphasic speech, patients with Wernicke's aphasia also have significantly impaired comprehension. This deficit is apparent in all modalities (i.e., whether spoken or written language), although patients may show slightly improved comprehension with written material. Unlike patients with Broca's aphasia who only have difficulty with more complex items, patients with Wernicke's aphasia fail on a range of comprehension tasks from single word comprehension to sentence comprehension.

Relative to patients with Broca's aphasia, patients with Wernicke's aphasia appear less aware of the severity of their language deficits. Patients with Wernicke's aphasia are less likely to self-correct errors in their speech production. This may be due in part to their impaired comprehension, which extends to monitoring their own speech output.

Wernicke's aphasia has traditionally been associated with lesions in Wernicke's area, which generally is defined as the left posterior, superior temporal gyrus. However, the exact boundaries of this area vary from textbook to textbook, presumably because the boundaries were never clearly defined. An overlay of 11 patients' lesions from our center reveals that a

Figure 2 Average lesion map of 11 stroke patients with chronic Wernicke's aphasia. Lesions are centered in the middle temporal gyrus, rather than Wernicke's area.

lesion centered in the middle temporal gyrus is critical for a chronic, persisting Wernicke's aphasia (Figure 2). Other areas that are commonly affected include the posterior, superior temporal gyrus and inferior parietal cortex. These regions have been associated with auditory processing, lexical semantics, and verbal working memory.

Conduction Aphasia

Conduction aphasia was first described by Wernicke to characterize patients with relatively preserved comprehension and paraphasic speech. Later, Wernicke added to the list of deficits a disorder of repetition. Clinically, patients with conduction aphasia present with fluent speech and relatively good comprehension, but their speech is somewhat paraphasic and their ability to repeat is greatly reduced. Reading and writing, as well as naming, are also affected to a moderate degree. A clinical sample of such a patient's fluent spoken output describing the picnic scene follows:

> I see a bunch of people. There's a tree and a car and a house and water and the pier. Guy's fishing, and a couple o' guys that are saying hi to the sail's person. And a guy washing something next to a/hail/of sand and grass. A flag – is that a flag? And the wind and the pole and some more grass.

Despite such relatively fluent speech, patients with conduction aphasia exhibit significantly impaired repetition. Patients may get the gist or general meaning of what is said (as evidenced by their relatively good comprehension), but they are impaired at repeating material verbatim. For example, in an attempt to repeat the sentence 'The pastry cook was elated,' one patient responded "Something about a happy baker." This phenomenon suggests that patients with conduction aphasia are relying on a nonverbatim, semantic route since the phonological trace is no longer available. Dependence on this semantic route is also revealed by the fact that repetition is severely affected for nonsense words (e.g., 'meppen'). Such words have no meaning and thus cannot give rise to a paraphrase or synonym, let alone reproduction of the same word.

Although controversial, some researchers divide patients with conduction aphasia into two groups – reproduction and repetition conduction aphasia. These two groups reflect different parts of the complex repetition process. Repetition conduction aphasics are thought to primarily have a problem at the level of holding a memory trace – in other words, a deficit in verbal working memory. Reproduction conduction aphasics are thought to have their primary problem with the processing and production of phonological information. Researchers who maintain this division acknowledge that some patients diagnosed with conduction aphasia fall into both groups.

Paraphasic errors in patients with conduction aphasia may take the form of phonemic substitutions (e.g., 'free' for 'tree') or semantic substitutions (e.g., 'father' for 'brother'). However, they are more likely (than patients with Wernicke's aphasia) to attempt to correct their errors. For instance, a patient with conduction aphasia was asked to name a line drawing of a cactus and responded by saying "gaktus, no, gaksus, gackone, no, cackus, little screwed up there, cack, cactus! cactus!"

Traditional models of aphasia originally suggested that conduction aphasia should arise from lesions to the arcuate fasciculus, the white matter tract connecting Wernicke's and Broca's areas. Despite the fact that no data exist to support this model, most textbooks in psychology and neuroscience perpetuate this notion. Instead, patients with conduction aphasia most commonly have lesions centered in left posterior neocortex, most notably in inferior parietal cortex, not the arcuate fasciculus. Figure 3 shows a lesion overlay map of 13 patients with chronic conduction aphasia. As can be seen, the region of common overlap is centered in inferior parietal cortex. This region has been suggested to be critical for verbal working memory, which is consistent with the pattern of repetition deficits observed in this patient group.

Figure 3 Average lesion map of 13 stroke patients with chronic conduction aphasia, showing a region of common overlap in the inferior parietal cortex.

Figure 4 Average lesion map of seven patients with chronic global aphasia; showing that lesion typically involves a large portion of the left hemisphere.

Global Aphasia

Global aphasia is the most severe of all aphasia subtypes, with significant impairments across all aspects of language, namely impaired speech, comprehension, repetition, naming, reading, and writing. Patients with global aphasia may be able to utter automatic or stereotypic responses (e.g., "yes" and "no") but do so unreliably. For example, one patient with global aphasia when asked to describe the picnic scene from the WAB was only able to utter "no…no… because" on one occasion and "yeah" on another occasion. Other patients with global aphasia are only able to produce overlearned or automatic phrases (e.g., "How are you?"). Patients with global aphasia also have significantly impaired comprehension. They often have difficulty responding to very simple yes/no questions (e.g., "Are you a man?").

Although the severe loss of speech and language makes it very difficult for patients with global aphasia to communicate, they are sometimes able to convey information by varying the intonation in their voice or by using simple gestures. Importantly, patients with global aphasia can be shown to perform normally on nonverbal tasks (e.g., picture matching), demonstrating that they are not suffering from confusion or dementia.

As described previously, some patients with global aphasia have a preserved ability to utter automatic phrases or repetitive utterances. What is the brain basis of these abilities, if much of the language network is damaged? There is evidence that these automatic and overlearned phrases are generated by regions within the intact right hemisphere of the brain. The right hemisphere is also capable of supporting intonation in speech, musical ability, and emotional expression. Again, these are abilities that are sometimes preserved in patients with global aphasia.

As with the other aphasias, global aphasia is most commonly the result of a stroke in the middle cerebral artery that supplies blood to the lateral surface of the left hemisphere of the brain. Not surprisingly, lesions necessary for a persisting, chronic global aphasia are generally quite large and encompass large portions of the left peri-Sylvian region. Lesion overlays from seven patients with global aphasia are shown in Figure 4. This large lesion is responsible for the gross impairment in most aspects of speech and language since the entire language network is affected. Whereas other patients with smaller lesions may find ways of compensating for their language disabilities, patients with global aphasia have less brain reserve with which to do so.

Anomic Aphasia

Anomic aphasia is the mildest of the aphasias, with relatively preserved speech and comprehension but difficulty in word finding. The persistent inability to

find the correct word is known as anomia (literally, 'without names'). Anomia is actually a symptom of all forms of aphasia, but patients whose primary language problem is word retrieval are diagnosed as having anomic aphasia. In other words, patients with anomic aphasia have relatively preserved speech fluency, repetition, comprehension, and grammatical speech but sometimes have difficulty with word finding. The following is a sample from a patient with anomic aphasia describing the picnic scene:

> I see a boy who is flying a kite. I see a girl who pouring . . . um . . . the soda an' I see a girl who is listening her radios. I see a man who is reading a book. I see a man who is fishin' an' I see a dog who is waggin' his tail. I see a boy waiting . . . wading in the water.

Unlike the previous aphasia samples, this patient describes the scene using complete sentences and provides a relatively good level of detail. There are a few minor errors and some groping for words (e.g., 'soda'), but otherwise her speech is quite clear and communicative, typical of anomic aphasia.

When searching for a word, some patients with anomic aphasia paraphrase using words that they can easily retrieve. For instance, a patient shown a drawing of a pair of tongs said "You pick up things with it." Such circumlocutions demonstrate that patients with anomic aphasia have lost neither conceptual understanding nor the ability to build coherent sentences and phrases.

Whereas circumlocutions may be a characteristic feature of the speech of some patients with anomic aphasia, the main characteristic displayed by other patients may be periods of slow and halting speech as they search for the correct word. For instance, when shown a picture, a patient might say, "It's a, ummm, uhhh, a, a, a . . . I know what it is, it's a . . . Aww hell, it's there but I just can't get it." Such hesitancy may be so frequent that a patient may be incorrectly classified as having Broca's aphasia. Not surprisingly, patients with anomic aphasia benefit greatly from cueing, such as providing the first sound of the target word.

Low-frequency words are typically more difficult for a patient with anomic aphasia to retrieve and produce than frequently used words. It is very common for proper names to be more difficult to retrieve than common nouns, and common nouns are often more difficult to retrieve than adjectives or verbs. Thus, both the grammatical function of a word and its frequency can affect word retrieval in patients with anomic aphasia.

Lesions associated with anomic aphasia are the least well defined because word finding is sensitive to damage throughout much of the peri-Sylvian region.

Figure 5 Average lesion map of 37 patients with chronic anomic aphasia, in which there was no single, common region of overlap.

As shown in Figure 5, there is no single, common region of overlap in this group of 37 patients with anomic aphasia but, rather, the lesions span a wide range of areas in the left hemisphere.

Transcortical Aphasias

The transcortical aphasias are a group of aphasia syndromes that all have in common a relatively preserved ability to repeat, despite other significant language deficits. Transcortical motor aphasia is similar to Broca's aphasia; that is, patients exhibit nonfluent speech and relatively good comprehension, but the ability to repeat is relatively preserved. Transcortical sensory aphasia is similar to Wernicke's aphasia, with patients exhibiting fluent speech and poor comprehension and also a relatively preserved ability to repeat. Finally, mixed transcortical aphasia is similar to global aphasia but with relatively preserved repetition. Compared to the other aphasias, the transcortical aphasias are relatively rare.

The following is a speech sample from a patient with transcortical motor aphasia describing the picnic scene:

> The girl is.. the girl is .. drinking the soda. The girl .. no .. the guy is .. no .. yeah. The guy is playing the radio. The people who . . . OK .. flying a kite. The dog is playing around the people. The uh .. the .. the . . . the . . . dog is .. no .. the fly a kite. And uh, the people who rented a boat was my friends.

Figure 6 Lesion locations in two patients with chronic transcortical sensory aphasia.

This patient with transcortical motor aphasia exhibits hesitation, word-finding problems, and some grammatical errors – all symptoms reminiscent of a person with Broca's aphasia. However, when asked to repeat 'The pastry cook was elated,' the same patient does so flawlessly. Such intact repetition is quite remarkable given the level of impairment in spontaneous speech, and this preserved ability is what distinguishes the transcortical aphasias.

Lesion correlates of the transcortical aphasias have not been as clearly defined as the other aphasias, in part due to the fact that these aphasias are less commonly observed. Figure 6 shows the location of lesions in two different patients with transcortical sensory aphasia, the form of aphasia reminiscent of Wernicke's aphasia but with preserved repetition. As can be seen, one patient suffered a subcortical stroke, whereas the other suffered a posterior stroke that affected temporal and parietal cortex. Both patients' lesions are quite distinct from lesions typically observed in Wernicke's aphasia. Also, the lesions spare regions associated with repetition ability, such as those affected in conduction aphasia.

Conclusion

For more than 100 years, scientists have studied and characterized speech and language impairments in patients with brain injury. Such efforts have provided an important framework for our understanding of both the cognitive linguistic aspects of language and the localization of these processes in the brain. One difficulty has been that the aphasia syndromes involve a constellation of speech and language symptoms that significantly overlap across subtypes, as is apparent from the previous discussion. For this reason, newer approaches to the study of language focus on the neural correlates of discrete speech and language symptoms rather than the entire aphasic syndrome. New neuroimaging techniques such as functional MRI and voxel-based lesion symptom mapping facilitate the visualization of discrete neural regions associated with performance on specific language behaviors. These techniques will allow us to further our understanding of aphasia as well as the neural correlates of speech and language in the normal brain.

Introduction

The auditory stimulus in speech perception is shaped and constrained by the acoustical properties of the human vocal tract. Speech is produced through the coordinated movement of the glottis, tongue, velum, lips, and jaw. The form of this signal is often understood in terms of a simple source-filter model in which acoustic energy produced by subglottal pressure and the vibration of the vocal folds, or turbulence produced when airflow is directed against a barrier, is given spectral shape by the natural resonances of coupled natural cavities created by different vocal tract configurations. The component sounds produced by articulation consist of simultaneous frequency-limited resonances with time-varying frequencies called formants, as well as silences, pops, clicks, and brief bursts of frequency-limited noise. Movement of articulators changes the shape of resonators, which in turn changes the frequencies of formants over time. Additionally, release of air when constrictions are released, or noise produced when constrictions are narrow but incomplete, produces noise. These sounds overlay an overall periodic structure caused by the opening and closing of the vocal folds during much of speech and a quasi-periodic structure caused by changes in subvocal pressure and vocal fold vibration.

While the specific acoustic form of spoken language reflects the microstructure of articulation defined in both time and space, this relation is complex. For example, the same [r] sound can be produced by radically different tongue movements. Conversely, the vocal tract configurations that produce [i] and [u] sounds in some contexts produce [j] and [w] sounds in others. This relationship is simplified somewhat by the fact that there is often a nonlinear or quantal relation between individual articulations and their acoustic consequences that maximizes the acoustic contrast between speech sounds, while providing relatively stable acoustic properties within them. For example, when producing a segment with the feature 'nasal,' such as [n], [m], or [ng], speakers move the velum to produce an opening between the oral and nasal cavities. While the act of opening involves a continuous articulation, there is a critical point at which the opening is large enough to allow acoustic coupling, which is marked by the appearance of a new spectral prominence, the nasal pole, which marks the segment as a nasal.

The primary computational problem posed by the perception of spoken language is created by the variability of the speech signal relative to the linguistic categories that are perceived by the listener. Spoken language is perceived as a sequence of more or less discrete events such as words, syllables, or component speech sounds. However, coarticulation, the overlapping articulation of adjacent speech sounds, often makes it impossible to draw a one-to-one mapping between a single speech sound and any interval of sound. Moreover, the acoustic realization of any unit of spoken language is highly variable, and may be influenced by a variety of factors including speaking rate, individual differences in vocal tract anatomy, language or dialect, articulatory style, the emotional state of the speaker, or social context.

Each level of linguistic representation is related to somewhat different properties of the speech signal, although these properties overlap. Word recognition relies on the perception of 'segmental' properties. These tend to be collections of relatively brief acoustic events. At typical natural speaking rates, speakers produce roughly 15 segments per second, with wide variability in the duration of different segments and temporal overlap in the distribution of properties associated with any one segment. At the level of sentence or discourse structure, 'suprasegmental' or intonational properties may provide information about syntactic constituent structure or the relative importance of individual words or phrases. These properties are typically defined over larger temporal regimens than segmental properties, and are encoded primarily in relative changes in pitch, intensity, and timing between different parts of an utterance.

These linguistic entities are perceived despite the enormous variance in how they are realized in the acoustic signal. Different research groups are currently pursuing four contrasting approaches to the issue of variance. One approach is to identify relatively invariant acoustic properties of speech sounds. While early research found an invariant correlate of one characteristic of a subset of syllable initial consonants, subsequent work has yielded few successes. A second approach focuses on possible normalization processes that may play a role in categorization or recognition. Work in this vein has demonstrated a variety of normalization processes, most notably processes of rate normalization in the classification of duration-dependent feature cues. A third approach is built on the premise that speech gestures are less

variable than the acoustic forms produced by their combination. Within this approach, researchers are concerned with trying to determine whether speech perception is mediated by articulatory representations. Finally, a fourth approach suggests that words or other linguistic units are stored for the purpose of recognition in the form of multiple exemplars that present relatively veridical representations of individual tokens encountered in the past (similar to machine speech recognition). There is evidence that listeners have access to memory of specific speech tokens. However, it is not clear whether this type of memory plays a role in the online perception of spoken language. The ultimate solution to the variability problem may involve some combination of these approaches.

Unique Neural Mechanisms for Processing Language Acoustically?

At the earliest stages of processing, both speech and nonspeech stimuli are processed using the same pathways, and are subject to the same processes. Transduction of acoustic energy by cochlear hair cells with frequency-selective tuning curves breaks acoustic input down into a representation of the intensity of acoustic energy at different frequency bands. An unresolved question is whether complex stimuli like speech are represented entirely by the spatial pattern of activation across tonotopically organized cortex, the temporal pattern of neural activity, or both. At some point, the processing of acoustic signals as linguistic entities diverges from processing acoustic signals as other types of stimuli. But whether that point occurs at the stage of processing the acoustic signal itself, or only after linguistic categories have been activated, remains a debated issue.

For some time, a considerable number of researchers argued that listeners applied different analytic processes to sounds that were and were not speech. The existence of what were thought to be unique aspects of speech perception – such as the inability to discriminate synthesized acoustic signals that did not fall into different phonemic categories while being able to discriminate signals with equivalent acoustic differences when they were perceived as being linguistically different (so-called categorical perception) – was considered strong evidence for this position. Confidence in the implications of such findings eroded when it was discovered that nonhumans show comparable phonetic discrimination effects. Similarly, psychophysical evidence suggests that humans are able to resolve temporal order of linguistic events with substantially more precision than that of nonlinguistic events. This again suggests a relatively low-level divergence between linguistic and general auditory processing streams. However, it has been suggested that this difference may be related to differences in the ability of linguistic versus nonlinguistic components to be represented at more global levels.

More recently, the question has been addressed on the basis of the location of neural responses to processing acoustic properties of linguistic and nonlinguistic stimuli. A challenge facing this approach is to equate the complexity of the speech and nonspeech stimuli while at the same time eliminating speechlike properties from the nonspeech stimuli that could cause activity in areas that are in fact uniquely devoted to processing acoustic stimuli as speech. Different research groups have taken different positions on the appropriate control stimuli. Some results suggest that perception of segmental acoustic properties as meaningful speech uniquely involves a region in the left superior temporal lobe anterior to the primary auditory cortex, but the issue remains open. Even fewer studies have examined the question of whether processing of acoustic signals to yield intonation contours utilizes the same brain regions as processing of acoustic signals to yield nonlinguistic representations, such as musical structures. One study reported that one patient whose abilities to discriminate melodies was impaired had comparable difficulties with intonation contours, but whether the same parts of the complex lesion in this patient were responsible for both functional impairments is unclear; to our knowledge, no functional neuroimaging studies have addressed this question.

Segmental Processing

The targets of segmental perceptual processes are abstract representations of the sounds of words. Phonological theories are essentially unanimous in maintaining that the sounds of words consist of a number of structures. In many models, the critical structures are 'phonemes' – abstract segments representing idealized units of sound whose presence is required for a word to be individuated. For instance, the word 'cat' consists of three phonemes, [k], [æ], and [t], in that order. A change in one of these segments to another phoneme (e.g., of [k] to [s]) turns 'cat' into a different word or into a nonword. Phonemes, too, are conceived of as complexes of 'features' – characterizations of positions and trajectories of articulatory organs and qualities of the sounds thereby produced. Examples of such features are 'stopped' (indicating full closure of the vocal tract), 'high' (referring to the position of the body of the tongue), and 'voiced' (indicating vibration of the vocal cords). Like phonemes, phonological features are abstract entities,

identified on the basis of many aspects of the sound patterns of words and other phenomena in a language. For instance, most models of features utilize a binary system, despite the continuous nature of articulatory postures, because generalizations that arise with respect to high-level phonological properties of words (e.g., effects of word formation on phonemes) can be best captured in such a system. Words also have phonological structure above the phoneme level, such as the level of syllables. In all languages, syllables in multisyllabic words have different degrees of prominence, represented as either lexical stress or tone patterns. English is a stress language (e.g., the difference between torment' [noun] and tor'ment [verb]); Chinese is a tone language (e.g., the word 'ma' can be produced with four different tones to mean 'mother,' 'hemp,' 'horse,' or 'scold').

The dominant view in psychology is that words are recognized by a process whose front end maps properties of the acoustic waveform onto phonological features and phonemes. Two literatures converge to support the significance of features in the representation of speech. A large body of work in acoustic-phonetics has identified acoustic characteristics that correspond to proposed features, and has demonstrated that systematic manipulation of these characteristics or cues leads to predictable changes in the perception of speech sounds or words. Similarly, linguists have shown that systematic variations in the sound patterns of the world's natural languages are best predicted and understood at a level of featural representation.

Based on the importance of features and feature cues in theory, the existence of phonetic feature detectors has been a subject of great interest. The strongest evidence for feature detectors comes from studies of selective adaptation effects. In selective adaptation experiments, listeners hear a series of words or syllables that share a common feature, and are then asked to make phonetic judgments about a continuum of speech sounds that differ in terms of that feature. For example, they may hear a series of syllables that begin with voiced consonants (e.g., [bu], [do], [ge]), and are then asked to categorize a series of syllables in which voicing cues are manipulated to create a continuum from [ba] to [pa]. Results show that categorization is shifted after adaptation, with listeners showing a greater likelihood of classifying ambiguous segments as being unvoiced ([pa]) (Figure 1). This result is interpreted as the result of fatigue on the part of voicing detectors. Some observers have challenged this interpretation, noting that fatigue could be occurring at many levels, including the level of raw auditory representation, feature cue, feature, syllable, or, in some cases, lexical representation.

Figure 1 Schematic results showing categorical perception and selective adaptation effects in phoneme identification. Listeners are asked to identify tokens taken from a synthetic /ba/–/pa/ continuum created by increasing voice onset time. In the adaptation condition, listeners may first hear a series of consonant–vowel syllables with voiced onsets (e.g., *bu*, *do*, *ge*). Listeners in both conditions show identification curves consistent with categorical perception, but the function is shifted after adaptation as listeners show an increased bias toward perceiving segments as voiceless.

While there is little work directly examining neural responses to specific segmental features in humans, there are several studies that have looked at neural responses to phonetic feature cues in animals. In studies of the macaque, it has been shown that short voice onset time (a characteristic of segments like [b], [d], and [g]) produces a single onset transient in A1, while longer voice onset times (characteristic of voiceless segments such as [p], [t], and [k]) produce two transients. More recently, it has been found that voice onset time and aspiration (another acoustic characteristic associated with voicing) are represented in discrete tonotopic regions in A1 by synchronous activation patterns involving large populations of neurons.

Evidence from humans with normal and impaired language processing suggests that these temporospectral cues to feature identity appear to be integrated in unimodal auditory association cortex lying along the superior temporal sulcus immediately adjacent to the primary auditory koniocortex. Many language processes are lateralized, with the left hemisphere being the sole site in which they occur, but whether this is true of these early acoustic–phonetic mappings is an unsettled issue. Some researchers have suggested that the unconscious, automatic activation of features and phonemes, such as occurs as a stage in word recognition under normal conditions, occurs bilaterally, and that the dominant hemisphere is the sole site of phonemic processing that is associated with

controlled processes (such as subvocal rehearsal) and conscious processes (such as explicit phoneme discrimination and identification, making judgments about rhyme, and other similar functions). Other researchers believe that even the unconscious processes that map acoustic properties onto phonological features and phonemes in the process of normal word recognition are lateralized. The evidence for the involvement of both hemispheres in these processes is stronger for vowels than for consonants. It has been suggested that this is because the left hemisphere is specialized for perceptual categorization of acoustic signals that is based upon rapidly changing acoustic properties, though a recent authoritative review downplays this possibility on the grounds that a left hemisphere advantage is only seen for linguistic stimuli and not nonlinguistic stimuli with such temporal characteristics.

The stage of processing that follows acoustic-phonemic processing is lexical access. Most models maintain that a language user has a store of the phonological properties of words in a long-term memory structure (the 'phonological input lexicon') and that acoustic-phonemic mapping identifies features and phonemes that in turn activate these representations. Other models conceive of the long-term representations of the forms of words as distributed sets of features without discernible listings of individual words. In these models, activation of the units over which features are distributed settles into stable patterns that suffice to activate semantic and syntactic features associated with individual words. Activation of items in a phonological input lexicon is not an entirely bottom-up process, however. Prevailing models maintain that bottom-up processes are supplemented top-down in important ways by information about words and context. Indeed, listeners fill in masked gaps in the middle of words so well that they are unable to discriminate masked gaps from masked segments (the 'phoneme restoration effect').

Based on functional neuroimaging results, activation of the long-term representations of the sound patterns of words is thought to occur in the left superior temporal gyrus. Scott and her colleagues have argued that there is a pathway along this gyrus and the corresponding left superior temporal sulcus such that word recognition occurs in a region anterior and inferior to primary auditory cortex, roughly corresponding to the parabelt region of auditory cortex in the monkey, and word meanings are activated yet further along this pathway in anterior inferior temporal lobe bilaterally (Figure 2). This pathway constitutes the auditory counterpart to the visual 'what' pathway in the inferior occipital-temporal lobe, in which cells respond to features of objects

Figure 2 Depiction of the areas in the left superior temporal lobe that are involved in processing sounds and spoken words. PCG, precentral gyrus; SMG, supramarginal gyrus; AG, angular gyrus; MTG, middle temporal gyrus; aSTP and pSTP, anterior and posterior supratemporal planes; STS, superior temporal sulcus; FO, frontal operculum; PO, parietal operculum; H, transverse temporal gyrus of Heschi; STG, superior temporal gyrus. Reproduced from Hickok G and Poeppel D (2004) Dorsal and ventral streams: A framework for understanding aspects of the functional anatomy of language. *Cognition* 92: 67–99, with permission from Elsevier.

and objects themselves. In both the auditory and visual modalities, these temporal lobe pathways extract categories that are associated with meaning, with the difference being that the forms that are extracted from auditory stimuli are words, which are associatively linked to meaning, while those extracted from visual stimuli are structural descriptions of objects, which are partially constitutive of meaning.

The combination of bottom-up and top-down processing streams in language perception is one of the factors that makes it difficult to delineate the auditory component of language processing. Speech sounds map onto words, which in turn map onto representations of meaning, syntax, discourse, and world knowledge. To the extent that activation flows both ways between these representations, higher level representations may influence activation in auditory areas. Any understanding of auditory processing in language must involve an appreciation of these connections.

Speech perception is connected to speech production, especially during language acquisition, when imitation is crucial for the development of the child's sound inventory and lexicon. On the basis of lesions in patients with repetition disorders known as 'conduction aphasia,' the neural substrate for this connection has been thought to consist of the arcuate fibers of the inferior longitudinal fasciculus, which

connect auditory association cortex (Wernicke's area in the posterior part of the superior temporal gyrus) to motor association cortex (Broca's area in the posterior part of the inferior frontal gyrus). Recent functional neuroimaging studies and neural models have partially confirmed these ideas, providing evidence that integrated perceptual-motor processing of speech sounds and words makes use of a 'dorsal' pathway separate from that involved in word recognition. Again, the parallel with perception of visually presented objects has been emphasized, with the dorsal speech pathway corresponding to the parietal-based pathway that links object recognition with object use.

Once items are identified in the phonological input lexicon, it is possible, in principle, for a great deal of subsequent language processing to be carried out on syntactic and semantic properties of words and to be far removed from what would ordinarily be considered 'auditory' processing. However, the processes that construct the forms and meanings of sentences and discourse are not as independent of auditory processing as one might imagine. The products of segmental auditory processing, believed to be based in the dorsal pathway, play an important role with respect to these levels of language through subvocal rehearsal. The exact role of subvocal rehearsal in language comprehension is debated, but there is wide agreement that it is used as at least an ancillary mechanism to keep words in an active available form, to be reconsidered by comprehension mechanisms when structures are hard to build or have to be revised.

Suprasegmental (Intonational) Processing

Intonation (or prosody) refers to the pitch contours of words and phrases. Like lexical structures, intonational structures have been characterized in abstract representational terms, of which the Tones and Boundary Indices (ToBI) system is the most widely used. The ToBI assigns various levels of height to 'tones' that indicate intonational contours, and numerical levels to types of intonational breaks between words. For instance, the sentence "I like football, hockey, and soccer" might be spoken as one intonational phrase (IP), with several smaller intermediate phrases (ips), as in $[_{IP}$ $[_{ip}$I like football], $[_{ip}$hockey], $[_{ip}$and soccer]].

Like phonemes and their features, these tones and breaks are abstract characterizations of sound, and an active field of study investigates the mapping between them and acoustic properties. Many acoustic features of ToBI notational elements have begun to be identified. Some of these features are local. For instance, longer word nucleus duration and lower fundamental frequencies tend to occur at intonation phrase boundaries compared to intermediate phrase boundaries. The higher the pitch, or the bigger the pitch rise on a word, the more intonationally prominent the word is. Sentence-final rising intonation is associated with questions rather than statements. However, many ToBI notational elements are determined by relational properties of discontinuous portions of the acoustic waveform and features. For instance, whether a boundary is an intonational or an intermediate phrase boundary is determined in part by pitch, duration, and pause features adjacent to that boundary relative to these features at other boundaries.

Listeners use intonation to obtain information about syntactic and discourse structure. At the level of syntax, intonational boundaries are relevant to how phrases are attached to one another. For instance, the sentence "When the woman washed the clothes fell off the shelf," is usually initially misanalyzed, with listeners (and readers) taking 'the clothes' to be the object of 'washed,' and then are left with an apparently ungrammatical end to the sentence. A pause (or, in writing, a comma) after 'washed' indicates the clause boundary and makes the sentence understandable. At the level of discourse, intonation provides a great deal of information, including the focus of the discourse, the illocutionary force of a sentence (statement, question), and other semantic features. For instance, the sentence "Senator Eastland doesn't grow cotton to make money" is ambiguous, conveying either the sense that Senator Eastland grows cotton for some reason other than to make money or that Senator Eastland makes money by not growing cotton. An intonational contour that places a rising and then falling tone on 'cotton' followed by an intonational phrase break after 'cotton' leads to 'cotton' being the focus of the sentence. This leads to the usually unpreferred sense that the senator makes money by not growing cotton.

The mapping between intonation and other levels of linguistic structure is complex; intonational structures tend to correlate with, but not be isomorphic to, other structures. The sentence "The man who walked the dog that chased the squirrel tripped" consists of a series of relative clauses attached to noun phrases, and its syntactic structure can be roughly sketched as $[_{S}$ $[_{NP}$ The man who walked $[_{NP}$the dog that chased the squirrel]] tripped]. Its intonational contour, however, is different, grouping the objects of each clause with their verbs ([The man who walked the dog] [that chased the squirrel] tripped]). Intonation thus gives some strong and relatively direct cues regarding higher level linguistic representations (as in the case of focus) and some less direct cues as to these structures.

The neural basis of perceiving intonation has been less intensively studied than that of word-level phonology. These studies follow the same lines as those of segmental aspects of spoken language, dividing into those that that focus on the perception of the elements that determine intonational percepts and those that focus on the mapping of intonation onto higher linguistic categories.

One topic in the first set is pitch perception. Pitch is a derived percept that stands in a complicated relationship with its acoustic counterpart, fundamental frequency, or F0. The perceived pitch that creates intonation patterns is the product of vibration of the vocal cords, which pulse energy through the vocal tract as they open and close. Pitch information may be present throughout a wide frequency range due to the presence of harmonics – bands of energy found at integer multiples of the fundamental frequency. Behavioral evidence suggests that the perception of pitch in complex tone stimuli (including language) is a constructive process involving the full harmonic structure of a signal. Evidence for this view comes from the missing fundamental phenomenon in which listeners perceive pitch even when the fundamental is removed through filtering. Interestingly, pitch perception involves anatomically dissociable mechanisms in pitch-present versus missing fundamental stimuli, suggesting the existence of multiple cortical pitch extraction mechanisms. Evidence from imaging and lesion studies in humans and animals typically points to bilateral involvement of primary auditory cortex, with a dominant role in pitch perception played by the right hemisphere. So, for example, neurons in both left and right primary auditory cortex have been found that are sensitive to pitch change and pitch direction, but behavioral tasks involving the pitch direction discrimination appear to depend on intact right hemisphere primary auditory cortex. One of the great challenges in the study of the neural correlates of pitch perception has to do with the problem of encoding. While both temporal and place encoding models of cortical pitch representation has been proposed, it is clear that neither class of models adequately relates physiological data to psychophysical data across the relevant frequency span.

Turning to the mapping of intonational percepts onto other linguistic representations, studies are scarce and results are inconsistent. One study from our lab examined the processing of intonation in the context of linguistic processing. We found that syntactic statements pronounced with question intonational contours led to increased blood oxygen level-dependent (BOLD) activity in bilateral inferior frontal and temporal regions, compared to the corresponding statements with statement intonation. Other studies, however, have found only right hemisphere activation related to intonation signaling questions, albeit in different contrasts (contrasting sentences with intonation signaling a statement or question, against sentences with the same or different tone on the final word, in Chinese). One preliminary finding of interest is that different intonational features may activate different brain regions. For instance, in one study, the areas activated by Chinese listeners making judgments about the location of contrastive stress (relevant to discourse focus) were more left lateralized than the areas activated by the same listeners making judgments about whether an intonational contour expressed a question or a statement. Many aspects of design and analysis will need to be addressed before a clear picture is likely to emerge regarding this question.

Future Directions

This brief overview indicates that many basic questions about the processing of acoustic information to yield linguistic representations remain unanswered. The application to these questions of modern investigational methods in psychology, functional neuroimaging, and neurophysiology, though in its infancy, has already added enormously to the information we have about these processes and their neural bases. Beyond these areas lie questions about closely related matters, such as the processing of indexical information, emotional state, and other percepts as separate or related processing streams. Models of the neural mechanisms that are responsible for processing the acoustic stimulus in linguistic terms are guaranteed to deepen and change as these topics are further explored.

Language: Cortical Processes

D Caplan, Massachusetts General Hospital, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

The study of language–brain relationships is almost exclusively focused on the neural basis of the largely unconscious normal processes of speaking, understanding spoken language, reading, and writing. Data bearing these relations come from a variety of sources.

Correlating lesions with deficits provides evidence regarding brain areas that are necessary for a function. The original approach of postmortem analysis has largely been supplanted by magnetic resonance imaging (MRI), positron emission tomography (PET), and other imaging techniques. Data are also obtained by intraoperative stimulation, subdural electrode placement, and transcranial magnetic stimulation focally in normal individuals, which interfere with functions in most cases. The second approach to the study of language–brain relations is to record physiological and vascular responses to language processing in normal individuals using event-related potentials (ERPs) and magnetoencephalography (MEG), intraoperative and subdural recordings, optical imaging, and, most commonly, PET and functional MRI. Regions in which differences in neurovascular activity are associated with differences in performance on two tasks support the operations that differ in the two tasks. Functional neuroimaging in patients can reveal brain areas that are involved in an operation only postinjury.

Neural Structures Involved in Language

Beginning in the late nineteenth century, the application of deficit–lesion correlations based on autopsy to the problem of the regional specialization of the brain for language yielded important findings that remain undisputed. Chief among these is the fact that human language requires parts of the association cortex in the lateral portion of one cerebral hemisphere, usually the left in right-handed individuals. This cortex surrounds the Sylvian fissure and runs from the pars triangularis and opercularis of the inferior frontal gyrus (Brodman's area (BA) 45 and 44; Broca's area) through the angular and supramarginal gyri (BA 39 and 40) and into the superior temporal gyrus (BA 22; Wernicke's area) in the dominant hemisphere (Figure 1).

Data from other sources – deficit–lesion correlations based on antemortem neuroimaging and functional neuroimaging – have provided evidence that regions outside the peri-Sylvian association cortex also support language processing. Written language appears to involve cortex closer to the visual areas of the brain and sign language brain regions closer to those involved in movements of the hands than movements of the oral cavity. Some ERP components related to processing improbable or ill-formed language are maximal over high parietal and central scalp electrodes, suggesting that these regions may be involved in language processing. Both lesion studies in stroke patients and functional neuroimaging studies suggest that the inferior and anterior temporal lobe is involved in aspects of language processing. Injury to the supplementary motor cortex along the medial surface of the frontal lobe can lead to speech initiation disturbances; this region may be important in activating the language processing system, at least in production tasks. Activation studies have shown increased regional cerebral blood flow (rCBF) and blood oxygen level-dependent signal in the cingulate gyrus in association with many language tasks, although this activation appears to be nonspecific because it occurs in many nonlinguistic tasks as well. It has been suggested that it is due to increased arousal and deployment of attention associated with more complex tasks.

The same sources of data provide evidence that subcortical structures are also involved in language processing. Several studies report aphasic disturbances following strokes in the deep gray matter nuclei (the caudate, putamen, and parts of the thalamus). It has been suggested that subcortical structures involved in laying down procedural memories for motor functions, particularly the basal ganglia, are involved in 'rule-based' processing in language, such as regular aspects of word formation, as opposed to the long-term maintenance of information in memory, as occurs with simple words and irregularly formed words. The thalamus may play a role in processing the meanings of words. In general, subcortical lesions cause language impairments when the overlying cortex is abnormal (often, the abnormality can be seen only with metabolic scanning techniques) and the degree of language impairment is better correlated with measures of cortical than subcortical hypometabolism. It may be that subcortical structures serve to activate a cortically based language processing system but do not process language. In some activation studies involving language, the cerebellum also has increased rCBF. This may be a result of the role of this part of the brain in processes involved in timing and temporal ordering of events or because it is directly involved in language and other cognitive functions.

Ongoing studies have also clarified data regarding hemispheric dominance for language. In approximately

Figure 1 Depiction of the left hemisphere of the brain showing the main language areas.

98% of right-handed individuals, the left hemisphere is dominant. Approximately 60–65% of non-right-handed individuals are left-hemisphere dominant, approximately 15–20% are right-hemisphere dominant, and the remainder appear to use both hemispheres for language processing. The relationship of dominance for language to handedness suggests a common determination of both, probably in large part genetic. The neural basis for lateralization was first suggested by Geschwind and Levitsky in 1968, who discovered that part of the language zone (the planum temporale, a portion of the superior temporal) was larger in the left than in the right hemisphere. Subsequent studies have confirmed this finding and identified specific cytoarchitectonically defined regions in this posterior language area that show this asymmetry. Several other asymmetries that may be related to lateralization have been identified. The exact relationship between size and function is not known. In general, however, relative size is a good predictor of lateralization and an example of the 'bigger is better' principle that applies elsewhere to communication systems (e.g., to song nuclei in birds).

An important finding is that the 'nondominant' hemisphere is involved in many language operations. Evidence from the effects of lesions and split brain studies, experiments using presentation of stimuli to one or the other hemisphere in normal subjects, and functional neuroimaging studies indicate that the nondominant hemisphere understands many words, perhaps representing them more generally than does the left hemisphere, and suggest that it is involved in other aspects of language processing as well. Some language operations may be carried out primarily in the right hemisphere. The best candidates for these operations are ones that pertain to processing the discourse level of language, especially revising inferences, interpreting nonliteral language, and appreciating humor.

Models of Organization of the Brain for Language Processing

Two general models of the relationship of areas of the brain to components of the language processing system have been developed. Localizationist theories maintain that language processing components are localized in specific parts of the brain. 'Holist' theories maintain that linguistic representations and processes require broad areas of the brain. Five basic models, which capture the set of logically possible relations of brain areas to language processes, can be extracted from these two conceptualizations: invariant localization, variable localization, even distribution, invariant uneven distribution, and variable uneven distribution.

Invariant localization hypothesizes that only a small area of the brain supports a function. Variable localization hypothesizes that different small areas of the brain support a function in different individuals. Distribution hypothesizes that a large region of the brain supports a function. Traditional distributed models assumed an even distribution of distributed functions: All parts of the region contributed equally to the function. If a function is evenly distributed throughout a region, there can be no individual variability in its neural basis. If a function is unevenly distributed throughout a region, it may be distributed the same way in everyone (invariant uneven distribution) or differently in different individuals (variable uneven distribution). Other models are extensions of these basic five. Degeneracy is a variant of localization in which more than one structure independently supports a function; degeneracy can either be invariant (the same areas independently support the function in everyone) or variable (different areas independently support the function in different people). Variable localization could be constrained so that a function is localized more often in one area than another.

It is not possible to review all the areas of language whose neurological basis has been studied. Here, syntactic processing is discussed.

Syntactic structures determine the relationships between words that allow sentences to convey propositional information – information about thematic roles (who is initiating an action, who is receiving it, etc.), attribution of modification (which adjectives are assigned to which nouns), scope of quantification, co-reference, and other relations between words. The propositional content of a sentence conveys a

great deal of information beyond what is conveyed by words alone and is crucial to many human intellectual functions. Propositions are the source of much of the information stored in semantic memory. Because propositions can be true or false, they can be used in thinking logically. They serve the purpose of planning actions. They are the basic building blocks of much of what is conveyed in a discourse.

Unlike models of the neural basis for lexical access and lexical semantic processes, a variety of models have been proposed regarding the neural basis for syntactic processing. Of the five theories of functional neuroanatomy reviewed previously, four have been proposed regarding syntactic processing on the basis of deficit–lesion correlations: localizationist models that claim that Broca's area plays a critical role in connecting moved constituents and their antecedents; variable localization models; traditional, evenly distributed models; and invariant unevenly distributed models.

Evidence supporting these models is based on correlating deficits in syntactic comprehension with lesions. There is considerable disagreement about how to characterize these deficits. Syntactic comprehension deficits are typically established by showing that patients can understand sentences with simple syntactic structures (e.g., 'The boy chased the girl') and sentences with complex syntactic structures in which the relationships between the nouns and verbs can be inferred from knowledge of real-world events (e.g., 'The apple the boy ate was red') but not sentences with complex structures in which the relationships between the nouns and verbs depend on a syntactic structure that needs to be constructed (e.g., 'The boy the girl pushed was tall'). However, there are two issues that must be dealt with. First, it is not clear whether a patient with a performance of this type has a deficit in a particular parsing operation or has what might be called a reduction in the resources available to accomplish syntactically based comprehension. Second, there is virtually no consistency of individual patients' performances across tasks, raising questions about whether it is correct to say that a patient who fails on a particular structure has a parsing deficit.

Assuming, however, that performances such as those outlined previously on a single task are properly analyzed as deficits in particular parsing operations, the empirical basis that relates these deficits to lesions is so limited that none of the models that have been championed have been tested rigorously. The vast majority of claims about the neural basis for syntactic processing are based on patient data and do not examine lesions quantitatively. Many are based on the assumption that Broca's or nonfluent patients have 'anterior' lesions and Wernicke's, fluent, conduction and anomic patients have 'posterior' lesions, whereas the reality is far more complicated. We recently reported the most detailed study of patients with lesions whose syntactic comprehension has been assessed. Forty-two patients with aphasia secondary to left hemisphere strokes and 25 control subjects were studied for the ability to assign and interpret three syntactic structures (passives, object-extracted relative clauses, and reflexive pronouns) in enactment, sentence–picture matching, and grammaticality judgment tasks. Neither the most direct prediction made by distributed models (that lesion size correlates with performance level) nor the most commonly made claim about localization of syntactic operations (that the insertion of traces into syntactic structures occurs in Broca's area) have been tested quantitatively on the basis of radiological data. We recently began to address this question. We measured accuracy, reaction time, and self-paced listening times in picture matching and grammaticality judgment. We obtained MRI and 5-deoxyglucose PET data on 31 patients and 12 controls. The percentage of selected regions of interest that was lesioned on MRI and the mean normalized PET counts per voxel in regions of interest were calculated. In regression analyses, lesion measures in both peri-Sylvian and non-peri-Sylvian regions of interest predicted performance. Patients who performed at similar levels behaviorally had lesions of very different sizes, and patients with equivalent lesion sizes varied greatly in their level of performance. The data are consistent with a model in which the neural tissue that is responsible for the operations underlying sentence comprehension and syntactic processing is localized in different neural regions in different individuals.

Functional neuroimaging has supplanted deficit–lesion correlations as the principle source of information regarding the localization of syntactic processing in sentence comprehension. These studies have led to localizationist models. Many researchers advance models in which some aspect of parsing or sentence interpretation is localized in Broca's area or in portions of this region. Some authors have argued that the innate capacity that underlies the ability to acquire the syntax of natural language is localized in this region. However, despite the numerous advocates for localization of syntactic operations, most neuroimaging studies show that multiple cortical areas are activated in tasks that involve syntactic processing, and different areas have been activated in different tasks. Overall, these data suggest variation in the localization of the areas that are sufficient to support syntactic processing within the language area across the adult population, with perhaps some constraint on the areas

in which processing is localized as a function of the proficiency of individuals to assign syntactic structure and determine the meaning of sentences.

Conclusion

Human language is a unique representational system that relates aspects of meaning to many types of forms (e.g., phonemes, lexical items, and syntax), each with its own complex structure. Deficit–lesion correlations and neuroimaging studies are beginning to provide data about the neural structures involved in human language. It appears that many areas of the brain are either necessary or sufficient in representing and processing language, with the left peri-Sylvian association cortex being the most important such region. How these areas act to support particular language operations is not understood. There is evidence for both localization of some functions in specific regions and either multifocal or distributed involvement of brain areas in other language functions. It may be that some higher level principles are operative in this domain. For instance, content-addressable activation and associative operations such as those that underlie phoneme recognition, lexical access, and lexical semantic activation may be invariantly localized, whereas combinatorial computational operations such as those that constitute the syntax of natural language may not. However, many aspects of these topics remain to be studied with tools of modern cognitive neuroscience.

Language: Learning Impairments

J L Evans, San Diego State University, San Diego, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

In this article, the characteristics of a group of children with language learning impairments are described. These children do not have problems that are usually associated with language-learning impairments, such as hearing impairment, intellectual impairments, and/or neurological damage. In the research literature, 'specific language impairment' (SLI) is the most widely used term for this group of children, and it is the one that is used here.

The criteria for SLI are quite precise. They include Performance IQ in the normal range; normal hearing; no recent episodes of otitis media with effusion; no evidence of seizure disorders, cerebral palsy, or brain lesions; no medication for control of seizures; no oral–motor structural abnormalities; and no symptoms of impaired reciprocal social interactions (e.g., autism). Typically, nonverbal IQs of these children are on average 85–100, whereas standardized language assessment scores are 1.25 standard deviations or more below one's expectations. These children pass pure-tone hearing screenings at 20 dB in both ears at frequencies of 500, 1000, 2000, and 4000 Hz. They have no focal brain lesions, traumatic brain injury, cerebral palsy, or seizures. Important is the exclusion of children who have problems with volitional control of oral–motor structures, which does not rule out mild neuromaturational delays. Interestingly, some children with SLI may be more clumsy, have slower motor responses, and have poorer fine motor skills than peers.

A final exclusion criteria is the absence of all of the symptoms listed for pervasive developmental disorder 'not otherwise specified' in the *Diagnostic and Statistical Manual of Mental Disorders*. Hence, no problems using gaze and gestures to regulate social interactions, or stereotypic, repetitive motor movements characteristic of children with autism, are seen in these children. This is not to say that they do not experience substantial difficulties in social interactions as a result of their language disorders.

The prevalence of SLI is approximately 7% of school-aged children. Although it was commonly believed that the incidence of SLI is higher in males than females, large-scale epidemiological studies now report a ratio of SLI in males to females of 1.1:1. Thus, the 'often reported' higher rate of males to females with SLI may instead be a reflection of referral bias in the public schools, the overidentification of males with SLI, and the underidentification of female children with SLI. Approximately 70% of very young children (2-year-olds) who experience delays in language production may catch up to their peers by the time they are 3 or 4 years of age; however, if a child is still classified as having language difficulties by the time he or she is in kindergarten, it is likely that he or she will continue to have language impairments throughout adolescent and adulthood. This suggests that a 'wait-and-see' approach for children beyond the age of 4 years puts them at extreme risk for pervasive and continued language impairments and may result in significant costs to health care and educational systems.

Language Abilities of Children with SLI

The work reviewed here includes only studies investigating American- and British-English-speaking children with SLI (although cross-linguistic work suggests similar findings). Children with SLI have difficulty comprehending and producing new words. Vocabulary growth is slow, and expressive vocabulary, as measured by standardized assessments, is smaller than that of age-matched peers. First words appear at older ages in children with SLI, with the average age of first word being 23 months in contrast to 12 months for typically developing children. The types of words used by children with SLI, however, mirror those of typically developing children, with names of objects/animals/substances comprising approximately 55% of their first words, words referring to actions comprising 12% of first words, and words referring to properties of objects also comprising 12%. Moreover, verb stem errors are extremely rare in children with SLI, reportedly occurring in only 7:2998 verb tokens in the speech of preschool children with SLI.

Experimental word-learning studies show that children with SLI need, on average, at least twice the number of exposures to a novel word compared to their peers before they can successfully comprehend and/or produce it. The trajectory of word learning is also qualitatively different. Children with SLI exhibit a concave word learning trajectory, with initial performance being poor but improving rapidly with increased exposure, compared to typical children, whose word learning trajectory is convex, with rapid improvement in comprehension and production accuracy after initial exposure to novel words, followed by a leveling off and stabilizing of performance. Additional semantic cues presented with a novel word increase comprehension accuracy for children with SLI, whereas phonological cues increase production

accuracy in these children but not in typical peers. Errors made by children with SLI in extending a newly learned word to a novel object mirror those of younger language-matched typical children, with the referent receiving the incorrect label when it is both perceptually and functionally similar to the target object. Studies of lexical abilities in school-aged children with SLI parallel the findings when these children were younger.

Difficulty acquiring and using grammatical morphology, including inflectional affixes such as past tense *-ed* and plural *s*, characterizes the difficulties seen in children with SLI and has been proposed as a possible phenotype marker for this disability. Typically developing children have acquired these morphological forms by the time they are approximately 4 years of age, whereas learning these forms is difficult for children with SLI, who are well into school-aged years before they learn them. On tasks designed to probe comprehension of various syntactic forms, young children with SLI are unable to identify syntax errors in sentences, such as tense marking and subject–verb agreements; have difficulty comprehending passive constructions; and rely heavily on comprehension strategies in the absence of full comprehension. Not surprising, children with SLI have more difficulty identifying syntactic violations despite easily identifying semantic violations.

In a given language, the use of grammatical morphology is highly predictable. Because of this regularity, its use is often viewed as being 'rule governed,' and children's use of these forms is an indication that they have inferred the 'rules' governing the generation of a given linguistic form. Moreover, in typically developing children, this rule can be extended to new and novel linguistic contexts, with such extensions providing critical evidence that the child has completely extracted the rule and is able to use the rule generatively (e.g.. affixing plural *s* to 'wug'). In discrimination-learning studies, in which a child is asked to extract 'regularities' from recurring stimulus presentations and then extend them to new stimulus items consistently, children with SLI are unable to extend linguistic regularities from trained to untrained forms.

The use of argument structure by children with SLI in spontaneous and elicited utterances suggests that underlying knowledge of these forms in these children may be learned through exposure to specific verbs in individual sentence constructions. Although most argument structures are evident in the speech of children with SLI, they do not consistently produce these forms. For example, children with SLI produce elements that add substantially to the information content of an utterance but which are not obligatory. Although 7- to 9-year-old children with SLI resemble typical 5-year-olds in the rate at which they use adverbial forms to express temporal relationships, they are unable to provide additional contextual information when necessary (e.g., 'the dog left' is not sufficient).

Theoretical Accounts

A critical question with regard to this population is whether SLI is a primary deficit in an independent grammar module or whether more general-purpose processing mechanisms underlie the language impairments seen in these children. Several processing mechanisms have been proposed and include but are not limited to auditory processing deficits, limited verbal working memory, slower speed of processing, and generalized limited processing capacity.

Processing capacity and speed of processing accounts view processing as trade-offs between task demands and cognitive resources. Limited capacity accounts of SLI share the tenet that children have a fixed pool of operational resources available to perform computations, and when the demands of a task exceed available resources, both processing and storage of information will be degraded. A consistent finding across both verbal and nonverbal tasks that are designed to simultaneously tax the processing and storage of information in children with SLI is that when they are required to allocate more of their working memory resources to processing information, they are left with substantially fewer resources for the storage of information compared to their unimpaired peers. Processing capacity tasks have high specificity and sensitivity in the identification of children with SLI and account for a significantly greater proportion of the variance in language abilities in SLI than standardized measures of grammatical knowledge.

Speed of processing is often viewed as a processing resource in the sense that it is finite and the faster/slower processing is performed, the better/worse the resulting level of cognitive performance will be. Children with SLI are consistently slower than their peers across a myriad of verbal and nonverbal tasks. Both large-scale meta-analysis studies and direct comparisons of reaction time (RT) data for children with SLI show that their speed of processing information is between 20 and 30% slower than that of age-matched controls. One problem in invoking a general processing mechanism account of SLI is that it is not clear whether limited capacity and/or speed of processing reflect a fundamental limitation of the underlying cognitive system or if they are themselves emergent

properties of the system, arising naturally as a consequence of interactions within the cognitive system. Limited capacity and speed of processing have been treated as separate constructs in the study of SLI.

Historically, slower reaction times in children with SLI have been interpreted as the processing of each successive step in a given task being slower by a constant proportion. By this account, the more complex the task (e.g., the greater the number of processing steps), the progressively slower reaction times will be for children with SLI. Importantly, RT data alone cannot rule out alternative slowing accounts, such as cognitive processes being slowed but speed of sensorimotor processes not being slowed, or slowing increasing proportionately with each successive processing step. Event-related potentials (ERPs) provide a means of examining speed of processing with and without higher cognitive processing. Comparisons of behavioral RTs and P300 latencies of children with SLI indicate that P300 ERP latencies are no slower than those of age-matched peers despite RTs being significantly slower. In contrast, N400 latencies, a measure of higher cognitive processing, are significantly longer in children with SLI compared to peers. Taken together, ERP data suggest that slowing in SLI may not be the primary deficit but an artifact of poorly specified and/or degraded extant knowledge in these children, requiring greater processing resources to maintain in active memory than for typically developing children.

Another hypothesized cause of SLI is impaired auditory processing. The nature of auditory processing difficulties in SLI remains open to debate, however. Some researchers have championed the idea that temporal processing deficits are the cause of SLI. Others have proposed reduced storage for phonological material in working memory or poorly specified long-term phonological representations. Studies of auditory processing accounts in children with SLI use several experimental methods, including temporal order judgment tasks, just noticeable difference tasks, phoneme identification tasks, categorical perception tasks, and mismatch negativity (MMN).

Some of the earliest studies of temporal order judgments in SLI showed that children with SLI did not differ from their peers in the interstimulus interval (ISI) needed to detect two separate tones; however, they needed much longer interstimuli durations to correctly report the order in which the tones appeared. Follow-up work has shown that children with SLI are able to successfully report the order of the steady-state vowels but not the order of the CV syllables. These data have been interpreted as a temporal processing deficit, specifically that children with SLI are unable to process rapidly changing acoustic features of speech stimuli.

In just noticeable differences tasks, children with SLI listen to pairs of stimuli and decide if they are the same or different. Typically, one of the pair is a clear exemplar of a given target stimuli, whereas the second is designed to contrast an acoustic dimension of interest. In these tasks, children with SLI require greater acoustic difference between stimulus pairs to discriminate stimuli (e.g., /ba/-/pa/ or /ba-da-ga/) compared to peers. Findings of phoneme-identification studies show the same pattern, in which children with SLI are able to easily distinguish phonemes that are spectrally dissimilar vowels [i] and [a] at both long and short durations, but they have difficulty distinguishing phonemes with greater spectral similarity (e.g., [i]-[I]). (An important finding from auditory processing work is that children with SLI who have both speech and language impairments (articulation impairments as well as language impairments) have greater difficulty with both identification and temporal order judgments.)

The extent to which children with SLI perceive speech sounds categorically has been studies extensively. What is interesting about studies of categorical perception in children with SLI is that, given the ubiquitous nature of categorical perception across species, a deficit in categorical perception in children with SLI would indicate a profound neurocognitive impairment in these children – a finding not in keeping with the perceptual and cognitive abilities seen in these children. Children with SLI consistently exhibit similar crossover points (CPs) as their peers in identification but show less-consistent labeling of unambiguous endpoint tokens and reduced discrimination. Historically, however, these studies of CP in children with SLI used synthetic speech stimuli. A series of CP studies comparing natural and synthesized speech stimuli revealed that poor speech discrimination is evident only for synthetic speech stimuli. The consistent finding of poor auditory processing under synthetic speech conditions suggests that the auditory 'perceptual' deficits in children with SLI are not the result of deficits in auditory processing *per se* but, rather, from increased processing demands inherent in synthesized speech.

MMN, a component of the auditory ERP that reflects the outcome of an automatic comparison processing between different acoustic stimuli, is a measure of sensory memory. Typically, it is elicited when a deviate stimuli occurs in a series of identical stimuli. Both pure tones and speech stimuli have been used in investigations of central auditory

processing in children with SLI. Interestingly, children with SLI have attenuated amplitudes for MMNs to speech stimuli (e.g., /ba/ /da/ /ga/) compared to age-matched peers but not for simple tone stimuli differing in either frequency (1000 vs. 12 000) or duration (175 vs. 100 ms).

Classification and Labels

The study of SLI dates back to the first half of the nineteenth century with the introduction of the term congenital aphasia (the term 'hearing mutism' was used in Germany during this same time period). Other terms used in the late 1800s and early 1900s included delayed speech development, congenital auditory imperception, and congenital verbal auditory agnosia. Interestingly, because clear neurological damage was not evident in these children, as early as the 1880s it was suggested that attention and memory were possible underlying causes of the language disorder. At the turn of the century, English and French researchers began to use the term 'congenital aphasia.' In the 1960s, terms such as developmental aphasia and congenital aphasia began to disappear, and developmental dysphasia began to be used. This shift to *dys-* reflected the differentiation of children with neurological insults and 'acquired aphasia' from children who had language impairments in the absence of brain injury. The shift also reflected the emphasis in the 1960s on detailed description of the linguistic deficit profiles of these children as well. Currently, the terms 'language/learning disabled' or 'language/learning impaired' are often used in studying the academic skills of these children, reflecting the fact that having a label of 'language impaired' does not exclude these children from being labeled as learning disabled in schools. The term 'developmental language disorder with expressive and expressive–receptive subtypes' is also used in the *Diagnostic and Statistical Manual of Mental Disorders*.

Three different approaches characterize the grouping of children with SLI: clinical, psychometric, and linguistic classifications. Clinical taxonomies of language disorders, such as that proposed by Rapin and Allen, closely parallel acquired language disorders in adults with aphasia and include phonological, syntactic, semantic, and pragmatic skills. Alternatively, Aram and Nation classify children with SLI using standardized psychometric tests assessing phonological, syntactic, and semantic aspects of language. In contrast, Crystal, Fletcher, and Garman classify children with SLI based on linguistic measures that include assessment of semantic referencing, phonology, grammar, and structure building. These different approaches have yielded not only different labels for SLI but also different theoretical accounts of the disorders, as well as different subgroupings within SLI.

Neurobiological Correlates

A common but largely unsubstantiated hypothesis in the 1950s was that left hemisphere damage was the cause of SLI. The development of computed tomography scan technology allowed for direct investigation of the hypothesis that SLI was due to left hemisphere damage. However, these studies revealed a remarkable absence of neuroradiological abnormalities in children with SLI. Because research failed to demonstrate that the language disorders seen in children with SLI stemmed from focal brain damage, researchers compared the language abilities in children with known lateralized brain lesions to those of children with SLI. Interestingly, children with unilateral brain lesions manifest profiles of language disorders that are very similar to characteristics of children with SLI. One outcome of this research was a shift in focus from models of SLI that involved left hemisphere damage to models of SLI that involved bilateral or more diffuse areas of the brain.

In unimpaired individuals with normal language abilities, the planum temporale and pars triangularis are larger in the left hemisphere than the right. Children with SLI have abnormal asymmetry of the prefrontal region (right greater than left) and abnormal symmetry in the parietal region. Moreover, the area containing the left planum is significantly smaller in children with SLI, or reverse asymmetry is seen in the region containing the planum temporale in children with SLI. Quantitative anatomical differences in the brains of children with SLI and age-matched controls shows three majors differences: Children with SLI have significantly narrower right hemispheres, have significantly smaller pars triangularis in the left hemisphere, and do not have leftward asymmetry of the pars triangularis, planum temporale, and the planum compared to their age-matched peers. Whereas the left pars triangularis is significantly smaller in children with SLI, the right pars triangularis does not differ in children with SLI and their peers.

Cerebral blood flow measures (single-photon emission computed tomography) in phoneme discrimination indicate that children with SLI do not show predominant activation of the left hemisphere. Moreover, functional magnetic resonance imaging and event-related potential (ERP) studies of toddlers at risk for SLI (e.g., late talkers), children with SLI, and even parents of children with SLI exhibit different patterns of coordinating activation among brain regions relative to controls, suggesting the possibility

of qualitatively different brain organization for language in this population.

Genetics and Heritability

There is a familial component to SLI. The concordance rate for monozygotic twins with SLI is almost 100%, and it is 50–70% for dizygotic twins. Molecular genetic studies implicate: (1) the linkage of a severe autosomal dominant speech and language disorder to the region of 7q31 (*SPCH1*) and (2) translocation in the *SPCH1* region and evidence of linkage on both chromosome 16q and 19q. Furthermore, work indicates that 16q and 19q may represent universally important loci in SLI and, more broadly, a risk factor for developmental language impairments. Importantly, in the SLI consortium study, there is no evidence for linkage to 7q near FOXP2, a gene that has been implicated in severe speech impairment and which is located in a region that may also include a major locus for autism. A study completing a genome scan for SLI used both dominant and recessive models for the three phenotype classifications: (1) clinical diagnosis, language impairment; (2) reading discrepancy; and (3) evidence for linkage between 13q21 using the recessive reading discrepancy model. Results from this study also suggest that additional loci, on 2p22 and 17q23, may comprise part of the phenotype of SLI.

SLI or Dyslexia?

One question is the extent to which SLI and dyslexia are distinct or overlapping disorders. On the one hand, SLI and dyslexia, by diagnostic criteria, are two distinct developmental language disorders, with SLI being characterized by semantics, syntax, and discourse processing difficulties, and dyslexia characterized by phonological processing deficits and problems in word reading. However, children with dyslexia exhibit deficits in semantics and syntax in addition to deficits in phoneme processing. Alternatively, children with SLI, in addition to language impairments, also exhibit substantial deficits in phonological processing. Reviews of behavioral, neurological, and genetic evidence, as well as large-scale epidemiological studies of children with SLI and dyslexia selected from a population-based sample, suggest that these two clinical populations represent two different but overlapping developmental disorders. In a large-scale population-based study, where the participant sample from which the children in the study were drawn included 527 school-aged children, the prevalence of dyslexia was examined in second, fourth, and eighth grade among children who were classified with SLI in kindergarten. A statistically significant, but limited, overlap between SLI and dyslexia existed, but the majority of the children with SLI did not have dyslexia during the school years.

An Implicit Learning Impairment?

Learning is a gradual, often unconscious process that initially is slow and inefficient, but with sufficient exposure it becomes automatic and efficient. Recent studies suggest that language impairments seen in SLI may be secondary to deficits in implicit learning. Procedural learning is the system involved in the learning of new cognitive and/or motor sequences. Grammar is also a regular pattern of sequences. Based on the idea that the lexical declarative memory system is relatively spared in children with SLI, it has been argued that the grammatical systems in these children are impaired, specifically due to neurological damage in the corticostriatum and association areas.

Research has begun to examine this directly using both statistical word learning (SWL) paradigms and a classic task of procedural learning of sequential pattern – the serial reaction time task (SRT). In SRT tasks, a child presses a button corresponding to a spatial location of a visual stimulus, trial by trial. Embedded within a random order of stimuli are patterns of locations. The learning of these embedded patterns within the sequence is evidenced by shorter reaction times of button pressing of the patterned sequence in contrast to the random sequences. Adolescent children with SLI are significantly impaired in their ability to learn the embedded sequence. Moreover, performance on the SRT task accounts for a significant amount of the variance in grammatical knowledge in these children.

Statistical word-learning paradigms also show that children with SLI are significantly impaired in the ability to implicitly discover word boundaries within continuous speech. Whereas school-aged children are able to implicitly learn novel words after only 3 min of exposure, performance of children with SLI after 20 min of exposure is at chance. Importantly, after double the exposure (40 min) to the same speech stream, the performance of children with SLI is greater than chance and no different from the performance of their peers. It is argued that implicit learning is such a primitive cognitive construct that there should be no differences across an individual's performance. However, ERP studies using the same SWL paradigm show that high word learners evidence rapid and early sensitivity to word boundaries seen in the N100 waveform

prior to demonstrating this knowledge behaviorally in posttesting, whereas poor word learners do not. Clearly, a key aspect of learning language is the tracking of the regularities in the language input. One can see how impairment in the mechanisms involved in implicitly tracking the regularities in the language input could have profound implications for language learning and suggest a single mechanism account of the pattern of deficits seen both across language domains and developmentally over time in children with SLI.

Language: Nonhuman Animals

D M Rumbaugh and E S Savage-Rumbaugh, Great Ape Trust of Iowa, Des Moines, IA, USA

Traditionally, language is considered to be a uniquely human characteristic. However, in recent years a number of significant research reports strongly suggest basic language functions in the communication systems of a variety of mammalian and avian species. These reports justify reconsideration of language as being unique to humans and continued study of its foundations in learning and culture. At the core of these communicative systems, including human language, is the production and transmission of signals, as well as the perception, processing, and appropriate response to the signals of others.

All human languages are said to be made up of a finite set of arbitrary, discrete, and largely meaningless elements that, when combined, refer to external events or entities not necessarily present or tangible. Novel meaning can be constructed by recombining these elements based on rules, and similar or identical combinations of elements can maintain single or multiple meanings. Messages need not be honest, accurate, or meaningful. Users of a language learn their languages culturally from more experienced counterparts and retain the potential to learn new meanings or entirely different systems throughout their life span.

These features of human language have been used and misused in an attempt to evaluate the linguistic competencies of various nonhuman species. Still, the features do accurately, if not incompletely, characterize many human languages. It should not be surprising, therefore (at least in an evolutionary sense), that the features describe a number of nonhuman animal communication systems as well. Thus, the central question underlying much of the animal language research during the past century is whether or not human language is fundamentally and comprehensively different from other communicative systems.

The study of the capacity for language in nonhuman animals, particularly the great apes, has contributed richly to our understanding of human language as well as its phylogeny and evolution. One compelling perspective that has emerged as the result of ape language research is that the foundations of language are in the functional exchange of relatively complex information between two or more interactants. Therefore, rather than an 'all or none' phenomenon, language is more accurately viewed as a suite of capacities that evolved as an accretion and integration of competencies for communication and cognition.

In the early twentieth century, a number of studies were initiated that sought to determine whether or not apes were capable of acquiring and speaking human language. However, none succeeded, in large part due to anatomical constraints of their vocal tracts. In the mid-1960s, Allen and Beatrix T Gardner renewed interest in the field with their Project Washoe, aimed at establishing two-way communication between humans and a chimpanzee (*Pan troglodytes*). Because they were familiar with past failures with regard to vocal production on the part of the ape subjects, the Gardners chose American Sign Language (viewed widely as a natural language system) as a means to communicate with their female subject, Washoe. Although Washoe did not acquire signs solely through observation, she was able to learn a relatively large number of signs through training. Researchers would shape Washoe's hands into the correct positions and reward her for successive improvements. This method proved to be a great success. By 3 years of age, Washoe reliably produced 85 signs in appropriate contexts, used signs to communicate novel information in new logically relevant contexts, and combined various signs together. Washoe and other apes with her seemed to master the meaning of the gestures, and they invented ways to express themselves through both the combination of signs and the invention of novel signs.

At approximately the same time, Project Sarah was initiated by David Premack, who used tokens of varying shapes and colors to function as words in an attempt to conduct an experimental analysis of language functions. Sarah, a chimpanzee that was 5 years old at the study's onset, was trained to associate the arbitrary tokens with real-world referents and then to arrange the magnetized pieces on a metal board. Sarah was able to learn these associations, but the work was criticized for its noncommunicative nature. Sarah's behavior, rather than indicative of communicative linguistic ability, could be described adequately as complex problem solving or matching-to-sample skills.

A second project, known as the Language Analogue (LANA) Project, was initiated by Rumbaugh and colleagues in the early 1970s. A computer-based research system provided Lana, a young female chimpanzee, with a keyboard that held 125 keys, each embossed with a distinctive geometric symbol called a

lexigram. Each lexigram functioned as a word, and lexigram use was monitored by a computer. In response to various strings of lexigrams, the computer was programmed to dispense foods or drinks or to activate a number of devices that might present movies or slides on a screen, play music, open a window, invite persons into Lana's area, and so on. Lana readily learned to employ her lexigrams to request items and to respond to experimenter queries for the names and/or colors of 36 test objects, composed of six items in six different colors. Lana also initiated goal-directed conversations and innovatively modified stock sentences that she had been taught in order to facilitate her conversations and to achieve goals other than the specific ones for which the lexigrams were designated. For example, Lana used them to attract attention to malfunctioning food vendors and other devices. Comprehensive analyses indicated that even Lana's innovative use of lexigrams in novel strings gave strong evidence of the grammar demanded by the system's computer. Her use of lexigrams could not be attributed satisfactorily to simple learned sequences or to imitation.

Similar research with other great ape species has demonstrated that gorillas and orangutans can acquire and effectively use derivatives of human signed languages. The fact that it has been shown that both gorillas and orangutans have the potential for human linguistic competency may suggest that some basic competencies were present in the common ancestor of all apes and humans.

All of the research on the linguistic competencies of great apes had focused on the subjects' abilities to produce communicatively appropriate utterances (e.g., gestures, sounds, and lexigrams). However, relatively little attention was paid to whether or not (or the degree to which) the apes comprehended the symbols. In other words, it was still unknown, or at best relatively unclear, if the apes truly understood that the symbols they were so adeptly producing, and in some cases combining, were meaningful and with semantic foundations. Did they function as valid symbolic references for actual items and events in the real world?

In order to address this issue directly, Savage-Rumbaugh began work with two co-reared male chimpanzees named Sherman and Austin. Using a variation of Lana's keyboard, the focus was on symbol-based communication and cooperation between the apes and not necessarily between ape and experimenter.

The categorization skills of Sherman and Austin were examined further in an experiment designed to determine if they demonstrated the capacity to classify correctly 17 different lexigrams into the categories of 'food' or 'tool.' (The lexigrams were geometric symbols that identified various foods and tools, such as banana, apple, wrench, key, and straw.) The chimpanzee subjects could not look at the actual foods or tools when making their decision but only at each lexigram, in turn. Sherman and Austin were taught on only three exemplars each of food and tool. They were not taught how the other 17 test word-lexigrams would be classified. They could make this determination only by looking at each word in turn, recalling the actual item represented by that word, and then determining the function of that item – whether they ate it or used it to open puzzle boxes. Their performance was perfect on these controlled test trials with but one error. Clearly, their symbols had solid semantic foundations.

Sherman and Austin were taught all aspects of their language – how to request food/drinks, how to name/label items without ever receiving them, and even how to comprehend what the symbols represented (e.g., the lexigrams were embossed on the keys of their computer-monitored keyboards). After learning how to request food/drinks, they required additional training to learn how to label those items (e.g., to name them and not receive them).

It is of note that through extensive experience on tasks in which they had to coordinate their behaviors through the use of symbols, they began to employ symbols much as people do – that is, to announce their intended actions. For example, after viewing a random array of food and drinks, they would make a choice, state the name of it on the keyboard, and then give it to the experimenter – as though the experimenter had presented the object to them to be named.

This was a major milestone in the history of ape language research. Not only had strong scientific data been provided indicating nonhuman animals were able to comprehend human symbols but also the work made two additional significant contributions. First, because the apes were using a lexigram keyboard (composed of discrete visual symbols), the subjects' messages were unequivocal. Second, the subjects were (in experimental settings) communicating with one another, not human researchers. Therefore, criticisms regarding imitation were not relevant to this work.

Subsequent research with other apes built on these insights as well as the belief that the fundamental component of language was comprehension, not necessarily production. Accordingly, instead of attempting to train apes to use language, methods focused on cultivation of their comprehension.

Research by Savage-Rumbaugh and colleagues with the bonobo (*Pan paniscus*) Kanzi was the

first to demonstrate a great ape's ability to learn the meanings of symbols spontaneously. All previous ape subjects mastered their vocabularies (e.g., manual gestures, tokens, and lexigrams) as a result of specific training procedures. In contrast, Kanzi acquired lexigram competencies (and spoken English comprehension) observationally – at first, while observing his mother's training sessions and then through interactions with caregivers and researchers. Researchers working with Kanzi would use spoken language in conjunction with the lexigram keyboard during communicative interactions with Kanzi as well as with one another in Kanzi's presence. They would discuss individuals, items, and events in their environment. Kanzi was also given access to a lexigram keyboard, and in time he began to use the keyboard in conjunction with his other communicative modalities to participate in conversations with his human counterparts. In this way, Kanzi's language acquisition more closely resembled that of a typical human child – less through formal teaching and much more through observation and interaction.

Kanzi's comprehension of spoken English was evaluated experimentally to determine how thoroughly Kanzi understood the requests that were made of him. To ensure that Kanzi was responding to the words he heard, and not to context clues or cues from experimenters, requests were spoken to Kanzi by an experimenter located in another room. Kanzi responded appropriately to approximately three-fourths of more than 600 novel requests presented to him verbally in rigidly controlled experimental conditions. His performance was comparable to that of a 2½-year-old child who was included in the study for comparison. Neither Kanzi nor the human child had the benefit of people modeling the requests, nor had they been trained to do what was requested of them.

The work with Kanzi has been replicated with both a female bonobo and a female chimpanzee, who similarly acquired comprehension of spoken English and lexigrams as well as the production of lexigram utterances observationally. This collection of research is fundamentally different from previous studies in that the focus was on language comprehension and not production. Accordingly, rather than training apes to use language, methods focused on cultivation of their comprehension of speech and lexigram utterances. Caretakers and researchers spoke to and with the apes about events and things in their environment, and they concomitantly utilized the lexigram keyboard to supplement their spoken words. This integration of speech with lexigram use by researchers has resulted in the apes similarly supplementing their use of lexigrams on their keyboard with other communicative modalities, such as vocalizations and gestures, to participate in dialogues with their human counterparts.

This approach revealed the following:

- Apes possibly have a sensitive period in early infancy during which they can come to comprehend hundreds of spoken words uttered by their caretakers.
- The apes' speech understanding is not limited to single words but, rather, can include the syntax of novel spoken sentences of request at levels that compare favorably with those of a 2½-year-old child (typical sentences from the set of more than 600 included 'Go get the lettuce that's in the microwave,' 'Give the doggie some carrots,' 'Take the mushrooms outdoors,' 'Now, could you wash your ball?' and 'Put the tomato on the blanket.').
- In this type of setting, apes will spontaneously begin to produce rule-based utterances by using the word-lexigram keyboard system and gestures. Such productions are novel, incorporate a simple grammar, and are spontaneous.
- Apes can also comprehend 'reversed sentences' (e.g., 'Make the doggie bite the snake' vs. 'Make the snake bite the doggie'), indicating that they can acquire the basic principles of syntactically based word order. In addition, comprehension of sentences referring to items not immediately present was demonstrated in response to sentences such as 'Go outside and get some flowers' or 'Go outdoors and find the carrot.' Retrieval of nonpresent items was comprehended accurately even when a similar referent was present (e.g., retrieval of the carrot that was outside when there was also a carrot indoors).
- The apes participate in communicative interactions with humans, and analysis of these exchanges reveals patterns and regularities in the apes' utterances. These interactions share characteristics with human conversation because the apes participate in turn-taking and respond to and produce requests.
- In these situations, the apes employ vocalizations as a regular part of their communicative repertoire and produce structurally distinct vocal utterances that vary predictably with the semantic context in which they are produced.
- During these complex communicative interactions, the apes are able to map new words onto novel items after only a few exposures to the items, and they do so without visual contact with the items.

The initial question in the field of ape language research regarding 'the ability that apes have for language' in terms of the human standard of speech (i.e., phrase and sentence construction) led to the misguided, if not basically incorrect, conclusion that

apes do not and cannot have language, on the one hand, and that language is a uniquely human attribute, on the other hand. Alternatively, contemporary language research with apes, focused on the parameters of symbol acquisition and rearing methods in relation to their competent use, has served to

- elucidate the evolutionary and ontogenetic roots of language;
- provide training materials and techniques which greatly benefit children who, because of developmental disabilities, have language deficiencies; and
- reveal that if there are absolute 'basics' to language competence, they are probably (1) the ability to symbolize – that is, to come to use symbols to represent things not necessarily present in time/space – and (2) the ability to use learned symbols to communicate information that otherwise could not be exchanged via the unlearned modes of communication.

Early Environment and the Importance of Logic-Structures

Early environmental stimulation can have general facilitating effects on development, but it is in the logic structure of early environment that the specific basic dimensions and interests of cognition and competence are defined. Logic structure refers to recurring patterns of communication, language use, music, movement patterns as in dancing, acrobatics, etc. A corollary of this important principle is that the specific effects of the logic structure probably depend on brain size and complexity: early environment is probably much more critical to the cognitive development of children and apes than it is to monkeys and prosimians. Segerdahl, Fields, and Savage-Rumbaugh advance the significance of culture and context in both the acquisition and the comprehension of language and that language is to be understood adequately with the culture past and present.

Principles of Continuity

As a result of the research with bonobos, particularly with Kanzi, a noted comparative psychologist, Michael Domjan, concluded that the psychological, as well as the biological, continuity postulated between animals and humans has been confirmed. The child linguists Elizabeth Bates, Donna Thal, and Virginia Marchman also support the continuity perspective of language. The shattering of the "wall that separates man from chimpanzee" presents a challenge to our thinking, "but [we] believe that the world will be the better for it."

Neuroanatomical Continuities

One salient feature of language processing in the human brain is lateralization of function to one hemisphere compared to the other. According to the classical model popularized in the second half of the nineteenth century, two cerebral cortical areas in the left hemisphere are most commonly associated with language functions: a receptive region for the processing and integration of auditory sensory information commonly referred to as Wernicke's area and a productive region concerned with the encoding of vocal signals into meaningful words and sentences referred to as Broca's area. In other words, Broca's area functions primarily in the planning and execution of speech, whereas Wernicke's area functions to 'make sense' of the speech that a listener perceives. Humanlike left hemisphere neuroanatomical asymmetries have also been identified in both posterior temporal lobe and inferior frontal regions of the chimpanzee brain – regions considered homologous to Broca's and Wernicke's areas, respectively. Furthermore, asymmetry of the chimpanzee inferior frontal gyrus (the location of the Broca's area homolog) is associated with hand use during gestural communication. These results suggest that both a biological and a behavioral continuity exists between human language and the communicative systems of great apes.

Conclusion

Intensive research during the past 30 years has documented that apes

- have the ability to learn and use symbols to represent things/events not necessarily present, which is the basis of semantics;
- have the ability to use learned symbols among themselves and/or with humans to solve problems via the exchange of information;
- readily organize their learned symbols into conceptual categories (e.g., foods, tools, people, and conspecifics);
- acquire language optimally not by formal training but, rather, through daily experiences garnered during infancy; and
- comply with basic rules of grammar and comprehend novel sentences that they hear – sentences that have their meanings syntactically embedded.

Language research with animals has made fundamental contributions to knowledge and has caused us to reassess long-standing assertions and questions that pertain to claims regarding language and human uniqueness. Are humans unique? Yes, but probably

no more so than most other species of animal life. Are humans a 'creature apart' from other species with regard to advanced cognitive competencies? The answer clearly is "Perhaps more in degree than in kind."

Large Conductance Calcium-Activated Potassium Channels

A Alioua, P Kundu, R Lu, Y Kumar, J Ou, E Stefani, and L Toro, University of California at Los Angeles, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Large conductance voltage- and calcium-activated potassium channels are tetramers of the pore-forming α subunit, $K_{Ca1.1}$. This class of channels is highly selective for K^+, has large single channel conductance (~120 pS in physiological solutions), and is widely distributed throughout the nervous system. Membrane depolarization and increases in intracellular Ca^{2+} concentration – two parameters which are under dynamic change during a neuronal action potential – allosterically activate (open) $K_{Ca1.1}$ channels (also known as MaxiK and BK), leading to their participation in the control of neuronal excitability. $K_{Ca1.1}$ channels also play important physiological roles in organs containing smooth muscle and contribute to the control of blood pressure, uresis, and erectile function, among others.

In the tetrameric channel, each $K_{Ca}1.1$ subunit is encoded by a single gene (KCNMA1) which is capable of generating multiple splice variants (i.e., isoforms) yielding distinct phenotypes. Also, $K_{Ca}1.1$ channel phenotype can be modified by regulatory β subunits (β_1–β_4), with β_4 being abundant in brain. For efficient signaling, native $K_{Ca}1.1$ channel has been shown to form complexes by tight association with a variety of partner proteins.

The physiological implication of the $K_{Ca}1.1$ channel in the nervous system has been further appreciated by studying mice knockout models of the α ($K_{Ca}1.1^{-/-}$) or β subunit ($\beta^{-/-}$) genes. Furthermore, some types of neuronal disorders seem to be associated with inherited mutations in the KCNMA1 gene or decreased expression of $K_{Ca}1.1$ channel protein, as in schizophrenia and autism.

This article discusses advances with regard to $K_{Ca}1.1$ channel structure, distribution, and *in vivo* physiological roles, with emphasis on the nervous system.

Structural Correlates of $K_{Ca}1.1$ Channel Function

Native $K_{Ca}1.1$ currents were first recorded in 1981 from chromaffin and muscle cells. Since then, these channels have been found in a wide variety of cell types, including neurons, microglia, and astrocytes. As mentioned previously, the minimal functional arrangement of $K_{Ca}1.1$ channels allowing K^+ flow consists of four α subunits, which may not be identical due to splice variation of the same gene, thus resulting in a large number of channel isoforms with potentially distinct functions. In addition, association with regulatory β subunits, with signaling partners, and/or posttranslation modifications can increase channel diversity and function (Figure 1).

$K_{Ca}1.1$ Subunit

$K_{Ca}1.1$ was first cloned from *Drosophila* (d*Slo*) and subsequently from a number of other species, including human, mouse, and rat. Human $K_{Ca}1.1$ protein is encoded by the KCNMA1 gene, which contains 27 constitutive exons and multiple alternative exons spanning approximately 769 kb of human chromosome 10 (10q22.3) (Figure 1(a)). The translation product of constitutive exons is highly conserved among mammals, with approximately 98% amino acid sequence identity encoding for a protein of approximately 125 kDa (although splice variation can give rise to numerous isoforms). $K_{Ca}1.1$ primary structure exhibits significant similarity to signature regions of other α subunits of the voltage-dependent potassium channel superfamily, Kv. However, unlike the α subunit of other voltage-dependent potassium channels, $K_{Ca}1.1$ monomer has seven (S0–S6) instead of six (S1–S6) transmembrane domains, with four additional hydrophobic (S7–S10) segments located in its long intracellular C-terminus. Based on structure–function studies, $K_{Ca}1.1$ can be visualized as comprising four modules contributing to distinct functions in the tetrameric channel: the extracellular N-terminus and S0 to β subunit coupling, S1–S4 to voltage sensing, S5–S6 to the potassium selective pore, and the intracellular C-terminus to Ca^{2+}-sensing/signal transducing (Figure 1(b)).

N-Terminus and S0 The N-terminus of the $K_{Ca}1.1$ protein is exposed extracellularly followed by the S0 transmembrane segment. Both domains – the extracellular N-terminus and S0 – are essential for the $K_{Ca}1.1$ increase in apparent Ca^{2+} sensitivity by the β_1 subunit. This property can be modified by the length of the NH_2 terminus and the presence of splice inserts in the C-terminus of $K_{Ca}1.1$. Whether these structures are also involved in $K_{Ca}1.1$ functional association with the neuronal β_4 subunit is unknown. The length of the NH_2 terminus can vary as $K_{Ca}1.1$ mRNAs predict translation products from any of four potential start codons in exon 1 (corresponding to the protein's methionines 1–4, M1–M4; Figure 1(a)). It is unknown whether native proteins are translated from the first initiation codon (ectopic expression has been

Figure 1 Gene structure and proposed membrane topology of K_{Ca}1.1 and associated β subunits. (a) Human gene KCNMA1, encoding for K_{Ca}1.1 protein, is composed of 27 constitutive exons. Three possible translation start methionines are shown (M1–M4). Gray boxes, coding sequences. (b) Topology of K_{Ca}1.1 (α subunit) and β subunits. Functional modules of K_{Ca}1.1 protein showing the N-terminal β subunit interactive site (N-terminus and S0), the voltage-sensing domain (S1–S4), the potassium selective pore (S5–S6), and the Ca^{2+}-sensing/signal transducing C-terminus. Iberiotoxin (IbTX) binds to the pore region; RCK1 (regulator of K^+ conductance 1) and Ca^{2+} bowl domains are involved in Ca^{2+} sensing. (c) A functional K_{Ca}1.1 channel is composed by the assembly of four (α) subunits (inset) able to associate with regulatory (β) subunits. The extracellular loop of β subunits projects toward the conducting pore of the channel. K_{Ca}1.1 partners associate with the channel mainly via its C-terminus (top view).

reported from the second and third but not the first initiation codon; a GC-rich sequence may hinder translation from the first initiation codon). Proteomic analysis of immunopurified K_{Ca}1.1 has provided experimental evidence that in rat brain, the native protein can start from M2.

Voltage-sensing domain In K_{Ca}1.1, the S1–S4 transmembrane segments form the voltage-sensing domain as in other voltage-gated ion channels, and charged residues in the S4 transmembrane segment together with residues in S2 and S3 serve as the gating charges. The K_{Ca}1.1 voltage sensor can couple membrane depolarization to pore opening without the need for Ca^{2+}; likewise, at negative membrane potentials where voltage sensor activation is minimized, the channel open probability increases in response to increasing intracellular Ca^{2+} concentrations, indicating that Ca^{2+} and voltage activation are two separate but interdependent processes.

Pore region In analogy to crystal structures of K^+ channels, the ion conduction pore region of K_{Ca}1.1 is formed by S5, S5–S6 linker (pore helix), and S6 α helices arranged in a tetrameric structure. The pore helix contains the conserved amino acids GYG responsible for K^+ selectivity, and a ring of aspartic acids in both inner and outer vestibules of the pore facilitates K^+ flux underlying its large conductance. The pore helix also contains the receptor for binding of the specific blocker iberiotoxin. The specificity of iberiotoxin binding toward the K_{Ca}1.1 channel has made this toxin an invaluable pharmacological tool to decipher the channel tissue distribution and to determine its physiological roles.

C-Terminus The intracellular C-terminus of K_{Ca}1.1 carries an extra four hydrophobic segments, S7–S10. This domain is approximately two-thirds of the total protein and contains multiple regulatory sites: the 'Ca^{2+} bowl' and regulator of conductance for K^+,

'RCK,' domains, which carry Ca^{2+}-sensing residues (Figure 1(b)); a Mg^{2+} sensor within the RCK domain; and multiple phosphorylation sites for cAMP- and cGMP-dependent protein kinases, for protein kinase C, and for tyrosine kinases. At least two leucine zipper domains and several protein–protein binding motifs allowing $K_{Ca}1.1$ to interact with a growing list of surrounding signaling partners have been identified. In addition, plasma membrane sorting sequences are also present in the $K_{Ca}1.1$ long carboxyl domain, indicating that the $K_{Ca}1.1$ channel possesses intrinsic signals that define its targeting.

Regulatory β Subunits

$K_{Ca}1.1$ channel regulatory β subunits (β_1–β_4) are encoded by distinct genes (KCNMB1–4) which may undergo splicing. All β subunits share a common topological structure: two transmembrane domains with both an N- and a C-terminus that are intracellular, a large extracellular loop, two or three N-linked glycosylation sites, and four conserved extracellular cysteine residues which may form disulfide bridges (Figure 1b). Functionally, co-assembly of the $K_{Ca}1.1$ channel with β subunits affects the channel biophysical and pharmacological properties. All four subunits alter $K_{Ca}1.1$ channel scorpion toxin blockade (i.e., charybdotoxin and iberiotoxin) to different degrees, with β_4 conferring high resistance to toxin block. β_1 and β_2 greatly increase $K_{Ca}1.1$ channel apparent Ca^{2+} sensitivity, β_2 and β_3 variants produce channel inactivation, and β_4 may modify $K_{Ca}1.1$ channel function in a phosphorylation-dependent manner. β_1 and β_2 subunits can also downregulate channel surface expression by favoring $K_{Ca}1.1$ endocytosis.

In contrast to $K_{Ca}1.1$, which displays a ubiquitous expression, β subunits seem to be expressed in a tissue-specific manner. In this respect, β_2 and, in particular, β_4 are enriched in the nervous system, showing differential distribution of transcript expression. At the protein level, β_2 (hippocampal neurons) and β_4 (spinal cord and astrocytes) have been detected in the central nervous system as measured by $K_{Ca}1.1$ channel electrophysiological/pharmacological properties and by proteomic analysis of coimmunopurified α and β subunit complexes from whole brain. In addition, molecular biology methods (expression of green fluorescent protein under the control of β_4 promoter in the $\beta_4^{-/-}$ mouse) predict the highest expression of β_4 protein in the dentate gyrus of the hippocampus. Thus, at least in certain regions of the brain, $K_{Ca}1.1$ channels are formed by a combination of $4K_{Ca}1.1(4\alpha)/\beta_2$ and/or $4K_{Ca}1.1(4\alpha)/\beta_4$ subunits, although the precise α:β stoichiometry or localization of subunits is still a matter of research. The following sections discuss particular characteristics of $K_{Ca}1.1$ channels (four α subunits) in association with β_2, β_3, or β_4 subunits.

β_2 (KCNMB2) In general, $K_{Ca}1.1$ currents are non-inactivating, as observed in smooth muscle and most types of neurons. However, in some cells, such as hippocampal CA1 neurons, fast-inactivating (A-type) $K_{Ca}1.1$ currents are present. This inhibition is Ca^{2+} and voltage dependent, and it can be removed by trypsin applied to the intracellular part of the channel. The molecular basis of this inactivating phenotype is the association of the $K_{Ca}1.1$ channel with the β_2 subunit(s). Similar to native channel properties, heterologous co-expression of both subunits reproduces channel fast-inactivation properties due to a depolarization-induced block of the channel by the first 19 N-terminal amino acids of the β_2 subunit. In addition to inducing fast inactivation of the $K_{Ca}1.1$ channel and similar to the β_1 subunit, the β_2 subunit enhances apparent Ca^{2+} sensitivity (induces a negative shift in the voltage activation curves), induces slower activation and deactivation kinetics, reduces the sensitivity toward charybdotoxin blockade, and catalyzes endocytosis of the $K_{Ca}1.1$ channel protein. β_2 promotes $K_{Ca}1.1$ endocytosis via two leucine-based signals in its C-terminus, LL and ΨL, where Ψ is a bulky hydrophobic residue.

β_3 (KCNMB3) Four N-terminal splice variants of different lengths termed β_3a–d can be generated from a single gene. β_3a–d mRNAs have been detected in spleen, liver, kidney, pancreas, adrenal glands, stomach, and testis; however, in brain, their transcripts are barely detectable. Isoforms β_3a–c induce inactivation of $K_{Ca}1.1$ to different degrees, with β_3b producing inactivation that is so rapid that currents appear to activate fast and rectify at low intracellular calcium. β_3a and -c, but not β_3b or -d, induce a positive shift in the voltage activation of the channel, which is opposite the effect of β_2. Remarkably, none of the β_3 isoforms increase the apparent Ca^{2+} sensitivity of the channel, and β_3d does not seem to affect any biophysical properties of $K_{Ca}1.1$. Thus, its functional role remains to be determined. Interestingly, a single base pair deletion mutant that yields a β_3b truncated protein with impaired inactivation has been proposed to associate with an increased risk of idiopathic generalized epilepsy.

β_4 (KCNMB4) Because of its striking transcript abundance in the brain, the β_4 subunit has been called the 'neuronal' β subunit. The β_4 subunit confers a key pharmacological phenotype to $K_{Ca}1.1$ channels – a profound resistance to blockade by scorpion toxins

iberiotoxin and charybdotoxin, compared to the reduced sensitivity conferred by β_1 and β_2 subunits. Apparently, the long extracellular loop of β_4 is responsible for greatly slowing charybdotoxin and iberiotoxin associations with its receptor in the $K_{Ca}1.1$ channel pore. This hindrance can be experimentally overcome by increasing toxin concentration (from the nanomolar to the micromolar range) and exposure times (from a few minutes to several tens of minutes) because the toxin association rate is dependent on its concentration. In addition to toxin-resistant channel phenotypes, β_4 produces $K_{Ca}1.1$ channels with slower activation and deactivation kinetics and also has a dual effect on apparent Ca^{2+} sensitivity: decreasing Ca^{2+} sensitivity at intracellular Ca^{2+}concentrations ($[Ca^{2+}]_i$) $<10\,\mu M$ and increasing it at $[Ca^{2+}]_i > 10\,\mu M$.

In summary, the neuronal $K_{Ca}1.1$ channel tetrameric structure can be composed of a combinatorial assembly of $K_{Ca}1.1$ subunit isoforms resulting from alternative splicing; this diversity is enhanced by potential heteromultimeric co-assembly with regulatory β subunits (β_2 and β_4) and association with other protein partners that modify channel function. A major challenge is to dissect the complex structural combinations present in different types of neurons that underlie the distinct physiological roles of the $K_{Ca}1.1$ channel in regulating neuronal excitability.

$K_{Ca}1.1$ Channel and Associating Partners in Mammalian Brain

Functional as well as immunochemical studies have reported a tight coupling/proximity between diverse signaling molecules (e.g., protein kinases and phosphatases) and the neuronal $K_{Ca}1.1$ channel. The long carboxyl domain of its α subunit, $K_{Ca}1.1$, which encompasses two-thirds of the protein, contains motifs for protein–protein interactions, and therefore the C-terminus of the channel may serve as a recognition module. Indeed, the list of proteins that interact with the mammalian $K_{Ca}1.1$ C-terminus is growing, although the mechanisms of association (direct or indirect or via scaffolding/adapter proteins) are only beginning to emerge.

Association with Ca^{2+} Channels

$K_{Ca}1.1$ from rat brain plasma membranes or microsomes physically interacts with voltage-gated calcium channels (Cav) of the L (Cav1.2; α1C), P/Q (Cav2.1; α1A), N (Cav2.2; α1B), and T (Cav3.2; α1H) types and modulatory Cavβ subunits (Cavβ1b, Cavβ2, and Cavβ3). The $K_{Ca}1.1$ L-type Ca^{2+} (Cav1.2; α1C) channel association may involve the presence of two other partners: β_2-adrenergic receptor and A-kinase-anchoring protein (AKAP150). The close association between $K_{Ca}1.1$ and Cav detected by biochemical means is also supported by electrophysiological measurements which estimate a separation of approximately 10 nm between these two types of channels. This proximity is critical because it enables $K_{Ca}1.1$ channels to be near Ca^{2+} sources that increase local Ca^{2+} to levels required for its activation. In other words, Ca^{2+} influx during an action potential via Cav channels can provide the $K_{Ca}1.1$ channel with micromolar levels of intracellular Ca^{2+} for its robust activation in restricted subplasmalemmal microdomains. This mechanism can act as a negative feedback to restrict neurotransmitter release and serve to avoid unnecessary increases in global intracellular Ca^{2+}, which would otherwise be lethal for the cells. The precise sites in $K_{Ca}1.1$ mediating association with Cavα or Cavβ subunits or the kinds of associations in different types of neurons remain to be identified.

Association with Presynaptic and Synaptic Proteins

$K_{Ca}1.1$ channels are abundantly expressed at both presynaptic and postsynaptic terminals. In these neuronal compartments, $K_{Ca}1.1$ can be visualized in close proximity with established markers of pre- and postsynaptic structures such as syntaxin-1A and PSD95, respectively. Also, in biochemical studies, $K_{Ca}1.1$ has been found associated with both proteins in brain. In particular, the synaptic membrane protein syntaxin-1 interacts with $K_{Ca}1.1$ through its C-terminus and S0–S1 loop. The interaction, which is Ca^{2+} independent, has functional consequences because it leads to reduced activation of the Ca^{2+} channel by depolarization. Interestingly, another partner of $K_{Ca}1.1$, the N-type Ca^{2+} channel (Cav2.2; α1B), also associates with syntaxin-1A by means of the intracellular loop connecting domains II and III of the channel but in a Ca^{2+}-dependent manner, being maximum near the threshold of neurotransmitter release. However, the Cav2.2 II–III loop/syntaxin-1A/$K_{Ca}1.1$ trimeric complex may not exist because syntaxin-1 was unable to simultaneously associate with the Cav2.2 II–III loop and $K_{Ca}1.1$ (although they associated independently) as if they competed for the same domain in syntaxin-1. Thus, it is conceivable that $K_{Ca}1.1$ association with syntaxin-1 may result in reduced neurotransmitter release by displacing the Cav2.2 II–III loop from syntaxin-1 and in increased excitability by reducing channel activity. The distinct Ca^{2+} dependency of syntaxin-1A association with $K_{Ca}1.1$ and N-type Ca^{2+} channels may further fine-tune the regulation of transmitter release at presynaptic terminals.

Association with Other Proteins

Ankyrin-repeat family protein (ANKRA) ANKRA interacts directly with $K_{Ca}1.1$ *in vitro*, in rat cerebral cortex, and in cultured hippocampal neurons. The ANKRA–$K_{Ca}1.1$ interaction, which has functional consequences, involves the ANKRA N-terminus with the C-terminus of $K_{Ca}1.1$. ANKRA modifies activation and deactivation kinetics of $K_{Ca}1.1$ currents in a Ca^{2+}-dependent manner; however, steady-state voltage- and Ca^{2+}-dependent activation are unaltered. At submicromolar $[Ca^{2+}]_i$ (resembling resting conditions), ANKRA accelerates channel closing within milliseconds, whereas at micromolar $[Ca^{2+}]_i$ (resembling local Ca^{2+} during bursts of action potentials), ANKRA slows down channel closing and accelerates channel activation supporting channel activity. Thus, from a physiological standpoint, ANKRA–$K_{Ca}1.1$ interaction seems well suited to efficiently control neuronal excitability. One can expect that by promoting channel opening at high local Ca^{2+}, ANKRA potentiates the hyperpolarizing effect mediated by $K_{Ca}1.1$; likewise, by favoring channel closing at low local Ca^{2+}, ANKRA keeps the channel silent at rest.

Cereblon Cereblon (CRBN; a member of the ATP-dependent Lon protease) is an enzyme implicated in memory and learning. Interestingly, CRBN and $K_{Ca}1.1$ are both highly expressed in the same areas of the brain, including the hippocampus, which is known for its involvement in memory and learning. These two proteins bind directly to each other via the C-terminus of $K_{Ca}1.1$ *in vitro*, and their proximity in brain has been confirmed biochemically and by visualization of immunolabeled complexes in cultured hippocampal neurons. Ectopically expressed CRBN suppresses $K_{Ca}1.1$ surface expression by disrupting the formation of tetramers and therefore functional channels. The physiological consequences of the interaction between CRBN and $K_{Ca}1.1$ remain to be explored, although inherited mutations of the human cereblon gene (CRBN) or $K_{Ca}1.1$ lead to mental retardation disorders.

Kinases and phosphatases Protein kinase A (PKA), protein phosphatase 2A (PP2A), and the Ca^{2+}/calmodulin phosphatase, calcineurin, can associate with $K_{Ca}1.1$. The PKA catalytic subunit associates with $K_{Ca}1.1$ via a leucine zipper motif located downstream the RCK domain that facilitates complex assembly. PP2A association with $K_{Ca}1.1$ is variant specific (associates with the C-terminal variant $K_{Ca}1.1$_DEC but not with C-terminal variants $K_{Ca}1.1$_ERL and $K_{Ca}1.1$_VYR), and direct protein–protein interaction with calcineurin's β subunit occurs within sequences flanked by the S7–S9 hydrophobic domains of the $K_{Ca}1.1$ C-terminus. Because phosphorylation/dephosphorylation can affect $K_{Ca}1.1$ channel activity in a variant-specific way, it is critical to determine cell-specific $K_{Ca}1.1$ variant expression patterns and their fine-tuning by specific kinases/phosphatases.

Cytoskeleton $K_{Ca}1.1$ channel activity is increased by disruption of the actin cytoskeleton, underscoring their physical/functional coupling. In fact, $K_{Ca}1.1$ channels associate directly with proteins that form complexes with the cytoskeleton, such as β-catenin, microtubule-associated protein 1A, and cortactin. In particular, cortactin binds to actin and is considered to play a central role in connecting signaling pathways with cytoskeleton dynamics. Cortactin binds directly to a noncanonical SH3 binding motif present in the $K_{Ca}1.1$ C-terminus and serves as a bridge to couple $K_{Ca}1.1$ channel activity to the actin cystoskeleton since $K_{Ca}1.1$ with an SH3 binding domain mutated is not activated by disruption of actin cytoskeleton. In brain, a protein complex assembled by actin/cortactin/$K_{Ca}1.1$ has been detected biochemically, and in proximal dendrites of cultured hippocampal neurons cortactin and $K_{Ca}1.1$ have been visualized in close proximity.

It is evident that the $K_{Ca}1.1$ channel has a multiplicity of domains that allow associations with different kinds of signaling/adapter partners (Figure 1c). A major goal is to dissect the localization and composition of molecular complexes as well as their dynamics in different brain cells to explain specific functional roles of the $K_{Ca}1.1$ channel in physiology and pathophysiological settings.

$K_{Ca}1.1$ Distribution in the Brain

$K_{Ca}1.1$ is expressed throughout the central nervous system in a differential way depending on the region. For example, using radiolabeled iberiotoxin – a high-affinity and specific $K_{Ca}1.1$ channel blocker – as a ligand, synaptic membranes from frontal cortex exhibit an approximately sevenfold higher channel density (190 fmol/mg protein) than the hypothalamus (29 fmol/mg protein). In brain slices, both mRNA and protein levels (evaluated with antibodies) also support regional differences in $K_{Ca}1.1$ distribution, with very high to high overall protein expression in the cerebellum, hippocampus, and cerebral cortex and low expression in the hypothalamus and midbrain (except in the interpeduncular nucleus, in which there is very high expression). In finer detail, confocal

and electron microscopy imaging have shown $K_{Ca}1.1$ protein in somatodendritic areas, axons, and presynaptic and postsynaptic terminals. This versatile subcellular distribution predicts $K_{Ca}1.1$ diverse functional roles in different types of neurons and in different regions of the same cell.

Physiological Roles of $K_{Ca}1.1$ Channels in the Nervous System

$K_{Ca}1.1$ channels are known to participate in the control of neurotransmitter release at prejunctional sites in mammalian tracheal smooth muscle and at the neuromusculoskeletal junction and rod synapses of amphibians. In mammalian central neurons, $K_{Ca}1.1$ channels are involved in action potential repolarization and generation of fast afterhyperpolarization (fAHP); their role in neurotransmitter release is supported by the visualization of the α subunit, $K_{Ca}1.1$, in synaptic terminals and by functional studies in hippocampus organ culture. Much of our knowledge of the previously mentioned physiological roles of $K_{Ca}1.1$ channels derives from the usage of iberiotoxin and paxilline, two specific inhibitors of $K_{Ca}1.1$ channels, and their induced modifications in the corresponding electrical responses. These drugs can also provide an indication of the molecular composition of the channels. Iberiotoxin at nanomolar concentrations and paxilline at micromolar concentrations readily inhibit channels formed by $4K_{Ca}1.1$ or $4K_{Ca}1.1/\beta_2$ subunits within seconds. However, unlike paxilline, 100 nM iberiotoxin is unable to inhibit $K_{Ca}1.1$ channels assembled by $4K_{Ca}1.1/\beta_4$ subunits within the same experimental time frame. Iberiotoxin can only inhibit $4K_{Ca}1.1/\beta_4$ if used in the micromolar range and for long periods of time. This type of pharmacology has been found in dorsal horn neurons in which activation of NMDA receptors coupled to 'iberiotoxin-resistant' $K_{Ca}1.1$ channels inhibits opioid release possibly via a mechanism whereby Ca^{2+} influx through NMDA receptors opens adjacent $K_{Ca}1.1$, leading to hyperpolarization and inhibition of opioid release.

On the other hand, $K_{Ca}1.1$ currents sensitive to nanomolar concentrations of iberiotoxin are found in CA1 and CA3 pyramidal neurons of the hippocampus, predicting a $4K_{Ca}1.1$ or $4K_{Ca}1.1/\beta_2/\beta$? multimeric assembly. In CA1 pyramidal neurons, $K_{Ca}1.1$ current is transient (likely assembled by $4K_{Ca}1.1/\beta_2$ subunits) and its inactivation contributes to frequency-dependent spike broadening and decreased fAHP with high-frequency discharge. In agreement, iberiotoxin broadens the action potential of the first two spikes and eliminates the fAHP of the first spike. However, a role in neurotransmitter release is less clear in this cell type because iberiotoxin is unable to increase the probability of transmitter release, as evident by its failure to decrease the paired-pulse facilitation ratio of presynaptic fibers in stratum radiatum. This is surprising because $K_{Ca}1.1$ protein is visualized near the release sites. In CA3 pyramidal neurons, $K_{Ca}1.1$ channels contribute to repolarization and fAHP of their soma action potential but have no apparent functional role in action potentials from their presynaptic axon terminals (as assessed by iberiotoxin effects or lack thereof). These properties highlight different roles of $K_{Ca}1.1$ channels in distinct regions of the same cell (Figure 2).

Null Mice Models

α subunit null mice, $K_{Ca}1.1^{-/-}$ Three neuron-related physiological roles have been attributed to $K_{Ca}1.1$ using null mice: cerebellar function and motor coordination, hearing, and control of circadian output.

Motor coordination $K_{Ca}1.1^{-/-}$ mice display a cerebellar ataxic phenotype with deficit in locomotion, motor coordination, and eye-blink reflex which is in agreement with the large amount of $K_{Ca}1.1$ in the cerebellum of wild-type animals. At the cellular level, $K_{Ca}1.1^{-/-}$ induced severe suppression of the intrinsic electrical properties of Purkinje cells: a reduction of fAHP (Figure 2, inset), a depolarized membrane potential (approximately −45 mV), and firing rates approximately 6 times lower than those of wild-type cells. However, the repolarization phase of action potential in Purkinje cells was marginally affected in $K_{Ca}1.1^{-/-}$ (although it was affected by channel blockade in wild-type cells; Figure 2, inset), suggesting that compensatory mechanisms restore this function in the $K_{Ca}1.1^{-/-}$ cerebellum. The reduced firing rates in $K_{Ca}1.1^{-/-}$ could be explained by a tonic inactivation of Na^+ channels due to the depolarized membrane potential. In general, these findings underscore a critical role of $K_{Ca}1.1$ channels in fAHP in Purkinje cells. Consistent with this idea, immunocytochemistry shows that $K_{Ca}1.1$ protein is highly expressed in soma and dendrites of this class of cells in wild-type animals.

Hearing In mammals, sound waves reaching the ear induce a mechanical vibration that excites hair cells in the cochlea. The hair cells transduce the mechanical vibrations into electrical signals and release neurotransmitter onto the afferent nerve terminals, which then reach the brain. There are two distinct types of hair cells – outer hair cells (OHCs) and inner hair cells (IHCs). $K_{Ca}1.1$ localizes in the supranuclear part of IHCs and in efferents to the OHCs, and its specific role in mammalian hearing is under debate. Two

Figure 2 Schematic representation of neuronal pre- and postsynaptic terminals. Coupling of the $K_{Ca}1.1$ channel with Na^+ and Ca^{2+} channels at axonal, presynaptic, or postsynaptic localizations will have functional consequences on action potentials and neurotransmitter release. (Traces) Role of the $K_{Ca}1.1$ channel in repolarization of the action potential (AP) and fast afterhyperpolarization (fAHP, inserts) as observed by altering these components with iberiotoxin (IbTX) and by $K_{Ca}1.1$ gene ablation ($BK^{-/-}$). Scale bar = 2 ms/20 mV (fAHPs) and 0.5 ms/30 mV (APs). Copyright (2004) The National Academy of Sciences.

independent models of $K_{Ca}1.1^{-/-}$ have been utilized with IHCs that display normal morphology and synaptic innervation. However, in one of these models, hearing loss occurred progressively with age (>8 weeks) at high but not low frequencies and was linked to OHC degeneration and KCNQ4 ion channel reduction. A second $K_{Ca}1.1^{-/-}$ model did not display hearing loss at low or high frequencies at 12 weeks of age but showed increased resistance to noise-induced hearing loss. Nevertheless, both $K_{Ca}1.1^{-/-}$ models support a role of $K_{Ca}1.1$ in the primary afferent neuron because there was an increase in the first peak latency in the auditory brain stem responses (representing transmission through the IHC–afferent dendrite synapse), a slowed IHC membrane time constant, and spike rates of afferent auditory nerve fibers were reduced. It is possible that $K_{Ca}1.1$ has several roles in the hearing process that are underscored differentially in these knockout models for unknown reasons. Interestingly, neither β_1 nor β_4 ablation induced any changes in hearing, in contrast to the role claimed for the β_1 subunit in nonmammalian cochlea.

Circadian output In mammals, circadian behavior is controlled by the activity of suprachiasmatic nucleus (SCN) neurons of the hypothalamus. These neurons have intrinsically timed, approximately 24-h circadian electrical discharges, which are important for defining the circadian output. During daylight, rat, mouse, and hamster SCN neurons have high action potential frequency and are depolarized, whereas during the night their activity is drastically decreased. Consistent with a role of $K_{Ca}1.1$ in contributing to spike frequency rhythms of mouse SCN, its transcripts and protein levels oscillate with approximately twice the expression during dark compared to light cycles, and spike frequency rhythms are practically abolished with iberiotoxin. In addition, $K_{Ca}1.1^{+/+}$ but not $K_{Ca}1.1^{-/-}$ null mice follow the bimodal electrical states of SCN. $K_{Ca}1.1^{-/-}$ shows a clear increase in SCN firing rates during the night when electrical activity of these neurons is practically null in wild-type animals. Because mice are nocturnal, the role of $K_{Ca}1.1$ in human SCN circadian activity may be different.

β_4 subunit null mice, $\beta_4^{-/-}$ Despite the high expression of β_4 transcripts in brain, deletion of this subunit does not cause severe damage to brain function. Nevertheless, consistent with high expression of β_4 in the

dentate gyrus of the hippocampus – a structure that prevents abnormal high-frequency input from neocortex to the hippocampus – mice lacking the β_4 subunit ($\beta_4^{-/-}$) display temporal lobe seizures. Dentate gyrus granule cells of $\beta 4^{-/-}$ mice display a gain-of-function phenotype as $K_{Ca}1.1$ acquires fast gating activity and the density of functional channels per membrane patch increases. These characteristics coincide with increased firing frequencies and seizures in this animal model, whereas the slow gating activity of the wild-type $K_{Ca}1.1/\beta_4$ channel complex correlates with prolonged burst durations which would protect against seizures in normal animals. Thus, the β_4 subunit can be regarded as protective from temporal lobe seizures. These findings led to the hypothesis that pathological gain of function of $K_{Ca}1.1$ channels would favor epileptic bursting behavior. In line with this view, in cortical neurons of the epileptic mouse, fast-activating $K_{Ca}1.1$ channels are responsible for epileptic bursting behavior, and in humans a missense mutation that increases $K_{Ca}1.1$ channel activity leads to a syndrome of generalized epilepsy.

Neuroprotective Role

Results from gene silencing models suggest that $K_{Ca}1.1$ and β_4 subunits play moderate roles in the nervous system. Studies suggest that the roles of the neuronal $K_{Ca}1.1$ channel may be more prominent under pathological situations such as ischemia to improve cell survival. In brain cortical slices, $K_{Ca}1.1$ channel activity was silent under normal conditions and appeared only when neocortical pyramidal neurons started to deteriorate. Also, in an *in vitro* model of ischemia, blockade of the $K_{Ca}1.1$ channel by iberiotoxin deprived the cells from a neuroprotective mechanism, and they tended to die as a consequence. Therefore, it has been speculated that $K_{Ca}1.1$ channels may function under pathological states to provide protection to neurons.

Neurovascular Coupling

It is well known that blood flow, carrying nutrients and oxygen, increases to active brain regions due to microvascular dilation. The cellular and molecular mechanisms underlying this important physiological phenomenon are attributed to the coupling between neurons, astrocytes, and smooth muscle of the microvascular cerebral arteries. Active cortical neurons release the neurotransmitter glutamate, which in turn activates metabotropic glutamate receptors (mGluRs) in astrocytes. Activated mGluRs increase intracellular Ca^{2+} and initiate waves of Ca^{2+}, which propagate to the end-feet of astrocytes, activating astrocytic $K_{Ca}1.1$ channels and inducing K^+ efflux via these channels. Local increases in K^+ concentration in the perivascular space activate inward rectifier K^+ channels in the smooth muscle cells, producing hyperpolarization and dilation of cerebrovascular vessels. The mechanisms involved in different neurovascular beds may be distinct because in the retina light-evoked vasodilations seem not to be related to efflux of K^+ from glia with a subsequent increase in inward rectifying currents.

Channelopathies

Alteration in the function and expression of $K_{Ca}1.1$ channels may lead to human disease, including neuropsychiatric and neurodegenerative disorders. A hereditary gain-of-function mutant correlates with coexistent generalized epilepsy and paroxysmal dyskinesia, a loss-of-function mutant is linked to autism, and decreased expression in the brain has been found in schizophrenic patients.

Conclusion

Since the cloning of the first genes encoding for the mammalian $K_{Ca}1.1$ channel in the early 1990s, major advances have been realized with regard to the molecular structure, distribution, and physiological function of $K_{Ca}1.1$ channels in the nervous system. A major challenge is to elucidate the subproteome of $K_{Ca}1.1$ channels in distinct types of neural cells and visualize their subcellular distributions and dynamics as they contribute to specific functions. Identification of neuronal disorders associated with the $K_{Ca}1.1$ channel due to inherited mutations in the $K_{Ca}1.1$ protein and the possible role of the $K_{Ca}1.1$ channel as a neuroprotective mechanism make this channel an excellent candidate in the development of drugs to prevent/ameliorate neurological disorders.

Large Dense Core Vesicles (LDCVs)

T Kögel and H-H Gerdes, University of Bergen, Bergen, Norway

© 2009 Published by Elsevier Ltd.

Introduction

Large dense core vesicles (LDCVs), also known as secretory granules (SGs), store and release neuropeptides and hormones such as neuropeptide Y, enkephalins, the adrenocorticotrophic hormone, or insulin in response to various stimuli. The release involves a Ca^{2+}-dependent fusion of LDCVs with the plasma membrane (PM) and is termed regulated exocytosis. LDCVs were discovered by electron microscopy more than 50 years ago as membrane-enclosed spherical organelles of up to several hundred nanometers in diameter characterized by an electron-dense core. Presynaptic terminals of neurons display only few LDCVs (in contrast to the numerous translucent small synaptic vesicles, which contain classical neurotransmitters), whereas endocrine cells contain high numbers of LDCVs (Figure 1). For this reason, LDCVs have been studied mainly in endocrine cells and, accordingly, the data summarized here primarily refer to insights obtained from these cells. However, it is thought that the major physicochemical and functional properties of LDCVs of endocrine cells also apply to their neuronal counterpart. Numerous studies during the past few decades have revealed that SGs originate from the *trans*-Golgi network (TGN) as short-lived vesicular intermediates. These intermediates, termed immature SGs (ISGs), go through a complex maturation process resulting in mature SGs (MSGs) (Figure 2). The process includes propeptide and prohormone processing, condensation of cargo, as well as the removal of proteins and membrane not destined for MSGs. Furthermore, MSGs undergo priming and docking to achieve competence for exocytosis. Upon appropriate stimulation of the cells, SGs fuse with the PM to release their content (Figure 2(a)).

During the past decade, the exploitation of fluorescent proteins, advanced *in vitro* systems, and mouse models has led to new insights in the biogenesis, transport, and exocytosis of LDCVs. This article summarizes both basic knowledge and new developments and concepts in the field of LDCV research.

Markers and Diversity of LDCVs

LDCVs are found in all neuroendocrine, endocrine, and exocrine tissues. They comprise spherical vesicles consisting of an acidic lumen with electron dense material surrounded by a limiting membrane (Figure 2(b)). The dense core content is composed of tightly packed aggregates of soluble proteins, whose composition varies with the respective type of tissue, and other cargo molecules including catecholamines, monoamines, and ATP. The limiting membrane contains proteins required for secretory granule acidification, uptake of nonproteinaceous molecules, transport, targeting, and fusion. SGs are typically distinguished by their morphological appearance and immunoreactivity for cell type-specific neuropeptides, hormones, or other cargo molecules including biogenic amines. Widespread markers for LDCVs are acidic proteins belonging to the granin family. These are chromogranin A (CgA), chromogranin B (CgB; also known as secretogranin I), secretogranin II (SgII; also known as chromogranin C), secretogranin III (SgIII), secretogranin IV (SgIV), secretogranin V (SgV; also known as 7B2), and secretogranin VI (SgVI). Another group of widely distributed marker proteins for SGs are the proneuropeptide and prohormone processing enzymes that convert their substrates into bioactive peptides. These enzymes include prohormone convertases 1/3 (PC1/3) and 2 (PC2) as well as carboxypeptidase E/H (CPE).

Besides the cell-type-specific diversity of SGs, the presence of different SGs in the same cell was also demonstrated in the same cell. Examples for SG diversity at the cellular level are LDCVs of gonadotrophs containing either luteinizing or follicle-stimulating hormone, whose release is independently controlled. Likewise, also in chromaffin cells, two morphologically distinct types of LDCVs containing epinephrine and norepinephrine, respectively, have been documented.

Biogenesis of LDCVs

Sorting of Proteins to LDCVs

Regulated secretory proteins (RSPs) and constitutive secretory proteins are synthesized in the rough endoplasmic reticulum and take the same intracellular route to and through the Golgi apparatus. In the most distal part of the Golgi complex, the TGN, their transport routes diverge. Constitutively secreted proteins enter constitutive secretory vesicles (CVs), which fuse with the plasma membrane without a stimulus (Figure 2(a)). RSPs are sorted into ISGs, which undergo a complex maturation process that includes budding of ISG-derived vesicles (IDVs) to remove cargo not destined for MSGs (Figure 2(a)). Two key mechanisms involved in the sorting of RSPs were elucidated: the selective (co)aggregation of RSPs and 'signal'-mediated targeting of RSPs to SGs (Figure 3).

Aggregation Morphological evidence demonstrating the presence of aggregates of RSPs in the TGN triggered the idea that aggregation is involved in the targeting of RSPs to SGs. Further evidence for this concept was obtained by biochemical studies showing that RSPs of the granin protein family, namely CgA, CgB, and SgII, aggregate at millimolar Ca^{2+} concentrations and at a pH below 6.5 – conditions which mimic the milieu of the TGN. Protons and divalent cations are thought to neutralize the repulsive negative charge of RSPs, thus inducing their dense packaging. Furthermore, constitutive markers were excluded from the formed aggregates (Figure 3). Similar conditions were found for the aggregation of other RSPs, such as pro-opiomelanocortin (POMC), von Willebrand factor, proinsulin, prolactin, CPE, and PC2. Further supporting this hypothesis is evidence that not only can constitutive proteins be separated from RSPs by aggregation of the latter but also different populations of RSPs can be segregated. This was demonstrated for the egg-laying hormone in type I neurons of *Aplysia californica*, which is processed in the TGN and results in the different sorting of the two processing products to different types of SGs. Furthermore, abundantly expressed RSPs may function as sorting helpers by providing aggregation

Figure 1 Large dense core vesicles (LDCVs) in neurons versus endocrine cells. The presynaptic terminal of neurons (a) contains only a few LDCVs, whereas the endocrine cells (b) comprise numerous LDCVs.

Figure 2 Trafficking of different vesicle types undergoing exocytosis. (a) Immature SGs (ISGs) bud from the TGN and may fuse homotypically. Clathrin-coated ISG-derived vesicles (IDVs) bud from maturing SGs and fuse with the PM/endosome without a stimulus. Mature SGs (MSGs) fuse with the PM in a stimulated manner upon Ca^{2+} influx. Constitutive secretory vesicles (CVs) bud from the TGN and fuse with the PM without a stimulus. Small synaptic vesicles (SSVs)/small synaptic-like microvesicles (SLMVs) bud from the endosome, are subsequently loaded with neurotransmitters, and fuse with the PM in a stimulated manner upon Ca^{2+} influx. After exocytosis, the SSV/SLMV-specific membrane patch is recycled from the PM by clathrin-mediated endocytosis. (b) Electron microscopic picture of isolated SGs from PC12 cells. Note that the trafficking of SGs, which is the focus of this article, is shown in black/color.

Figure 3 Sorting of regulated secretory proteins. (a) A mixture of constitutive (red triangles) and regulated secretory proteins (RSPs; gray squares) as well as lysosomal proteins (open triangles) arrives at the TGN. (b) RSPs with a protein- or membrane-binding signal (gray squares with red or black half-circles, respectively) aggregate in a Ca^{2+}/pH-dependent manner. RSPs with membrane-binding signals interact with specific, cholesterol-rich membrane patches (green lines) in the TGN. RSPs with protein-binding signals function as adaptors to link aggregated cargo to membrane-bound RSPs. (c) Upon progressive condensation of RSPs in ISGs, lysosomal and constitutive secretory proteins are excluded from the aggregates and are concentrated in nascent IDVs (lysosomal proteins bind to MPRs). (d) Mature SGs are densely packaged with aggregated RSPs.

seeds for those RSPs, which are present at a very low concentration and thus incompetent for sufficient aggregation on their own. Such a helper function was shown for CgB in AtT20 cells, in which its overexpression promoted the efficient sorting of a 23 kDa POMC fragment into SGs. Also, RSPs which lack specific targeting sequences but are competent for aggregation can be sorted via coaggregation with those RSPs possessing the collective sorting information for selective packaging in SGs (aggregative properties and specific targeting sequences) (Figure 3). This was demonstrated by using the vaccinia expression system, which shuts off the host cell protein synthesis and thereby allows the study of selected RSPs in a null background of endogenous RSPs. In this manner, a deletion mutant of CgB that lacked specific targeting sequences was expressed by a recombinant vaccinia virus and the protein and was found exclusively in CVs. However, coexpression of this mutant with non-mutated CgB by double infection rescued the sorting of the CgB mutant, thus suggesting its sorting via coaggregation. Taken together, compelling evidence exits that aggregation is a key mechanism for targeting of RSPs to SGs.

Sorting signals The search for specific sorting signals that direct proteins to SGs was mainly concerned with soluble cargo (RSPs) and, to a much lesser extent, membrane proteins of SGs. The latter include the type 1 membrane-spanning proteins peptidyl-α-amidating monooxygenase, phogrin, and muclin from exocrine SGs. In the case of phogrin, the granule sorting domain is located in the cytoplasmic tail of the protein, and it was shown that this domain binds the clathrin adaptor protein complexes AP-1 and -2. In order to find short sequences for SG-specific targeting in soluble cargo proteins, a variety of RSPs have been intensively analyzed using recombinant DNA technology for more than 30 years. Although short sequences of RSPs with targeting information were found, no consensus sequence for a sorting signal to SGs emerged. One of the identified signals consisted of an N-terminal disulfide-constrained loop structure. This loop is present in CgA and CgB, and their sequences are highly homologous. The loop of CgB was found to be sufficient to direct secretory cargo to SGs. It is of note that a constitutive reporter molecule fused with two CgB loops, one at each terminus, was sorted more efficiently compared to the fusion proteins possessing only one CgB loop. A similar loop, which is composed of a different sequence, was found in POMC. This loop was also found to be essential and sufficient for directing secretory cargo to SGs. As a second signal providing sorting information to SGs, short α-helical domains present in several RSPs were identified. Such domains were found in CPE, PC1/3 and PC2, prosomatostatin, CgA, and VGF. As a third motif, paired basic amino acids have been reported to accomplish SG-specific sorting in some proteins. These include prorenin, proneurotensin, prothyrotropin-releasing hormone, and progastrin. It appears that these paired basic amino acids constitute cleavage sites for one of the granule-resident prohormone convertases PC1/3 or PC2 because exchange of the

cleavage site to one recognized by furin, another protease that cleaves its substrates in the TGN, results in constitutive secretion of the respective products.

Thus, it appears that instead of a single sorting signal as found for the trafficking of proteins to other cellular destinations, a variety of targeting sequences emerged during evolution to accomplish sorting of RSPs to SGs. These multiple signals may function in a synergistic manner and/or may reflect the functional differences of SGs in various types of tissues or even in the same cell.

Cargo–membrane interaction The specific membrane composition of SGs implies that during the biogenesis of SGs a selective interaction of cargo molecules with specific membrane components in the TGN must occur. In the search for specific interaction sites, distinct structures of RSPs were found to be responsible for tethering RSPs to membranes specific for SGs. These structures were found to be identical to some of the aforementioned sorting signals. For CgB, it was shown that the disulfide-constrained loop mediates membrane binding in the TGN of rat pheochromocytoma (PC12) cells. In analogy to the sorting efficiency, two loops had a synergistic effect on the membrane binding efficiency compared to one loop. CPE, PC1/3, and PC2, were shown to interact with membranes through their short α-helical domains. The α-helices at the C-terminus of PC1/3 may be masked until the enzyme undergoes a conformational change in the TGN in which the tail has been proposed to unfold and render the enzyme fully active. Results suggest that these α-helices possess hydrophobic patches segregated from charged patches of amino acids to allow a shallow membrane interaction. With regard to the existing evidence that these structural motifs direct the sorting of the respective RSPs to SGs, their binding to membranes has to occur in the TGN and/or ISGs, as was shown in the case of the loop structure of CgB. However, it appears that cargo–membrane interaction is not mediated through binding to a classical sorting receptor encompassing a transmembrane domain with a cytoplasmic tail for coat assembly. In this respect, the hypothesis that CPE functions as a classical sorting receptor is controversial.

What are the requirements for the membrane binding of the aforementioned targeting sequences? A first clue about the binding site was provided by the finding that in AtT20 cells cholesterol depletion inhibited the formation of SGs, suggesting the involvement of cholesterol-rich rafts in this process. Subsequent studies provided evidence that PC2, CPE, and SgIII specifically bind to cholesterol-rich membrane patches (Figure 3). Note that in contrast to PC2 and CPE, SgIII was not found in a Triton X-100 insoluble membrane fraction. Therefore, distinct membrane patches might recruit different RSPs with specific sorting signals.

Other RSPs were shown to achieve SG-specific targeting through the interaction with membrane-tethered RSPs (Figure 3). One example is the binding of POMC to CPE via its N-terminal loop domain. This interaction was displaced by several other RSPs but not by constitutive secretory proteins. Furthermore, proinsulin, proenkephalin, and brain-derived neurotrophic factor have been proposed to interact with CPE to promote their retention in SGs. Similar to the POMC–CPE interaction, it was found that CgA was linked to SG membranes via SgIII. The finding that dibasic cleavage sites are targeting sequences for SGs suggests that PC1/3 and PC2 can act as sorting chaperones for their substrates in addition to being processing proteases.

Taken together, these data indicate that RSPs are not recruited to SGs through a single sorting motif or mechanism but, rather, through a wide variety of strategies that still have to be investigated in detail. Often, but not always, several sorting signals are combined in one protein. This might be the underlying reason for the observed phenomenon that the same protein can be sorted differently in different cell types.

Maturation of LDCVs

During maturation of SGs, progressive acidification of the lumen along with processing and packaging of soluble cargo leads to further condensation of the matrix and dense core formation. Notably, ISGs are the predominant site of proneuropeptide and prohormone conversion into bioactive peptides. The processing is accomplished by PCs at dibasic amino acid cleavage sites of RSPs. Examples of this are the conversion of POMC to adrenocorticotrophic hormone and proinsulin to insulin.

Maturation of ISGs also includes refinement of the content and remodeling of the membrane of newly formed ISGs. This process involves the homotypic fusion of ISGs and budding of IDVs from maturing SGs (Figure 2(a)). In PC12 cells, between three and five ISGs appear to fuse with the help of the soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) protein syntaxin 6 and synaptotagmin IV to form an MSG. Since MSGs are typically smaller than ISGs, homotopic fusion seems not to be obligatory for other types of neuroendocrine cells.

Membrane remodeling also consists of sorting away a specific set of proteins such as mannose-6-phosphate receptor (MPR), furin, carboxypeptidase D, and the SNAREs syntaxin 6 and VAMP4 in IDVs. This sorting depends on the ADP-ribosylation-factor (ARF)-1-dependent recruitment of AP-1 to MPR,

furin, and VAMP4 in a phosphorylation-dependent manner involving casein kinase II. In conjunction with the presence of clathrin coats on ISGs but not on MSGs, AP-1 has been proposed to recruit clathrin to ISGs and thereby promote the budding of IDVs during the maturation process. GGA (Golgi-associated γ-ear-containing ARF-binding protein) has been shown to be implicated as an essential factor in the recruitment of clathrin and thus IDV budding.

In addition to sorting away selected membrane proteins from ISGs, it is believed that soluble proteins not prone to aggregation (e.g., C-peptide, a processing product of proinsulin) are removed from maturing SGs in IDVs in a stimulus-independent manner – a process termed constitutive-like secretion. Likewise, excess membrane released by the progressively condensing core of maturing SGs is likely to be removed by the same pathway. It is an open question whether IDVs fuse with the endosomal system and/or directly with the PM. With respect to the variety of cargo molecules removed from ISGs, it is tempting to speculate that distinct subsets of these proteins may be removed in distinct IDVs.

Two levels of sorting to the regulated pathway of protein secretion can be distinguished: sorting in the TGN during formation of ISGs (termed sorting for entry; Figures 3(a) and 3(b)) and sorting in ISGs during their maturation (termed sorting by retention; Figures 3(c) and 3(d)). The relevance of sorting at these two levels appears to vary between cell types. In neurons, membrane traffic to the somatodendritic or axonal cell surface diverges in the TGN, which is located at the neuronal cell body. Thus, in this case, the TGN is likely to be the major site of sorting of RSPs and constitutive secretory proteins. This may be different for certain exocrine cells and endocrine cells such as pancreatic islet β cells, in which a considerable portion of sorting has been shown to take place at the level of ISGs.

Is There a Master Gene for LDCV Biogenesis?

CgA has been proposed to act as a master gene for the 'on/off' switch of SG biogenesis. This hypothesis was based on two lines of observations. One was that silencing of CgA expression in PC12 cells resulted in a loss of visible SGs. The other was that the expression of CgA in cells which lack a regulated secretory pathway induced the formation of vesicles with an electron dense core. However, this has raised controversy because several other findings argue against such a master gene concept. First, deletion of single SG genes in mice, including that of CgA, precludes neither the expression of other SG genes nor the biogenesis of SGs. Second, the absence of CgA in mice results in a compensatory overexpression of other granins. Third, the expression of other RSPs in cells that lack the regulated secretory pathway is also capable of inducing the formation of vesicles with an electron dense core. Taken together, these data suggest that CgA is replaceable by other SG-specific cargo molecules. It therefore seems plausible that the induction of granule-like dense core vesicles by the expression of RSPs in cells, which do not normally make granules, merely reflects the self-aggregating properties of RSPs and the general ability of the TGN to form SGs. In this respect, it is of note that the induced SGs were mainly characterized by their morphology, and it remains to be shown if such SG-like vesicles have all the key properties of *bona fide* SGs. Further arguments against a master gene function of CgA are supported by data demonstrating the convergent evolution of SGs in different species (e.g., vertebrates and ciliates), which infers that granules arose independently in different lineages.

Transport of LDCVs

During the past decade, fluorescent protein-based live cell imaging has made it possible to monitor the transport dynamics of SGs in time and space. Green fluorescent protein (GFP)-fusion proteins targeted to the lumen of SGs were shown to fluoresce despite the aggregative and acidic milieu. The imaging of newly formed ISGs on their way to the cell cortex is challenging because a neuroendocrine cell contains thousands of stored SGs with a half-life of several days. ISGs represent only a small percentage of the total SG population (Figure 4(c)). Therefore, selective labeling of ISGs is necessary to follow their route. This was achieved by employing a pulse/chase-like system based on the expression of human CgB, tagged with a temperature-sensitive GFP mutant (CgB)–GFP(S65T) in PC12 cells. The temperature-sensitive GFP mutant folds to its fluorescent form at 20 °C but not at 37 °C. Once properly folded at 20 °C, the fusion protein remains fluorescent at 37 °C. When cells were incubated at 20 °C, a temperature at which the formation of secretory vesicles is blocked, an accumulation of the fluorescent protein, selectively in the TGN, was observed (Figure 4(a)). Upon reversal of this block at 37 °C, hCgB–GFP(S65T) fluoresced in newly formed ISGs (Figure 4(b)). With this protocol, pools of SGs of a defined age were generated and followed through the cell. This revealed that ISGs move straight and in a microtubule-dependent manner from the TGN to the F-actin-rich cortex (Figure 4(c)). Similarly, in insulinoma cells, a fast and unidirectional movement of SGs was documented upon glucose stimulation. Biochemical studies showed that such movement

Figure 4 Transport of SGs. (a, b) GFP-based pulse/chase-like staining. (a) GFP-labeled secretory cargo (green) is concentrated selectively in the TGN of a PC12 cell during 20 °C incubation. (b) Green fluorescent SGs synthesized during 90 min after the release of the 20 °C block. Red, immunostained TGN38; asterisk, TGN of an untransfected cell. (c) Scheme illustrating the transport of newly formed ISGs as observed by the pulse/chase-like system. After their synthesis at the TGN, fluorescent ISGs (green solid circles) are transported outward along microtubules (red line, arrow) to the cortical area (gray), where they move along F-actin (double-arrow). Note that open circles indicate MSGs synthesized before application of the 20 °C block. (d) The transport of SGs along microtubules is kinesin dependent, whereas the transport along F-actin is myosin Va dependent. The respective motor proteins bind to SGs via linker proteins. (a, b) From Rudolf R, Kögel T, Kuznetsov SD, et al. (2003) Myosin Va facilitates the distribution of secretory granules in the F-actin rich cortex of PC12 cells. *Journal of Cell Science* 116: 1339–1348.

depends on the ATP-dependent conventional kinesin (Figure 4(d)). Whether this motor protein is common for other types of ISGs remains to be investigated. During their maturation, ISGs were found to move in a myosin Va-dependent manner in the F-actin-rich cortex (Figures 4(c), 4(d), and 5(a)). The role of myosin Va was investigated by the expression of a dominant-negative mutant of this motor protein. This revealed that myosin Va captures SGs and distributes them in the F-actin-rich cortex of PC12 cells. Based on these data, it has been proposed that newly formed SGs move in a microtubule-dependent manner to the cell cortex and in a myosin Va-dependent manner in the F-actin-rich cortex. Further studies under conditions in which myosin Va activity was blocked by a dominant-negative mutant of myosin Va or by RNA silencing implicated myosin Va in the exocytosis of SGs of PC12 cells and pancreatic MIN6-β cells.

In search of linker proteins recruiting myosin Va to SGs, the myosin Va-dependent transport of melanosomes served as a blueprint. According to this model, myosin Va is associated with melanosomes through a 'receptor complex' consisting of the small GTPase Rab27a and melanophilin/Slac2-a (synaptotagmin-like protein (Slp) lacking C2 domains-a). In agreement with this, it was shown that Rab27a associates with SGs in both chromaffin and PC12 cells and with insulin-containing SGs in pancreatic β cells. Furthermore, the interaction partners of Rab27a on SGs were also found to be similar to melanophilin, namely Slac2-c/MyRIP in chromaffin and PC12 cells and Slp4/granulophilin in pancreatic and MIN6 β cells. Slac2-c/MyRIP was shown to interact with Rab27a/b, myosin Va, and actin *in vitro*. However, a functional link between the 'receptor' complex and myosin Va remains to be shown *in vivo*. In all studied cases, myosin Va is bound to SGs via Rab27 and a rabphilin homolog.

The Last Steps toward Exocytosis

Before fusion with the PM, the SGs eventually undergo priming and docking in the F-actin cortex, which leads to segregation into different vesicle pools. In particular, a readily releasable pool undergoing immediate exocytosis upon stimulation and a slower reacting pool(s) that facilitates long-lasting exocytosis under sustained stimulation have been described. Key regulators for the transit of SGs from the reserve to the readily releasable pool are Ca^{2+}, cortical F-actin together with its interaction partners, and the SNARE complex at the PM. In numerous cortical areas, F-actin was shown to be

Figure 5 Scheme illustrating the involvement of myosin Va in mobilizing SGs from reserve pools toward exocytotic sites. (a) Myosin Va is associated with ISGs and mediates their F-actin-dependent movement. (b) Upon Ca^{2+} influx, scinderin is activated and disassembles F-actin. Myosin Va transports SGs from the reserve pool toward the PM along remaining F-actin tracks. (c) Further increase in Ca^{2+} concentration results in the dissociation of calmodulin from myosin Va and the binding of the latter to syntaxin 1A. Note that through these consecutive steps SGs are confined to the PM. From Eichler TW, Kögel T, Bukoreshtliev NV, and Gerdes H-H (2006) The role of myosin Va in secretory granule trafficking and exocytosis. *Biochemical Society Transactions* 34 (Pt. 5): 671–674.

disassembled upon elevated cytosolic Ca^{2+} levels during stimulation. A large body of evidence exists indicating that this process is delicately balanced by the action of many regulating factors. These include the F-actin severing proteins scinderin (Figure 5(b)) and gelsolin as well as proteins promoting F-actin assembly, such as the Rho GTPase Cdc42 and the guanine nucleotide exchange factor intersectin-1L.

Notably, in the cortical areas depleted of F-actin, fine filaments remain and are thought to guide SGs from the reserve pool to the exocytotic sites (Figure 5(b)). This, in conjunction with the finding that priming of SGs is ATP dependent, suggested the involvement of an F-actin-dependent motor protein, which was subsequently identified as myosin Va (Figures 4(d) and 5). After its arrival at the PM, myosin Va interacts with components of the docking complex as suggested by *in vitro* experiments. It was shown that micromolar Ca^{2+} concentrations lead to a replacement of calmodulin (CaM) light chains at an IQ motif of myosin Va by the t-SNARE syntaxin 1A (Figure 5(c)). Syntaxin 1A confines SGs to the exocytotic site and is part of the SNARE complex that carries out the actual fusion. However, myosin Va does not seem to play a role in the final exocytosis event since its interaction with the fusion machinery constituents *N*-ethylmaleimide-sensitive factor/α-soluble *N*-ethylmaleimide-sensitive factor attachment protein (α-SNAP) was shown to release it from the SNARE complex *in vitro* and cell depolarization induced the dissociation of myosin Va from chromaffin vesicles *in vivo*. In this context, rabphilin has been discussed as a possible bridging protein between myosin Va and SG-associated Rab27.

During recent years, the sequence of actions of the components of the SNARE complex during tethering and fusion has been dissected. Vesicle delivery and weak tethering depend on the Sec1/Munc18-like protein Munc18-1, which binds to the t-SNARE syntaxin. Syntaxin and SNAP25 are proposed to form the fusion complex in concert with the v-SNARE synaptobrevin. Thus, the demonstrated interaction of myosin Va and rabphilin as two likely components of the motor complex of SGs with the components of the fusion complex provides insights into how the transition of SGs from tethering in the F-actin cortex to docking at the PM is accomplished at the molecular level. The fusion complex initiates exocytosis only when the inhibitory effect of synaptotagmin is removed upon elevated levels of Ca^{2+}. Nevertheless, there is evidence that not all SGs are consumed by exocytosis. The fate of nonexocytosed SGs has been elucidated in chromaffin cells by the expression of atrial natriuretic factor fused to a fluorescent protein, which changes its color over time. Newly synthesized SGs were shown to be immobilized below the PM and were exocytosed preferentially, whereas older SGs seemed to be retrieved from the actin cortex to the inner cell. This elegant study corroborated previous indications that newly formed SGs are secreted foremost.

Latrotoxin

M V Khvotchev, University of Texas Southwestern Medical Center, Dallas, TX, USA

Introduction

α-Latrotoxin is a large, approximately 130 kDa protein neurotoxin found in the venom of widow spiders (genus *Latrodectus*). α-Latrotoxin mediates all toxic effects of the spider envenomation in vertebrates, whereas closely related latroinsectotoxins and latrocrustatoxin also present in the venom target insects, crustaceans, and other invertebrates. A single bite of the highly poisonous black widow spider (*Latrodectus mactans*) delivers only minute quantities of α-latrotoxin and is rarely life-threatening for humans but can readily kill a domestic cat or other small mammal. α-Latrotoxin poisoning (latrodectism) produces a number of local and systemic symptoms, such as pain, muscle cramps, anxiety, headache, nausea, excessive salivation, lacrimation, and sweating, that can persist for several days. The principal sites of α-latrotoxin action in the body are synaptic junctions (particularly neuromuscular junctions) and several types of secretory cells. In all affected terminals and cells, α-latrotoxin induces massive and uncontrolled release of neurotransmitters and mediators via exocytosis of the carrier vesicles. Under experimental conditions, the toxin stimulates exocytosis of all known neurotransmitters in a wide range of synapses and cells (e.g., acetylcholine from frog neuromuscular junctions, glutamate from mammalian excitatory synapses in hippocampus, and catecholamines from chromaffin cells in adrenal glands); thus, α-latrotoxin acts on a basic conserved feature of exocytic machinery. The effects of the toxin are chronic and in most cases irreversible; afflicted nerve terminals often degenerate. The molecular mechanism of α-latrotoxin action is complex and not completely understood. It involves binding to specific cell surface receptors, insertion into plasma membrane, and unknown downstream activity that induces massive exocytosis of vesicles. Intensive study of α-latrotoxin for more than 30 years has provided important insights into mechanisms of exo- and endocytosis, neurotransmitter release, and synapse function, exemplifying the essential role of natural toxins for the advancement of neuroscience.

Synthesis and Molecular Organization of α-Latrotoxin

α-Latrotoxin is synthesized by glandular cells of the widow spiders as an inactive, approximately 160 kDa precursor protein (Figure 1). The precursor protein initially accumulates in the cytoplasm and is secreted into the lumen of the venom gland by a holocrine mechanism which involves rupture of the whole cells. Maturation of α-latrotoxin consists of a two-step proteolytic processing (removal of 20 amino acid residues at the N-terminus and approximately 200 residues at the C-terminus) and formation of intramolecular disulfide bonds and leads to activation of the toxin. Mature α-latrotoxin is divided into two structural domains (Figure 1). The N-terminal domain is unique and only found in latrotoxins. It contains three essential conserved cysteine residues and two hydrophobic regions that can potentially span the plasma membrane. The C-terminal domain of α-latrotoxin is made of 22 ankyrin repeats (repeats 1 and 16 are not perfect). Ankyrin repeats are found in many intracellular proteins and are thought to mediate stable protein–protein interactions. The high-resolution three-dimensional (3-D) structure of α-latrotoxin is not available. Lower-resolution cryoelectron microscopy has revealed that the toxin forms stable dimers in solution that further assemble into tetramers or higher-order oligomers in the presence of divalent cations. Each toxin monomer consists of three compact 3-D domains (Figure 1) called 'wing' (which contains most of the N-terminal domain), 'body' (which contains the rest of the N-terminal domain and the first six ankyrin repeats), and 'head' (which contains the last six ankyrin repeats). Functional α-latrotoxin can be purified from the venom or venom glands of widow spiders or produced and purified *in vitro* using various heterologous expression systems.

Receptors of α-Latrotoxin

High target selectivity of α-latrotoxin is mediated by specific plasma membrane receptors that recruit the toxin to the sites of action. Members of the three protein families have been identified as functional receptors for α-latrotoxin: neurexins, CIRLs/latrophilin/CLs, and receptor-like protein tyrosine phosphatase-σ (PTP-2; Figure 2). Surprisingly, these receptors have no obvious sequence similarity but are capable of binding α-latrotoxin with nanomolar affinities. In all three receptor families, the toxin binding site is situated in close proximity to the plasma membrane. The best-studied α-latrotoxin receptors, neurexins, are encoded by three genes (neurexins 1–3) with alternative use of two sets of promoters (long α and short β isoforms) and multiple splice sites that give rise to thousands of potential protein isoforms in mammals. The neurexin 1α isoform is the most abundant α-latrotoxin receptor in

Figure 2 Receptors of α-latrotoxin. (Left) Schematic structure of α- and β-neurexins, CL1 (also called CIRL1 and latrophilin), and receptor-like protein tyrosine phosphatase σ (PTP-σ). Dotted rectangle depicts the area essential for α-latrotoxin binding. In neurexins, binding of α-latrotoxin is negatively regulated by the presence of an insert at site 4. (Right) List of major domains and motifs found in α-latrotoxin receptors.

the brain; however, other neurexins also bind the toxin. Different from CLs and PTP-σ, neurexins bind α-latrotoxin only in the presence of calcium. The interaction is also regulated by alternative splicing. Only neurexins lacking insert at the splice site 4 are functional receptors (Figure 2). Neurexins and their endogenous ligands, neuroligins, are implicated in normal synapse formation and maintenance and in pathological dysregulation of synaptic function in various forms of familial autism. CLs are a family of three orphan G-protein-coupled receptors with unknown function. CL1 and CL2 isoforms bind α-latrotoxin with high affinity, whereas CL3 does not. Extensive biochemical, physiological, and genetic studies suggest that neurexins and CLs recruit α-latrotoxin to the target plasma membrane *in vivo* but do not transduce a signal that initiates massive exocytosis. Much less is known about the physiological significance of PTP-σ as an α-latrotoxin receptor.

Membrane Active Properties of α-Latrotoxin

α-Latrotoxin forms nonselective cation channels and pores in membranes. This activity was initially observed in artificial lipid bilayers that contain no α-latrotoxin receptors. However, α-latrotoxin only forms channels and pores in the native membranes that contain the toxin receptors. The effects of α-latrotoxin on the membranes *in vivo* are strictly concentration dependent. At low, subnanomolar concentrations, α-latrotoxin induces individual, low-conductance channels permeable to sodium, calcium, magnesium, and other cations. At higher concentrations (in the low nanomolar range), the toxin also forms pores permeable to low-molecular-weight substances. Finally, at high concentrations α-latrotoxin causes detergent-like lysis of membranes and the release of soluble cytosolic markers.

Effects of α-Latrotoxin in the Presence or Absence of Extracellular Calcium

α-Latrotoxin induces massive release of acetylcholine at the neuromuscular junctions independent of external calcium. After application of low concentrations of the toxin, exocytosis of acetylcholine-filled small synaptic vesicles persists for a long time without major morphological changes at the presynaptic

Figure 3 α-Latrotoxin stimulates spontaneous glutamate release at hippocampal synapses independent of external calcium. Representative traces illustrating excitatory miniature postsynaptic currents recorded from high-density hippocampal neuronal cultures under basal conditions (top) and after application of α-latrotoxin in the presence (middle) or absence (bottom) of external calcium.

terminals. In the absence of calcium, prolonged exposure of neuromuscular junctions to α-latrotoxin eventually leads to depletion of the synaptic vesicles at the presynapse and significant bloating of the plasma membrane, probably due to the failure of compensatory endocytosis. α-Latrotoxin also causes sustained release of glutamate and GABA at the central nervous system synapses independent of extracellular calcium (Figure 3). Higher concentrations of α-latrotoxin overwhelm the release machinery at these terminals and induce depletion of the vesicle cluster, mitochondria swelling, plasma membrane extension, ATP loss, and, finally, disintegration of the terminal. In sharp contrast, α-latrotoxin stimulates exocytosis of large dense core vesicles (e.g., neuropeptide-filled vesicles at the synapse or catecholamine-filled granules in chromaffin cells and PC12 cells) only in the presence of external calcium. α-Latrotoxin-induced release of norepinephrine and dopamine from brain synaptosomes is partially calcium dependent, probably due to the intermediate nature of the carrier vesicles for these neurotransmitters that share properties of small synaptic vesicle and large dense core vesicles. The requirement for external calcium in α-latrotoxin-induced exocytosis is an intrinsic property of the release machinery and is not mediated by differential involvement of calcium-dependent (neurexins) or calcium-independent (CLs and PTP-σ) receptors.

Mechanism of α-Latrotoxin Action

α-Latrotoxin is a potent, selective, and complex neurotoxin that exerts multiple effects on the secretion apparatus of synapses and secretory cells. The specificity of the toxin action is achieved by interaction with multiple high-affinity receptors. The stimulation of exocytosis by α-latrotoxin occurs downstream of the receptor binding by a receptor-independent action that involves insertion of the toxin into the plasma membrane. To induce exocytosis, α-latrotoxin requires basic fusion machinery (e.g., SNARE and SM proteins) but not the calcium sensing and priming modules involved in physiological membrane fusion (e.g., synaptotagmins and Munc13). Under physiological conditions, α-latrotoxin can stimulate exocytosis by a simple ionophoric mechanism with calcium ions entering through nonselective cation channels formed by the toxin. However, the ability of α-latrotoxin to induce massive exocytosis independently of external calcium points to an unknown direct activity of the toxin on the fusion machinery that overrides normal calcium control of the exocytosis. Future studies will address the exact molecular mechanism employed by this fascinating neurotoxin to hijack the tightly controlled release machinery of neurons and secretory cells.

Learned Flavor Aversions and Preferences

Determinants of Food Selection

A biological imperative for animals, including humans, is the identification, selection, and ingestion of nutritious foods and the rejection of toxic substances that can cause harm to the body. Deciding which potential food items to select and which to avoid typically involves the evaluation of flavor stimuli (taste, odor, texture). Many species have innate predispositions to accept some flavors (i.e., sweet taste) and to reject others (i.e., bitter taste), presumably because the flavors are predictive of naturally occurring nutritious and toxic materials, respectively. These inborn determinants of food choice, however, are very limited in number, particularly for omnivorous species, which eat a wide range of foods. However, animals readily acquire new flavor aversions and preferences through associative learning processes. In particular, if an animal consumes a novel flavored food or fluid and subsequently experiences visceral malaise, it will avoid that flavored substance in the future. This form of learning is referred to as taste aversion conditioning when the novel flavor is a pure taste (sweet, salty, sour, bitter) or flavor aversion conditioning when complex taste, odor, and/or texture stimuli are involved. Animals also learn to prefer the flavors of foods and fluids that provide positive nutritive consequences or recovery from nutritional deficiencies. Food selection is also guided by observational learning, social interactions and, in humans, cultural factors, although these are not discussed here.

Flavor Aversion Learning

Flavor aversion learning represents a powerful adaptive defense mechanism that minimizes the ingestion of toxic foods and fluids. It has been observed under natural conditions and demonstrated experimentally in many species of invertebrates and vertebrates. John Garcia was the first to introduce flavor aversion learning in the laboratory to investigate the behavioral effects of exposure to irradiation. He demonstrated that rats exposed to gamma radiation following ingestion of a novel saccharin solution readily learned to avoid this solution subsequently. Since then, flavor aversion learning has attracted the interest of many psychobiologists and neuroscientists. It is extensively used to study food selection processes and to screen drugs for potential aversive effects and, more generally, is used as a model to study neural mechanisms of learning and memory.

Behavioral Characteristics

Flavor aversion learning is a form of Pavlovian conditioning in which the flavor cue (conditioned stimulus; CS) is associated with exposure to a toxic agent (unconditioned stimulus; US) that produces nausea, gastrointestinal distress, or some other aversive state. Flavor aversion learning has special characteristics that distinguish it from traditional forms of Pavlovian conditioning:

1. Cue-consequence specificity. For many species, it is the flavor, and particularly the taste, of foods rather than other sensory properties (e.g., color, shape, location) that is associated with illness.
2. Long-delay learning. Unlike conventional forms of defense conditioning, flavor aversion learning can be established after delays of several hours between exposure to the CS and delivery of the US in a single learning trial.
3. CS–US unconscious association. Administration of deep anesthesia with pentobarbital or other general anesthetics, applied after the consumption of the CS flavor but before the administration of the toxic US, does not prevent flavor aversion learning.

Experimental Assessment

In the laboratory, flavor aversion learning is usually performed with highly motivated animals (food or water restricted) presented with a novel flavored food or fluid. Flavored solutions and thirsty animals are most commonly used for ease of measurement and preparation. Many different procedures are available to expose the animal to the flavor CS and US agent during conditioning.

Bottle technique In this standard procedure, thirsty animals are given limited access (usually 15 min) to one bottle of water for several days. When water intakes are stable, the animals are offered a novel flavored solution (the CS; e.g., saccharin solution) instead of water, the consumption of which is followed after some delay by the administration of a toxic US, such as an intraperitoneal injection of lithium chloride (LiCl). Control animals receive an injection of isotonic sodium chloride (NaCl). After 1 or 2 days of recovery, during which only water is

available, the animals may be given additional training trials with the CS and US or may be presented with the CS alone. The learned flavor aversion is revealed in the LiCl-treated group by a marked decrease in the intake of the CS solution compared to its first presentation and compared to its intake by the control group. In a common variation of this procedure, a two-bottle test (e.g., saccharin vs. water) is used to assess the strength of the conditioned flavor aversions. Two-bottle tests are generally more sensitive than are one-bottle tests in revealing the flavor aversion, because they allow the animal to satisfy its thirst while avoiding the CS solution.

Intraoral infusion method With the intraoral infusion method, animals are fitted with an intraoral (IO) catheter, which allows for the automatic infusion of the flavor stimulus into the oral cavity. Typically, thirsty animals are adapted to consume IO-infused water. Then a CS solution is infused, followed by administration of the toxic US. In a subsequent test session the learned aversion is revealed when the animal rejects the flavor by letting the CS solution drip out of its mouth. One advantage of the IO technique is that it can be used with neonatal animals or neurologically compromised adult animals that do not voluntarily consume the CS solution. The technique has also been used to determine the temporal onset of the flavor aversion by infusing the CS solution every 5 min after the US is administered.

Taste reactivity test Reduced consumption is typically taken as evidence for a conditioned flavor aversion. This measure, however, does not necessarily reflect changes in the hedonic value (or palatability) of the CS flavor. The taste reactivity test developed by Grill and Norgren in 1978 is thought to provide a more direct measure of flavor palatability. In this test, orofacial and other motor responses to IO infusions of flavored solutions are videotaped for off-line analysis of ingestion and rejection responses. Naive rats infused with inherently preferred solutions (e.g., sweet sugar solutions) display a sequence of ingestive reactions (tongue protrusions, paw licks, rhythmical mouth movements) that are distinct from aversive reactions (gapes, chin rubs, head shakes, paw treads) elicited by infusions of unpreferred solutions (e.g., bitter quinine solutions). Rats conditioned to avoid a sucrose solution by pairing its intake with LiCl or apomorphine subsequently display quinine-like aversive reactions when reexposed to the sucrose solution. However, other unconditioned stimuli, such as lactose or amphetamine, which suppress sugar intake in bottle tests, do not elicit aversive motor responses to the CS solution in taste reactivity tests. These findings suggest that some but not all US treatments condition a decrease in the hedonic evaluation of the CS flavor. Conditioned reductions in CS intake are sometimes referred to as a 'flavor aversion' when they are associated with decreased hedonic reactivity, and a 'flavor avoidance' when hedonic evaluation is not changed.

Brain Mechanisms

Flavor aversion learning involves the neural integration of sensory stimuli from the oral cavity (taste, odor, texture) and sensory stimuli from the gastrointestinal tract or generated by circulating toxins and the development of long-term flavor memories that can guide food selection. Electrophysiological and neuroanatomical studies have demonstrated convergence of gustatory and visceral information in several brain structures and provide strong clues to investigate the neural substrate of integration of oral–postingestive sensory information underlying the formation of taste aversion learning.

Lesion studies Brain areas involved in flavor aversion learning have been extensively investigated by analyzing the effects of electrolytic and excitotoxic lesions in animals.

Nucleus tractus solitarius. The nucleus tractus solitarius (NTS) is the first brain relay nucleus for gustatory and visceral sensory information. Taste aversion conditioning alters the electrophysiological response of NTS neurons to tastants, but rostral NTS lesions are reported not to block the acquisition or retention of taste aversion produced by LiCl. These lesions may have spared more caudal taste-responsive neurons that are sufficient to process the taste CS.

Area postrema. Chemosensitive neurons in the area postrema (AP) can detect blood-borne toxins, and AP lesions block or attenuate flavor aversions produced by a variety of toxic agents, including LiCl and copper sulfate. AP lesions do not, however, prevent other nausea-inducing drugs (apomorphine) from conditioning flavor aversions.

Parabrachial nucleus. In rodents and rabbits the medial parabrachial nucleus (PBN) relays gustatory information from the NTS to the forebrain, while the lateral PBN relays viscerosensory information. PBN lesions produce the most consistent and profound deficits in taste aversion learning. Lesions of medial PBN, lateral PBN, or combined lesions completely block LiCl-induced taste aversion learning. This deficit does not result from an inability to detect the taste stimulus or a failure to experience the malaise induced by LiCl. Preoperatively acquired taste aversions remain intact, indicating that the medial PBN is critical for the acquisition, but not the expression, of

conditioned taste aversions. Medial PBN lesions are also reported to block odor aversion learning, to partially attenuate aversion conditioning to complex flavors, and to spare aversion conditioning to a trigeminal stimulus (capsaicin).

Although an intact PBN is necessary for taste aversion learning, the PBN along with other hindbrain nuclei are not sufficient to mediate such conditioning. Chronic decerebrate rats, which display relatively normal acceptance and rejection responses to IO infusions of sucrose and quinine, respectively, do not learn to reject a sucrose solution when it is paired with LiCl injections. These results indicate that the forebrain is essential for taste aversion learning.

Thalamus. The parvocellular subdivision of the ventroposteromedial nucleus of the thalamus (VPMpc) relays gustatory information to the insular cortex (IC) for further processing. Excitotoxic lesions of VPMpc have little effect on taste aversion learning but accelerate its extinction. These disruptive effects are not produced when electrophysiologically guided small lesions confined to the VPMpc are performed, indicating that this thalamic nucleus is not critical for acquisition of taste aversion learning.

Insular cortex. Early studies indicated that lesions of the insular cortex impair both the acquisition and retention of taste aversion learning, leaving the taste detection and categorization functions intact. Aspiration of IC did not disrupt the development of LiCl-induced taste aversion learning as measured with the conventional bottle method, but dramatically blocked taste aversion learning as evidenced by the failure of the lesions to produce a palatability shift of the CS taste. More recent studies demonstrate that excitotoxic lesions of IC before conditioning only attenuate taste aversion learning but accelerate the extinction of the conditioned aversion when the CS flavor is presented on several days after conditioning. Furthermore, IC lesions made after the acquisition of taste aversion disrupt the retrieval of the learned aversion, indicating that the integrity of IC is required for the retention and retrieval, rather than the acquisition of taste aversion learning. Combined lesions of VPMpc and the gustatory part of the insular cortex, however, almost completely block the establishment of conditioned taste aversion, indicating that sensory inputs to these areas are essential for taste aversion learning.

Amygdala. Large electrolytic lesions of amygdala (AMY) produce deficits in flavor aversion learning whereas excitotoxic lesions, which spare fibers of passage, do not block conditioned taste aversion. More recently, excitotoxic AMY lesions have been observed to impair taste aversion learning when the CS solution is presented by IO infusions, but not when available in bottles. Inconsistent results have also been reported with selective lesions of individual AMY nuclei. These findings, along with neuroimaging data, indicate AMY involvement in taste aversion learning, but this remains to be clarified.

Hypothalamus. Early studies reported that electrolytic lesions of the lateral hypothalamus (LH) disrupted flavor aversion conditioning but that excitotoxic lesions spared taste aversion learning. Recently, excitotoxic LH lesions have been found to block flavor aversion conditioning when there is a long delay (2 h) between the CS and US, but not with shorter or no delays. These finding suggest that LH lesions may accelerate the decay of the flavor memory trace.

c-Fos neuroimaging studies The expression of immediate-early genes, such as *c-fos*, has been used in rodents to map neural pathways involved in flavor aversion learning. Fos-like immunoreactivity (FLI) is induced in the medial intermediate division of the NTS by presentation of a CS taste (sucrose, saccharin) that was previously paired with LiCl; the response to the CS is similar to that induced by LiCl alone. Lesions of either the IC or AMY or hemidecerebration abolish the conditioned expression of FLI in the NTS to the CS taste, but not the unconditioned response to LiCl. This indicates that the increased *c-fos* expression in the NTS is modulated by forebrain structures. With repeated CS–US pairings, FLI expression was obtained in other structures involved in taste aversion learning, such as the central nucleus of AMY and PBN.

Neuropharmacological studies Glutamatergic and cholinergic neural activities are implicated in taste aversion learning. Administration of the muscarinic receptor antagonist, scopolamine, in the IC before presentation of a CS taste impairs the acquisition and consolidation of the taste aversion, whereas IC injection of the glutamatergic antagonist, AP-5, impairs only the consolidation. Recent studies stress the importance of IC cholinergic activity in processing taste information, and glutamatergic activity in the basolateral nucleus of AMY in processing visceral information generated by gastrointestinal malaise. Furthermore, these studies show that AMY glutamatergic efferents to IC are crucial in the association of taste and visceral stimuli during taste aversion learning.

Other neurotransmitters, such as dopamine, are involved in taste aversion learning. Dopamine transmission within the nucleus accumbens, a structure located in the ventral striatum and involved in

food-related reward processes, has been found to be critical for the strengthening of the memory trace of the taste cue, a process indispensable for long-delay taste aversion learning. LH dopamine activity is also implicated in taste aversion conditioning.

Conditioned Flavor Preferences

Flavor preference conditioning by nutrients is well documented in rodents, ruminants, and insects, although only a few human studies have been published. Flavor preferences may be reinforced by both the orosensory and postingestive properties of nutrients, and once acquired can be long lasting. The most common paradigm used to study conditioned flavor preferences is to pair one flavor (CS+) with the nutrient US and a different flavor (CS−) with water on alternate days, and then assess the conditioned preference by presenting the CS+ and CS− flavors in a two-choice test. There are two types of learned flavor preferences, flavor–flavor conditioning and flavor–postingestive nutrient conditioning.

Flavor–Flavor Conditioning

In flavor–flavor learning, the animal develops a preference for a neutral flavor that is paired with an already preferred flavor (e.g., sweet taste). For example, rats that drink an almond-flavored saccharin solution on some days and vanilla-flavored water on other days show a preference for almond over vanilla in a two-bottle test, with both flavors presented in water. Similar preferences are conditioned for flavors added to a sucrose solution, although in this case the postingestive nutrient effects of the sugar may contribute to the preference. Humans learn to prefer odors added to sweet solutions, if they rate the sweet solution as being pleasant, and they also report that the odor has a sweet taste in the absence of the sugar.

Flavor–Postingestive Nutrient Conditioning

To demonstrate flavor–postingestive nutrient learning, the nutrient is typically infused directly into the stomach, thereby eliminating the flavor of the nutrient as a potential US. Holman, in 1968, was the first to report a conditioned flavor preference in rats by pairing the intake of a flavored solution with intragastric (IG) infusions of a liquid diet. Flavor preferences can be conditioned by IG infusions of complete diets or individual macronutrients (glucose, sucrose, maltodextrin, corn oil, casein), as well as of ethanol. In rodents, nutrient-based learning is very robust, can occur over CS–US delays, can convert the innate aversion to bitter and sour tastes into strong preferences, and are long lasting and resistant to extinction. In some but not all cases the preference is associated with an increased hedonic evaluation of the CS+ flavor, as revealed by taste reactivity tests. Also, in some but not all cases IG nutrient infusions may condition an increase in flavor acceptance; animals may consume substantially more of the CS+ flavor paired with the IG nutrient infusion than they do of a CS− flavor paired with IG water infusions.

The nature of the conditioning signal or signals generated by the postingestive actions of nutrients is not well understood, but these signals appear to be distinct from nutrient-produced satiety signals. Evidence suggests that the nutrient US originates in the intestine and/or liver, but not in the stomach. The US does not appear to be transmitted to the brain via vagal afferents, thus implicating nonvagal or humoral pathways. Nutrients differ substantially in their preference-conditioning effects (e.g., glucose vs. fructose), which indicates that there are nutrient-specific unconditioned stimuli, although a more general signal related to energy metabolism may also exist. IG nutrient infusions condition flavor preferences in food-restricted, as well as in freely fed, animals, so energy repletion is not an essential aspect of flavor preference learning. However, flavor preferences can be conditioned by stimuli related to restoration of specific nutrient deficiencies (amino acid imbalance, calcium deficiency).

Brain Mechanisms

Only recently have studies investigated brain mechanisms involved in flavor preference learning and therefore the available information is limited. Initial studies have focused on brain structures implicated in flavor aversion learning.

Area postrema The area postrema is implicated in taste aversion learning and also in detection of circulating nutrients. However, AP lesions do not block flavor preference conditioning produced by IG nutrient infusions.

Parabrachial nucleus Lesions of the medial parabrachial nucleus prevent animals from learning to prefer a CS+ taste (sour, bitter) paired with IG nutrient infusions. The same lesions only attenuate preference conditioning when the CS+ is a complex flavor that has a strong odor component. The preference learning deficit appears to represent a problem with forming a CS–US (taste–nutrient) association rather than a problem in detecting the CS taste or nutrient US, although this issue requires further study.

Amygdala Lesions of the basolateral amygdala attenuate, but do not block, flavor preference conditioning by IG nutrient infusions. Flavor preference

conditioning is completely blocked, however, by large lesions that include all AMY nuclei. The same lesions impair, but do not prevent, taste preference conditioning by IG nutrients. Thus, the sensory learning deficits produced by AMY lesions are opposite to those produced by PBN lesions.

Lateral hypothalamus Lateral hypothalamus lesions do not prevent rats from acquiring preferences for flavors paired with IG nutrient infusions, although the preferences are weaker than those displayed by intact rats. The lesions, however, totally block preference learning when the IG nutrient infusions are not concurrent with consumption of the CS+ flavor but instead occur after a short delay (15 min). It is possible that this learning deficit reflects a lesion-induced decay in the CS+ memory trace, but where and how this trace is maintained are unknown.

Insular cortex The insular cortex receives gustatory, olfactory, and visceral information, suggesting a role in flavor perception and modification by postingestive feedback. However, the IC does not seem to be critical for flavor preference learning, since large lesions, including gustatory and visceral regions, do not prevent rats from learning to prefer a CS+ flavor paired with IG nutrient infusions.

Neuropharmacological Studies

Evidence implicates brain dopamine systems in flavor preference conditioning by nutrients. Rats trained to prefer a bitter solution by pairing its intake with IG nutrient infusions subsequently showed enhanced dopamine (DA) release in the nucleus accumbens when drinking the solution, compared to unconditioned animals offered the same solution. Flavor preference conditioning by IG nutrient infusions is blocked by systemic treatment with the D1 receptor antagonist SCH23390 during training trials. However, the same drug does not prevent the expression of a previously conditioned flavor preference when administered at the time of two-bottle testing. Treatment with a D2 receptor antagonist (raclopride) has little effect on the acquisition or expression of preference conditioning by IG nutrient infusions. In contrast, both D1 and D2 receptor antagonists prevent flavor preference conditioning by the sweet taste of fructose, and SCH23390 also attenuates the expression of the sweet-taste-based preference. These data indicate differential involvement of dopamine receptors in flavor–flavor and flavor–postingestive nutrient conditioning.

To date, systemic treatment with the opioid receptor antagonist naltrexone has not interfered with the acquisition or expression of flavor preferences conditioned by the sweet taste or postingestive actions of sugar. This contrasts with the well-documented effect of opioid antagonists on the intake of sweet solutions. The influence of other neurotransmitter systems on flavor preference learning remains to be investigated.

Learning and Memory in Invertebrate Models: *Tritonia*

W N Frost and E V Megalou, Rosalind Franklin University of Medicine and Science, North Chicago, IL, USA

© 2009 Elsevier Ltd. All rights reserved.

Why Study Learning in Invertebrates?

Deciphering the neuronal mechanisms by which we acquire, store, and recall memories represents one of the major challenges for modern neuroscience. This topic is being pursued simultaneously in both vertebrate and invertebrate preparations. Given the indisputable relevance of studying learning mechanisms in vertebrates, it seems appropriate to consider why many investigators choose to work on invertebrates. First, invertebrates display many of the same types of learning enjoyed by vertebrates, including habituation, dishabituation, sensitization, classical conditioning, second order conditioning, sensory preconditioning, latent inhibition, overshadowing, blocking, context conditioning and, operant conditioning. Second, the synaptic plasticity mechanisms that appear to encode learning turn out to be highly conserved. Thus, invertebrates have been shown to have synapses that undergo the same types of experience-dependent plasticity studied in vertebrates, including paired-pulse facilitation, homosynaptic depression, presynaptic inhibition, presynaptic facilitation, posttetanic potentiation, long-term potentiation, and long-term depression. Third, molecular mechanisms also appear to be conserved, including the involvement of particular second messenger systems in short-term memory and the requirement for gene expression for the formation of stable, long-term memories. Finally, a key reason for studying learning mechanisms in invertebrates is their seemingly made-for-science nervous systems. For example, invertebrate neurons are larger (up to 1 mm in diameter) and far fewer in number than those of vertebrates and are conveniently located on the outside of their ganglia, where they can be seen and penetrated with electrodes or observed with optical recording techniques. Many of these neurons can be recognized as unique individuals, making it possible to map out discrete circuits and to return to the same neurons and synapses in successive preparations in order to characterize their role in information storage. Furthermore, because these neurons and circuits can often be studied *in situ*, the specific behavioral function of these synapses, and thus the information they encode, can often be determined, a feat seldom possible in vertebrates.

An Invertebrate Model System: The Marine Mollusk *Tritonia*

On contact with the tube feet of its sea star predators, the nudibranch mollusk *Tritonia diomedea* launches a stereotyped escape response consisting of a rapid withdrawal of gills, rhinophores, and the affected body site, followed by a vigorous escape swim (Figure 1). This rhythmic behavior consists of a series of alternating ventral and dorsal whole-body flexions that serve to get the animal up off the substrate and into the current, where it is wafted away to safety. The escape swim has a duration of 2 to 20 flexion cycles that take up to 2 min to play out. As the swim ceases, the animal then settles to the substrate and typically crawls for several minutes.

Work by several laboratories has defined the major components of the neural network mediating the *Tritonia* escape swim. Aversive skin stimuli are detected by the S-cells, a group of central afferent neurons that send an axon out to the skin. The polymodal S-cells respond to both tactile and chemical skin stimuli, including a substance present in the tube feet of predatory sea stars and many other echinoderms. The S-cells in turn make monosynaptic connections onto the Tr1 and dorsal ramp interneuron (DRI) command neurons. DRI is a paradigm example of a gating command neuron: it is activated by sensory stimuli, and its own firing is both necessary and sufficient for sensory input to trigger the swim motor program. DRI is able to exert such impact because sensory input is funneled to DRI, and it in turn makes the strongest excitatory synaptic connections yet recorded in *Tritonia*, onto the dorsal swim interneurons (DSIs) of the swim central pattern generator (CPG). Action potentials in DRI elicit nearly one-for-one firing of the six DSI neurons of the CPG. The swim CPG was described 20 years ago as consisting of three neuron groups, the DSIs, ventral swim interneurons (VSIs), and cerebral interneuron 2 (C2). This group of neurons was suggested to oscillate by virtue of their synaptic connections to one another, with no neurons having intrinsic bursting properties of their own. The DSIs have also been found to utilize the transmitter serotonin to rapidly modulate the excitability and synaptic strength of the other CPG neurons, a process believed to play a central role in reconfiguring the resting crawling network into a temporary swim CPG. This represents an example of intrinsic neuromodulation, in which modulatory neurons are embedded in the network, causing it to modulate itself every time it is activated. This is quite different from the more familiar extrinsic neuromodulation, in which the

Figure 1 *Tritonia* escape behavior and its underlying swim motor program. The sea slug *Tritonia diomedea* is shown in mid-escape from its sea star predator, *Pycnopodia helianthoides.* Also shown are three simultaneous intracellular recordings from the interneurons of the escape swim central pattern generator: dorsal swim interneuron (DSI), ventral swim interneuron (VSI), and cerebral interneuron 2 (C2). Each burst of action potentials drives one full dorsal or ventral body flexion of the rhythmic escape swim. Record duration: 25 s.

modulation is optional because the modulatory neurons are located outside the network.

The Escape Swim Is Produced by a Multifunctional Neural Network

A remarkable feature of *Tritonia*'s swim network is its degree of multifunctionality; it has been suggested to play a role in at least three different behaviors: reflexive withdrawal, swimming, and crawling. Multifunctional networks are well documented in invertebrates, in which they have typically been found to mediate structurally similar motor programs, such as those mediating different rhythmic aspects of feeding. *Tritonia*'s network is notable with respect to how dissimilar the behaviors it mediates are to one another. Reflexive withdrawal is a brief muscle-mediated retraction of body areas to skin stimulation. Swimming is a 1–2 min rhythmic behavior involving a series of alternating whole-body dorsal and ventral contractions mediated by body wall muscles. Crawling is a nonrhythmic, nonmuscular behavior mediated by the beating of millions of microscopic cilia on the animal's foot. After the swim, the same DSIs that fired rhythmically to mediate the swim then continue to fire tonically for up to an hour, when, via excitatory connections to identified foot cilia neurons, they mediate crawling. While multifunctional networks have been described in many preparations, *Tritonia*'s swim network is unusual in that it involves the most dissimilar behaviors yet found to be mediated by a single neural network, cilia-mediated, nonrhythmic crawling and muscle-mediated, rhythmic swimming.

Experience-Dependent Modifications of the Swim

Tritonia is being used to study how experience alters behavior. These studies have so far focused on prepulse inhibition and on two forms of nonassociative learning: sensitization and habituation.

Prepulse Inhibition

Most animals experiencing an unexpected strong stimulus respond with a startle response – in *Tritonia*'s case, its high-threshold escape swim. Given their robust, protective nature, it can be surprising to discover that startle responses are often significantly inhibited if a weak stimulus of almost any modality is experienced just beforehand. This experimental paradigm, termed prepulse inhibition (PPI), exposes an inhibitory sensorimotor gating mechanism whose underlying cellular mechanisms have attracted increasing interest ever since PPI was found to be defective in schizophrenia. It has been widely speculated that reduced PPI may contribute to the distractibility and sensory flooding experienced by sufferers of this disease. Could invertebrate preparations be used to gain insights into the nervous system mechanisms mediating the clinically relevant phenomenon of PPI? Pursuing this line of thinking, *Tritonia* was recently tested and shown to have PPI that is parametrically similar to that of vertebrates. In this paradigm, a brief vibrotactile stimulus delivered to the animal's midbody beginning just before a tail shock startle stimulus prevents the startle response (escape swim) that normally occurs to the shock alone. PPI does not involve learning; it is a brief, inhibitory sensorimotor gating mechanism that works, in humans and seaslugs, the very first time the prepulse is presented.

Further research has revealed two related neuronal mechanisms for PPI in *Tritonia*. First, the inhibitory interneurons that mediate PPI were identified. These were found to do so, in part, via a well-known mechanism, presynaptic inhibition of transmitter release, acting on the startle pathway

afferent neurons, reducing their ability to excite the swim circuitry. These neurons also produce conduction block of incoming action potentials in the startle pathway, causing many to fail before reaching their release sites. Because afferent pathways as well as many or most central interneuronal synapses in vertebrates are subject to presynaptic inhibition, these basic mechanisms described in *Tritonia* seem suitable to mediate PPI in vertebrates as well.

Nonassociative Learning: Sensitization

Sensitization is a form of nonassociative learning (experienced by most or all animals) in which the memory of a startling or aversive stimulus is encoded as a period of enhanced general defensive responsiveness. The neural mechanisms mediating sensitization have been studied extensively in the marine mollusk *Aplysia*, in which a single tail shock enhances the animal's tail- and siphon-elicited withdrawal responses for about an hour.

Tritonia is also being used to explore the cellular and network mechanisms mediating sensitization. Following a single aversive swim-eliciting stimulus, *Tritonia* becomes sensitized, as revealed by an hour-long period of enhanced defensive responsiveness. During this time, the animal's gill and rhinophore withdrawal reflexes display a shorter onset latency, and test swims have a lower threshold, faster onset latency, and higher cycle number.

Two nervous system alterations have been identified so far that appear to mediate these learning-related behavioral modifications: the functional strength of the synapses made by CPG neuron C2 become markedly enhanced, and the DSI neurons undergo an hour-long period of elevated spontaneous firing. Since, as discussed above, the DSIs produce a direct, modulatory enhancement of the synapses made by C2 and other CPG neurons, this prolonged DSI firing may represent a primary locus of the memory for sensitization, actively maintaining C2 synapses in their enhanced state. This is supported by the additional finding that forcing the DSIs to fire at an elevated tonic rate causes the same shortening of swim onset latency as seen in sensitization. The *Tritonia* preparation thus has allowed us to determine the information content, that is, behavioral impact, of a specific memory storage locus by selectively implanting it into the naive brain and determining its contribution to the motor program changes seen in learning.

Nonassociative Learning: Habituation

Habituation is a universal form of nonassociative learning. In habituation, behavioral responsiveness to a test stimulus decreases with repetition. It has the important function of enabling us to ignore repetitive, irrelevant stimuli so that we can remain responsive to sporadic stimuli, typically of greater significance. The widespread occurrence of habituation across phyla supports its importance, and the strong similarity in its parametric features across species is consistent with the possibility that common mechanisms mediate it. As with sensitization, the memory for habituation can be short term, lasting minutes to hours, or long term, lasting days. The neural mechanisms underlying habituation are of clinical interest. For example, long-term habituation is deliberately induced in therapeutic procedures used to treat chronic anxiety and posttraumatic stress disorder. In part because these conditions may involve an impaired ability to habituate to stressful stimuli, studies have begun using effects on habituation as a screening test for developing and comparing anxiolytic drugs.

Based on observations in the open ocean, *Tritonia*'s escape swim habituation may help prevent animals from unnecessary swimming, which would tend to carry them away in water currents and thus away from their spatially restricted food supply. In the laboratory, repeated swim stimuli lead to the progressive alteration of several behavioral features, including a lengthening of gill and rhinophore withdrawal latency, lengthening of swim onset latency, and a decrease in swim cycle number and swim flexion speed. Habituation of the *Tritonia* swim shows several of the parametric features of vertebrate habituation, including response decrement with a negative exponential time course, spontaneous recovery, faster decrement with shorter intertrial intervals, dishabituation, increased threshold, and stimulus site generalization. These similarities are consistent with the likelihood that habituation in *Tritonia* may share cellular mechanisms with those mediating habituation in vertebrates.

As mentioned above, the motor program mediating the swim can be elicited and studied in isolated brain preparations, in which cellular mechanisms can be more readily studied. Repeatedly elicited isolated brain swim motor programs habituate with the same negative exponential time course as the behavior, indicating that the key sites of plasticity are located in the central nervous system. Swim habituation thus cannot be explained by peripheral effects such as receptor adaptation or muscle fatigue.

The cellular loci mediating habituation in *Tritonia* are not yet well characterized. As in many organisms, the strength of the sensory neuron synapses mediating the test response decreases profoundly when the sensory neurons are made to fire single action potentials separated by several seconds. Recently, the probable transmitter of the sensory neurons was identified to

be glutamate, opening the way for studies of whether the activity-dependent synaptic decrement at these synapses is mediated by pre- or postsynaptic processes. In addition to this possible sensory neuron memory locus, the demonstration that habituation produced by stimulation of one sensory population generalizes to unstimulated sensory neurons suggests that the memory for habituation may involve interneuronal sites of plasticity as well.

Studies of Other *Tritonia* Behaviors

Recent observations of *Tritonia* in its natural habitat have documented several behaviors in their natural context that have long been observed in the laboratory, including feeding, mating, rheotaxis, and escape swimming following contact with the tube feet of predatory sea stars. Olfaction appears to play an important role in the natural habitat. Time lapse video studies have shown that *Tritonia* crawls upstream toward food and mates, and downstream away from predators. As described above, crawling occurs via the beating of cilia on the bottom of the foot. These are under neuronal control, and their rate of beating, and thus the speed of locomotion, is modulated by the transmitter dopamine as well as by peptide neurotransmitters. An important crawling behavior displayed by *Tritonia* is rheotaxis – orientation and crawling toward the direction of water flow. This ability is mediated via neurons having axons in the lateral branch of cerebral nerve 2, as well as by a number of identified pedal ganglion motor neurons. One neuron that controls turning while crawling, pedal neuron 3, acts by lifting the foot margin on the side ipsilateral to the direction of the intended turn, removing those cilia from contact with the substrate.

Tritonia has also been shown capable of orienting to the earth's magnetic field, which has been speculated to help it navigate with respect to potential food sources. Pedal ganglion locomotion neurons have been identified that alter their firing in response to artificially induced changes in the orientation of the magnetic field surrounding the animal.

In summary, *Tritonia* holds promise for investigations of the neural basis of many interesting aspects of behavior present in higher animals. These include prepulse inhibition, sensitization, and habituation, as well as specific behaviors such as swimming, locomotion, and magnetic field orientation.

Introduction

The survival of all animals is dependent on their capacity to adapt to their environment by modifying their behavior. The experience-induced modification of behavior is a manifestation of learning, whereas memory is the retention of a learned behavior over time. A conceptual scheme that has driven the investigation of learning rests on the distinction between associative and nonassociative forms of learning. Nonassociative forms of learning include habituation and sensitization. Habituation is defined as the gradual waning of a behavioral response to a weak or moderate stimulus that is presented repeatedly. Following habituation, the response may be restored to its initial state, either passively with time (i.e., spontaneous recovery) or with the presentation of a novel stimulus (i.e., dishabituation). Sensitization is defined as the enhancement of a behavioral response elicited by a weak stimulus following another, usually noxious, stimulus. Sensitization can also develop in response to a moderate stimulus that is presented repeatedly at relatively short intervals.

Associative learning refers to the formation of an association either between two stimuli (i.e., classical conditioning) or between a behavior and a stimulus (i.e., operant conditioning). In classical conditioning, a novel or weak stimulus (conditional stimulus (CS)) is paired with a stimulus that generally elicits a reflexive response (unconditional stimulus (US) and unconditional response(UR)). After sufficient training with contingent CS–US presentations (which may be a single trial), the CS comes to elicit a learned response (conditional response (CR)), which often resembles the UR (or some aspect of it). The emergence of the anticipatory CR reveals that the CS has become a reliable predictor of the US. Operant conditioning is an experimental procedure in which the behavior of an animal may be followed by either a desirable or an aversive stimulus, arranged by the experimenter. The desirable stimulus (e.g., food) typically increases the future occurrence of this behavior (a process called positive reinforcement). An aversive stimulus (e.g., a noxious electric shock) tends to decrease the future probability of this behavior (a process called punishment). A behavior can also be reinforced when it becomes contingent with the removal of an aversive stimulus from the animal's environment (i.e., negative reinforcement). Thus, through the processes of operant conditioning an animal learns the outcomes of its behavior.

Humans and other animals are capable of displaying more complex forms of learning than the four types just described. However, these four types are likely to constitute the building blocks for more complex forms of learning. Thus, a major goal of neurobiologists is to explain the anatomical, biophysical, and molecular processes of the nervous system that underlie simple forms of learning and memory. Specifically, what parts of the nervous system are critical for learning? How is information about a learned event acquired and encoded in neuronal terms? How is the information stored, and, once stored, how is it retrieved? Most neuroscientists believe that the answers to these questions lie in understanding the ways in which the properties of individual nerve cells in general, and synaptic connections, in particular, change when learning occurs.

Emerging Principles

As a result of research on several vertebrate and invertebrate model systems, some general principles have emerged: (1) at least short-term forms of learning and memory require changes in existing neural circuits; (2) these changes may involve multiple cellular mechanisms within single neurons; (3) second-messenger systems appear to play a role in mediating cellular changes; (4) changes in the properties of membrane channels are commonly correlated with learning and memory; (5) changes in synaptic efficacy are correlated with short- and long-term memory; and (6) long-term memory requires new protein synthesis and growth, whereas short-term memory does not.

One animal that is well suited for the examination of the molecular, cellular, morphological, and network mechanisms underlying neuronal plasticity and learning and memory is the marine mollusc *Aplysia*. This animal has a relatively simple nervous system with large identifiable neurons that are accessible for detailed anatomical, biophysical, and biochemical studies. Neurons and neural circuits that mediate many behaviors in *Aplysia* have been identified. In several cases, these behaviors have been shown to be modified by learning. Moreover, specific loci within neural circuits at which modifications occur during learning have been identified and aspects of the cellular mechanisms underlying these modifications have been analyzed and modeled.

Behaviors and Neural Circuits

The siphon-gill and tail-siphon withdrawal reflexes of *Aplysia* have been used extensively to analyze the neuronal mechanisms contributing to nonassociative and associative learning. Feeding behavior has also emerged as a useful model system to study associative learning. It exhibits both classical and operant conditioning and neural correlates and mechanisms of both types of associative learning have been identified. In this article, we first focus on the analyses of habituation, sensitization, and classical conditioning of defensive reflexes; later, we describe the analysis of operant and classical conditioning of feeding behavior.

Withdrawal Reflexes

Within the mantle cavity is the respiratory organ of *Aplysia*, the gill, and protruding from the mantle cavity is the siphon (Figure 1). The siphon-gill withdrawal reflex is elicited when a tactile or electrical stimulus is delivered to the siphon and results in the withdrawal of the siphon and gill (Figure 1(a)). A second behavior that has been examined extensively is the tail-siphon withdrawal reflex. Tactile or electrical stimulation of the tail elicits a coordinated set of defensive responses, two components of which are a reflex withdrawal of the tail and the siphon (Figure 1(b)).

A prerequisite for the analysis of the neural and molecular basis of learning is an understanding of the neural circuit that controls the behavior. The afferent limb of the siphon-gill withdrawal reflex consists of sensory neurons with somata in the abdominal ganglion. The siphon sensory neurons (SN) monosynaptically excite the gill and siphon motor neurons (MN) that are also located in the abdominal ganglion (Figure 2(a)). Activation of the gill and siphon motor neurons leads to the contraction of the gill and siphon. Excitatory, inhibitory, and modulatory interneurons (INs) in the withdrawal circuit have also been identified, although only excitatory INs are illustrated in Figure 2. The afferent limb of the tail-siphon withdrawal reflex consists of a bilaterally symmetric cluster of sensory neurons that are located in the left and right pleural ganglia. These sensory neurons make monosynaptic excitatory connections with motor neurons in the adjacent pedal ganglion, which produce the withdrawal of the tail (Figure 2(b)). In addition, the tail sensory neurons form synapses with various identified excitatory and inhibitory INs. Some of these INs activate MNs in the abdominal ganglion, which control the reflex withdrawal of the siphon. Moreover, several additional neurons modulate the tail-siphon withdrawal reflex (see Figure 3(a)).

The sensory neurons for both the siphon-gill and tail-siphon withdrawal reflexes are similar and appear to be important plastic elements in the neural circuits. Changes in their membrane properties and the strength of their synaptic connections (synaptic efficacy) are associated with learning and memory. Moreover, the properties of these neurons are modulated by *in vitro* analogs of behavioral training.

Cellular and Molecular Mechanisms in Sensory Neurons Contributing to Habituation and Sensitization in *Aplysia*

Short-Term Memory for Habituation

Upon brief repetitive stimulation, the withdrawal reflexes of *Aplysia* undergo short-term habituation,

Figure 1 Siphon-gill and tail-siphon withdrawal reflexes of *Aplysia:* (a) siphon-gill withdrawal; (b) tail-siphon withdrawal reflex. (a) Shows a dorsal view of *Aplysia* (1) in a relaxed position and (2) after a stimulus (e.g., a water jet, brief touch, or weak electric shock) was applied to the siphon, causing the siphon and the gill to withdraw into the mantle cavity. (b) Shows *Aplysia* (1) in a relaxed position and (2) after a stimulus was applied to the tail, eliciting a reflex withdrawal of the tail and siphon.

Figure 2 Simplified circuit diagrams: (a) the siphon-gill reflex; (b) tail-siphon withdrawal reflex. Stimuli activate the afferent terminals of mechanoreceptor sensory neurons (SN) whose somata are located in central ganglia. The sensory neurons make excitatory synaptic connections (triangles) with interneurons (IN) and motor neurons (MN). The excitatory interneurons provide a parallel pathway for excitation of the motor neurons. Action potentials elicited in the motor neurons, triggered by the combined input from the SNs and INs, propagate out peripheral nerves to activate muscle cells and produce the subsequent reflex withdrawal of the organs. Modulatory neurons (not shown here, but see **Figure 3(a)**), such as those containing serotonin, regulate the properties of the circuit elements and, consequently, the strength of the behavioral responses.

which has been attributed primarily to activity-dependent depression of the sensorimotor synapse. This depression, which is termed homosynaptic, leads to a decreased recruitment of MNs and decreased magnitude of the withdrawal reflexes. A proposed mechanism of short-term homosynaptic depression involves presynaptic changes in transmitter release. Experimental and computational studies of the sensorimotor synapse have suggested that short-term activity-dependent changes in transmitter release are in part determined by the dynamics of vesicle mobilization in presynaptic terminals and are limited by the gradual depletion of available vesicles.

In addition to presynaptic mechanisms of depression, postsynaptic mechanisms have also been implicated. For example, challenging the sensorimotor synapse with physiological bursts of activity results in its depression, partly due to the desensitization of postsynaptic receptors. In addition, more prolonged depression of the sensorimotor synapse (i.e., around 2 h) relies on the activation of postsynaptic *N*-methyl-D-aspartate (NMDA)-like receptors and a rise in postsynaptic Ca^{2+}. Thus, despite the apparent operational simplicity of habituation and synaptic depression, the underlying mechanisms appear to be complex and to involve multiple targets.

Long-Term Memory for Habituation

Both short- and long-term habituation share aspects of a common mechanism, synaptic depression. However, whereas short-term synaptic depression arises primarily from transient changes in release, long-term depression has been attributed to persistent structural changes in SNs. Extensive morphological analyses of SNs from habituated animals have revealed that the number of synaptic contacts is reduced compared to controls. Moreover, the structure of presynaptic terminals is affected, with fewer synaptic vesicles and reduced size of active zones (the sites of transmitter release).

Short-Term Memory for Sensitization

Short-term sensitization is induced when a single brief train of shocks to the body wall results in the release of modulatory transmitters, such as serotonin (5-HT), from a separate class of INs, referred to as facilitatory neurons (**Figure 3(a)**). These facilitatory neurons regulate the properties of the SNs and the strength of their connections with postsynaptic INs and MNs, a process called heterosynaptic facilitation (**Figures 3(b) and 3(c)**). The molecular mechanisms contributing to heterosynaptic facilitation are illustrated in **Figure 3(d)**. The binding of 5-HT to one class of receptors on the outer surface of the membrane of the SNs leads to the activation of adenylyl cyclase, which, in turn, leads to an elevation of the intracellular level of the second-messenger adenosine-3′,5′-monophosphate (cAMP) in SNs. When cAMP binds to the regulatory subunit of cAMP-dependent protein kinase, protein kinase A (PKA), the catalytic

Figure 3 Model of heterosynaptic facilitation of the sensorimotor connection that contributes to short-term sensitization in *Aplysia:* (a) sensitizing stimuli activate facilitatory interneurons (IN) that release modulatory transmitters, one of which is serotonin (5-HT); (b) action potential in a sensory neuron (SN) in the control; (c) action potential in a SN after the sensitizing stimulus; (d) molecular events in the sensory neuron. In (a), the modulator leads to an alteration of the properties of the SN. In (c), the sensitizing stimulus results in greater transmitter release and, hence, a larger postsynaptic potential in the motor neuron (MN) than an action potential prior to the sensitizing stimulus (shown in (b)). For short-term sensitization, the enhancement of transmitter release is due, at least in part, to the broadening of the action potential and an enhanced flow of Ca^{2+} into the SN. In (d), 5-HT released from the facilitatory interneuron (a) binds to at least two distinct classes of receptors on the outer surface of the membrane of the SN, which leads to the transient activation of two intracellular second messengers: DAG and cAMP. These second messengers, acting though their respective protein kinases, affect multiple cellular processes, the combined effects of which lead to enhanced transmitter release when a subsequent action potential is fired in the SN. cAMP, cyclic adenosine-3′,5′-monophosphate; DAG, diacylglycerol; I_{Ca}, calcium current; $I_{Ca,Nif}$, nifedipine-sensitive Ca^{2+} current; $I_{K,S}$, S-K^+ current; $I_{K,V}$, delayed K^+ current; PKA, protein kinase A; PKC, protein kinase C.

subunit is freed and can now add phosphate groups to specific substrate proteins and, hence, alter their functional properties.

One consequence of this protein phosphorylation is an alteration of the properties of membrane channels. Specifically, the increased levels of cAMP lead to a decrease in the S-K^+ current ($I_{K,S}$), a component of the calcium-activated K^+ current ($I_{K,Ca}$) and the delayed K^+ current ($I_{K,V}$). These changes in membrane currents lead to the depolarization of the membrane potential, enhanced excitability, and an increase in the duration of the action potential.

Through the activation of PKA, cAMP also appears to mediate a membrane potential- and spike-duration-independent process of facilitation, represented in Figure 3(d) (large open arrow) as the mobilization of transmitter-containing vesicles from a storage pool to a releasable pool, making more transmitter available for release with subsequent action potentials in the SN. The phosphoprotein synapsin may be involved in the regulation of synaptic vesicle availability. Under basal conditions, synapsin associates with vesicles as well as the cytoskeleton, forming a proteinaceous meshwork that limits vesicle mobilization. Upon phosphorylation by PKA, synapsin dissociates from vesicles, thus rendering them available to be mobilized to release sites. Another molecule recently implicated in the regulation of vesicle mobilization is the Ca^{2+}-activated enzyme calpain. The combined effects of spike broadening and vesicle mobilization appear to contribute to the short-term cAMP-dependent enhancement of transmitter release.

5-HT also appears to act through another class of receptors to increase the level of the second

messenger diacylglycerol (DAG). DAG activates protein kinase C (PKC). PKC, like PKA, is involved in the spike-duration-independent process of facilitation. In addition, a nifedipine-sensitive Ca^{2+} current ($I_{Ca,Nif}$) and $I_{K,V}$ are regulated by PKC. Thus, $I_{K,V}$ is dually regulated by PKC and PKA. The modulation of $I_{K,V}$ contributes significantly to the increase in the duration of the action potential (Figure 3(c)). Because of its small magnitude, the modulation of $I_{Ca,Nif}$ appears to play a minor role in the facilitatory process.

The consequences of the activation of these multiple second-messenger systems and the modulation of multiple cellular processes become apparent on test stimulation of SNs at various times after the sensitizing stimuli (Figure 3(c)). More transmitter is available for release as a result of the mobilization process, and each action potential is broader, allowing a greater influx of Ca^{2+} to trigger the release of the available transmitter. The combined effects of mobilization and spike broadening lead to the enhanced release of transmitter from the SN and consequently a larger postsynaptic potential in the MN. Larger postsynaptic potentials lead to an enhanced activation of INs and MNs and thus an enhanced behavioral response (i.e., sensitization). Detailed mathematical models have been developed, which capture key aspects of the modulation of membrane channels and the dynamics of second-messenger systems, calcium regulation, and transmitter storage and release.

Long-Term Memory for Sensitization

Repeating the sensitizing stimuli over a 1.5 h period leads to the induction of long-term sensitization, the memory of which can persist for days to weeks. Repeated training leads to more prolonged phosphorylation and activation of nuclear regulatory proteins by PKA. Such proteins affect the regulatory regions of DNA and lead to the increased transcription of RNA and, hence, the increased synthesis of specific proteins. Some of the resulting proteins may be transcription factors that can activate other genes, some of which may be able to maintain their own activation. One of the newly synthesized proteins initiates the internalization and degradation of neuronal cell adhesion molecules (NCAMs), altering the interaction of the neuron with other cells and allowing the restructuring of the axon arbor. The sensory neuron could then form additional connections with the same postsynaptic target or make new connections with other cells. Other newly synthesized proteins such as intermediate filament proteins (IFP) are also likely to contribute to the new growth. Increased synthesis of calmodulin (CaM) also occurs, but the functional significance of this effect has not been determined.

Prolonged stimulation and increased cAMP also lead to the induction and subsequent expression of a gene encoding the protein ubiquitin C-terminal hydrolase (Uch). This neuron-specific enzyme enhances the degradation of certain proteins, including the regulatory subunits of PKA. With fewer regulatory subunits of PKA to bind to catalytic subunits, the catalytic subunits are persistently active and they may contribute to the long-term facilitation of transmitter release through the same cAMP-dependent processes seen in the short term. Some of these cAMP- and PKA-induced changes include a decrease in $I_{K,S}$ and enhanced excitability, as well as, perhaps, a prolongation or amplification of their effects on nuclear regulatory proteins. As with short-term sensitization, the enhanced release of transmitter from existing contacts of SNs on to MNs and INs underlies the long-term enhanced responses of the animal to test stimuli. However, unique to long-term sensitization, increases in axonal arborization and synaptic contacts may contribute to the enhanced activation of follower INs and MNs.

In addition to the cAMP–PKA cascade, another kinase cascade involving the mitogen-activated protein kinase (MAPK) has been identified as essential for long-term synaptic facilitation. Prolonged application of 5-HT results in the persistent phosphorylation (and subsequent activation) of MAPK. Activated MAPK translocates to the nucleus, where it may regulate gene transcription, possibly through the inhibition of cAMP response element binding protein (CREB) 2. Because under basal conditions CREB2 acts as a repressor of gene transcription, its inhibition leads to derepression and net gene expression in concert with CREB1 (see Figure 4). The involvement of additional transcription factors such as *Aplysia* activating factor (ApAF) and *Aplysia* LAPS18-like protein (ApLLP) in learning-induced gene expression is currently being investigated.

One of the genes that is expressed in response to long-term sensitization treatment encodes the *Aplysia* tolloid/bone morphogenetic protein-like (ApTBL) protein. ApTBL is a metalloprotease that may activate latent forms of transforming growth factor (TGF)-β. Similar to 5-HT, TGF-β also produces long-term increases in synaptic strength and excitability of the sensory neurons. Interestingly, TGF-β also activates MAPK and induces its translocation to the nucleus. Because TGF-β plays key roles in development, its involvement in sensitization may provide insights into the mechanistic relationship between development and learning. Another molecule that activates MAPK and is necessary for long-term synaptic facilitation is the peptide sensorin. Sensorin is secreted by SNs and regulates axonal growth and the formation of

Figure 4 Simplified scheme of the mechanisms in sensory neurons that contribute to long-term sensitization and some aspects of short-term sensitization. Sensitization training leads to cAMP-dependent regulation of short-term effectors (see Figure 3(d)) and CREB1. 5-HT also activate MAPK, either through a cAMP-dependent, or through a seperate, cAMP-independent pathway. MAPK, in turn, regulates CREB2. Whereas CREB1 acts as an initiator of gene transcription, CREB2 acts as a repressor of gene transcription. The combined effects of activation of CREB1 and derepression of CREB2 lead to the regulation of the synthesis of at least ten proteins, only three of which (ApTBL, ApCAM, and ApUch) are shown. ApTBL is believed to activate latent forms of TGF-β, which can then bind to receptors on the sensory neuron. TGF-β activates MAPK, which can have both acute and long-term actions. One of its acute effects is the regulation of transmitter release. MAPK may also act by initiating a second round of gene regulation by affecting CREB2-dependent pathways. 5-HT, serotonin; ApUch, *Aplysia* ubiquitin C-terminal hydrolase; ApTBL, *Aplysia* tolloid/bone morphogenetic protein-like protein; ApCAM, *Aplysia* cell adhesion molecules; cAMP, cyclic adenosine-3′,5′-monophosphate; CREB, cAMP response element binding protein; MAPK, mitogen-activated protein kinase; MEK, mitogen-activated protein kinase kinase; PKA, protein kinase A; TGF, transforming growth factor.

new presynaptic varicosities associated with expression and maintenance of long-term memory.

Intermediate-Term Memory for Sensitization

It has recently been suggested that memory for sensitization comprises three physiologically and molecularly distinct phases: two of them, short- and long-term, have already been discussed; the third (and newly discovered) phase is intermediate-term memory (ITM), which lasts up to 3 h following sensitization training. Induction of ITM is protein synthesis-dependent but RNA synthesis-independent. In contrast, short-term memory requires neither protein nor RNA synthesis, whereas long-term memory requires both. Moreover, ITM expression requires persistent PKA activity.

An intermediate-term facilitation (ITF) of the sensorimotor synapse, which is produced by the application of five pulses of 5-HT (an analog of sensitization training), corresponds to the ITM as it displays similar temporal dynamics and requires protein synthesis but not RNA synthesis. This latter feature of ITF distinguishes it from short-term facilitation, which requires neither protein nor RNA synthesis, and long-term facilitation, which requires both. Depending on the induction protocol, ITF may require intermediate-term activation of PKA or PKC. These kinases can be activated for hours following prolonged treatment with 5-HT. Finally, the activation of previously silent release sites has also been implicated in ITF and could be a mechanism for memory consolidation.

Associative Learning in *Aplysia*

Classical Conditioning of Withdrawal Reflexes

The withdrawal reflexes of *Aplysia* can display classical and operant conditioning. Studies using a neuronal analog of differential classical conditioning indicate that a cellular mechanism called activity-dependent neuromodulation contributes to short-term classical conditioning observed at the behavioral level. Delivering a US, such as an electric shock to the tail or a peripheral nerve, activates a modulatory system, such as 5-HT, that nonspecifically enhances transmitter release from the SNs. This nonspecific enhancement contributes to short-term sensitization. The temporal specificity characteristic of associative learning results from the pairing of a CS (e.g., spike activity in one sensory neuron) with the US, which causes a selective amplification of the modulatory effects of the US in that specific SN. Unpaired activity does not amplify the effects of the US. The amplification of the modulatory effects in the paired SN leads to a pairing-specific enhancement of transmitter release from the SN. The proposed mechanism suggests that increased Ca^{2+} levels resulting from spike activity alter adenylyl cyclase via CaM and increase

the cAMP level produced by 5-HT. Thus, Ca^{2+} and CaM appear to play a role in the activity-dependent neuromodulation that may underlie associative conditioning of the tail and gill withdrawal reflexes.

Apart from activity-dependent presynaptic neuromodulation, another mechanism that has been implicated in classical conditioning is long-term potentiation (LTP). LTP of *Aplysia* sensorimotor synapses requires coincident presynaptic release of glutamate from SNs and postsynaptic depolarization of MNs. Glutamate binds to NMDA-type postsynaptic receptors, which leads to increased postsynaptic calcium concentration. Under resting conditions, the postsynaptic NMDA receptors are blocked by Mg^{2+}, and the binding of glutamate fails to activate them. However, when the postsynaptic MN is depolarized, the NMDA receptors are relieved of the Mg^{2+} block and respond to presynaptically released glutamate, thus elevating postsynaptic calcium. Recent results indicate that both LTP and activity-dependent neuromodulation are necessary for classical conditioning of withdrawal reflexes.

An important conclusion is that an aspect of a mechanism for short-term associative learning is an elaboration of the cAMP-dependent mechanisms that contribute to a simpler form of learning, sensitization. This finding raises the interesting possibility that even more complex forms of learning may be achieved by using these simpler forms as building blocks. Indeed, a mathematical description of the learning rule (activity-dependent neuromodulation) for simple classical conditioning, when incorporated into appropriate neural circuits, has the capability to simulate higher-order features of classical conditioning such as second-order conditioning and blocking, as well as features of operant conditioning.

Operant and Classical Conditioning of Feeding Behavior

Although this article focuses on the use of withdrawal reflexes of *Aplysia* as a model system to study learning and memory, the study of the feeding behavior of *Aplysia* has also recently revealed some of the mechanisms underlying operant and classical conditioning. In an operant conditioning paradigm, the delivery of a reinforcing stimulus is contingent on the expression of a designated behavior. In the case of feeding behavior, the operant behavior is ingestive or biting movements and the reinforcement is a stimulus to the esophageal nerve (En), which is enriched in dopamine processes and signals presence of food in the mouth (Figure 5). Stimulation of the En each time the animal performs a spontaneous biting movement (contingent reinforcement) results in an increase in the number of

Figure 5 Operant conditioning of feeding behavior in *Aplysia*. While unrestrained in the experimental chamber, an animal moves about freely and engages in spontaneous behaviors (top left). Throughout the experiment, the animal is observed and all bites are recorded. A bite is a stereotypic movement, defined as opening of the jaws (top right) and protraction of the radula (a tongue-like organ; bottom right). Upon completion of a bite, electrical stimulation is delivered to the esophageal nerve (En; bottom left). The electrical activity induced by En stimulation resembles the pattern of activity induced by the presence of food in the esophagus. Therefore, this activity serves as a positive reinforcer of biting. Operant conditioning is manifested as an increase in the probability of spontaneous bites. Animals that receive En stimulation independently of biting (yoke control) do not display operant conditioning.

spontaneous bites during a test period. In classical conditioning of feeding behavior, touching the animal's lips with a brush can serve as the CS, which comes to elicit biting movements when it predicts stimulation of En (i.e., the US). Both classical and operant conditioning of feeding behavior appear to rely on the actions of the neuromodulator dopamine.

The development of behavioral protocols for operant and classical conditioning, as well as *in vitro* analogs, allowed for further investigations into the mechanisms underlying associative learning. Neural correlates of associative learning were investigated through the study of identified key cells in the buccal ganglia, where the central pattern generator that gives rise to the feeding behavior is located. One of these cells, B51, is a key element in the generation of ingestive-like buccal motor programs, which are patterns of activity generated by the central pattern generator (CPG) and that underlie biting movements. Investigation of the cellular properties of B51 in ganglia from operantly conditioned and control animals revealed that operant conditioning was correlated with significantly higher B51 input resistance but significantly lower burst threshold. These changes serve to increase the probability of B51 activation and would therefore facilitate the generation of the neural activity underlying biting movements in the trained animals. In contrast, classical conditioning was correlated with a significant increase in burst threshold, without a change in input resistance. The increase in burst threshold decreases the probability of B51 activation, thus placing its activity under the control of very specific input pathways, presumably the ones signaling the CS. These data suggest that B51 is an important locus of plasticity in both operant and classical conditioning of feeding behavior. They also suggest that intrinsic cellwide plasticity may be one important mechanism underlying operant conditioning, whereas synapse-specific plasticity may underlie classical conditioning. Interestingly, pairing spike activity with a puff of exogenous dopamine leads to the same biophysical changes in B51 which are produced by operant conditioning *in vivo*, indicating that spike activity in B51 may enhance the modulatory effects of dopamine. This mechanism is similar to the activity-dependent enhancement of the 5-HT effects that was proposed as a model of classical conditioning of withdrawal reflexes. Thus, activity-dependent neuromodulation may be a common mechanism for both operant and classical conditioning of various *Aplysia* behaviors.

Introduction

In the 1960s Sydney Brenner and many colleagues shared the view that most of the 'interesting' problems of molecular biology had been, or were close to being, solved. It was their opinion that the nervous system was the next frontier of science, as it appeared to pose the most challenging questions. As a result, the search began for an organism that would allow for a global approach that focused on investigating the nervous system by means of genetic dissection. Brenner, after searching through many zoology texts, and examining a number of animals, settled on our organism of discussion, *Caenorhabditis elegans*. The worm, as it is often affectionately called, fit his search criteria for the ideal model organism: (1) it has a rapid lifecycle allowing for growth of large populations in a short period of time (*C. elegans* begins laying eggs at 3 days of age), (2) it has a simple reproductive cycle and genome (hermaphrodites can reproduce clonally, reducing the problem of differing genetic background between individuals), and (3) it is small in size and can be successfully frozen and thawed alive, making for easy storage in the lab.

Since the beginning of its development as a model organism a great wealth of knowledge has accumulated, including a fully sequenced genome, a complete wiring diagram of the nervous system, the developmental lineage for every cell present in the adult worm, and thousands of genetic mutants. The worm is amendable to *in vivo* whole-organism molecular analyses through the combination of microscopy and genetic-based fluorescence imaging, allowing for insight into protein localization and function. Past research has shown that to a great extent the cellular machinery and processes used by the worm are homologous to those found in the other organisms, including mammals. And of interest to the neuroscientist, *C. elegans* exhibits many basic types of behaviors which can be analyzed at behavioral, neural circuit, and genetic levels.

Although the tiny worm has the smallest nervous system of all multicellular learning and memory model systems, with only 302 neurons at its disposal, it shows a remarkable ability to learn and remember. It has been shown capable of both associative and nonassociative learning and has recently been developed as a model in which to study cellular mechanisms of learning and memory. This article discusses the behavioral paradigms used to study learning and memory in *C. elegans* as well as the proposed cellular and molecular mechanisms. The different paradigms are divided and discussed based upon their sensory modalities.

Mechanosensory Learning and Memory

The first type of learning described for *C. elegans* was habituation to a mechanosensory stimulus. In this learning paradigm the worm receives a mechanical stimulus, a tap, applied to the side of the petri plate within which it resides. The tap results in the worm changing from a forward swimming motion to a backward one for a brief period of time, after which it swims forward again. This reversal response is termed the 'tap withdrawal' response. This is indeed habituation to the mechanical stimulus and not sensory adaptation or fatigue, as the worm's response to tap can be dishabituated. After habituation training the application of a more intense stimulus, such as an electrical shock administered through the agar, causes dishabituation such that worms will respond to the subsequent presentation of the tap stimulus as if it were novel.

The neural circuit that mediates this response has been mapped and consists of mechanosensory neurons, command interneurons, and motor neurons (Figure 1). The pair of ALM cells and the AVM cells are the sensory neurons that sense head touch, while the pair of PLM cells are the sensory neurons responsible for sensing tail touch. The simultaneous stimulation of these neurons results in the reversal response seen following tap. These touch sensory neurons synapse onto the anterior ventral command interneurons (AVD, AVB, and AVA) and the posterior ventral command interneuron (PVC), which process information and project to appropriate motor neurons. The site of plasticity within the neural circuit for the response to tap is proposed to be at the glutamatergic synapses between the mechanosensory neurons and the command interneurons. Upon repeated administration of tap, worms habituate as measured by the decrease in their reversal lengths after each subsequent tap.

Short-Term Memory for Habituation

C. elegans can demonstrate both short-term memory and long-term memory (LTM) for habituation to tap. Short-term habituation is induced by administering 30 stimuli at a 10 or 60 s interstimulus interval (ISI), followed by testing for spontaneous recovery

Figure 1 Schematic diagram of the main components of the neural circuits that mediate mechanosensory, chemosensory, and thermosensory behaviors that have been studied in learning and memory paradigms in *C. elegans*. Chemical synaptic connections are represented by lines with arrowheads, while electrical gap junctions are represented by lines terminating in ovals. From Giles AC, Rose JK, and Rankin CH et al. (2006) Investigations of learning and memory in *Caenorhabditis elegans*. Neurobiology of *C. elegans*. *International Review of Neurobiology* 69: 37–71.

at 30 s, 5 min, and 10 min after delivery of the last tap. Short-term habituation differs depending upon the ISI used (Figure 2). Short ISI produce deep levels of habituation that show rapid spontaneous recovery, whereas long ISI produce intermediate levels of habituation that show slower spontaneous recovery. These behaviorally different forms of short-term habituation are hypothesized to correlate with multiple molecular forms of short-term memory.

Genes involved in short-term habituation Thus far, four genes have been shown to be important for short-term habituation to tap: *eat-4*, encoding a homolog of the mammalian glutamate vesicular transporter, VGlut1; *cat-2*, encoding a homolog of the mammalian tyrosine hydroxylase; *dop-1*, encoding a homolog of the mammalian type 1 dopamine receptor; and *hab-1*, whose gene product has yet to be identified. The *eat-4* mutant worms show normal response to tap

Figure 2 Habituation of mean response amplitude (reversal length in millimeters) to 40 tap stimuli delivered at a 10 s (top) and a 60 s (bottom) interstimulus interval (ISI). Habituation to stimuli presented at short ISS (10 s) produces greater levels of habituation and a more rapid decrement of the response than does habituation to stimuli presented at longer ISS (60 s).

but habituate in a more rapid manner and to a deeper level than do wild-type worms. They also show slower spontaneous recovery and interestingly do not show dishabituation. This suggests that presynaptic release of glutamate from the mechanosensory neurons is vital for wild-type short-term habituation. Both *cat-2* and *dop-1* mutant worms habituate more quickly and deeply than do wild-type worms when response is measured by the number of animals reversing to tap, but not when measured by reversal length. This may suggest that dopamine modulates the balance between the head touch circuit and the tail touch circuit and perhaps is not directly involved in the mechanism responsible for habituation. Worms with mutations in HAB-1 are reported to habituate more slowly than do wild-type worms but show normal response to tap and dishabituation. This mutation is interesting, as it appears to have the opposite phenotype from all the other known mutations affecting short-term habituation to date.

LTM for Habituation

LTM for habituation in *C. elegans* can last for as long as 48 h, is protein synthesis dependent, and is induced by spaced training. The protocol for spaced training in *C. elegans* that induces LTM consists of four blocks of 20 taps administered at a 60 s ISI with a 1 h rest period between each training block (Figure 3(a)). Worms that receive this spaced habituation training show significantly smaller mean reversal lengths compared to untrained control worms 24–48 h after the last training session. Massed training (the same number of stimuli as in spaced training, but no rest is given between blocks), on the other hand, does not induce LTM for habituation.

Genes involved in LTM for habituation Several genes involved in glutamate transmission that are found at the proposed site of plasticity have been investigated for their role in LTM in this system: *eat-4*, encoding a glutamate vesicular transporter homologous to mammalian VGlut1; *glr-1*, encoding a homolog to a mammalian kainate/α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type glutamate receptor subunit, and *nrm-1*, encoding a homolog to the mammalian *N*-methyl-D-aspartate (NMDA)-type glutamate receptor subunit. The *eat-4* and *glr-1* mutant worms are deficient for forming LTM of habituation, but, interestingly, worms do not appear to require NMDA-type glutamate receptors for memory formation, as *nmr-1* mutant worms show normal LTM (Figure 3(b)). Confocal imaging of transgenic worms expressing GLR-1 fused to a green fluorescent protein (GFP) and quantitative reverse transcriptase polymerase chain reaction (RT-PCR) have shed some light on the functional importance of GLR-1. When measured 24 h after spaced training, GLR-1 expression levels are observed to decrease; suggesting that LTM for habituation is molecularly mediated by a down-regulation of GLR-1 expression (Figure 3(c)).

Context Associations with Habituation to Tap

C. elegans is also capable of forming chemosensory context associations with habituation to tap. When worms plated on agar treated with Na^+ (taste worms are attracted to) are habituated with 30 taps at a 10 or a 60 s ISI, then are transferred onto plain agar for a 1 h rest period and, finally, rehabituated on Na^+-treated agar, they show greater retention of the earlier training (demonstrated by smaller reversal lengths in the second round of habituation) than do worms that were trained and tested on plates without the Na^+ taste. This form of associative conditioning has been shown sensitive to extinction (you do not see this effect if you leave the worms in the same context that they are trained and tested in for the 1 h rest period) and latent inhibition (preexposure to the context for 1 h before training diminishes the context effect).

Figure 3 Long-term memory (LTM) paradigm and corresponding genetic analysis. (a) Protocol for spaced training in *C. elegans* that induces LTM. Trained worms receive four blocks of 20 taps administered at a 60 s ISI with a 1 h rest period between each training block, while control worms receive one tap. After 24 h, ten taps are administered to both control and trained worms to test for memory. Memory is seen when trained worms show significantly smaller responses than do control worms. (b) Mean reversal lengths of wild-type worms and of *eat-4, nmr-1*, and *glr-1* mutants during the ten test taps, 24 h after training, measured as a percentage of control reversal lengths for trained and control worms. Wild-type and *nmr-1* mutants show normal LTM, whereas *eat-4* and *glr-1* do not. (c) Fluorescent imaging of a GLR-1–GFP fusion protein 24 h after LTM training in trained and untrained control worms. GLR-1 expression levels are observed to decrease for trained worms. Scale bar = 20 μm.

Chemosensory Learning and Memory

Worms are attracted and migrate toward cations, anions, cyclic nucleotides, and volatile chemicals; this behavior is termed chemotaxis (Figure 4). Chemotaxis is usually measured through either one of two common assays: the first is orientation, quantified by tracking the path of individual worms as they migrate toward or away from a chemical, and the second is accumulation, quantified by counting the number of worms that collect at the location of the chemical. This behavior has been found subject to several forms of learning in *C. elegans*: habituation to low levels of odorants, state-dependent adaptation to high levels of odorants, classical conditioning, and aversive learning.

The neural circuit that mediates chemotaxis has been mapped (Figure 1) and consists of many more sensory neurons than do the other behaviors discussed in this article. In total, 11 pairs of sensory neurons in the head region of the worm are responsible for chemotaxis. Eight pairs have sensory endings that are in contact with the external environment and for the most part detect water-soluble attractants. The additional three pairs are enclosed in the amphid sheath and their main role is to detect volatile chemicals. Because these 11 pairs of neurons respond to such a large number of different chemical substances, it is thought that single chemosensory neurons are capable of detecting multiple chemicals, and, further, this

Figure 4 Schematic diagram of chemotaxis and the adaptation, habituation, state-dependent learning, and classical conditioning paradigms. In chemotaxis, worms migrate toward an attractive odor (green) such as diacetyl, rather than to a control stimulus (blue) such as water. Adaptation and habituation are produced by preexposing worms to an attractive chemical stimulus for an extended period of time. When worms are later tested for chemotaxis they no longer show a preference for that chemical over a control chemical. Adaptation is induced by exposing worms to high concentrations of the stimulus, whereas habituation to Na^+ or diacetyl is induced by exposure low concentrations. Once worms are habituated to Na^+ or diacetyl they can be dishabituated* by exposing them briefly to a high concentration of that chemical; this does not occur for adaptation. In the paradigm for state-dependent learning starved or inebriated worms are preexposed to an odor and learn to associate this odor with their physiological state. Thus, when worms are later exposed to that odor they only show adaptation when they are in the same physiological state as when they were preexposed. In the differential classical conditioning paradigm worms are first preexposed to an odor (conditioned stimulus, CS+; green) in the presence of food (unconditioned stimulus, US) and then preexposed to another odor without food (CS−; red). When worms are later placed in the presence of both odors they show a preference for the odor that was previously paired with food (CS+).

suggests that one site of plasticity for chemotaxis behavior may be intraneuronal.

Adaptation

Adaptation, a decrease in responding after lengthy exposure to a stimulus (i.e., no longer noticing an odor after a long exposure to it), itself is not considered learning; however, it can have associations formed so that it plays a role in associative learning in experiments of state dependency. In the adaptation paradigm worms are exposed to a high concentration of a particular odorant for a determined period, called the adaptation period. After the worms are moved to a chemotaxis assay plate (test odorant on one side and a control substance on the other) (Figure 4), the chemotaxis index ((number migrated to test − number migrated to control)/total number) is measured.

State-dependent learning *C. elegans* can show state-dependent learning – that is to say, they can make associations between their physiological state and stimuli in their environment (Figure 4). Worms can associate a feeding state or an inebriated state, induced by ethanol, with adaptation to an odor. When starved worms are preexposed to odor, in this case benzaldehyde, they show greater adaptation to that odor than do unstarved control worms. When worms are preexposed to the odor in the presence of an excess of food, they show less adaptation than do control worms. The neurotransmitter serotonin, which is known to be important in other feeding-state-dependent behaviors, has been shown to mediate this feeding-state-dependent association. Similar to the feeding-state experiments, inebriated worms preexposed to an odor only show adaptation to that odor

when they are tested in the presence of inebriating doses of ethanol.

Habituation

Habituation to some chemosensory stimuli can also be observed in *C. elegans*. Preexposure to weak concentrations of either Na^+ or diacetyl causes the worms to habituate to that chemical; this can be observed as a decreased percentage of worms migrating in the direction of the chemical stimulus. This habituation can be differentiated from adaptation by the application of a dishabituating stimulus, a short exposure to a higher concentration of the chemical. This brief exposure immediately reverses the behavior such that an increase in the percentage of worms migrating in the direction of the weak concentration of the chemical stimulus is seen (Figure 4). This does not occur for adaptation. Whether worms habituate to either Na^+ or diacetyl or adapt to these chemical stimuli is determined by the concentration of the chemical. Habituation is seen at low concentrations of these chemicals, whereas adaptation is seen at higher concentrations.

Classical Conditioning

Differential classical conditioning, a form of associative learning, has been shown to exist in *C. elegans*. The first paradigm used to investigate this type of learning consisted of preexposing worms to two odors and pairing one odor with (conditioned stimulus; CS+) and the other odor without (CS−) food. After training, worms placed on a test plate that contain both the CS+ and CS− odors significantly preferred the odor which had been paired with food (Figure 4). Differential classical conditioning can also be demonstrated by pairing an aversive stimulus, such as garlic, with the CS+ odor. In this paradigm worms significantly prefer the CS− odor that was not paired with the aversive stimulus. Since the development of these paradigms, several others have been intoduced. These include pairing odors with feeding states and tastes. Thus, these studies illustrate that the small worm with its tiny nervous system is capable of complex chemosensory learning.

Genes involved in classical conditioning Several genes identified by means of genetic screens and behavioral investigations are important for differential classical conditioning. Two as yet unidentified genes, *lrn-1* and *lrn-2*, show normal chemotaxis and chemotactic habituation but are deficient for conditioning. As discussed earlier, the glutamate receptor subunit, GLR-1, is important for LTM for habituation to mechanosensory stimulus; the gene for this receptor subunit has also been shown to be an important gene for chemosensory learning: *glr-1* mutants show deficiencies for both chemotactic habituation and differential classical conditioning. Last, mutations in the gene *hen-1*, whose gene product is a low-density lipoprotein (LDL) receptor-like secretory protein, lead to abnormal sensory integration of chemosensory signals and no observed learning.

Aversive Learning

One of the most recent forms of learning discovered in *C. elegans* is the capacity to modify its chemosensory preferences after being exposed to pathogenic bacteria. This means that *C. elegans* can learn to avoid odors or tastes associated with familiar pathogenic bacteria and in turn increase its preference for odors or tastes associated with familiar nonpathogenic bacteria. In this paradigm, worms were placed on pathogenic bacteria for 4 h and subsequently for 4 h on nonpathogenic bacteria. This was followed by a choice test whereby half of the agar plate contained the pathogenic bacteria and the other half contained the nonpathogenic bacteria. Worms were observed to avoid the pathogenic bacteria and were attracted to the nonpathogenic bacteria. This study also identified serotonin and the gene *mod-1*, the gene product of which is a serotonin-gated chloride channel, as important components to this behavior.

Thermotactic Learning and Memory

Behavioral plasticity has also been shown in *C. elegans* for thermotactic behavior. Thermotaxis is defined as movement toward or away from a thermal stimulus. Worms can learn to associate a particular temperature with the presence or absence of food. This can be measured by placing the worms on a temperature gradient; if the worms have recently been well fed in an environment at a constant temperature they will migrate to this temperature when placed on the gradient (Figure 5). Conversely, if the worms have recently experienced starvation at a constant temperature they will avoid this temperature when placed on the gradient. This behavior is termed isothermal tracking.

The circuit that mediates thermotaxis has been mapped and consists of one pair of anterior sensory neurons (AFD) in the head region that project to several anterior interneurons (AIY, AIZ, and RIA) which compute the information (Figure 1). Through laser ablation experiments it has been demonstrated that AIY may signal for thermotaxis to warmer temperatures, while AIZ may signal for thermotaxis to cooler temperatures. These two interneurons converge onto RIA, which is proposed to be a site of thermotactic integration.

Figure 5 Schematic representation showing wild-type thermotactic behavior (isothermal tracking) and the various mutant phenotypes observed when mutations affect thermotactic behavior. Athermotactic phenotypes show no preference for any temperature. Cryophilic phenotypes show a preference for cooler temperatures than the temperature that was previously paired with food. Thermophilic phenotypes show a preference for warmer temperatures than the temperature that was previously paired with food. Adapted from Giles AC, Rose JK, and Rankin CH (2006) Investigations of learning and memory in *Caenorhabditis elegans.* Neurobiology of *C. elegans*. *International Review of Neurobiology* 69: 37–71.

The site of plasticity within the neural circuit for thermotaxis is proposed to lie within the AFD sensory neurons and the AIY interneuron.

Parsing Thermotactic Learning into Its Components

After worms learn the association of a temperature with a presence or absence of food, this memory is not resistant to future modifications, as the associated temperature can be 'reset.' Worms raised at a particular cultivation temperature with food show a preference for that temperature when placed on a temperature gradient, as stated earlier, but this association with food can be transferred to another temperature if the cultivation temperature is shifted to the new temperature in the presence of food.

This isothermal tracking can be parsed into two components: the response to a temperature shift and the change in behavior due to the presence of food. This is accomplished by observing how long it takes worms to learn a new temperature or feeding state after having already committed this type of association to memory. When worms are switched from their cultivation temperature to a new temperature, it takes them 2–3 h to learn this new association, and this learning is temperature independent. When worms are transferred to a different feeding state under the same temperature, they learn this new association in a temperature-dependent fashion. When they are transferred from a nutrient-rich to a nutrient-poor environment at cooler temperatures (17 °C), they are capable of learning the new association after 3 h, whereas at warmer temperatures (25 °C) it takes them only 30 min to make this new association. When they are transferred from a nutrient-poor to a nutrient-rich environment, they are able to learn this association in under 10 min. Similar results are seen when a double switch of temperature and feeding state are performed. This suggests that the environmental temperature is encoded through a relatively long process, while a relatively short process encodes the pairing of the feeding state to the stored temperature.

The roles that different neurotransmitters play in thermotaxis have been investigated to further dissect the two components of this behavior. The neurotransmitter serotonin is proposed to mimic a well-fed state in *C. elegans*, and an exogenous application of this neurotransmitter to starved worms during conditioning to a temperature mimics the effect of a food-rich environment, meaning that when they are placed on a temperature gradient they thermotax to the temperature at which serotonin was applied. The neurotransmitter octopamine is thought to mimic a starved state in *C. elegans*, and when exogenous octopamine is applied to well-fed worms during cultivation, worms later avoid the cultivation temperature when placed on a temperature gradient. This evidence supports the hypothesis that these neurotransmitters play a role in the associative learning for thermotaxis.

Genes Involved in Thermotactic Learning and Memory

Investigations into this behavioral plasticity have begun to identify some of the genes involved in thermotactic behaviors. The original mutant screens developed to identify genes important for thermotaxis grouped positive mutants into one of three phenotypic categories: thermophilic, worms which migrate to temperatures that are higher than their cultivation temperatures; cryophilic, worms which migrate to temperatures that are lower than their cultivation temperatures; and athermotactic, worms which show no preference for any temperature. This screen identified a plethora of mutants with thermotactic deficits,

such as *tax-2, tax-4, ttx-3*, and *lin-11*, which have mutations in genes that encode cyclic nucleotide-gated channels and transcription factors (Figure 5).

To investigate mutants defective for forming associations between temperature and food a genetic screen was done that looked for worms abnormal for updating their isothermal tracking. From this, three mutants, *aho-1, aho-2,* and *aho-3,* were identified. These mutants show normal thermotaxis when they are cultivated in a well-fed state, but they cannot learn to avoid the cultivation temperature if they are conditioned in a starved state. The deficit exhibited by these mutants implies that these mutations interfere with associating the encoded temperature with the feeding state, but does not interfere with the encoding of the temperature itself. Thus, on top of identifying genes involved in this learning paradigm, this screen also illustrates that the two aspects of thermotaxis exist (the thermal memory and the associative learning).

Several other genes implicated in thermotaxis have been also been identified. One such gene encodes neuronal calcium sensor-1 (NCS-1); *ncs-1* mutants perform cryophilically on the thermotactic learning assay. Selective rescue of NCS-1 in the AIY interneuron led to a full behavioral recovery. Rescue of NCS-1 in AIY with a transgene containing a point mutation in the calcium-binding region did not result in a behavioral recovery, suggesting that intracellular calcium signaling in the AIY interneuron may be important for thermotactic learning. Lastly, *hen-1* (shown to play a role in chemosensory learning) is also involved in thermotaxis learning. Mutants deficient for this gene will migrate to their cultivation temperature independent of the feeding state with which it was previously paired. The involvement of HEN-1 in both chemosensory and thermotactic learning provides support for a role of this protein in general sensory integration.

Conclusion

Investigations into behavioral plasticity in *C. elegans* have demonstrated that this simple worm is capable of many forms of learning and memory in a variety of sensory modalities. Simple forms of learning include chemosensory and mechanosensory habituation and dishabituation. The complex learning behaviors exhibited by the worm include classical conditioning, context conditioning, state-dependent learning, and aversive learning. Several important genes for these behaviors have already been identified and investigations into identifying other genes continue, as do studies attempting to link the molecular mechanisms responsible for learning and memory.

This rich learning and memory repertoire exhibited by *C. elegans* along with its mapped nervous system and fully sequenced genome make it an ideal invertebrate model organism to study learning and memory. Other advantages to using *C. elegans* for this are the plethora of mutants available for analysis, the increasing number of fluorescent fusion proteins for studying protein localization and function, and homology between worms and higher organisms. These all suggest that important findings on learning and memory of general interest are possible and very likely using the worm as a model system.

Learning and Memory in Invertebrates: *Drosophila*

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Much progress has been made in the understanding of learning and memory from the neurobiological investigations in invertebrates. The fruit fly *Drosophila melanogaster*, in particular, offers numerous advantages compared to other model systems for studying learning and memory. Fruit flies are small and relatively inexpensive to culture. These aspects offer the capability of performing behavioral experiments on hundreds or thousands of subjects. The fly has a robust repertoire of behaviors that can be studied. For instances, flies can learn about olfactory, visual, taste, and tactile cues. In addition, the cellular and molecular events underlying learning can be easily related to observable and quantifiable learned behaviors using mutants and transgenic animals. Further genomic studies are now facilitated with knowledge of the complete DNA sequence of the organism. Moreover, recently developed optical imaging techniques have offered a way to peer into the brain of the animal as it learns and to observe changes in the neural activity in populations of neurons due to learning. Finally, to date, studies on genes involved in learning have revealed a remarkable structural and functional conservation of these genes with mammalian counterparts in human and mouse, offering confidence that the molecular principles underlying learning as deduced from the fly are of general importance. In this article, we describe some of the important *Drosophila* learning assays that have been developed and what they have revealed, in conjunction with molecular, cellular, and neuroanatomical tools, about the molecular and cellular biology of learning.

Olfactory Conditioning

Aversive Olfactory Conditioning

Mild electric shock has been generally employed as the aversive stimulus for two general types of aversive olfactory conditioning: operant olfactory conditioning and classical conditioning. The earliest studies employed operant olfactory conditioning in which flies learned to avoid walking into a tube containing a certain odor, after a training session that paired an odor with mild electrical shock as a negative reinforcer. Flies were allowed to run alternatively into one of two plastic tubes that contained different odorants and were shocked in only one of the two tubes and in the presence of only one of the two odors (Figure 1). After training, the flies' memory of the odor with shock versus the control odor was measured by observing their avoidance of walking into fresh tubes containing the same two odors but without shock. This measurement provided an index of selective avoidance, named the performance index, after training to an odor linked with electric shock, and therefore represented an index of olfactory learning. Since the flies were required to move into the chamber in order to experience the odor and shock, this type of conditioning has been classified as operant.

Classical olfactory conditioning is similar but utilizes an odor carried in an airstream moving past the flies, which are contained in a chamber whose floor is composed of an electrifiable copper grid (Figure 1). Using this setup, the odor and shock cues are delivered to the flies rather than having the flies move to the cues. The flies are then transferred to a T-maze where they make a binary choice between the odor associated with electric shock and a control odor. The performance index after one cycle of classical conditioning is much higher than that obtained with olfactory operant conditioning, for reasons that remain unclear. The memory of olfactory classical conditioning after a single cycle of training is generally about a day, but this can be extended to several days by conditioning flies with 5–10 cycles, one right after each other (massed training). Memory is even more prolonged if a rest of 15 min is allowed between each cycle (spaced training).

Numerous single gene mutants have been isolated that have impaired performance after olfactory operant and/or olfactory classical and aversive conditioning. Knowledge of the products of these genes has contributed to three concepts for the physiological basis for olfactory memory formation. First, seven different gene products are elements of the cyclic adenosine monophosphate (cAMP) signaling pathway. The *dunce* gene encodes cAMP phosphodiesterase; *rutabaga*, an adenylyl cyclase; *neurofibromin*, an activator of adenylyl cyclase; *DCO*, the catalytic subunit of protein kinase A; *PKA-R1*, a repressor of protein kinase A; *amnesiac*, a putative neuropeptide activator of adenylyl cyclase similar in sequence to mammalian pituitary adenylyl cyclase-activating peptide (PACAP); and *dCreb*, a transcription factor known as the cyclic AMP response element binding protein that is responsive to alterations in intracellular cAMP levels. Mutants in the first five genes impair acquisition or the formation of short-term memory. The *amnesiac*

Figure 1 Aversive olfactory learning in *Drosophila*. (a) Schematic diagram of the apparatus used for operant olfactory learning. Flies are placed in a start tube and walk up the tube due to negative gravitaxis and positive phototaxis. The five tubes on the top of the apparatus can be slid horizontally so that any one of them is in register with the start tube. Flies are first allowed to walk into the tube containing odor A and electric shock for a period of 30 s. They are then tapped back into the start tube and allowed to walk into the tube containing odor B for 30 s. The animals are then tested by allowing them to walk into a fresh tube containing odor A without shock (tube 4), and the fraction of flies that avoid the odor is recorded. The flies are then tested with odor B in the last tube. Selective avoidance, after training, of the tube containing odor A but not the tube containing odor B is taken as an index of performance. (b) A schematic diagram of the apparatuses used for olfactory aversive classical conditioning. Flies are placed in a tube and odors are drawn through the tube in an air current. Electric shock is delivered when only one of the two odors is passed through the tube. After training, the animals are tested in a T-maze in which they must choose to avoid odor A or odor B, the odors being carried to the choice point in air currents. Modified with permission from John Wiley & Sons, Inc: Roman G and Davis RL (2001) Olfactory learning in *Drosophila*. *BioEssays* 23(7): 571–581. Copyright 2001 by John Wiley and Sons, Inc.

gene is thought to be involved in medium-term memory, and *dCreb*, in long-term memory. The involvement of these gene products provides compelling evidence that olfactory learning occurs, in part, through signaling by the cAMP system, although how specifically this signaling alters the physiology of the neurons involved in learning remains unknown.

The second concept for a physiological basis for olfactory memory formation is that other genes involved in the formation of short-term olfactory learning include *Volado*, which encodes a cell adhesion receptor of the integrin family, and *fasII*, which encodes a cell adhesion receptor of the immunoglobulin superfamily. These genes indicate that cell adhesion and/or signaling through cell adhesion receptors, perhaps at the synapse, are critical for acquisition or the formation of short-term memory. This observation, in retrospect, is not surprising since cell adhesion receptors represent some of the elements needed for proper communication between neurons, but nevertheless, *Drosophila* genetic studies have revealed the specific identify of the molecular players.

Third, the products of several genes required for normal long-term memory are involved in directed transport of ribonucleoproteins and local translation. The *pumilio* gene product participates in microtubule-dependent, subcellular targeting and localized mRNA translation. Protein products of *oskar*, *staufen*, and *eIF-5C* are involved in the translocation of ribonucleoprotein particles to distinct cellular compartments and their local translation. Thus, long-term olfactory memory in *Drosophila* may be served by local translation near synapses using the functions of this set of gene products.

Where in the *Drosophila* brain are olfactory memories formed and stored? The majority of the evidence based on the expression patterns of genes involved in olfactory learning, ablation experiments, neuron-specific disruption experiments, and functional imaging indicates that the mushroom body neurons are principal sites for olfactory memory formation. Blocking the synaptic output of these neurons blocks retrieval, suggesting that the functional changes underlying learning occur upstream of the output synapses of mushroom body neurons. Mutants that impair the formation of one axon branch of the mushroom body neurons, known as the vertical branch, impair long-term but not short-term memory. Thus, long-term memory may form within a specific axon branch of these neurons, or the output of these neurons, to guide behavior from long-term memory, is through this branch. However, other evidence indicates that there are at least two other areas of the brain in which olfactory memories form. Functional imaging studies have revealed that a change, or memory trace, in synaptic transmission after training occurs in the antennal lobe, although this memory lasts for only a few minutes after conditioning. In addition, functional imaging and mutant studies suggest that

the dorsal posterior medial neurons may participate in medium-term memory. Importantly, both the antennal lobe and the dorsal posterior medial neurons innervate the mushroom bodies, consistent with the possibility that all memory retrieval must pass through the mushroom body neurons.

An important recent advance that highlights the utility of *Drosophila* for studying the neurobiology of learning and memory is the development of techniques to control the expression of transgenes in the dimensions of both time and space. It is now possible to express a normal transgene in selected neurons of the nervous system and turn the expression on or off with temperature or by feeding flies the antiprogestin, RU486. This provides the investigator the ability to test whether expression of a wild-type transgene in specific neurons, and only at certain developmental times, is sufficient to rescue the learning impairment associated with mutants. These technologies have been used to show that a wild-type *rutabaga* transgene rescues the learning impairment of *rutabaga* mutants if the transgene is expressed in the adult mushroom bodies. These important experiments prove that the normal *rutabaga* gene functions in a physiological sense in the adult, rather than being involved in some aspect of brain development that impairs learning.

Appetitive Olfactory Conditioning

Drosophila can also learn about olfactory stimuli through their associations with appetitive cues. Like in operant olfactory aversive conditioning, *Drosophila* can be trained by allowing them to run alternatively into one of two plastic tubes that contain different odorants, with sucrose solution in only one of the two tubes, and in the presence of only one of the two odors. After training, the flies' attraction to the odor with sucrose versus the control odor is measured in fresh tubes containing the same two odors but without shock. Classical appetitive olfactory conditioning has also been developed in which the animals receive the olfactory cue just before or simultaneously with sucrose. The latter paradigm has been used to investigate neuromodulatory influences required for aversive versus appetitive conditioning. From these studies, the general conclusion has been formed that dopaminergic innervation of the mushroom bodies is required for aversive conditioning and octopaminergic activity is required for appetitive conditioning.

Visual Learning in the Flight Simulator

Visual conditioning in *Drosophila* has been extensively studied using an experimental setup known as a flight simulator (Figure 2). In this paradigm, a single fly is tethered in mid-air by a wire that is glued to its thorax and/or head. The wire feeds into a torque meter and a negative feedback is established between the fly's yaw torque and the angular velocity of a cylindrical visual panorama that surrounds the animal. As the fly attempts to turn left or right in flight, the negative feedback is translated into rotation of the surrounding visual panorama so that the fly detects environmental movement that simulates appropriate directional changes. A common type of experiment in the flight simulator involves T-shaped patterns that are placed on the cylindrical panorama in either an upright or inverted position. A heat beam from a lamp can be used as a negative reinforcer when the fly heads toward upright Ts and this heat can be turned off when the fly adjusts its flight towards an inverted T pattern. Memory in this paradigm is

Figure 2 *Drosophila* flight simulator. The fly is attached to a torque meter by a thin wire that is glued to its head and/or thorax. The visual panorama surrounding the fly contains a visual cue (either an upright or an inverted T in this diagram) in every one of its four quadrants. Prior to training, flies exhibit no preference for either of the two cues as they fly in different directions. The fly's yaw torque is detected by an attached computer, which controls the angular velocity of the surrounding panorama in a negatively proportional manner. Thus, the panorama rotates and simulates changes in the fly's visual field that would correspond to movements in free flight. During training, a heat beam is directed to the fly's thorax and abdomen. The beam is turned on or off at the boundaries between quadrants that contain specific visual patterns using a shutter system that opens and closes based on the angular position of the panorama. Flies can be trained to associate an upright T, for example, with an aversive heat stimulus. After training, even with the heat turned off, flies will avoid the heat-reinforced quadrants and exhibit a preference for those quadrants that contain the visual cue that was not associated with heat. Reprinted by permission from Macmillan Publishers Ltd: [Nature] Liu L, Wolf R, Ernst R, et al. (1999) Context generalization in *Drosophila* visual learning requires the mushroom bodies. *Nature* 400: 753–756, copyright [1999].

measured as the tendency for the fly to avoid the heat-reinforced visual pattern after discontinuing the heat contingency.

Drosophila learning in the flight simulator is thought to be a combination of both classical and operant conditioning. The learning is operant in the sense that the fly controls heat reinforcement by its motor behaviors and classical in that the visual cues function as conditioned stimuli, with heat as the aversive unconditioned stimulus. Experiments to dissect the contributions of each type of learning have been performed. In a flight simulator without visual cues, flies can be punished with heat when they make either right- or left-hand turns. Their continued avoidance to make the turn associated with the reinforcer illustrates memory of this operant task. If the flight simulator is set so that the fly's movements are disconnected from controlling the environment, the flies can be trained to associate the visual cues of T patterns with heat, independent of their motor actions. In essence, the operator controls what the fly sees directly ahead and whether heat is provided or not. During testing, the torque meter is reconnected and the flies exhibit avoidance of the heat-reinforced patterns, thus exhibiting classical conditioning. Similar to olfactory associative conditioning, repeated training using a spaced protocol yields a long-term memory that is protein-synthesis dependent. Likewise, flies can exhibit an anesthesia-sensitive short-term memory lasting up to 20 min and an anesthesia-resistant memory from 20 min to 3 h.

Studies of visual learning in the flight simulator have provided several interesting findings regarding *Drosophila* visual learning and memory. The role of context, which is composed of stimuli of different modalities, has been investigated for this paradigm. For instance, changing the background illumination between the training and testing phases – from white to a monochromatic color, say blue or green, or from unpatterned white light to white light interspersed with dark stripes – produces no discernible effect on the performance of the flies. These experiments show that flies are capable of learning discrete pattern elements in different contexts. In other words, they exhibit context generalization. However, removing the mushroom bodies impairs the flies' ability to generalize such that they display memory only when tested in the same context as the initial training. Thus, mushroom bodies are required for context generalization. The importance of mushroom bodies has also been studied in *Drosophila* choice behavior. Flies can use both color and shape cues simultaneously in visual learning. However, when faced with a color/shape dilemma, for example, being trained to associate punishment with an upright blue T but having to choose between an upright green T or an inverted blue T during the test phase, the fly makes a discrete and firm choice based on the saliency of the visual cues. At low color intensities, the fly uses shape as the cue, whereas at high color intensity its decision is based on color. Mutant flies with absent or malformed mushroom bodies are unable to make a discrete choice for the more salient stimulus. Thus, while the mushroom bodies are dispensable for simple forms of visual learning using the flight simulator, they have a role in more complex tasks that require flies to evaluate the relative importance of different features of a complex visual environment.

The roles for other brain structures in visual learning have also been studied. Flies in the flight simulator analyze visual cues based on at least five different pattern parameters: size, color, elevation in the panorama, vertical compactness, and contour orientation. It has been demonstrated that a small group of neurons in the fan-shaped body of the central complex of *Drosophila* is important in short-term memory for the pattern parameters of 'elevation' and 'contour orientation.' The adenylyl cyclase encoded by the *rutabaga* gene is required in this brain region for flies to learn specific visual patterns. Specifically, restoring *rutabaga* function in fan-shaped body neurons that extend into layer 5 of *rutabaga* mutant flies rescues the memory defect for pattern elevation. Likewise, expression of a constitutively activated form of $G\alpha_s$ protein subunit in this brain region is sufficient to abolish the fly's memory for pattern elevation. Using a similar approach, memory for the pattern parameter of 'contour orientation' is restored in *rutabaga* mutants when a wild-type *rutabaga* transgene is expressed in neurons that extend into layer 1 of the fan-shaped body. These discoveries using the flight simulator provide encouraging initial clues toward understanding the circuitry that underlies visual pattern recognition.

Most learning paradigms used in the laboratory are used to deconstruct and reduce the learning that takes place into separable cues. However, this does not occur in nature. Another interesting discovery using the flight simulator involves crossmodal interactions in *Drosophila* learning. By adding olfactory cues during visual learning in the flight simulator it has been shown that concurrent visual and olfactory cues (bimodal conditioning) reduce the threshold for either visual or olfactory cues during memory retrieval. Furthermore, flies exhibit crossmodal memory transfer wherein sensory preconditioning of flies by simultaneous exposure to color and shape cues without reinforcement, followed by training using only a

single cue, leads to transfer of memory of one cue for the other. For example, flies simultaneously preexposed to odor and a visual cue, followed by conditioning by pairing heat punishment with the visual cue, can learn to avoid the olfactory cue that was associated with the visual cue in the preconditioning step. Sensory interactions like these may be important for fly learning in a natural environment.

Courtship Conditioning

Another type of learning that occurs within the normal behaviors of sexual courtship is courtship conditioning. Courting males perform a characteristic sequence of behaviors that includes orienting toward and following a female, tapping her with his forelegs, vibrating one wing, licking her genitalia, and mounting. Virgin females are generally receptive and quickly accept these advances of a male. If a male *Drosophila* is paired with a female that has already been courted and fertilized by another male, however, the female will reject the advances of the new male. This experience decreases the subsequent courtship activity of the rejected male so that the rejected male will not court other young virgin females for time periods that depend upon the strength of the initial courtship activity that led to rejection. If the male is paired with the fertilized female for a period of 1 h, courtship suppression lasts for 2–3 h afterwards. If the male experiences the fertilized female for 5 h, courtship suppression can persist for up to 1 week. Experience-dependent courtship suppression is an associative form of learning because it requires the presence of the trainer fly (usually a fertilized female) and associated aversive pheromones emitted by the mated female.

Mushroom bodies are also involved in the memory of courtship conditioning. Male flies missing their mushroom bodies due to chemical ablation suppress their courtship like control males do immediately after training with a fertilized female, but begin courting again about 30 min after the experience. Thus, mushroom bodies are required for memory after 30 min when trained with a fertilized female for a period of 1 h. Flies without mushroom bodies that receive extended training of 5 h exhibit no memory when tested 1 day (or more) later, suggesting that mushroom bodies are required for long-term memory after extended conditioning.

However, these specific effects of mushroom body ablation on later memory are observed only when the animals are trained in the light. If training is performed in dim red light, which flies do not detect very well, immediate memory tested within a few minutes after training is also impaired. These results are compatible with the model that courtship conditioning employs both visual and olfactory pathways, and in the absence of the visual pathway (dim red light), mushroom body ablation disrupts the major sensory pathway necessary for memory. In the presence of light, mushroom body-less flies are less amnestic, because memory traces presumably exist in the visual system and partially compensate for the impairment in the olfactory pathway. Studies of mutants and flies expressing dominant negative transgenes have revealed a requirement for *dunce*, *rutabaga*, *amnesiac*, and calcium/calmodulin-dependent kinase II for normal courtship conditioning.

Heat-Box Learning

Insects do not internally control body temperature and therefore have body temperatures that closely approximate the ambient temperature of their environment. Rapid modifications of behavior are therefore critical to avoid extreme fluctuations in body temperature that could produce death. *Drosophila* are able to sense local differences in temperature, preferring 24 °C and avoiding higher and lower temperatures when tested in a heat gradient. They are also very sensitive to temperature fluctuations and can adjust their behavior in less than a minute to avoid temperature fluctuations of more than a few degrees celsius. Using an apparatus called a heat box, *Drosophila* researchers have shown that flies are able to learn place or position.

The heat box (**Figure 3**) is a laterally transparent rectangular chamber with Peltier elements comprising the upper and lower surfaces. The Peltier elements are kept at a permissive temperature (25 ± 2 °C) or are heated to a higher restrictive temperature (usually 37 ± 2 °C) using a computerized control circuit. The chamber is divided into two halves using a directionally selective infrared light gate, invisible to the fly, which monitors whether the fly is in one or the other half. The clear plastic sides allow the transmission and detection of infrared light, and when the fly walks the length of the chamber it casts a shadow on the light gate array and a computer detects this signal.

For heat-box training, a single fly is allowed to walk freely between the two halves in complete darkness. When the fly enters one side of the chamber, the whole chamber is heated to the elevated temperature, and when the fly runs back to the other side, the chamber is cooled to the lower temperature. Flies learn from this experience, within minutes, to avoid the side of the chamber that elevates temperature. Memory of this experience is displayed by continued

Figure 3 *Drosophila* place learning paradigm in the heat-box. Schematic of the heat-box learning assay. During the pretest, single flies are allowed to walk freely in the chamber. During training, the whole chamber heats to the restrictive temperature whenever the fly walks into a predesignated 'punished' half (the left half in this diagram). A photodetector at the middle of the chamber sends a signal to a computer whenever the fly moves from one side to the other, which subsequently controls the Peltier elements that control chamber temperature. The whole chamber cools to the permissive temperature when the fly returns to the unreinforced side. Memory is tested following training in the absence of reinforcement, during which normal flies exhibit a preference for the unreinforced side. Adapted with permission from Cold Spring Harbor Laboratory Press: Putz G and Heisenberg M (2006) Memories in *Drosophila* heat-box learning. *Learning & Memory* 9: 349–359. Copyright 2006 by Cold Spring Harbor Laboratory Press.

avoidance of the punished side even in the absence of the heat contingency.

This operant conditioning paradigm yields significant place memory for up to 2 h after training, which is dependent on tactile and self-derived idiothetic cues, probably based on walking steps and turns that allow the flies to orient themselves in the chamber. The place memory is independent of visual and olfactory stimuli. Flies lacking mushroom bodies have normal place memory. However, *rutabaga* mutants are impaired in the task, indicating a requirement for adenylyl cyclase activity outside of the mushroom bodies.

Introduction

An understanding of fundamental mechanisms of learning and memory is a major challenge for neuroscience. Well-documented descriptions of how learning is expressed in the generation of behavior have been especially difficult to obtain from studies of complex nervous systems. A strategy that has been productive in addressing these issues is to examine learning at both the behavioral and the cellular/molecular levels in animals with relatively less complex nervous systems. Using Pavlovian conditioning of invertebrates as a model for associative learning has led to the identification of cellular and synaptic mechanisms underlying the formation of basic associations. However, an understanding of associative processes underlying Pavlovian conditioning requires an explanation of not only the mechanisms of temporal contiguity and/or predictability between the conditioned stimulus (CS) and unconditioned stimulus (US), but also how conditioning-dependent changes in the relevant neural circuitry of the nervous system are expressed in the generation of the conditioned response (CR). Studies with invertebrates have provided the opportunity to examine how mechanisms of associative learning are expressed in the neural circuitry supporting the generation of learned behavior.

The nudibranch mollusk *Hermissenda crassicornis* has contributed to an understanding of Pavlovian conditioning at the cellular, molecular, and systems level. The *Hermissenda* central nervous system is relatively simple, which provides for the opportunity of studying modifications in identifiable neurons in the neural circuitry that supports conditioning. Identified neurons in the CS pathway have been studied in detail using biochemical, biophysical, and molecular techniques. The two sensory structures mediating the CS and US are central and thus their synaptic projections remain totally intact after surgical isolation of the nervous system or in experiments using semi-intact preparations. Studies of semi-intact preparations provide for the opportunity to examine the development of CS–US associations at identified sites in the nervous system and their contributions to the expression or generation of behavior. Mechanisms of CS–US contiguity have been identified and have been the focus of biophysical, biochemical, and molecular analyses. Recent studies have led to the identification of neurons that contribute to the neural circuitry supporting both the unconditioned response (UR) and the CR. Since conditioning can be studied in semi-intact preparations, an understanding of how Pavlovian conditioning is expressed in the generation of the CR is now feasible.

Pavlovian Conditioning

Pavlovian conditioning of *Hermissenda* involves stimulation of visual and graviceptive sensory pathways. The conditioning procedure consists of pairing light, the CS, with rotation or orbital shaking, the US. Rotation of the statocyst, the gravity-detecting organ, is an adequate stimulus for evoking depolarizing generator potentials and an increase in spike activity in the primary graviceptive sensory neurons, the hair cells. Two unconditioned responses, a reduced rate of forward locomotion and reflexive foot-shortening are elicited by rotation. Therefore, Pavlovian conditioning in *Hermissenda* results in the acquisition of two different CRs: inhibition of light-elicited locomotion and CS-elicited foot-shortening (see Figure 1). Dark-adapted *Hermissenda* exhibit a well-documented positive phototaxic response to illumination. Conditioning produces both light-elicited inhibition of the normal positive phototaxis and CS-elicited foot-shortening. Inhibition of phototaxis produced by conditioning is expressed by a light-dependent inhibition in the initiation of locomotion and a reduced rate of forward locomotion in light (see Figure 1). The two CRs are proposed to develop independently, which is in agreement with recent cellular studies showing that the URs involve different components of the neural circuitry responsible for foot contraction and ciliary locomotion. In this example of associative learning, both conditioning-dependent modifications of synaptic function and intrinsic cellular excitability in identified components of the neural circuit supporting ciliary locomotion result in the generation of the CR, phototaxic inhibition.

Conditioning in the two different behavioral response systems supporting the two CRs is sensitive to both CS–US contiguity and forward interstimulus-interval manipulations. Moreover, both foot contraction and inhibition of phototaxis produced by conditioning involve the development or emergence of a new response to the CS, not the potentiation (through US presentations) of an already existing response to the CS, referred to as reflex potentiation

Figure 1 Pavlovian conditioning of foot-shortening and phototaxic inhibition in *Hermissenda*. (a) Foot length in light (conditioned stimulus; CS) before conditioning. (b) Conditioned response, foot-shortening elicited by the CS. Red outline indicates foot length in light before conditioning. (c) Light-elicited locomotion toward a light source (phototaxis) assessed before conditioning. (d) Inhibition of light-elicited locomotion detected after Pavlovian conditioning. Random or pseudorandom presentations of the CS and the unconditioned stimulus produce neither inhibition of phototaxis nor CS-elicited foot-shortening. Copyright 2004 by Cold Spring Harbor Laboratory Press.

or alpha conditioning. In both of the CRs there is a transfer of functional aspects of the response-evoking properties of the US to the CS. This important characteristic of Pavlovian conditioning may be expressed in *Hermissenda* due to the increased complexity of the circuit supporting the CS and US, the multiple sites of convergence in the CS–US pathways, and multiple synaptic interactions within the neural network supporting the generation of behavior.

Primary Sensory Neurons of the CS and US Pathways

The morphology and physiology of the two sensory structures that are stimulated by the CS and US have been described in detail. In addition, the convergence sites providing for synaptic interactions between the CS and US pathways have been identified and examined using intracellular recording techniques.

Photoreceptors

Each eye of *Hermissenda* contains five photoreceptors: three classified as type B and two as type A. The general classification of photoreceptors can be identified further based upon their location within the eye. There are medial and lateral A and B photoreceptors and one central B photoreceptor. The synaptic connections between type B photoreceptors and between type B and type A photoreceptors are in the neuropil of the cerebropleural ganglion, and the synaptic interactions between type B photoreceptors are mutually inhibitory. The photoreceptors of *Hermissenda*, like many invertebrates, are both sensory transducers and spike generators. Light produces a depolarizing generator potential and an increase in spike activity in both type A and type B photoreceptors.

Hair Cells

The sensory structures stimulated by the US are the two central gravity-detecting statocysts. Each statocyst contains 13 hair cells whose cell bodies are located around the perimeter of the statocyst. Hair cells that are located in opposite positions in the statocyst are mutually inhibitory. Statocyst hair cells contact calcium carbonate particles, referred to as statoconia, by interactions with motile cilia that project into the lumen of the statocyst from the apical region of the somas. Rotation or gravity causes the statoconia to press against the motile cilia of hair cells in front of the centrifugal or gravitational force vector, resulting in a depolarizing generator potential and an increase in spike activity. Like the photoreceptors, statocyst hair cells are sensory transducers and support the generation of action potentials.

Interneurons in the UR Pathway

Statocyst hair cells project to photoreceptors and three identified types of interneurons located in the cerebropleural ganglia. Hair cells form monosynaptic connections with both photoreceptors and type I_e and type I_i interneurons. In addition, hair cells project polysynaptically to type I_b interneurons. Type I_e and

type I_i interneurons project polysynaptically to type III_i inhibitory interneurons, and type III_i interneurons inhibit ciliary activating motor neurons. In summary, rotation or orbital shaking, the US, depolarizes statocyst hair cells, resulting in excitation of type I_e interneurons, which produces excitation of type III_i inhibitory interneurons that inhibit or decrease the spike activity of ciliary motor neurons. Therefore, an increase in the spike activity of type III_i interneurons results in inhibition of ciliary locomotion. Activation of the identified components of the circuit supporting the US provides an explanation of the effect of rotation on ciliary locomotion.

Convergence of the CS and US Pathways

There are multiple sites of synaptic interactions between cells in the CS and US pathways. The initial site of convergence between the CS and US is at the primary sensory neurons of the visual and graviceptive pathways. The synaptic projections from statocyst hair cells to the photoreceptors are both monosynaptic and polysynaptic. Hair cells and photoreceptors form reciprocal monosynaptic inhibitory connections. Caudal hair cells inhibit photoreceptors, and cephalic hair cells are inhibited by type B photoreceptors. The second site of convergence between the CS and US pathways involves aggregates of identified interneurons in the cerebropleural ganglia. The synaptic organization of the interneurons that make up the convergence site between the visual and graviceptive pathways has now been characterized. Photoreceptors and hair cells project to aggregates of 'on' and 'off' cells designated as type I_e and type I_i cerebropleural interneurons (see Figure 2). An additional site of convergence between the CS and US pathways is the type I_b interneurons that form monosynaptic connections with foot contractile motor neurons and ciliary-activating motor neurons.

Figure 2 Intrinsic changes in synaptic efficacy and excitability in the components of the conditioned stimulus–conditioned response (CS–CR) pathway supporting Pavlovian conditioning of *Hermissenda*. Changes in both synaptic efficacy and cellular excitability contribute to CS-elicited inhibition of ciliary locomotion. Inserts a–f: Neural activity from a conditioned preparation (red), and a pseudorandom control (green). (a) The CS evokes a larger generator potential in sensory neurons (SN) (type B-photoreceptors) of conditioned animals as compared to pseudorandom controls. (b) Conditioning results in intrinsic enhanced excitability of SNs. (c) The monosynaptic excitatory postsynaptic potential in type I_e interneurons (IN) is facilitated in conditioned animals. (d) The monosynaptic inhibitory postsynaptic potential in type I_i interneurons is facilitated in conditioned animals. (e) Conditioning results in intrinsic enhanced excitability of type I_e interneurons. The net effect of the changes in synaptic efficacy and intrinsic enhanced excitability results in an increase in CS-elicited spike activity of type III_i interneurons, which produces an inhibition of ciliary motor neuron activity. (f) The CS inhibits spike activity in ciliary motor neurons (MN) and produces an increase in spike activity recorded from motor neurons of pseudorandom controls. The inhibition of ciliary motor neurons produces phototaxic inhibition in conditioned animals. Note: the broken connections between type I interneurons and the type III_i interneurons indicate an established polysynaptic projection. A monosynaptic connection between type I and type II interneurons, and type II and type III interneurons, has not been established. Cellular and Molecular Mechanisms of Conditioning in Sensory Neurons and Interneurons Contributing to Pavlovian Conditioning in *Hermissenda*

The primary sensory neurons of the CS pathway (photoreceptors) and type I interneurons are identified sites of plasticity involving both intrinsic enhanced excitability and synaptic facilitation. Cellular correlates of conditioning in type B photoreceptors are expressed by enhancement of the CS-elicited generator potential and increased CS-evoked spike frequency, increased excitability to extrinsic current, modification of light-dependent, Ca^{2+}-dependent, and voltage-dependent membrane currents, and increased phosphorylation of several identified proteins. In addition to changes in primary sensory neurons, facilitation of monosynaptic and complex postsynaptic potentials (PSPs) in type I_e and type I_i interneurons is

produced by conditioning. The increased amplitude of the CS-elicited generator potential and the increase in the number of action potentials elicited by the CS are major contributors to the increased duration and amplitude of CS-elicited complex PSPs and modifications in spike activity in type I interneurons of conditioned preparations. However, the facilitation of the amplitude of monosynaptic PSPs between type B photoreceptors and type I_e and type I_i interneurons may involve both pre- and postsynaptic mechanisms (Figure 2). In addition to synaptic facilitation of the connections between B photoreceptors and type I interneurons, type I_e interneurons also express intrinsic enhanced excitability (Figure 2).

Signal Transduction Pathways

Signal transduction pathways contributing to the modifications of excitability and synaptic efficacy in type B photoreceptors of conditioned animals involve protein kinase C (PKC), extracellular signal-regulated protein kinase (ERK), cyclin-dependent kinase 5 (Cdk5), and Rho GTPase activity and its downstream target, ROCK.

Light (CS) and rotation (US) have spatially separate physiological consequences in type B photoreceptors. However both the CS and US increase cytosolic Ca^{2+} levels. Light activates phospholipase C (PLC) to produce inositol trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 opens rhabdomeric Na^+ and Ca^{2+} channels, which results in a depolarizing generator potential and Ca^{2+} influx into the photoreceptors. IP_3 can also bind to its receptor (IP_3R), which triggers Ca^{2+} release from the smooth endoplasmic reticulum (ER). The Ca^{2+} influx from the rhabdomeric and the IP_3R-gated storage compartment can cause Ca^{2+} release from the ryanodine receptor-gated compartment. Rotation (US) elicits a monosynaptic GABAergic inhibitory postsynaptic potential (IPSP) in photoreceptors. The US is also proposed to activate a serotonergic polysynaptic pathway that enhances type B photoreceptor excitability. The GABAergic IPSPs in photoreceptors activate phospholipase A_2 (PLA_2) to liberate arachidonic acid (AA) and create a back-propagating wave of Ca^{2+} released from intracellular stores. When the CS and US are repeatedly paired, the Ca^{2+} influx, due to light, IP_3R stores, RyR stores, and voltage-gated Ca^{2+} channel activation sum together. The large increase in cytosolic Ca^{2+} combined with DAG and AA act to synergistically activate PKC by translocation of PKC to the membrane. Each pairing of the CS and US may thus incrementally increase the proportion of PKC translocated to the membrane. Activation of PKC is necessary for the induction of plasticity in *Hermissenda* and contributes to the phosphorylation of proteins in sensory neurons associated with conditioning. Downregulation of PKC or pretreatment with kinase inhibitors blocks the induction of short-term excitability, but not long-term excitability, suggesting the involvement of other signaling pathways. ERK, Cdk5, and the Rho/ROCK signaling pathways have been investigated in conditioned *Hermissenda*. One-trial and multitrial Pavlovian conditioning results in the activation and phosphorylation of ERK. The increased phosphorylation of ERK is blocked by pretreatment with an inhibitor of ERK-activating kinase. Serotonin, a proposed transmitter in the US pathway, also activates ERK through both a Ca^{2+}-dependent PKC pathway and a PKC-independent pathway. Rho GTPase activity and its downstream target, ROCK, contribute to the phosphorylation of a protein (cytoskeleton-related protein 24; Csp24) contributing to intermediate-term memory (see next section). Cyclin-dependent kinase 5 (Cdk5) is also involved in Csp24 phosphorylation. Inhibition of ROCK by the ROCK inhibitor Y-27632 significantly increases Csp24 phosphorylation. The Rho activator lysophosphatidic acid (LPA) or the Cdk5 inhibitor butyrolactone decreases Csp24 phosphorylation. Treatment of the nervous system with LPA activates Rho, while exposure to serotonin decreases Rho activity. The relationship between Rho GTPase activity and Cdk5 activity and enhanced excitability has not been established.

Proteins Regulated by Pavlovian Conditioning

Two proteins that are associated with conditioning in *Hermissenda* are regulated by conditioning-dependent phosphorylation. Calexcitin (CE) is a GTP- and Ca^{2+}-binding protein that can decrease K^+ currents in type B photoreceptors and may increase cytosolic Ca^{2+} concentration. CE is phosphorylated by PKC, and increased CE levels in B photoreceptors of conditioned animals results in increased excitability via K^+ channel inactivation and Ca^{2+} release from the ER due to increased CE binding to ryanodine receptors. A second protein regulated by conditioning is cytoskeleton-related protein 24, a member of the family of β-thymosin repeat proteins (i.e. proteins that contain multiple actin-binding domains). Csp24 is found throughout the circumesophageal nervous system and in the soma, axon, and terminal processes of type B photoreceptors. Actin is bound by Csp24, and actin binding is regulated in part by PKC phosphorylation of Csp24. The Rho/Rock and Cdk5 signaling pathways also contribute to the regulation of Csp24 phosphorylation. Csp24 is phosphorylated by one-trial and multitrial Pavlovian conditioning, and downregulation of Csp24 expression by an antisense oligonucleotide blocks the development of intermediate-term enhanced excitability associated with one-trial conditioning in identified type B photoreceptors. In isolated

photoreceptors, one-trial *in vitro* conditioning results in a reduction in the amplitude of the A-type transient K^+ current (I_A) and a depolarized shift in the steady-state activation curve of I_A without altering I_A inactivation. The conditioning-dependent reduction in I_A can be blocked by preincubation of isolated photoreceptors with a *Csp* antisense oligonucleotide. The regulation of Csp24 by conditioning may influence K^+ channel activity by the spatial and temporal control of actin dynamics.

Circuitry Supporting the Generation of the CR

Many marine mollusks exhibit a gliding form of locomotion produced by the movement of motile cilia on the surface of the foot. Animals are propelled forward by the movement of the cilia between a mucus film secreted from the foot and the underlying substrate. Studies in semi-intact *Hermissenda* preparations have shown that statocyst hair cell-mediated foot contraction and graviceptive ciliary locomotion involve different interneuronal circuit components from the circuit that supports light-elicited ciliary locomotion. The major components of the neural circuit underlying light-elicited ciliary locomotion in *Hermissenda* are shown in the diagram in Figure 2. Only one of the five photoreceptors in each eye, the lateral type B, is shown in the circuit. However, each identified type B and type A photoreceptor forms monosynaptic connections with different aggregates of 'on–off' cells; the type I_e and type I_i interneurons. Each photoreceptor projects to its own aggregate of at least two type I_e interneurons, and two type I_i interneurons. The synaptic connections between photoreceptors and type I interneurons are monosynaptic. The next component in the CR circuit involves converging polysynaptic projections from the type I interneurons to a type III_i inhibitory interneuron (see Figure 2). A direct monosynaptic connection between type I and type II interneurons, or type II interneurons and type III_i interneurons, has not yet been established. However, extrinsic current stimulation of type I interneurons evoke PSPs recorded in type III_i interneurons and ciliary motor neurons. Therefore, synaptic convergence from both I_e and I_i interneurons is found at the level of type III_i interneurons. Type III_i interneurons form monosynaptic inhibitory connections with identified ciliary motor neurons.

How does illumination modulate the spike activity of ciliary motor neurons? Illumination of the photoreceptors decreases the frequency of IPSPs recorded from identified ciliary motor neurons. The CS, light, regulates the activity of ciliary motor neurons by hyperpolarizing type I_i interneurons ('off' cells) and depolarizing type I_e interneurons ('on' cells). The integration of synaptic input from type I interneurons results in a net decrease in the spike activity of type III_i inhibitory interneurons during light. The decreased spike activity of type III_i inhibitory interneurons during the CS decreases the inhibition of ciliary motor neurons by type III_i interneurons, resulting in an increase in motor neuron spike activity and an increase in ciliary activity on the foot. In an untrained or normal animal, the light-induced hyperpolarization of type I_i interneurons is more effective in decreasing the frequency of IPSPs in ciliary motor neurons than is the concomitant excitation of type III_i interneurons provided by light-induced excitatory input from depolarized type I_e interneurons. Therefore, the effect of light on the activity of ciliary motor neurons is an increase in spikes and increased ciliary movement.

Conditioning-dependent reconfiguration of the neural circuitry underlying light-elicited ciliary locomotion has now been analyzed. Pavlovian conditioning produces changes in both intrinsic excitability and synaptic function in identified photoreceptors. Conditioning results in a significant increase in CS-elicited spike activity in type I_e interneurons as compared to type I_e spike activity of controls that receive independent random presentations of the CS and US with the restriction that the two stimuli could not overlap in time (i.e., pseudorandom). CS-evoked complex EPSPs in type I_e interneurons following conditioning are larger in amplitude and exhibit a greater frequency of smaller EPSPs in conditioned preparations as compared with type I_e complex EPSPs recorded from pseudorandom controls. The monosynaptic EPSP in type I_e interneurons elicited by a single spike in a lateral B photoreceptor is facilitated in conditioned animals as compared to pseudorandom controls. Similar synaptic changes (facilitation) occur in type I_i interneurons in conditioned animals as compared to pseudorandom controls. The CS elicits a significantly larger amplitude complex IPSP recorded in type I_i interneurons of conditioned animals as compared to pseudorandom controls. The greater inhibition of type I_i interneurons evoked by the CS produces a significant decrease in spike activity of type I_i interneurons relative to pseudorandom controls. Therefore, the effect of light on the spike activity of type I_i interneurons results in a greater decreased excitation of type III_i interneurons in conditioned animals. Taken collectively, the conditioning correlates detected in type I interneurons can be explained by well-documented intrinsic changes in the type B photoreceptors. The increase in the amplitude of the complex PSPs in type I interneurons may be due to both the light-evoked enhanced excitability of the

photoreceptors produced by conditioning and the facilitation of the monosynaptic PSPs between lateral B photoreceptors and type I interneurons. However, postsynaptic changes intrinsic to type I interneurons could also contribute to the modifications of type I interneurons detected in conditioned animals. Intrinsic excitability of type I_e interneurons is enhanced in conditioned animals as compared to pseudorandom controls. The intrinsic enhanced excitability potential of type I_e interneurons detected in conditioned animals increases the frequency of IPSPs recorded in type III_i interneurons produced by light-evoked depolarization of the type I_e interneurons. In contrast to the effects of enhanced excitability in I_e interneurons with conditioning, the light-evoked hyperpolarization of type I_i interneurons observed before conditioning decreases spike activity of type III_i interneurons and produces a decrease in IPSP frequency of ciliary motor neurons. Extrinsic current stimulation of I_e interneurons in conditioned animals results in more IPSPs recorded in ciliary motor neurons as compared to pseudorandom controls. The increase in the number of IPSPs detected in ciliary motor neurons can be accounted for by the increase in the number of spikes in type III_i interneurons produced by the increased excitation of type I_e interneurons of conditioned animals as compared to controls. Extrinsic current stimulation of I_e interneurons produces a significant increase in IPSP frequency in ciliary motor neurons of conditioned animals relative to controls. Therefore, the presentation of the CS in conditioned animals results in a decrease in ciliary motor neuron spike activity and an inhibition of firing during the light (**Figure 2**). In contrast, pseudorandom controls exhibit an increase in spike activity recorded in ciliary motor neurons during the light.

In summary, a combination of intrinsic excitability changes and modifications in synaptic function at specific loci in the circuit responsible for light-dependent ciliary locomotion is involved in the generation or expression of the CR elicited by the CS. Before conditioning, the light-dependent inhibition of type I_i interneurons is very effective in regulating IPSP frequency of ciliary motor neurons and their subsequent firing. Indeed, the net effect of light-dependent excitation of type I_e interneurons and light-dependent inhibition of type I_i interneurons is a decrease in IPSP frequency of ciliary motor neurons, an increase in their spike activity, and increased ciliary movement. The induction of intrinsic enhanced excitability of type I_e interneurons produced by conditioning reconfigures the neural circuit such that light, the CS, now increases IPSP frequency in ciliary motor neurons, which leads to a decrease in their spike activity during illumination and inhibition of phototaxis.

Conclusions and Discussion

The research focused on how Pavlovian conditioning is expressed in the generation of phototactic behavior in *Hermissenda* involves the identification of the neural circuit controlling ciliary locomotion and its modulation by light (CS) and graviceptive input (US). The analysis of Pavlovian conditioning in the neural circuit generating ciliary locomotion indicates that both enhanced cellular excitability and synaptic facilitation are expressed in identified circuit components at different loci within the network. The distributed nature of cellular and synaptic plasticity associated with this example of Pavlovian conditioning suggests that an adequate explanation of conditioned behavior requires both an analysis of neural circuits and the identification of mechanisms of CS–US contiguity at convergence sites between the CS and US pathways. Consistent with the view that learning may initially involve changes in preexisting synaptic connections, inhibition of phototaxic behavior produced by conditioning involves modifications of existing synaptic connections between photoreceptors and identified type I interneurons. However, the potential formation with conditioning, of new connections between neurons in the neural circuit modulating ciliary locomotion or CS-elicited foot contraction cannot be dismissed.

The analysis of conditioning correlates has revealed that the first site of intrinsic cellular and synaptic plasticity is at the initial site of convergence between the CS and US pathways, the primary sensory neurons of the CS pathway. The mechanisms of temporal contiguity between the CS and US involve both enhanced cellular excitability and enhanced synaptic strength. The changes in photoreceptor excitability produced by conditioning involve reductions in several well-characterized K^+ conductances in type B photoreceptors. The second site of intrinsic enhanced excitability is the type I_e interneurons. An analysis of membrane conductances underlying enhanced excitability intrinsic to type I_e interneurons has not yet been undertaken. The cellular and synaptic changes identified following conditioning are distributed at several loci within the network and therefore are not localized to a single synaptic site or neuron. The distributed nature of learning-dependent changes in the neural circuit responsible for the expression of the CR may account for the complexity of Pavlovian conditioning in *Hermissenda*, specifically the emergence of a new response to the CS following conditioning.

Learning and Memory in Invertebrates: Honey Bee

R Menzel, Freie Universität Berlin, Berlin, Germany

© 2009 Elsevier Ltd. All rights reserved.

The social life of the honeybee colony forms the evolutionary framework for the individual animal's behavior and is crucial for the survival of each bee. Social bees are exposed to a large and unpredictable range of environmental conditions, and thus learning plays an important role both in the social context and in individual adaptations. The location of the nest site needs to be learned because individual bees cannot survive. Changes to the society's conditions have to be recognized and used to control individual behavior. Communication about potential nest sites and food, water, and resin resources involves a sophisticated behavioral routine – the waggle dance – during which receivers of the information learn about the location and the quality of the respective resource.

Most studies of learning in bees have focused on operant learning in the context of food collection and on appetitive olfactory conditioning of a response, the proboscis extension response (PER). When a searching bee discovers a source of sucrose solution (under natural conditions, nectar), it quickly learns to associate the surrounding visual and olfactory signals with the reward. Acquisition functions indicate that olfactory stimuli (e.g., floral odorants) are learned within one or two learning trials, colors within one to five learning trials, and black-and-white patterns from the fifth learning trial on. Most of this learning is forward conditioning because signals perceived before the reward are associated, whereas those perceived during the reward or departure flight are associated less effectively or not at all. However, stimuli in the further vicinity of the reward localization are also learned after feeding.

Reversal learning, overlearning, and multireversal learning are effective learning phenomena in the bee, as they are for other animals. The experimental procedures that test the ability of an animal to adapt its performance to reward schedules are continuous reinforcement (CR), fixed-ratio reinforcement (FR), and fixed-interval reinforcement (FI) schedules. Bees develop a higher resistance to extinction in an FR than in a CR schedule. In an FI schedule of reinforcement, bees exhibit lower response rates than in an FR schedule. FR schedules of up to one reinforcement out of 30 trials, and FI schedules with up to 90 s between reinforcements are reached after several days of training. Additional operant learning phenomena in honeybees have been studied in the tradition of experimental psychology.

Visual Stimulus Categorization

Categorization refers to the classification of perceptual input into defined functional groups. Categorization has been studied in free-flying honeybees trained to different visual stimuli (e.g., pattern orientation or bilateral symmetry). In the tests, bees were presented with novel patterns which belonged to the same category with regard to pattern orientation or symmetry. In such transfer tests, bees chose the appropriate patterns despite the novelty of the structural details. Interestingly, bees trained for symmetry chose the novel symmetric stimuli more frequently and came closer to and hovered in front of them longer than bees trained for asymmetry did for the novel asymmetric stimuli. It was thus suggested that bees have a predisposition for learning and generalizing toward symmetry. Such a predisposition can either be innate (and could facilitate a better and faster learning about stimuli that are biologically relevant) or be based on the transfer of past experience from predominantly symmetric flowers in the field.

The cases of categorical learning studied so far (orientation and bilateral symmetry of patterns) have been interpreted to demonstrate that bees focus their attention on a single feature at a time (orientation or bilateral symmetry) to solve the problem. In fact, it has been repeatedly argued that due to limited cognitive capabilities, bees are able to focus only on a single isolated feature at a time and cannot therefore attain levels of stimulus classification such as configural categorization as exhibited by humans. Recently, it was shown that a further level may exist in honeybee visual categorization. In addition to focusing on a single feature, honeybees were shown to assemble different features to build a generic pattern representation, which could be used to respond appropriately to novel stimuli sharing such a basic layout. Honeybees trained with a series of complex patterns sharing a common layout comprising four edge orientations remembered these orientations simultaneously in their appropriate positions and transferred their response to novel stimuli that preserved the trained layout. Honeybees also transferred their responses to patterns with fewer correct orientations, depending on their match with the trained layout. These results show that honeybees extract regularities in their visual environment and establish correspondences among

correlated features such that they generate a large set of object descriptions from a finite set of elements. In a related study, it was reported that honeybees have the ability to group similar natural images together. The authors suggested that configurational properties of the figures, in which specific features such as circular symmetry, angular periodicity, bilateral symmetry, and the presence of a horizontal high-contrast edge, the horizon, were integrated, could help the bees to classify the different stimuli. Thus, we can conclude that honeybees perform visual stimulus categorization.

Rule Learning

Rule learning presupposes the positive transfer of an appropriate response from a known set to a novel set of stimuli. One example is the detection of sameness and of difference. These rules are uncovered through delayed-matching-to-sample (DMTS) and the delayed-nonmatching-to-sample (DNMTS) experiments, respectively. Animals are exposed to regularly changing samples and then to a set of stimuli, one of which is either identical to the sample (DMTS) or different (DNMTS) and which is then reinforced. Honeybees foraging in a Y maze learn both rules when trained to either pairs of colors or patterns. Bees trained with colors and presented in transfer tests with gratings that they have not experienced before solved the problem and chose the grating identical to the sample at the entrance to the maze. Similarly, bees trained with the gratings and tested with colors in transfer tests also solved the problem and chose the novel colors corresponding to those of the sample grating at the maze entrance. Bees also transferred between olfactory and visual stimuli. Bees' ability to solve DMTS tasks has recently been verified. It was found that the working memory for the sample underlying solving a DMTS task is around 5 s. Moreover, bees trained in a DMTS task can learn to pay attention to one of two different samples presented successively in a flight tunnel (either to the first or to the second) and can transfer the learning of this sequence weight to novel samples.

Another case of rule learning, the transitive inference problem, was tested, and the result was that bees cannot solve it. In this problem, animals have to learn a transitive rule, that is, $A > B$, $B > C$, then $A > C$. Preference for A over C in this context can be explained by two strategies: (1) deductive reasoning in which the experimental subjects construct and manipulate a unitary and linear representation of the implicit hierarchy, $A > B > C$; or (2) responding as a function of reinforced and nonreinforced experiences, in which case animals choose among stimuli based on their associative strengths, that is, on the effective number of reinforced and nonreinforced experiences with the stimuli. Bees were trained using five different visual stimuli A, B, C, D, and E in a multiple discrimination task A+ versus B−, B+ versus C−, C+ versus D−, D+ versus E−. Training therefore involved overlapping of adjacent premise pairs ($A > B$, $B > C$, $C > D$, $D > E$), with an underlying linear hierarchy $A > B > C > D > E$. After training, bees were tested with B versus D, a nonadjacent pair of stimuli that were never explicitly trained together. Honeybees learned the premise pairs as long as these were trained as uninterrupted, consecutive blocks of trials, but if shorter and interspersed blocks of trials were used, such that bees had to master all pairs practically simultaneously, performance collapsed and the bees did not learn the premise pairs. It was concluded that bees do not establish transitive inferences between stimuli but rather guide their choices by the joint action of a recency effect (preference for the last rewarded stimulus, D) and by an evaluation of the associative strength of the stimuli (in which case, the preference for B should be evident).

Conditional Discriminations: Occasion Setting and Contextual Learning

Contextual learning is a term widely used for describing conditional discrimination, which can be subsumed in several cases of the occasion-setting problem. In these conditions, a given stimulus, the occasion setter, informs the animal about the outcome of its choice. In one situation, bees were trained to fly to two feeding stations, one in the morning and one in the afternoon. Thus, depending on the time of day, bees flew in one direction or the other, thus showing that temporal information can act as the occasion setter for a sensory–motor routine. When trained bees were captured after arriving at the hive and then released at the wrong site (i.e., at the afternoon site in the morning or at the morning site in the afternoon), they flew straight back to the hive. To fly homeward, the bees retrieved the memory for the correct flight path from long-term memory stores that were established during training and that related local landmarks to the flight path to the hive.

Olfactory cues can also act as occasion setters for the choice of appropriate navigation vectors. It was shown that free-flying bees trained to forage at two distinct feeders, placed at different outdoor locations and carrying different scents or colors, recalled the locations (or colors) of these food sites and flew to them when the training scents were blown into the hive and the scents and food at the feeders were removed. These results indicate that familiar scents can trigger navigational and visual memories in experienced

bees to define appropriate context-dependent responses. These observations resemble earlier reports in which bees were successfully stimulated to dance at night. It was found that they indicated the afternoon feeding place before midnight and the morning feeding place after midnight. Most interestingly, around midnight bees performed either unoriented dances or indicated both directions in successive runs.

Choice Strategies

A bee foraging in a patch of four artificial flowers learns continuously about the reward conditions of each flower. Both excitatory and inhibitory learning contribute to memory formation, but they do so asymmetrically. The bees' choice behavior was modeled by applying the Rescorla–Wagner version of the difference rule in learning, and it was found a best fit if a positive learning rate of 0.8 and a negative learning rate of 0.08 were assumed. From these results, we would expect risk-prone behavior in honeybees in a situation of flowers (artificial feeders) with variable amounts of reward because the occasionally experienced higher rewards should lead to better learning than the equally frequently experienced lower rewards. However, risk-averse behavior was found first both in bees and bumblebees foraging on artificial flowers offering variable or constant rewards. These data were interpreted as showing that bees optimize the mean rate of reward per flower. In later studies, no indication of risk-averse behavior was found in honeybees confronted with variance in sucrose solution concentration or in bumblebees confronted with variance in either sucrose concentration or volume. These latter studies on risk sensitivity by bees were hampered by the fact that the variance in reward introduced by the bees' choice behavior itself did not take into account unrewarded immediate revisits to the just-depleted feeders. A follow-up study, in which this parameter was carefully monitored and in which variance of reward was the only parameter systematically changed, found that bees distributed their choices with respect to the amount of reward and variance but that their choice behavior did not change with the amount of variance, consistent with a risk-indifferent strategy. Therefore, bees ignore the variance in reward, not because they cannot detect and learn the differences in the amount of rewards but, rather, because they appear to eliminate the parameter reward variance when they choose a particular feeder and refer only to the mean amount of reward rate.

Response Conditioning

Classical conditioning of innate responses is a most convenient way to study the behavioral and neural mechanisms of associative learning. In hungry honeybees, a sucrose stimulus at the antennae reliably releases the extension of its proboscis (the PER). Conditioning to olfactory or mechanical stimuli as a conditioned stimuli (CS) is quite effective, but colors can also be used and were indeed the stimuli used first to study associative learning in bees harnessed in a tube. The associative nature of PER conditioning was established by demonstrating that only forward pairing of CS–unconditioned stimulus (US) sequences is effective, by various control groups (unpaired CS and US, CS- or US-only presentations), and by differential conditioning of the two olfactory stimuli. The predictive value of the CS depends on the reliability with which it is causally related to the US. In differential conditioning, the reversal to the initially unpaired stimulus is slower after more frequent unreinforced preexposures than after a lesser number of preexposures. The same applies for US-only preexposures in an otherwise reinforced context. Partial reinforcement schedules have little effect on the acquisition function because extinction trials do not alter the CR probability but, rather, increase the resistance to extinction and other measures of learning.

Overshadowing and blocking experiments are used to characterize the informational content of the CS. Blocking has been found in some experiments and not in others, depending on which odors were used and how the results were related to control groups. It was concluded that attentiveness is not a limiting factor and that the salience or associability of a stimulus is indeed an important factor. Second-order conditioning is a procedure that tests whether a CS can acquire the potential of an US. Although the earlier studies lacked control groups, recent studies clearly document second-order conditioning.

Nonelemental Forms of Conditioning

In studies of nonelemental learning, paradigms have been developed for which the associative strength of a specific event, stimulus or reaction, is ambiguous and therefore cannot be predictive for solving a problem. In the honeybee, several recent studies have addressed the issue of elemental versus nonelemental learning using visual training of free-flying animals or olfactory conditioning of harnessed animals. In both modalities, bees are able to solve a biconditional discrimination (AB+, CD+, AC−, BD−). This capacity demonstrates that both visual and olfactory compounds are learned under certain circumstances as entities different from the simple sum of their elements. Similarly, negative patterning experiments (A+, B+, AB−) have also been performed in both the visual and the olfactory modality. Such discrimination can be

explained only if the compound AB is treated as being different from the simple sum of its elements. The results are interpreted according to a modified unique cue hypothesis. A unique cue is generated when bees receive olfactory input to both brain sides because bilateral olfactory input is required to solve a negative patterning task. A form of context-dependent conditioning can be established when bees receive differential conditioning of A+, B− via one antenna, and A−, B+ via the other. Bees learn to respond appropriately to the rewarded odor and inhibit their response to the nonrewarded odor on each side. Side-specific input was used to test the contribution of the mushroom body (MB) to elemental and nonelemental forms of conditioning. Bees with unilateral lesions of the mushroom bodies generated by larval treatment with hydroxyurea were trained under different olfactory conditioning designs. When odorants were delivered in a side-specific manner, bees with unilateral mushroom body lesions could not solve an unambiguous double discrimination (paradigm 1: A+, B− on one antenna, C+, D− on the other; A+B− / C+D−), whereas they could solve at least one of both discriminations of an ambiguous problem (paradigm 2: A+, B− on one antenna, A−, B+ on the other; A+B− / A−B+). In the latter case, they solved the discrimination proposed to their intact brain side. Non-ablated bees could learn both side-specific discriminations. When odorants were delivered simultaneously to both antennae (paradigm 3: A+B-C+D−), ablated bees learned slower than normal bees. Thus, in all three cases, the unilateral loss of a median calyx affected olfactory learning. It was proposed that MBs are required for solving elemental olfactory tasks whose complexity is enhanced by virtue of the number of stimuli involved (paradigms 1 and 3: four stimuli) and that MB ablations could have an effect on the inhibition of information exchange between brain hemispheres.

Operant Conditioning of Restrained Bees

The honeybee antennae can be operantly conditioned to assume a certain posture. In a more reduced preparation, the activity of the fast flagellum flexor muscle is recorded extracellularly from the scapus of the antenna. Whenever the muscle activity exceeds a defined reward threshold, the animal is rewarded with a drop of sucrose solution. After several US deliveries, the frequency of the muscle potentials increases significantly over the spontaneous frequency. The conditioned changes of frequency can be observed for 30 min after conditioning and do not occur in yoked controls, which were rewarded independent of nerve activity.

Sequential Memory Processing

A stable, lifelong memory is formed after even only a few learning trials in free-flying bees. The retention curve after a single learning trial follows a biphasic time course, which indicates that memory and retrieval are at first very high, fade to a minimum 2–3 min after learning, rise again within the following 20 min, and stay high for a number of hours; this is true both in PER conditioning and for free-flying bees. The early memory phase in the minutes range is particularly susceptible to both extinction and reversal learning, whereas the consolidated memory is much more resistant. The sensitizing effect of the appetitive stimulus overlaps with the early high response level, indicating that, at least in PER conditioning, the nonassociative memory initiated by the US contributes substantially to the response probability immediately after the single learning trial. Amnestic treatments (cooling, narcosis, and weak electroconvulsive brain stimulation), if applied within 2–3 min after the single-trial learning, erase the memory trace, indicating a susceptible short-term memory (STM). The memory initiated by a single conditioning trial consolidates within a few minutes so that it becomes resistant to retrograde amnestic treatments. The time course of retrograde amnestic sensitivity is independent of the kind of learning (operant color learning or olfactory PER conditioning), but depends on the particular structure of the brain where the treatment is applied. Several conditioning trials within STM make the memory trace immune to amnestic treatment.

Several forms of longer-lasting memory have been discerned on the basis of behavioral, biochemical, and pharmacological experiments performed with olfactory PER conditioning. The respective time courses and transitions between five forms of memory have been related to the temporal sequence during the foraging cycle:

1. Associative induction and early short-term memory (eSTM). eSTM covers the time window during which a foraging bee can expect to be exposed to the same stimuli because flowers most frequently occur in patches. No specific choices need to be performed at this time, and general arousal (depending on the strength of the US) will suffice to control whether the animal stays in the patch or postpones choices for a later time.

2. Late short-term memory (lSTM). The transition to the selective associative memory trace during lSTM is a rather slow process after a single learning trial lasting up to several minutes, and it happens very quickly after multiple learning trials. Thus, consolidation is both

time- and event-dependent, where events have to be associative experiences and not just CS or US repetitions. The behavioral relevance of these findings for foraging behavior has been related to the temporal separation between intra- and interpatch visits.

3. Mid-term memory (MTM). At the beginning of MTM, behavior is controlled by consolidated, highly specific memory. At this stage, memory is more resistant to extinction, conflicting information, and elapsing time, and some information about the context dependencies may have already been stored. Under natural conditions, bees have usually returned to the hive and departed on a new foraging bout within the time window of MTM.

4–5. Long-term memory (LTM), early and late. LTM requires multiple learning trials, indicating that specific information which can be extracted only from multiple experiences (signal reliability and context dependence) controls the transfer to LTM. Structural changes in the connectivity between neurons have been proposed as the substrates for LTM in vertebrates and invertebrates. In bees, direct evidence for LTM-related structural changes are lacking, but measurements of the volume of the subcompartments of the MBs indicated that more experienced bees have bigger dendrite volumes and more elaborate dendritic branches. The biological circumstances of two forms of LTM may be related to the distinction between those forms of learning which usually lead to lifelong memories (e.g., visual and olfactory cues characterizing the home colony) and those which are stable but need updating on a regular basis (e.g., visual and olfactory cues of feeding places).

> Perhaps these insects are little machines in a deep sleep, but looking at their rigidly armored bodies, their staring eyes, and their mute performances, one cannot help at times wondering if there is anyone inside. (Dethier, 1964)

This sentence concludes a remarkable paper published in 1964 by Vincent Dethier, in which he considers the evidence that the cognitive abilities of insects are equivalent to those of mammals. Since that time the comparative study of cognition has expanded considerably, particularly in the area of linguistics, tool use and social organization. For example, arousal and cognition are now studied in flies and bees. Reprinted with permission from Dethier VG (1964) Microscopic brains. *Science* 143: 1138–1145. Copyright [1964] [AAAS].

Contemporary students of molluskan behavior in general have not used concepts from comparative cognition to describe even complex and plastic behavioral responses. Students of learning and memory in octopus, a mollusk with brain regions equivalent in complexity to the mammalian cerebellum and with extremely flexible behavioral strategies, have not yet ventured into the realm of comparative cognition to find a framework for understanding the behavior of this remarkable animal. By contrast, our studies of learning and memory in *Limax maximus* (Limax) have been guided by the notion that, within the realm of odor learning, whatever a rodent can do, Limax can do. We have found this approach very productive in revealing the complexity of Limax odor learning, as detailed below.

Although mollusks and mammals diverged from their common ancestor some 600 million years ago, there is ample evidence for conserved genes, cellular signaling processes, mechanisms of neural integration, mechanisms of learning, and forms of learning used to solve analogous problems between the two taxa. These observations suggest that prospecting for mammalian memory mechanisms in the molluscan nervous system is a productive strategy, as amply demonstrated by dissection of short- and long-term memory storage mechanisms in *Aplysia*.

Commonalities between mollusks and mammals have emerged in a particularly clear way from analyses of the molecular, cellular, and network dynamics associated with associative learning in Limax, specifically in the realm of olfactory information processing and odor learning. Vertebrate and invertebrate olfactory processing systems share a number of basic design features as do mammals and mollusks. Within the gastropod mollusks, exemplified by the land snails and slugs, a common plan of olfactory system organization is evident as is a highly developed capacity for olfactory learning. The following will outline some of the universal design principles displayed by the olfactory information processing system of Limax.

Higher-Order Conditioning

In designing experiments to probe the complexity of Limax odor learning, it has proved to be remarkably productive to regard Limax as possessed of mammalian learning skills in the domain of associative learning about odorants as conditioned stimuli and aversive tastes as unconditioned stimuli. In particular, the Kamin blocking effect was an early striking example of higher-order conditioning shown robustly in Limax odorant conditioning. We have recently revisited the question as to how the blocking phenomenon, which requires that conditioned stimuli acquire predictive relationships with unconditioned stimuli, can be implemented logically and with plausible neurophysiological mechanisms, a subject of continuing interest to students of the mammalian and insect central nervous system (CNS).

The blocking phenomenon involves two phases of conditioning. In the first phase of conditioning a conditioned stimulus (CS1) is paired with the unconditioned stimulus (US). In the second phase of conditioning a compound stimulus consisting of CS1 and a second conditioned stimulus (CS2) is presented followed by the US. Blocking is evidenced by lack of association between CS2 and the US, as found in other invertebrates and mammals.

Our circuit solution to the blocking problem in Limax requires a facilitator neuron (FN) interposed between sensory inputs from CS1, CS2, and US on the one hand and the motorneurons executing the conditioned response. It also requires reciprocal inhibition between the CS1, CS2, and US inputs, which can be amplified by learning via activation of the FN. These interactions were explored in simulations based on an integrate-and-fire model used previously for spiking cortical neurons and synaptic connections that can show potentiation. There are several cellular loci in Limax that can potentially provide tests of the predictions of the proposed mechanism for blocking, including the serotonergic metacerebral giant cell, the Limax feeding command neurons, and the recently identified odor-responsive parietal neuron v-PN. The

recent demonstration of odor conditioning by the isolated Limax CNS greatly augments the feasibility of these experiments.

Serotonergic modulation of sensory neurons is a central element in plasticity of the *Aplysia* gill- and siphon-withdrawl circuit while depletion of serotonin impairs short-term but not long-term memory in Limax. While slugs will quickly learn to avoid a diet devoid of the essential amino acid tryptophan, if a tryptophan-deficient diet is the only food available, slugs will maintain normal levels of brain serotonin and function of the serotonergic metacerebral cell in spite of this dietary challenge. In mammals, cells in the anterior piriform cortex are sensitive to deficiencies in essential amino acids, based on uncharged transfer RNA inducing phosphorylation of eukaryotic initiation factor 2 via a nonderepressing 2 kinase. These findings in the mammalian system provide guidance to the search for neurons in the Limax CNS responding to diets devoid of essential amino acids and directing selective food avoidance.

Flexible Storage of Compound Odor Stimuli

The issue of how compound odor stimuli are stored in the CNS can be explored by training animals to associate an aversive US with a compound CS under conditions where they experience the compound of CS1 and CS2 as a spatially and temporally uniform mixture or as a spatially and temporally heterogeneous mixture. The heterogeneous mixture of CS1 and CS2 provides information on the components of the mixture as well as the mixture itself. The uniform mixture is more likely to be treated as a single odor object. A difference in storage mechanism is revealed by measuring the aversion to CS1 and CS2 presented alone after aversive compound conditioning to the mixture. Limax appears to store a uniform mixture of CS1 and CS2 as a unique odor object such that strong aversive responses are shown to the CS1 + CS2 compound but clear attraction to CS1 alone and CS2 alone remains. Conversely, pairing the US with a heterogeneous mixture of CS1 and CS2 leads to a different form of sensory storage because after conditioning slugs show strong aversion to CS1 presented alone and CS2 presented alone as well as strong aversion to the compound stimulus. Similar results were obtained using cooling-induced retrograde amnesia to probe the nature of CS storage after compound conditioning. Using cooling to alter stimulus representations, slugs appeared to learn a binary odor mixture as a unitary object when they had no exposure to the separate elements of the mixture. These experiments emphasize the synthetic role of olfactory processing and the critical role of learning in stimulus processing.

Evolution of the Form of the Memory Trace

Mollusks and mammals also share the use of oscillatory dynamics in early olfactory centers (procerebral (PC) lobe in terrestrial mollusks and olfactory bulb (OB) in mammals). The rosy wolfsnail, *Euglandina rosea,* uses chemosensation for hunting its prey and has a PC lobe with oscillating local field potentials (LFPs), as in Limax and *Helix*. Hunting dogs use olfaction for trail following and use active odor sampling, or sniffing as an essential component of their odor sampling strategy. Analogously, snails show a variety of 'rapid' tentacle (nose) movements associated with odor localization that may serve some of the same functions as sniffing. Sniffing may be associated with taking olfactory snapshots of odorants inputs when rapid sampling and decision making are required.

Providing Motivation for Learning Odor Associations

We have found that water deprivation is a potent motivational method for obtaining conditioned odor aversions in Limax. Slugs are weighed and then dehydrated by placing them in mesh cages in a container with dessicant and a fan (Figure 1). Dehydration continues until the slugs lose 35–40% of their initial fully hydrated body weight. Rapid dehydration produces maximally motivated slugs. Dehydrated slugs actively search for a source of water for contact rehydration, which occurs when the slug sits on a moist surface and absorbs water through its foot via a paracellular pathway. During training, dehydrated slugs are first offered saltwater containing quinine and NaCl for rehydration, paired with odor A. Contact of the slug with the saltwater elicits rapid withdrawal. Slugs are then offered safe pure water paired with odor B. Odor sources are placed under the mesh floor of the training chamber with the water source located directly above the odor source. The slug is given 30 min to rehydrate on the moist surface above odor B. The next day, slugs are dehydrated again and positioned between sources of odor A and odor B located under the mesh floor of the testing chamber. Latency to approach an odor source and time spent within a 9 cm circle centered on each odor source are recorded. In three experiments with six different odorants in which 31 slugs were trained with odor A signaling safe water and odor B signaling saltwater, 90% of trained slugs chose odor A. Since slugs can be

Figure 1 Method for appetitive conditioning of odor preferences with water reward: (a) slug is dehydrated to 60–65% of its fully hydrated weight within 30 min; (b) slug is offered dangerous water with odor A; (c) slug is offered safe water with odor B; (d) slug is again dehydrated; (e) dehydrated slug is offered a choice between spending time over odor A or odor B.

Figure 2 Zones of neurogenesis in the procerebral lobe are revealed by BrdU labeling: (a) PC lobe of a slug exposed to BrdU at 3 days posthatching and BrdU staining developed 1 day later; (b) PC lobe of a slug exposed to BrdU at 3 days posthatching and BrdU staining developed 2 months later. The apical region of the PC lobe is a site of continued neurogenesis over this period.

dehydrated in 40–60 min and survive repeated bouts of dehydration after contact rehydration, the method of water–odor pairing during contact rehydration is much more convenient than food deprivation, which can require many days to re-establish appetitive odor responses after feeding to satiation. It remains a mystery as to how an animal with a completely moist surface can show directed orientation to a localized source of water, as dehydrated slugs do.

Neurogenesis in Olfactory Pathways

Another design principle of olfactory information processing shared between mammals and mollusks is the addition of new circuit elements posthatching or postparturition to both the sensory periphery and the central processing structures – PC lobe and OB. To investigate the locus and extent of neurogenesis in the Limax PC lobe, newly hatched slugs (30–40 mg) were immersed in a saline solution containing bromodeoxyuridine (BrdU) for 90 min. After BrdU treatment slugs were rinsed with Limax saline and placed in containers with a moist substrate and their maintenance diet, rat chow. At various periods after BrdU treatment brains were harvested and processed as whole mounts for immunocytochemical demonstration of BrdU incorporation into DNA of dividing neurons. The CNS was processed with a protocol supplied with the BrdU *in situ* detection kit. Briefly, tissue was fixed, treated to open DNA strands, and then treated with biotinylated anti-BrdU antibody and streptavidin horseradish, peroxidase (HRP) secondary antibody. Preparations were developed with diaminobenzidine as the chromogen and mounted in glycergel prior to digital photography. Figure 2(a) shows the PC lobe from a slug given a BrdU bath 3 days posthatching and the PC lobe harvested 1 day later and developed to reveal BrdU labeled neurons. The zone of neurogenesis is clearly visible at the apical pole of the PC lobe, which is also the site of initiation of activity waves that traverse the apical–basal axis at 0.7 Hz in isolated preparations.

Figure 2(b) shows the band of neurogenesis revealed in the PC lobe treated to reveal neuronal BrdU incorporation 2 months after BrdU exposure of the hatchling slug. As the apical neurons in the zone of neurogenesis shown in Figure 2(a) continue to divide, the more apical of the daughter neurons continue to divide so that the original BrdU labeled neurons are left behind and the apical region of the PC lobe extends. Since this active neurogenesis occurs during natural olfactory stimulation, it is possible that the diversity and intensity of olfactory experience, and perhaps odor learning, modulate the rate and extent of neurogenesis in the PC lobe or neuronal survival. Enhanced survival of new neurons in the mammalian olfactory bulb due to enriched odor stimulation has been documented, with a concomitant enhancement of short-term memory.

Procerebrum as an Olfactory Learning Center

The procerebrum or PC lobe is a division of the cerebral ganglion unique to terrestrial slugs and snails which is specialized for the processing of olfactory information. The PC lobe contains several tens of thousands of small (7–9 μm soma diameter) local interneurons comprised of at least two subpopulations, bursting (B) and nonbursting (NB) neurons. B neurons are a few percent of the total neuronal population and are coupled with each other by chemical and electrical synapses. B neurons have extensive synaptic connections with NB neurons. Stimulation of the superior tentacle with odorants results in inhibitory responses in 45% of NB neurons, while 11% of NB neurons show an excitatory response. The periodic membrane potential trajectories of B and NB cells lead to a phase-dependent response to sensory inputs. Both B and NB cells contain the mRNA for nitric oxide synthase and soluble guanylate cyclase, critical to the control of oscillation frequency in the PC lobe (see below). The B cells located in the apical region of the PC lobe are more excitable (shorter interburst interval) than the B cells located in the basal region of the PC lobe. Chloride-dependent periodic depolarizations in apical B cells have a higher amplitude than the chloride-dependent depolarizations recorded from B cells in the basal region of the PC lobe. This gradient of excitability and pattern of connectivity give rise to activity waves in the PC lobe traveling from apex to base at 1.1 mm s^{-1} at a repetition rate of 0.7 Hz *in vitro*. These traveling waves have also been found in mammalian cortex although their computational role is still unclear. Evidence for traveling waves in the PC lobe of intact behaving slugs is suggestive but not definitive, based on *in vivo* recordings of neuronal dynamics in the PC lobes of intact, awake, behaving slugs. There are direct interactions between the oscillatory circuitry in the PC lobe and motor neurons controlling nose positioning and between PC lobe circuitry and remote neurons in the pedal and buccal ganglia. A behavioral interaction between olfactory inputs and feeding motor responses has been documented. Other regions of the cerebral ganglion adjacent to the PC lobe may also show oscillatory local field potentials.

Increasing evidence indicates that the PC lobe is involved in odor learning in Limax. Optical studies of odor-elicited activity in the PC lobe showed changes due to prior conditioning of responses to an odorant. Wavelet-based analysis may help to characterize more completely the complex dynamics of local field potential activity as modified by odor input in the PC lobe. A small set of genes is specifically activated in PC lobe neurons due to odor learning. Antibodies to the gene product for one of the learning-activated genes have been made and used to show the enhanced levels of expression of the gene after odor learning.

A direct test of the role of the PC lobe in odor learning in Limax is based on studies of the effects of lesions of the PC lobe on subsequent odor learning. Ablation of the PC lobe 7 days prior to odor conditioning produced clear deficits in odor conditioning not evident in slugs given control operations. PC lobe ablation after odor conditioning also reduced avoidance of the aversively conditioned odor. Control experiments showed that PC lesioned slugs were not anosmic. These results strongly support evidence from optical, molecular, and activity-dependent dye uptake studies also indicating a selective role of the PC lobe in odor learning.

Other genes have been identified that are activated by noxious stimuli like those used as the US in odor conditioning. One kruppel-like factor (KLF) family transcription factor gene (Limax KLF; limKLF) is upregulated 30 min after depolarization of the isolated CNS with high potassium saline. An immediate early gene, CCAAT enhancer binding protein (C/EBP) was cloned by reverse transcription-polymerase chain reaction (RT-PCR). C/EBP was also activated by noxious electrical stimuli applied to the Limax body wall. It will be interesting to see if the aversive taste of quinine, used as the US in many odor conditioning experiments with Limax, also activates C/EBP.

The tentacular ganglion located just behind the nose in the superior tentacles also shows oscillatory local field potentials. Odor-elicited uptake of a fluorescent derivative of glucose has been demonstrated in the tentacular ganglion. The oscillatory activity of the tentacular ganglion is modulated by

ACh, 5HT, and GABA as identified immunocytochemically. Odor-elicited spike activity can be recorded in the tentacular nerve and correlated with oscillations in LFP. Recent work shows that the summed receptor potentials of the olfactory receptors, recorded as the electro-olfactogram (EOG), can also show oscillations, as previously found is several vertebrate olfactory epithelia. How the interactions of the peripheral EOG oscillation and the central LFP oscillation enhance odorant detection remains to be determined.

A variety of other cells and neurotransmitters have been shown to play some role in odor aversion learning by Limax. The v-PN neuron was first identified as an output neuron whose activity could be used to provide an index of aversive evaluation of odor input. Monitoring activity in v-PN was crucial to the demonstration of *in vitro* odor learning by the isolated Limax CNS. Among the 21 neurotransmitters known to play a role in Limax odor processing, serotonin has been shown to play an essential role in odor learning. The peptide FMRFamide may play a regulatory role in stimulating NO production by the neuronal nitric oxide synthase (nNOS) containing neurons in the PC lobe. Odor discrimination can be blocked by pharmacological block of nNOS. Nitric oxide plays a major role in controlling network dynamics in the Limax olfactory system both centrally and peripherally. NO is also a modulator of chemosensory processing in *Aplysia*. Serotonin and NO have complementary effects on elements of the olfactory processing network in Limax.

Learning and Memory in Invertebrates: Mollusks

Introduction

Over the past several decades, it has become evident that fundamental mechanisms of learning and memory are remarkably conserved among animals, ranging from humans and other higher mammals to lower vertebrates and invertebrates, such as fruit flies and mollusks. Molluskan species in particular have proven quite useful for cellular and molecular studies; they exhibit several types of learning, including nonassociative forms (sensitization, habituation, etc.) and associative forms (classical conditioning and operant conditioning). Because of the relative simplicity of their nervous systems, mollusks provide powerful models for examining the mechanisms of the induction and maintenance of memory. One of the main strengths of the molluskan systems is the ability to make direct links between the animal's behavioral plasticity and its underlying cellular and molecular mechanisms. Because of the space limitations of this review, we are unable to discuss the contributions of the numerous molluskan model systems (such as the terrestrial snail, *Helix*; the marine mollusk, *Tritonia*; and the terrestrial snail, *Limax*), each of which exhibits similar forms of learning to those we will describe; nor will we discuss the cephalopods (octopus, squid, and cuttlefish), which have complex nervous systems and are capable of more advanced forms of training, including spatial learning and observational learning. Rather, we will highlight three molluskan species that have made significant contributions to our understanding of the cellular and molecular mechanisms of learning and memory: the marine mollusk, *Aplysia californica*; the nudibranch, *Hermissenda crassicornis*; and the pond snail, *Lymnaea stagnalis*.

Aplysia

Of the molluks, *Aplysia* is perhaps the most extensively studied in the field of learning and memory. Because of the relative simplicity of its nervous system and the animal's large size, *Aplysia* is particularly amenable to combined behavioral, circuit, and cellular analyses. *Aplysia* exhibits several forms of memory, including both associative and nonassociative forms. Two behavioral systems have been the main focus of research in *Aplysia*: (1) the defensive withdrawal reflexes of the tail, siphon, and gill and (2) the feeding system. Multiple forms of memory have been studied in each. The withdrawal reflexes, which have been the most extensively studied, exhibit nonassociative forms of memory, including sensitization and habituation, as well as classical conditioning. The feeding system can also be conditioned using both operant and classical procedures. Very recently, it has also been shown that the gill reflex can also be operantly conditioned. The fortuitous finding that multiple forms of memory can be induced by a single simple circuit offers a unique opportunity to compare the cellular and molecular mechanisms that mediate different forms of memory in the same system.

Sensitization

The defensive withdrawal reflexes of the *Aplysia* tail, siphon, and gill show both sensitization, an increase in behavioral responsiveness following a noxious stimulus, and habituation, a decrement in a behavioral responsiveness following repeated, weak stimulation. In response to a weak tactile stimulation to the body wall or tail, *Aplysia* reflexively withdraws its gill, siphon, and tail. A strong, noxious stimulation, such as shock (e.g., to the tail or head), sensitizes these reflexes, producing an increase in their magnitude and duration in response to subsequent weak, tactile stimuli. Conversely, weak low-frequency stimulation habituates these reflexes. Although important research on habituation is currently being conducted, we will restrict the discussion here to sensitization because its mechanisms are better understood.

The experimental preparation often used is the tail-elicited siphon withdrawal (T-SWR). The amount and pattern of training trials is important in determining the type and the duration of the memory induced in many systems, ranging from insects to mammals. The efficacy of several training patterns has been explored in *Aplysia*. For example, a single tail shock induces short-term memory (STM) for sensitization, which lasts <30 min. Multiple (four or five) trials spaced by 15 min induces two long-lasting forms of memory: intermediate-term memory (ITM) that lasts 90 min–3 h, and long-term memory (LTM) that begins to be expressed about 10 h after training and lasts at least 2 days. Massed training, in which the same total amount of training is given but without any intervening intertrial intervals (ITIs), does not induce LTM, and induces only an early decaying form of ITM. Finally, multiple trials spaced over several days (one trial per day for 4 days) induce LTM that lasts several weeks.

Another training parameter that affects memory induction is neuronal activity. In the sensitization experiments described above, one site on the tail is used to test the reflex, and shock is applied to another site; thus the sensory neurons (SNs) at the test site do not fire during the tail shock. This form of sensitization is termed 'repeated-trial' (RT) sensitization. However, the shock site itself also shows sensitization, and this 'site-specific' sensitization differs from RT sensitization in that ITM induction requires only a single shock.

Related to the relationship between trial number and pattern is the question of how a prior learning experience influences later training. Recently, two forms of latent learning have been described in the T-SWR. Latent learning is a phenomenon in which learning-related changes occur, but these changes are subthreshold for detection by memory tests. The presence of latent learning is typically revealed as a facilitation of subsequent memory formation, often called savings. In one study, LTM was induced and then allowed to decay. After the T-SWR returned to baseline (the memory was 'forgotten'), animals were given stimulation that typically produces no learning. In previously trained animals, this stimulus pattern induced both ITM and LTM. In the second study, LTM was induced ipsilaterally, after which, animals were given a brief shock that is below threshold for induction of sensitization in otherwise untrained animals. This stimulus, given to the contralateral side, induced sensitization in previously trained animals.

Cellular and molecular mechanisms A major focus of recent research in *Aplysia* has been to relate the pattern of sensitization training to the molecular mechanisms involved in the induction and expression of memory. These experiments have been carried out using *in vitro* and semi-intact preparations. RT memory and site-specific memory have different requirements for protein kinase A (PKA) and protein kinase C (PKC) as well as different requirements for translation and transcription. RT-ITM is dependent on PKA and requires protein synthesis, and RT-LTM requires both translation and transcription, plus mitogen-activated protein kinase (MAPK) activation and tyrosine kinase activity. Site-specific ITM differs from RT-ITM in that it is dependent on PKC (PKM) and does not require protein synthesis. However, like RT-ITM, it requires MAPK activation.

A more thorough investigation of the molecular mechanisms of ITM and LTM has been achieved using a cellular model of sensitization, facilitation of tail SN–motor neuron (MN) synapses. Exogenous application of serotonin (5-HT), a neurotransmitter released by tail shock or tail nerve shock induces facilitation of SN–MN synapses. A single pulse of 5-HT induces short-term facilitation (STF) that lasts <30 min and requires activation of PKA (or PKC if the synapse has been previously depressed). Five pulses of 5-HT induce both intermediate-term facilitation (ITF), that lasts about 90 min and requires synthesis of new protein, and long-term facilitation (LTF) that lasts >24 h and requires both translation and gene transcription. Morphological changes in SN structure, including an increase in the number of varicosities, accompany LTF induction and are required for the maintenance of LTF from 24 to 72 h. The mechanisms of LTF have been widely studied and are described in depth elsewhere. Briefly, activation of PKA activates MAPK, ultimately resulting in cyclic AMP-responsive element binding protein (CREB)-mediated transcription that synthesizes immediate early genes (IEGs). Examples of IEGs that are important for the induction of LTF include CCAAT enhancer-binding protein (C/EBP) and ubiquitin hydrolase (Ap-Uch). Epigenetic mechanisms such as direct modification of DNA or histones have recently been found to be important for long-lasting synaptic modifications, both in vertebrate and in invertebrate models of learning and memory. In *Aplysia*, increasing histone acetylation facilitates the induction of LTF. Finally, secreted factors also appear to have a role in the induction of LTF. Both transforming growth factor-beta (TGF-β) and a TrkB ligand are involved, as well as an SN-specific peptide, sensorin. Not much is known about ITF, but this midrange form of memory seems to utilize some of the same players as LTF. For example, induction of ITF also requires both PKA and MAPK activation.

Synaptic correlates have also been found for site-specific memory. In site-specific memory, the test site is activated during training; thus, the cellular correlate for site-specific memory involves pairing a pulse of 5-HT with direct SN activation with current injection. This correlate is called activity-dependent (AD) facilitation, and a single pairing induces both ITF and LTF. As with the two different forms of memory, the two corresponding forms of facilitation have different molecular requirements. AD-ITF requires PKC, not PKA, for induction, and it does not require protein synthesis.

Associative Forms of Learning

Associative forms of memory include both classical, or Pavlovian, conditioning and operant conditioning. Classical conditioning is a form of learning in which a nominally neutral stimulus (conditioning stimulus, CS), when paired with a reinforcing stimulus (unconditioned stimulus, US) that causes an unconditioned reflexive response, gains the ability to cause the

response itself. When the CS and US are paired, the animal learns to associate the CS with the US such that, after training, the animal then responds to the CS alone. Operant conditioning is similar except that the animal learns to associate its own behavior with a reinforcer. Both classical and operant conditioning can be induced in the feeding system in *Aplysia*. The fact that both of these forms of learning impact the same circuit presents an opportunity to compare the cellular and molecular mechanisms underlying them.

Classical Conditioning

Classical conditioning in *Aplysia* was first described for the T-SWR, and its mechanisms were found to involve AD synaptic facilitation. More recently, classical conditioning has been investigated in the feeding system, in which tactile stimulation of the lips (CS) is paired with ingestion of food (US). Pairing of the tactile stimulation with seaweed leads to an increase in the number of bites the *Aplysia* makes in response to presentation of the CS alone. Ten trials spaced by 4 min induces memory in the form of an increase in the number of bites measured 1 h and 24 h after training.

Cellular mechanisms The cellular mechanisms of conditioning can be investigated in *in vitro* preparations in which the CS and US are substituted by nerve stimulation: stimulation of the antennal nerve, AT4 substitutes for the CS, and stimulation of a branch of the esophageal nerve, En2, substitutes for the US. The responses of central pattern generator (CPG) neurons to the CS are altered after paired training: B4/5 (increased number of ingestion-like buccal motor patterns (BMPs)), B31/32 (increase in the peak amplitude and net size of complex excitatory postsynaptic potentials (EPSPs)), and CB1–2 (increase in the number of action potentials).

Operant Conditioning

Operant conditioning in *Aplysia* was first described in the head-waving system. Three other forms of operant conditioning have since been described in *Aplysia*: aversive and appetitive feeding responses, and more recently, it has been found that the gill-withdrawal reflex can also be operantly conditioned. For appetitive operant conditioning, seaweed is presented to *Aplysia*, either with forceps or in a plastic net with a hole in it. The animal bites the food, pulls it into its buccal cavity, and swallows it. Since swallowing is the reinforcing stimulus, food is provided to the animal as long as it continues to feed.

In aversive conditioning, no holes are made in the net, so the food cannot be swallowed. After several failed swallowing attempts, the food is rejected. Over the training period, the animal decreases the frequency of its swallowing attempts. A single 5 min training session induces very short-term memory that lasts only 15 min and LTM that is expressed 12–24 h after training, a longer training session that lasts until cessation of responsiveness induces STM that lasts 30–60 min, and, finally, multiple training sessions (3×5 min, 30 min ITI) induce ITM that lasts up to 4 h. These results demonstrate that different phases of memory can be induced independently as one 5 min training session induces very short-term memory and LTF in the absence of STF and ITF. A requirement for protein synthesis for the induction of LTF is suggested by the finding that of the four described memory phases, only LTM was blocked by cooling the animal for 15 min immediately after training.

Aplysia has also been a useful model system in which to examine the modulatory effects of circadian rhythms on induction of memory. *Aplysia californica*, a diurnal species, shows greater memory for operant conditioning (as well as sensitization) when trained and tested during the day as opposed to at night; conversely, the nocturnal species, *Aplysia fasciata* exhibited improved memory when trained and tested at night.

Cellular mechanisms *In vitro* operant conditioning is induced by En2 stimulation (reinforcer) given, contingent upon spontaneous production of either ingestion-like behavior (appetitive conditioning) or egestion-like behavior (aversive). Thus, activity in a specific nerve, En2, acts as a general reinforcer during conditioning of feeding responses.

One CPG neuron, B51, has been found to be a site of modulation during operant learning. Activity in B51, a member of the CPG that produces BMPs, correlates with the occurrence of the ingestion-like motor patterns that can be induced by stimulation of nerve n2,3. B51's that have received contingent reinforcement show greater input resistance, an increase in the occurrence of plateau potentials, and decreased burst thresholds, but showed no change in V_m relative to either yoked or untrained controls.

Convergence of Different Forms of Memory Processing

Now that the mechanisms of various associative and nonassociative forms of memory have been described at the behavioral and cellular levels, it is possible to compare them on a mechanistic level. The first analysis of this sort involved comparing the cellular effects classical conditioning on interneuron B51 to what was already known for operant conditioning (see above). As in operant conditioning, classical

conditioning led to an increase in the number of CS-evoked plateau potentials; however, in contrast to operant conditioning, classical conditioning caused no significant change in input resistance, and in fact there was an increase in plateau potential threshold. Thus, although both types of conditioning result in an increase in the number of plateau potentials in B51, the mechanisms are not the same.

Another site of convergence of operant and classical conditioning is the requirement for dopamine (DA). DA plays an essential role in reward learning, both in vertebrates and in invertebrates. DA was found to be required for *in vitro* models of both operant and classical conditioning.

Over the last several decades, a wealth of information has been learned about several types of memory formation in *Aplysia*. The mechanisms of both associative and nonassociative forms of memory have been studied at the behavioral, synaptic, and molecular levels. As researchers continue to learn more about these mechanisms, they can also now begin to compare the signaling pathways involved between different types of associative memory, for example, between operant and classical conditioning in the feeding behavior (see above), and also between associative and nonassociative forms; for example, it has recently been shown that the gill-withdrawal reflex, long known to exhibit sensitization and habituation, also demonstrates operant conditioning.

Hermissenda

Rotation-induced inhibition of phototaxis in the nudibranch mollusk *Hermissenda* has been a powerful model for the study of classical conditioning. The circuitry involved in the behavior is more complex than either of the *Aplysia* circuits; however, the easily accessible sensory neurons (type B photoreceptors) are a site of convergence for the CS (light) and US (rotation) pathways, providing an excellent opportunity to examine the cellular and molecular mechanisms underlying the interaction of these two signals. Prior to conditioning, *Hermissenda* display a phototactic response by locomoting to a light source (CS). Conversely, when shaken or rotated vigorously (US), the animal contracts its foot and ceases locomotion. After CS–US pairing, *Hermissenda* exhibit two conditioned responses to the CS alone: (1) inhibition of light-induced locomotion and (2) foot shortening. This behavior has been extensively studied both experimentally and with computational models, and it has been found to share many of the characteristics of classical conditioning seen in mammals, including extinction and savings.

Recent studies have focused on two mechanistic levels. First, ongoing examination of the primary sensory neurons continues to further elucidate the cellular and molecular mechanisms of the convergence of the CS and US signals at the type B photoreceptors. Second, progress is being made to identify interneurons and motor neurons downstream of the primary SNs, and to determine (1) how their circuit and cellular properties are altered by conditioning, and (2) how these changes contribute to changes in conditioned behavior.

Memory for light-induced inhibition of phototaxis can exist in several temporal domains. One or two pairings induce STM, which lasts <10 min and requires activation of PKC. Multiple pairings induce longer-lasting forms of memory: ITM, which lasts about 2.5 h and requires protein synthesis, and LTM, which lasts ≥ 1 day and requires both translation and transcription. Recently, two forms of LTM have been differentiated mechanistically; consolidated LTM (CLTM) (which lasts up to 3 days) can be distinguished from LTM (which lasts only about 24 h) by its requirement for a second round of protein and RNA synthesis, and by its disruption by the arginyl-glycyl-aspartate (RGD) peptide, a competitive inhibitor of integrins.

One characteristic of LTM that is currently a subject of much investigation in mammalian systems, as well as in invertebrates, is its susceptibility to disruption by protein synthesis blockers during reactivation by the CS alone, a process called reconsolidation. Evidence for reconsolidation has been demonstrated in LTM in *Hermissenda*. Animals were given LTM training, followed a few hours later by a single retrieval test (CS alone) to reactivate the memory. If this test was followed by treatment with a protein synthesis blocker (anisomycin) within 10–30 min, LTM was not induced. Similar results were obtained if transcription was blocked with actinomycin or if bond formation between cell adhesion molecules (CAMs) was blocked with the RGD peptide.

Cellular and Molecular Mechanisms

Light activates rhodopsin in the cell membranes of two types of photoreceptors of the *Hermissenda* eye: type A and type B. The US, shaking or rotation of the animal, excites hair cells (HCs) in the statocysts. As mentioned earlier, the first site of convergence of the CS and US is at the primary SNs, namely the B-type photoreceptors. The HCs synapse onto the type B photoreceptors both directly through GABA-ergic synapses and indirectly via as yet unidentified serotonergic interneurons. After CS–US pairing, photoreceptors exhibit increased excitability, increased input resistance, increased firing frequency, and increased generator potentials in response to light. These cellular

changes are also observed in *in vitro* preparations using a single trial conditioning procedure in which light (CS) is paired with 5-HT application (US). We will focus here on the molecular mechanisms of convergence at the type B photoreceptors, though it should be kept in mind that there are further sites of CS–US interaction, including the first level of interneurons.

In the type B photoreceptors, the main effect of the combined CS and US signals is considered to be an enhanced increase in internal Ca^{2+} via activation of two different signaling pathways, which induces a persistent activation of PKC. Light activates rhodopsin on the B photoreceptor membrane, which, via G-protein interactions, activates a signaling cascade through PLC, DAG, IP3, and the IP3 receptor to release Ca^{2+} into the cytoplasm from endoplasmic reticulum (ER) stores. Activation of the HCs by shaking or rotation causes release of GABA from the HCs, which binds metabotropic GABA receptors on the photoreceptor and leads to Ca^{2+} release from intracellular stores through mechanisms that are not entirely known but are thought to involve phospholipase C (PLC) activation. In addition, HCs also make excitatory serotonergic connections onto the type B photoreceptors, probably through a polysynaptic pathway. 5-HT activates MAPK, through both PKC-dependent and PKC-independent pathways.

Accompanying the long-term physiological changes is a change in the morphology of the type B photoreceptors. Multiple paired training trials induce contraction of the terminal branches of the type B photoreceptors. This morphological response is sensitive to ryanodine receptor (Ryr) blockers and therefore is dependent on Ca^{2+} release from internal stores. The functional significance of the reduction in arborization is not yet clear.

Downstream Effectors of Transcription and Translation

Much of the focus of the molecular mechanisms of ITM and LTM in *Hermissenda* has been on the events occurring upstream of transcription. However, the protein products of conditioning-induced translation and transcription are currently being investigated. One class of molecules that appear to be necessary for intermediate- and long-term changes in synaptic efficacy is involved in actin stability. Cytoskeleton-related proteins play important roles in cell morphology and in the composition of the cell membrane, and the activity of several of these have been found to be altered by conditioning in *Hermissenda*. Conditioned stimulus pathway phosphoprotein 24 (Csp24) is a cytoskeletal-related protein with several actin-binding domains that are upregulated and phosphorylated by procedures that induce intermediate-term and long-term increases in excitability, and it is associated with a decrease in a specific potassium current, I_A. In single trial conditioning, 5-HT mediates phosphorylation of Csp24 through at least two pathways: (1) by inhibition of the Rho/ROCK pathway, and (2) by an increase in activity of the cyclin-dependent kinase 5 (cdk 5) pathway. Another protein that is upregulated by paired CS–US training is calexcitin, a GTP- and Ca^{2+}-binding protein. Calexcitin is activated by PKC and has the dual role of inactivating the K^+ currents I_A and I_{Ca-K} and binding to the Ryr receptor to release Ca^{2+} from internal stores.

Hermissenda is a model system that has provided a wealth of information about the cellular and molecular mechanisms underlying the convergence of CS and US pathways. What is missing now are many of the links between the various players, for example, the specific role of MAPK in the induction of LTM, the interaction between PKC activation, the role of 5-HT, and the function of the morphological changes for the expression of LTM. Recent work is now focusing on the role of the next order of cells, the effects of classical conditioning in the first level of interneurons. It will be of great interest to learn how the CS and US interact at these levels.

Lymnaea

Several forms of associative conditioning have been described in *Lymnaea*. These include operant conditioning of the respiratory response and classical conditioning of feeding behavior. The respiratory system in particular has the advantage of having a simple circuit, providing the opportunity to examine the specific roles of individual, identified neurons in the formation of memory. Specifically, the CPG neuron RPed1 has been shown to be a site of memory formation and storage. Similarly, feeding behavior, although it is composed of a slightly more complex circuit, has also provided an opportunity to study the role of a specific neuron, the cerebral giant cell (CGC) in memory formation. The feeding behavior is of further interest because this simple circuit is capable of rather complex conditioning. The emphasis of research in *Lymnaea* conditioning has been on the training parameters required for memory induction and on cell and circuit properties. Nevertheless, progress is also being made in the molecular mechanisms underlying cellular changes following conditioning.

Classical Conditioning

The *Lymnaea* feeding response can be classically conditioned, and both appetitive conditioning and conditioned taste aversion (CTA) have been demonstrated. By pairing either tactile stimulation (lip touch) or chemosensory stimulation (amyl acetate)

as the CS with sucrose (US), the CS gains the ability to elicit a feeding response. Appetitive conditioning can be induced with either multiple pairings or with a single pairing in animals that have been deprived of food for several days. To induce CTA, sucrose (CS) is paired with KCl (US). KCl alone decreases the feeding response and elicits a withdrawal response, and after pairing with sucrose, sucrose alone evokes a reduced feeding response that can last up to 1 month.

Classical conditioning in *Lymnaea* shares several features with classical conditioning observed in mammals, including taste discrimination and second-order conditioning. To test taste discrimination, animals were first tested separately with two CS stimuli, sucrose and carrot juice. CTA was established by ten pairings of CS1 (either sucrose or carrot juice) and the US (KCl). After conditioning, animals showed CTA to CS1, but not to the other unpaired CS. Thus, the animals can discriminate between different appetitive stimuli. To test second-order conditioning, these same animals were then given CS2 paired 10 times with CS1. When the animals were then tested with the presentation of CS2 alone, they showed a reduction in their feeding response, demonstrating that they are capable of second-order conditioning.

Cellular and molecular mechanisms In contrast to the extensive investigation into the behavioral aspects of learning and memory in the *Lymnaea* feeding system, examination of the molecular mechanisms required for memory induction is only beginning to be explored. As is typical of most memory systems, LTM of appetitive conditioning requires both transcription and translation, and, as was shown in *Aplysia*, the signaling pathways include MAPK, CREB, and C/EBP. At the cellular level, initial studies have found that injecting cAMP into a CPG neuron involved in the gating of the feeding response (CGC) induces LTF of synapses between CGC and feeding MNs, and this facilitation is blocked by injection of CRE oligonucleotides. The IEG C/EBP has been cloned in *Lymnaea*, and the level of C/EBP is modulated in MN B2 by CTA training. Training decreased LymC/EBP mRNA levels but increased translation and phosphorylation of LymC/EBP protein. Consolidation of LTM in *Lymnaea* appears to require nitric oxide (NO) signaling. Two different neuronal NO synthase genes have been cloned from *Lymnaea*, one of which shows a transient increase in mRNA levels after conditioning.

Operant Conditioning

Lymnaea have the capability to breathe through two different mechanisms. They can either absorb oxygen from the water directly through their skin by cutaneaous respiration, or, under anoxic conditions, they will come to the surface and breathe air into their lungs by opening a respiratory structure called a pneumostome. In the laboratory, anoxic conditions can be introduced by bubbling N_2 into a beaker of water. Snails can be operantly conditioned to reduce the number of times they open their pneumostomes for respiration by applying an aversive tactile stimulus to the lip area of the pneumostome whenever it opens.

The pattern of training trials (trial number and spacing) affects the duration of the memory induced. In general, two training trials (10–45 min each) at an ITI of 10 min to 1 h induce a protein synthesis-dependent form of memory (ITM) that lasts up to 2–3 h. LTM, defined by a translational and transcriptional dependence, is induced by increasing the number of training trials, the ITI, or both. Depending on the precise pattern of induction, LTM can last from up to 24 h to several weeks.

Maintenance of LTM in *Lymnaea* can be manipulated by extinction training, and by disruption of protein synthesis during reactivation of the memory. Three 45 min training trials given over 2 days induce LTM that lasts up to 5 days. Extinction trials (three sessions over 2 days, without reinforcement), begun 1 h after the original training, lead to an increase in pneumostome openings within 2 h. When tested 24 h after extinction training, spontaneous recovery of the operant behavior is observed.

As in *Hermissenda*, memory in *Lymnaea* also exhibits a protein synthesis dependence during memory reactivation. In *Lymnaea* reconsolidation experiments, LTM lasting 7 days was induced in one group of animals using training trials spaced over 2 days. A second group of animals served as yoked controls. On day 7, a single training session was given to all animals. Four hours later, animals that received contingent reinforcement showed memory, whereas yoked controls did not. Reactivation-induced memory was blocked if animals were cooled for 1 h immediately after reactivation or were injected with actinomycin to block transcription.

Cellular and molecular mechanisms Much of the recent research in *Lymnaea* operant conditioning has focused on the role of an identified neuron of the respiratory CPG, RPeD1. The CPG circuit responsible for respiratory pumping consists of a three interneurons (RPeD1, VD4, and IP3I) that are connected by reciprocal excitatory and inhibitory synapses. These neurons and their connections can be studied in semi-intact preparations as well as in isolated cell culture. A decrease in activity in RPeD1 is important for the induction of LTM. The intrinsic membrane

properties of RPeD1 are not altered by conditioning; however, RPeD1 neurons were more often quiescent in ganglia from trained animals, and their synapses onto IP3 were weaker. Operant conditioning was also found to affect the synaptic connections between CPG neurons and between RPeD1 and the pneumostome muscles. Operant conditioning reduced the number of IP3-induced RPed1 bursts and reduced the percentage of cases in which RPed1 stimulation induced pneumostome closure. In addition, in a gain-of-function experiment, it was found that although 2×20 min training sessions do not normally induce 18 h LTM, this training regimen paired with hyperpolarization of RPeD1 during the intervening ITIs did induce LTM. A more direct role for RPeD1 was found by Scheibenstock et al. When these authors ablated the soma of RPeD1 by intracellular injection of pronase, (1) the animal still showed normal respiratory behavior 2 days later, (2) RPed1 maintained appropriate synapses with the other CPG cells, and (3) conditioning still induced ITM; however, LTM was not induced. If ablation of RPed1 was delayed until 1 h after training, LTM was induced, indicating that RPeD1 is a site of induction for long-term operant conditioning in *Lymnaea*. The role of RPeD1 has also been studied in the induction of extinction and reconsolidation. Ablation of RPeD1 either 1 h after operant conditioning or 2 days before extinction training blocks extinction, and ablation immediately after reactivation blocks reconsolidation.

The signaling pathways involved in operant conditioning in *Lymnaea* have not been fully examined. CREB1 and CREB2 have been cloned in *Lymnaea*. *In situ* hybridization with a CREB2 antisense reveals the presence of CREB2 throughout the central nervous system (CNS), while similar labeling with a CREB1 antisense indicates that a much smaller population of cells expresses this mRNA. Neurons that express CREB1 include the CGC which is involved in the feeding system and RPeD1. Thus, the stage is now set for the investigation of these transcription factors, which have been clearly implicated in LTM in other systems.

Lymnaea provides an important system for the study of learning and memory because both the feeding and respiratory systems exhibit rather complex learning, especially considering the simplicity of the CPG circuits involved in the behaviors. It will be of considerable interest to map the signaling pathways and the synaptic changes responsible for these forms of memory.

Concluding Remarks

In conclusion, several molluskan preparations have contributed importantly to our understanding of the cellular and molecular mechanisms of learning and memory. Each animal we have discussed exhibits very different types of memory in a variety of different response systems. Nonetheless, several striking similarities emerge. First, each system exhibits memories in three mechanistically distinct temporal domains. Second, many similar signaling cascades are implicated in memory formation, especially, PKA, PKC, and MAPK. Finally, LTM in each animal involves gene activation. Even more striking is the fact that these same temporal phases, signaling cascades, and transcriptional mechanisms are involved in a variety of forms of memory in higher mammalian species. Taken collectively, it appears that evolution has used a common tool kit to implement similar memory mechanisms across the animal kingdom.

Introduction

Neuromodulators, including dopamine, norepinephrine, acetylcholine, and serotonin, exert a wide and diverse collection of effects on a broad range of cortical and subcortical target structures. They are also critically implicated in many aspects of normal behavior and both neurological and psychiatric conditions. With the exception of acetylcholine, they are synthesized by neurons whose somas lie in relatively small subcortical regions such as the ventral tegmental area and substantia nigra pars compacta (for dopamine), the locus coeruleus (for norepinephrine), and the dorsal and median raphe nuclei (for serotonin). However, these neurons can have massive axonal arbors, innervating large areas. The activity of the neuromodulatory neurons and the release of their associated neuromodulators (which is subject to many factors other than the momentary spiking rates) onto the bewildering diversity of their pre- and postsynaptic receptors exhibit a large number of incompletely understood temporal and spatial regularities.

There are obviously huge gaps in our knowledge about neuromodulators, and there are doubtless many as yet undiscovered complexities. However, in some key respects, they appear to admit relatively simple theoretical characterizations associated with learning predictions of affectively important outcomes such as rewards and punishments, learning to choose actions that optimize those outcomes, and regulating and controlling certain general aspects of information processing. These are the most basic functions associated with the survival of mobile, decision-making organisms, and it turns out that a very helpful normative underpinning for these theories can be derived from statistics, operations research, and engineering. It should be acknowledged at the outset, however, that these theories ignore many important functions of the neuromodulators, such as their role in regulating sleep–wake cycles. Nonetheless, they are influential in organizing large bodies of experimental results and also in compelling new empirical approaches.

Under these theoretical views, neuromodulators report on two main quantities: (1) information associated with positive and negative outcomes and (2) information associated with uncertainty. It seems, at least to a crude approximation, that dopamine and serotonin play a special role in positive and negative affect, with norepinephrine and acetylcholine being particularly involved with uncertainty. Further, orthogonal to this distinction, the neuromodulators also have two main classes of effects on neural processing: (1) influencing neural plasticity and learning and (2) regulating different sources of input to neurons and controlling competition between networks of neurons.

This article first provides a somewhat general characterization of issues surrounding learning and then briefly discusses immediate effects of the neuromodulators on inference and regulation.

Learning

Long-term synaptic plasticity, that is, persistent facilitation and depression of the efficacies of synapses, can be characterized at many different levels of biological realism and according to many different theoretical abstractions. Unfortunately, experimental difficulties have hindered efforts to understand completely the range of effects of neuromodulators on plasticity; therefore this article proceeds at a more abstract level appropriate to the relevant normative theories.

The central concept for the learning associated with neuromodulators is prediction. Consider a very simple experiment comprising many trials, in each of which a particular image may or may not be presented and a drop of pleasant-tasting fruit juice may or may not be delivered (regardless of what the subjects do). If the juice is provided more often with than without the image, then subjects learn to expect or predict the delivery of the juice when the image is presented. Such predictions can be measured via behaviors such as anticipatory salivation or licking, which are thought to be triggered more or less directly and automatically by the prediction of the reward. This is a very simple instance of what is known as classical or Pavlovian conditioning. The image is called a conditioned stimulus, the juice is known as an unconditioned stimulus, and the predictive behaviors are termed conditioned responses.

Trial-Based Prediction

Reinforcement learning theories formalize this prediction learning by positing that the presence of the image on trial n is coded by the activity of a unit $x^n = 1$ (with $x^n = 0$ if the image was not presented). This unit makes a connection, via an abstract synapse with strength w^n, to a neuron. This neuron also receives information about the delivery ($r^n = 1$) or nondelivery ($r^n = 0$) of juice on trial n. The value r^n would be scaled

on the basis of the appetitive utility of the juice. The idea is that the synaptic connection should be modified according to a learning rule, such that the presence of the stimulus will predict the occurrence of the reward.

One rather general form of such a learning rule is

$$w^{n+1} = w^n + \alpha^n \delta^n x^n \qquad [1]$$

which indicates how w^n changes from one trial to the next. This update is a function of three quantities:

α^n (learning rate): scales the size of the change to the synapse.

δ^n (prediction error): incorporates information about unpredicted or incorrectly predicted outcomes and typically controls the direction of change

x^n (synaptic eligibility): here, limits synaptic change to those trials in which the image is presented ($x^n = 1$).

Different reinforcement learning theories posit different forms for these terms. Many early ideas in this area came from the field of mathematical psychology, where they were invented to describe the development of behavioral responding in conditioning experiments. Their relationship both with the neural data on the actual activities and concentrations of the neuromodulators and with normative computational ideas came substantially later.

One of the most important psychological learning rules is called the Rescorla–Wagner rule. This is based on the idea that the net prediction of juice on trial n is just the total presynaptic input, here $v^n = x^n \times w^n$, and derives learning from the prediction error, the difference between the juice that is provided and the juice that is predicted:

$$\delta^n = r^n - w^n \times x^n \qquad [2]$$

$$= r^n - v^n \qquad [3]$$

In its simplest form, the Rescorla–Wagner rule also suggests that the learning rate $\alpha^n = \alpha$ is constant. Figure 1(a) shows the operation of this rule, indicating how the values of r^n and x^n specify w^n over a whole set of trials.

Figure 1 Dopamine and learning rules. (a) The course of learning using the Rescorla–Wagner rule. The top plot shows the evolution of the weight w^n over the course of the 20 trials with an image and juice being provided as in the bottom plot. The learning rate $\alpha = 0.4$. The stochastic nature of the learning to a level around the asymptotic value of 0.8 is apparent. (b) Evidence for a prediction error at the time of reward expectancy is shown in the activity of dopamine cells. The four boxes show rasters and accumulated histograms of the activity of identified dopamine neurons in macaque monkeys (during 20 trials), where the reward is a small drop of juice (provided at the time marked by R). The plots are in accord with the prediction error of eqn [3]. (c) The activity of dopamine neurons in response to the presentation (marked by vertical lines) of a conditioned stimulus which either does not (upper) or does (lower) predict the future delivery of juice. These are consistent only with temporal difference learning and not the Rescorla–Wagner rule. (b) Adapted from Schultz W, Dayan P, and Montague PR (1997) A neural substrate of prediction and reward. *Science* 275: 1593–1599. Although extremely simple, this rule has quite a number of desirable computational properties and an excellent normative basis in engineering (where it is more usually known as the delta rule). Most important, it leads to correct predictions, at least on average. In particular, if the juice is always provided with the image, then the weight w^n will come to take the value 1; if the juice is provided on half the trials with the image, w^n will take the value of 0.5, and if the juice is never provided, then w^n will become 0. The rule also has a decent evidentiary trail in psychology, capturing many empirical phenomena surrounding the acquisition and extinction of conditioned behaviors in variants of the simple Pavlovian conditioning experiment discussed here.

Somewhat remarkably, the error signal δ^n in this form of the rule also appears to capture well some, but crucially not all, of the characteristics of the phasic spiking activity of dopamine cells as recorded electrophysiologically in the midbrain during a learning task like this. Figure 1(b) shows an example of this match. The figure shows a raster plot of the activity of a dopamine neuron in an awake, behaving macaque monkey at the time of the delivery or nondelivery of an unexpected or expected reward. If, indeed, the prediction error occasioned by delivery or nondelivery of juice is reflected by phasic bursts of activity above or below the slow, irregular baseline of neural firing, then from eqn [3], one should expect the following: suprabaseline activity for the delivery of the unexpected reward ($\delta^n = 1-0 = 1$; for instance, at the outset of learning, when the participant cannot make an accurate prediction); infrabaseline activity for the nondelivery of the expected reward ($\delta^n = 0-1 = {}^{-}1$); and, crucially, baseline activity when an expected reward is provided ($\delta^n = 1-1 = 0$). We would also expect baseline activity for the nondelivery of a nonexpected reward ($\delta^n = 0-0 = 0$). The figure, although not showing data collected in exactly this manner, shows just these expectations to be fulfilled. Note, though, that dopamine activity does not offer a completely linear code for δ^n. The potential fidelity of the coding of negative prediction errors is limited by the fairly low baseline activity of the neurons; there is also some evidence that the coding is adaptive, moulding itself to the appropriate statistical contingencies.

In sum, at the time at which reward delivery is expected, dopamine neurons appear to convey a form of prediction error for the delivery of reward, a signal that is exactly appropriate for training predictions (as in eqn [1]). This finding leads to a large range of questions about what happens when the temporal relationship between the image and the juice is manipulated (the data here showing that the Rescorla–Wagner rule is critically flawed) or when there are multiple predictive images or stimuli, how prediction learning and action learning are coupled, and how punishments (e.g., small electric shocks) are processed. There are also some data about the neural structures involved in the various components of this learning rule (i.e., x^n and w^n), notably implicating nuclei in the amygdala and the orbitofrontal cortex, together with their connections to the nucleus accumbens, all structures that receive a strong dopamine projection.

Temporal Prediction

The use of the word prediction hints at the critical role that time plays in conditioning experiments. Broadly speaking, to be a good predictor, it is important that the image precede (rather than coincide with or follow) the juice. This leads to both conceptual and psychological/neural problems. The conceptual problem is that it is necessary to change the goal of prediction – there is no point in predicting the amount of juice that will be provided at the same time as the image, since they are not delivered at the same time; rather, it is necessary to predict the amount that will come in the future. An important step in the field was the suggestion by Richard Sutton and Andrew Barto that participants should try to predict a long-run measure of the reward, such as its sum over a whole trial. Achieving this requires a different prediction error from that in eqn [3]. It also turns out that this new prediction error accounts for more features of the activity of dopamine neurons, specifically their firing patterns at the time of the image presentation.

To understand this new prediction error, one needs a new variable t to count time within each trial. For instance, the image might be presented at time $t = 2$, the juice at time $t = 5$, with the trial ending at $t = T$. Now the reward on trial n is indexed by time $r^n(t)$ with, for instance, $r^n(5) = 1$ on trials on which the juice is given. The new task of the participants is to predict $v^n(t)$ at time t within a trial as the sum of all the future rewards that will be provided on average during that trial after t. Assuming for the moment that rewards are delivered deterministically, this means that the following relationship should hold (for which is used the symbol $\triangleq$):

$$v^n(t) \triangleq r^n(t) + r^n(t+1) + r^n(t+2) + \ldots + r^n(T) \qquad [4]$$

The obvious trouble with this definition as a goal for prediction is that the right-hand side, measuring the actual delivery of juice, cannot be assessed until the end of the trial. The solution to this problem, which underlies the new prediction error, is to observe that the sum can be split into its first and

subsequent terms:

$$v^n(t) \triangleq r^n(t) + [r^n(t+1) + r^n(t+2) + \ldots + r^n(T)] \quad [5]$$

so if the prediction at time $t+1$, $v^n(t+1)$, is, as it should be, equal to $r^n(t+1) + r^n(t+2) + \ldots r^n(T)$, then,

$$v^n(t) \triangleq r^n(t) + v^n(t+1) \quad [6]$$

The new prediction error becomes the discrepancy between the left- and right-hand sides and can be computed after waiting just one timestep, without waiting for the end of the trial:

$$\delta^n(t) = r^n(t) + v^n(t+1) - v^n(t) \quad [7]$$

This is called the temporal difference prediction error because of the key role played by the change in the prediction over consecutive timesteps ($v^n(t+1) - v^n(t)$). Even though, during learning, it cannot be guaranteed that $v^n(t+1) = r^n(t+1) + r^n(t+2) + \ldots + r^n(T)$, it turns out that a learning rule like eqn [1], using $\delta^n(t)$ to update the weights associated with the prediction made at time t will also ultimately arrive at the correct values. Learning of this sort is said to involve bootstrapping because the predictions at one time are learned partly on the basis of predictions at the subsequent time.

The most important practical difference between the previous and present prediction errors (i.e., between eqns [3] and [7]) is the value of the new prediction error associated with the first presentation of the image (in this case, $\delta^n(1) = r^n(1) + v^n(2) - v^n(1) = 0 + v^n(2) - 0 = v^n(2)$). If the image is always followed by juice, then, once learning is complete, the prediction changes from $v^n(1) = 0$ to $v^n(2) = 1$ when the image is provided, resulting in a transient prediction error at time $t = 1$, $\delta^n(1) = 1$. The prediction then remains at 1 until the reward is actually delivered, so there is no difference between $v^n(t)$ and $v^n(t+1)$, and therefore $\delta^n(t) = 0$ for all t preceding the time of reward. At the reward time, (here $t = 5$), no further reward is expected in the trial, so $v^n(6) = 0$, and the error from eqn [7] is $\delta^n(5) = r^n(5) - v^n(5)$. Hence, this prediction error behaves similarly to that in the Rescorla–Wagner rule for all the situations shown in Figure 1(b).

Figure 1(c) shows that the activity of dopamine neurons at the time of the image follows exactly the pattern expected from eqn [7]. It is as if the activity that at the beginning of training happens at the time of the unexpected reward moves backward in time across the trial so that it is instead initiated by the earlier reliable predictor of that reward, namely, the image. The transient activity at the time of the image can play a number of important functions, notably, allowing a predictor of reward to act like a surrogate reward itself, an effect known in psychology as conditioned reinforcement.

The neural problem associated with temporal prediction is exactly that the predictors need to be able to count time; in this case, the time since the image was presented. The well-timed depression in the activity of the dopamine neurons when an expected reward is not delivered is clear evidence that exactly this happens (and incidentally argues strongly against certain other construals of the dopamine activity, for instance that it flags all 'salient' events without regard to their appetitive or aversive valence). However, although there are various suggestions about the involvement of the cerebellum, the hippocampus, the striatum, and the parietal and frontal cortices in counting time, the exact nature of this signal is not well understood.

Multiple Predictive Stimuli

So far only the case of just one potentially predictive image has been considered. Now consider the case in which there are multiple predictive stimuli. It turns out that only the temporally simple case (associated with the Rescorla–Wagner rule) has to be treated, since the issues about time t within a trial are orthogonal to those about the multiple stimuli.

The Rescorla–Wagner version of the learning rule (eqn [1]) was designed to address psychological phenomena that arise when there are multiple predictive stimuli. The main idea is to elaborate it to the following:

$$w_i^{n+1} = w_i^n + \alpha_i^n \delta^n x_i^n \quad [8]$$

where there are now multiple stimuli x_i^n, each with its own prediction weight w_i^n, but, critically, still with only one global prediction error δ^n.

The Rescorla–Wagner rule involves the net prediction v^n of juice, defined as the sum of the predictions associated with each stimulus:

$$v^n = x_1^n \times w_1^n + x_2^n \times w_2^n + \ldots \quad [9]$$

If, perhaps as a result of prior learning, one of the stimuli present on a trial already predicts the reward correctly, then the prediction error (of eqn [3]) will be 0 ($\delta^n = 0$), and therefore the synapses associated with any other stimuli which are also present, including those that do not yet predict the reward, will not change. This effect is known in the psychological literature as blocking. The ample behavioral evidence for blocking was taken as an early sign that learning is indeed driven by prediction errors rather than, for instance, simply correlations. There is also some evidence for blocking in the activities of dopamine neurons.

Stimulus multiplicity could also affect the other components of the learning rule. In particular, a number of competing learning rules that have been suggested on the basis of psychological data suggest that there are stimulus-specific predictions (and prediction errors) and invoke stimulus-specific (and changing) learning rates α_i^n. These rules treat the learning rates as associabilities, reflecting a measure of the attention that the learners lavish on the stimuli. The most celebrated of these accounts, due to John Pearce and Geoffrey Hall, suggests that stimuli should be associable to the degree that they have had surprising consequences. In this view, multiple stimuli can interact with one another to produce learning phenomena such as blocking at least partly through competition for these associabilities. This account has attracted many experimental and theoretical studies.

Experimentally, Peter Holland, Michela Gallagher, and their colleagues have collected evidence from lesion, pharmacological, and behavioral studies suggesting that associabilities are realized (at least in rats) through a pathway involving the central nucleus of the amygdala, attentional and control regions of the cortex, and, notably for the topic of this article, various parts of the acetylcholine system. Oddly, there appear to be different anatomical substrates for increases and decreases in stimulus associability.

From a theoretical perspective, the sort of surprise inherent in Pearce and Hall's suggestion can be formulated as a particular form of uncertainty (a fact that, together with Holland and Gallagher's six results and others, led to the suggestion that such uncertainty might be reported by acetylcholine). Normative theories of prediction learning arising in the fields of statistics and engineering actually suggest learning rules rather like eqn [8] and provide a precise characterization of what factors should control α_i^n. The best known and simplest of these theories, called the Kalman filter, suggests that the learning rates act to divide up the impact of the prediction error δ^n on the weights w_i^n for each of the stimuli such that the stimuli whose weights are least well known (i.e., most uncertain) are most susceptible to learning. That is, the more uncertain the prediction made by one stimulus (for instance, because it has been observed only a few times), the more it is deemed responsible for any nonzero prediction error δ^n, and so the more its prediction w_i^n changes. Variants of this theory also link a stimulus's uncertainty to the degree of surprise that has accompanied it, as for associability in the Pearce–Hall rule. Additionally, in noisy environments in which stimuli and rewards are inherently unreliable, the learner should expect substantial prediction errors even if its predictions are as good as can be. This should have the effect of reducing all the learning rates.

Although the Kalman filter certainly captures something of the flavor of the Pearce–Hall learning rule, its detailed predictions and putative cholinergic substrates have yet to be fully tested, either behaviorally or neurally. Norepinephrine also seems to exert rather general effects on the overall speed of learning, particularly in circumstances in which there are gross changes to an environment. One theoretical account of this suggests that norepinephrine reports a different form of uncertainty, that associated with the whole context. This is coupled to learning since contextual change typically induces a need for gross revision or fresh acquisition of predictions. There are two final issues associated with multiple stimuli. First, the task of combining the predictions of reward made by multiple stimuli can be considered an example of the more general statistical problem of combining multiple sources of evidence. There is ample psychological data suggesting that, as in most statistical accounts, this sort of combination is typically not additive (as in eqn [9]) but rather is competitive, with the predictions made by different stimuli being averaged together and the prediction of the most reliable (least uncertain) predictor being weighted most heavily. How important this is for prediction learning, and indeed what its neural substrate is, are presently unclear.

Second, the notion that each stimulus has its own independent, binary input feature x_i is too simple, particularly if the stimulus representations associated with prediction learning are those in refined areas such as prefrontal cortex. Rather, sophisticated cortical (and perhaps hippocampal) mechanisms will play a critical role in creating stimulus representations that are appropriately tailored to sensory experience.

Action Learning

So far, this article has considered prediction learning but not the selection of actions based on such predictions. Although the prediction of upcoming reward can in itself directly trigger conditioned behavioral responses, such as approach, or the salivation of Pavlov's dogs, these represent a fairly limited portion of the behavioral repertoire. Animals can also learn to take arbitrary actions (such as pressing a lever) in order to obtain rewards that are contingent on such actions. This learning is known as instrumental conditioning, and its neural substrates have actually been more extensively investigated than those of Pavlovian conditioning. This area has revealed some important complexities; for instance, in rats, an instrumentally conditioned behavior such as a lever press can apparently arise through either of at least two neurally and behaviorally dissociable pathways. One of these involves at least the prelimbic prefrontal

cortex and the dorsomedial striatum, may be somewhat independent of dopaminergic neuromodulation, and produces actions that can behaviorally be shown to be sensitive to the particular reward (such as food) expected. Such actions are therefore known as 'goal-directed.' The other pathway involves the dorsolateral striatum and the infralimbic prefrontal cortex, is strongly dependent on dopamine, and produces so-called 'habitual' actions. These are behaviorally characterized by their insensitivity to the particular reward expected; for instance, a rat may habitually press a food delivery lever even if it is not hungry.

There is both behavioral and neural evidence that the habitual action system is based on prediction learning of almost exactly the sort described above. This is consonant with a much larger body of evidence that dopamine is involved in action choice; besides habitual instrumental action, the neuromodulator is associated with addictive drugs, with self-stimulation experiments in which animals will work to receive electrical stimulation in some brain areas, and with motor pathologies such as Parkinson's disease. One particular view of action learning has recently received strong support from data on the activity of dopamine neurons in a task which involves monkeys' making choices between alternatives associated with different probabilities of reward. Under this scheme, the predictions should be not of the reward that will accrue after time t (written as $v^n(t)$ in eqn [4]), but rather of those that will accrue after time t if the learner chooses a particular action (say, a (t)) at time t. These so-called Q-values (written as $Q(t,a(t))$ were originally suggested by Christopher Watkins. If such predictions were known perfectly, action selection could ensue simply by choosing the action whose value is greatest, that is, the one predictive of the most reward. For a number of reasons, it can be prudent to choose somewhat randomly, assigning a greater chance to actions with greater Q-values:

$$P(a(t) = a) = \frac{e^{\beta Q(t,a)}}{\sum_b e^{\beta Q(t,b)}} \qquad [10]$$

Here, $\beta > 0$ controls how fierce the competition is; the larger β, the more likely the action with the largest Q-value will be chosen. One reason to employ such a probabilistic rule is to ensure exploration of unfamiliar alternatives and to avoid behavioral rigidity. It has been suggested that norepinephrine regulates exploration by controlling β, coupling the long-term success of a behavioral policy to reduced exploration and long-term failure to enhanced exploration. There is also starting to be some evidence (from functional imaging in humans) about the involvement of neural structures such as the frontal pole and the intraparietal sulcus in regulating exploration on a trial-by-trial basis.

The recent evidence from the activity of dopamine neurons during choice between several possibly rewarding actions favors a particular temporal-difference rule for learning the Q-values. Just as the prediction error $\delta^n(t)$ in eqn [7] is based on the difference between two successive predictions $v^n(t+1)$ and $v^n(t)$, this new prediction error is based on the difference between two successive predictions, $Q^n(t+1,a(t+1))$ and $Q^n(t, a(t))$, depending on the actions that are actually executed at times t and $t+1$:

$$\delta^n(t) = r^n(t) + Q^n(t+1, a(t+1)) - Q^n(t, a(t)) \qquad [11]$$

This prediction error can then be used at the heart of a learning rule just like that in eqn [1], with the prediction $Q^n(t,a(t))$ being updated on the basis of this prediction error.

Appetitive and Aversive Predictions

This article has discussed appetitive predictions and the role of dopamine. However, in many circumstances, it is actually even more important to predict aversive outcomes. Further, animals can certainly learn to execute particular actions to avoid punishments and can titrate their actions to balance the benefits and costs of rewards and punishments associated with particular actions. The difference between appetitive and aversive predictions and outcomes is completely transparent to the normative theories, which happily consider them to live at positive and negative segments of a single dimension of value. However, there is a huge body of psychological and neural data showing that animals treat them very differently. There are also many open controversies in the literature, including a very active debate about the role of dopamine in aversively motivated behaviors. Aversive predictions play a key role in psychiatric conditions such as anxiety disorders (whose basis may be nonfactual predictions of threat) and paranoid schizophrenia.

These various data have yet to be encompassed in the sort of integrated computational, psychological, and neurobiological account outlined here for appetitive prediction learning and action choice. A popular psychological idea is that separate, but interacting, opponent systems are involved in training appetitive and aversive predictions. One possibility, suggested by William Deakin and Frederico Graeff and still somewhat speculative, is that one part of the serotonin system acts as the aversive opponent to dopamine. The data supporting this idea mainly originate in studies of the behavior of animals under

pharmacological manipulation of serotonergic and dopaminergic function. Full tests of this hypothesis using electrophysiological recordings of serotonergic neurons are only just beginning.

Immediate Effects of Neuromodulators

This article has emphasized the effects of neuromodulators on learning. However, a more traditional view of neuromodulation, established most firmly in studies of central pattern generation in invertebrates, is that it regulates connectivity and excitability over the short term, allowing multiple functional networks to share a single anatomical substrate. Even in the context of the sorts of conditioning functions discussed here, there is indeed evidence that the neuromodulators exert short-term effects not mediated through learning. A few, in particular, have been most extensively investigated, including the impact of dopamine on working memory and on the vigor of responding, and the role of acetylcholine and norepinephrine in regulating different sources of information associated with making predictions.

There is quite some evidence that dopamine, like other neuromodulators, can immediately influence the excitability of neurons, often characterized by the gain of their input–output functions. If the neurons are connected in competitive networks (for instance, subserving the choice between multiple possible actions), then changing the gain (a bit like changing β in eqn [10]) can change the dynamics and stability of the competition. The effect of this on action choice has been studied in some detail by Jonathan Cohen and his colleagues. In prefrontal cortex, a similar effect of dopamine has been suggested as being important for gating the short-term storage of information (such as the fact that an image predicting reward was recently presented). As shown, this sort of storage plays a critical role in making appropriate predictions and therefore also in choosing appropriate actions.

Dopamine also appears to control the vigor or the force of behavioral responses. For instance, the overt effects of dopaminergic agonists such as amphetamine are hyperactivity; antagonists produce lethargy and affect the propensity to choose actions that have high costs. These effects also appear to be immediate, in that learning is not required for them to be exhibited. The reinforcement learning theories so far described do not encompass such phenomena, since they are designed to address choice among a discrete set of candidate actions and lack any analogue of a response vigor. A recent extension of the standard reinforcement learning picture accommodates free-operant tasks, in which subjects choose the latency of each of their responses, balancing the costs and benefits of vigorous responding. The model argues that tonic levels of dopamine report the average rate of reward and act as a form of opportunity cost which determines the optimal response vigor. The greater the opportunity cost, the greater the expectation of reward per unit time, and so the faster the participant must act to achieve this. This also implicates tonic dopamine in mediating the effects of motivation on response vigor. For instance, satiety, reducing the value of each reward, would decrease the net average rate of reward and thus result in lower tonic dopamine levels and more-sluggish responding.

Finally, if acetylcholine reports on the learner's uncertainty about aspects of its environment, then from a statistical viewpoint, it should influence not only learning but also the interpretation of sensory input – in statistical terms, inference. In particular, if uncertainty is high, then 'top-down' information about prior beliefs and expectations should be less trusted than 'bottom-up' information from sensation. This involves just the sort of regulation of connectivity that is implied by invertebrate neuromodulation. There is indeed substantial evidence that acetylcholine can boost the impact of bottom-up information compared with top-down information. Concomitantly, if norepinephrine reports on contextual change, then it should also have the effect of regulating the use of top-down information.

Summary

Neuromodulators are involved in some of the most basic adaptive functions of an organism, notably how it behaves and learns to behave appropriately in light of rewards, punishments, and other information. Dopamine and, putatively, serotonin appear to report prediction errors for future reward and punishment, to influence the acquisition of predictions and appropriate habitual actions, and to effect motivationally appropriate responding. Acetylcholine and norepinephrine seem to report on forms of uncertainty to control the allocation of learning among different possible predictors, the overall speed of learning, and the way that information from sensation is integrated with information based on past experience in an environment.

Accounts adapted from statistics, operations research, computer science, and engineering offer a normative underpinning for both the behavioral data and at least some key aspects of the neural substrates.

Lexical Impairments Following Brain Injury

R Casas and D Tranel, University of Iowa, Iowa City, IA, USA

Lexical retrieval, which refers to the ability to retrieve words, is an essential component of language communication. Production of an appropriate word for a given stimulus involves activation of multiple processes in the brain. Damage to brain areas associated with the processes involved in lexical retrieval can lead to naming deficits that disrupt fluent speech, which can greatly encumber an individual's ability to communicate. Such impairments are common sequelae of brain injury and thus are an important topic of clinical and scientific inquiry. The types of brain injuries that commonly lead to impairments in lexical retrieval include stroke, head injury, surgical resection to treat pharmacoresistant epilepsy (left temporal lobectomy), and degenerative diseases that have a proclivity for left hemisphere regions important for lexical retrieval (including Pick's disease and Alzheimer's disease). This article summarizes the nature and types of lexical impairments that can occur as a result of damage to specific brain areas.

Deficits in lexical retrieval refer to the inability to provide names for things such as concrete entities (typically named by nouns), actions (typically named by verbs), or spatial relationships (typically named by prepositions). Defined as 'anomia' in the medical and scientific literature, lexical retrieval impairments are a frequent part of the symptom complex that characterizes patients with aphasia. In general, aphasia can be defined as an acquired disturbance of the comprehension and formulation of verbal messages following damage to language-related brain structures (typically in the left hemisphere). Lexical retrieval, which requires the capacity to retrieve a particular word to designate an entity or event at the appropriate level of specificity, is different from the ability to recognize the entity or event. Whereas 'naming' refers specifically to knowing what something is called, 'recognition' involves semantic understanding of the entity or event and, hence, the ability to retrieve conceptual knowledge for it. Patients with anomia have lost the ability to retrieve names of things, but they have not lost the ability to recognize what things are. Hence, even when they cannot name things, anomic patients can usually produce accurate descriptions of those things or indicate by gestures and other nonverbal forms of communication that they have normal knowledge of things. For example, when shown a picture of a camel, the patient may say, "That is an animal that has humps on its back, lives in the desert, and can go for a long time without water." When shown a picture of Bill Clinton, the patient may say, "That guy was a president; had an affair, had a southern accent." Similar 'subclinical' forms of lexical retrieval problems occur fairly frequently in the realm of normal experience, particularly under conditions of fatigue, distraction, or in connection with normal aging. A related phenomenon is 'tip-of-the-tongue' state, which occurs when normal individuals experience the inability to retrieve a particular name (especially proper names) even though they know perfectly well what it is that they are attempting to name.

Neuropsychological studies of naming and recognition suggest that these two processes may be subserved by partially distinct brain networks. Some evidence for the neural separation of the processes involved in lexical retrieval and recognition comes from category-related deficits that are limited to the verbal modality, such as the famous case of patient 'CP.' CP was selectively impaired in the naming of artifacts (man-made objects such as tools and utensils). Although CP was able to recognize objects, he could not name them, indicating a lexical rather than conceptual deficit. Interestingly, CP could recognize and name objects from other stimulus categories (e.g., familiar faces and animals). Additional evidence compatible with the neural separation between conceptual and lexical retrieval processes comes from research with patients suffering from semantic dementia, who often have bilateral temporal atrophy. Studies have shown that these patients are impaired in both naming and recognition, whereas patients with damage limited to the temporal region tend to be impaired in naming but not in recognition. Additional evidence for the neural separation between the systems subserving lexical retrieval and recognition comes from studies which examined lesion overlap in patients who showed only naming problems and patients who showed both naming and recognition problems.

Relative to the main types of aphasia syndromes, pure anomia in the absence of additional speech or linguistic deficits is fairly uncommon. It occurs far less frequently than most of the 'classic' aphasia syndromes, such as Broca's aphasia and Wernicke's aphasia. For those cases for which lexical impairments occur as an isolated manifestation of acquired brain dysfunction, the designation of 'anomic aphasia'

applies. Studies of patients with anomic aphasia have identified distinct brain structures that are specialized for different categories of concrete entities (faces, landmarks, animals, tools, and fruits and vegetables) as well as for different types of words (i.e., words referring to concrete objects, actions, and spatial relationships). The classic aphasia syndromes are associated with brain damage in the vicinity of the Sylvian fissure in the left hemisphere (the left hemisphere is dominant for language in the vast majority (approximately 98%) of right-handed individuals and in the majority (approximately 70%) of left-handed individuals). Isolated defects in naming, however, which define anomic aphasia, are associated primarily with damage to structures in the left hemisphere outside the classic language regions. Specifically, anomic aphasia is most often caused by damage to the left anterior temporal lobe, the inferior and lateral aspect of the left temporal lobe, or the left occipitotemporal junction. Scientific investigations of patients with anomic aphasia, using modern neuroanatomical and neuropsychological techniques, have revealed a number of intriguing associations between specific brain structures and specific types of naming abilities. Studies in normal subjects, using functional neuroimaging procedures (positron emission tomography and functional magnetic resonance imaging), have corroborated several of these findings.

Category-specific lexical impairments following acquired brain injury have been observed and investigated by several researchers. With regard to the retrieval of words for various categories of concrete objects, work conducted in our laboratory has led to several general conclusions. First, there is strong left hemisphere specialization, as would be expected for word retrieval processes (although category-related word retrieval deficits have been reported in connection with right hemisphere lesions as well). Second, there is consistent evidence for category relatedness in the arrangement of systems that support word retrieval for different categories of concrete entities. Lesion studies have shown that defective naming of unique persons and unique landmarks is associated with lesions in the left temporal pole. Defective naming of animals is associated with lesions in left anterior inferior temporal (IT) areas, anterior insula, and the dorsal temporo-occipito-parietal junction. Defective naming of tools is associated primarily with lesions in the left posterior lateral temporo-occipito-parietal junction and with lesions in the inferior pre- and post-central gyri and the insula. Defective naming of fruits and vegetables is associated with lesions in left inferior pre- and post-central gyri and anterior insula. Defective naming of musical instruments is associated with lesions in the left temporal polar region and anterior IT, the posterolateral temporal region (close to the motion-related area known as MT), the insula, and the inferior pre- and post-central gyri. The degree of segregation for different categories varies, and is more or less defined, depending on the categories being contrasted. For example, the association between retrieval of proper names (persons and landmarks) and the left temporal polar region has been particularly strong, as has the association between retrieval of tool names and the left posterior lateral temporo-occipito-parietal junction. However, categories such as musical instruments and fruits and vegetables have not revealed highly localized and reliable neural correlates. Convergent findings have been reported by a number of other laboratories.

In addition to the category-specific distinctions for concrete entities, there are also intriguing distinctions between different types of words. For example, the brain regions that are important for retrieving words for concrete objects (nouns) are partially separate from those that are important for retrieving words for actions (verbs). As noted previously, the retrieval of words for actions is associated with neural structures in the frontal operculum (in front of the Rolandic sulcus) of the left frontal lobe. Researchers in our laboratory have conducted several studies focused on the neural correlates of retrieving words for actions. Specifically, these studies attempted to determine if the neural systems subserving lexical retrieval for objects and actions were segregated. They also investigated whether lexical retrieval for actions involved not only structures of the left inferior frontal gyrus, particularly the frontal operculum, but also intermediary structures located in left premotor/prefrontal areas. One such study used the lesion method and involved 75 subjects with focal, stable lesions in the left or right hemisphere. The experimental tasks were standardized procedures for measuring action and object naming. Results from the study indicated that lesions of the left anterior temporal and inferotemporal regions, which produce impairments in naming of concrete entities, did not cause action-naming deficits. Additionally, lesions associated with impaired action naming overlapped maximally in the left frontal operculum and in the underlying white matter and anterior insula. A follow-up analysis indicated that action-naming impairments, especially when they were disproportionate relative to concrete entity naming impairments, were associated with not only premotor/prefrontal lesions but also lesions of the left mesial occipital cortex and those of the paraventricular white matter underneath the supramarginal and posterior temporal regions.

Interestingly, some studies have suggested that noun–verb homophones (e.g., words such as 'hammer'

or 'duck', which are used frequently as either nouns or verbs) are retrieved by the brain system that fits the context in which the word is being used. For example, if 'hammer' is being used as a noun, the temporal lobe system will be used, but if 'hammer' is being used as a verb, the frontal lobe system will be used. Such dissociations may appear rather curious on the surface, but there are compelling explanations and theories of why the brain has organized knowledge in different regions to subserve words from different grammatical categories. For example, factors such as whether an entity is unique (e.g., 'Tom Hanks') or nonunique (e.g., a screwdriver), whether it is living (e.g., pig) or nonliving (e.g., a hammer), whether it is manipulable (e.g., a wrench) or nonmanipulable (e.g., a giraffe), or whether it makes a distinctive sound (e.g., a rooster) or not (e.g., a thimble) are important in determining which neural structures will be used in the mapping and retrieval of knowledge for entities, including their names. The dissociation between deficits in naming objects and deficits in naming actions is also confirmed in studies of patients with degenerative conditions, such as variants of primary progressive aphasia. Also, patients with semantic dementia (SD) have been shown to be impaired in their semantic knowledge concerning objects. The speech of patients with SD is fluent but dramatically marked by anomia. Interestingly, SD is characterized by prominent atrophy in anterolateral temporal cortex (one of the brain structures that, when damaged, has been associated with category-specific lexical impairments for concrete entities) of either the left or both the left and the right hemispheres. Patients with progressive nonfluent aphasia (PNFA), on the other hand, tend to be more impaired in action rather than object naming. Their speech is nonfluent and effortful, with grammatical and phonological errors. PNFA is also characterized by neuronal loss most prominent in inferior frontal and superior temporal regions. These findings are in general agreement with the findings from focal lesion patients, as noted previously.

Very little research has explored which neural systems may be important for retrieving words for spatial relationships (locative propositions such as 'in,' 'on,' and 'around'). Our laboratory has carried out exploratory work on this domain. In one lesion study, the hypothesis that processing the meanings of locative prepositions depends on neural structures in the left inferior prefrontal cortex and left inferior parietal cortex was tested. Seventy-eight subjects with focal, stable lesions to various parts of the telencephalon and a comparison group of 60 normal participants performed tasks that required production, comprehension, and semantic analysis of locative prepositions. In support of the hypothesis, it was found that in subjects with impaired knowledge of locative prepositions, the highest region of lesion overlap was in the left frontal operculum and the left supramarginal gyrus, and in the white matter subjacent to these two areas.

A second study on six patients who had pervasive defects for locative prepositions confirmed that such defects were associated specifically with damage to the posterior left frontal operculum, white matter subjacent to this region, and white matter underneath the inferior parietal operculum. These patients did not have basic impairments in spatial processing or working memory, and they had relatively well-preserved conceptual knowledge for actions and various categories of concrete entities (e.g., persons, animals, and tools). All six patients, however, had defects in naming actions, and some also had defective naming of some categories of concrete entities. Overall, the findings converge well with results from functional imaging, and with results from classic cases in the aphasia-based literature, and suggest that the left inferior prefrontal and left inferior parietal regions have crucial, albeit not exclusive, roles in processing knowledge associated with locative prepositions.

The anomic deficits described throughout this article can occur in connection with any sensory modality – for example, when a person is attempting to name a picture of something, a sound, a smell, or something that is felt by the hand. Anomia can occur in the course of verbal discourse, such as when one is speaking and suddenly cannot retrieve the name for a particular concept that is part of the intended utterance. The majority of scientific inquiries into the phenomenon of anomia, however, have focused on the visual modality and have used paradigms in which subjects are presented pictures (or actual objects) and asked to name them. This format, known as 'visual confrontation naming,' is also the standard paradigm for assessing naming in patients with brain injuries. As a consequence, most of our current knowledge regarding the brain underpinnings of word retrieval and most theoretical accounts of this process are heavily tied to the visual modality. However, evidence suggests that the modality in which a stimulus is perceived may not make much difference. For example, retrieval of the name 'rooster' when confronted with a picture of a rooster, or when confronted with the characteristic sound of a rooster, appears to depend on the same left temporal lobe region.

For the majority of individuals, those who have not acquired a brain injury or do not suffer from a neurodegenerative disorder, lexical retrieval comes naturally and effortlessly. However, the relative ease with which most of us are able to provide names for various objects, actions, and entities is somewhat

deceptive. There are a number of neural systems involved in the recognition and retrieval of appropriate word forms that, when disrupted by brain injury, can produce a variety of deficits. Lesion studies of patients with anomic aphasia have provided a unique opportunity to learn how the brain operates the processes associated with word retrieval. Results from these studies have identified different brain structures that are specialized for different types of words and different categories of entities. Future research on patients with anomic aphasia will continue to shed light on how the human brain operates language processes and, it is hoped, will help to inform rehabilitation efforts aimed at patients with acquired disturbances of naming.

LIM Kinase and Actin Regulation of Spines

Z Jia, Z Todorovski, Y Meng, S Asrar, and L-Y Wang, University of Toronto, Toronto, ON, Canada

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The dendritic spine is the major postsynaptic site of glutamatergic synapses and is thought to be important for synaptogenesis, synaptic regulation, and cognition. Spine changes and deficits are associated with a wide range of physiological and pathological conditions, including synaptic plasticity and mental disorders. For the last decade, a variety of techniques, including imaging, molecular perturbations, and genetic analyses, have been employed to investigate spine properties and their relation to synaptic regulation. As a result, a large number of molecules have been identified to regulate spine formation and morphology. Significantly, despite the diversity of these molecules, they appear to converge to affect signaling processes involved in the regulation of the actin cytoskeleton, the key structural component of the spine (Figure 1). In this article, we discuss the role of the LIM (Lin-11, Isl-1, and Mec-3) domain containing protein kinase (LIMK) family in the regulation of the neuronal actin network and structures. Although the members of the LIMK family are also present and important for presynaptic terminals, we focus our discussion on the postsynaptic specialization and functional significance, including spine morphogenesis, postsynaptic structure, synaptic plasticity, and cognition.

The Dendritic Spine, Synaptic Regulation, and Mental Diseases

In the mammalian central nervous system (CNS), glutamate is the major excitatory neurotransmitter that exerts its effects by activating various glutamate receptors, including *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and metabotropic G-protein-coupled receptors (mGluRs). The vast majority of excitatory synapses are formed on the head of the dendritic spine, a highly specialized dendritic protrusion where the glutamate receptors and associated molecules are localized. Therefore, it is not surprising that spine properties (e.g., spine density, morphology, and plasticity) have profound effects on synaptic structures and functions. For example, the size and geometry of the spine are linked to the numbers of synaptic glutamate receptors, Ca^{2+} dynamics, and the ability to undergo bidirectional changes in the efficacy of synaptic transmission. This includes hippocampal long-term potentiation (LTP) and long-term depression (LTD), the most extensively studied forms of long-lasting synaptic plasticity thought to be critical for proper neuronal connections and memory formation. Conversely, synaptic activities and learning experience are also found to regulate spine density, shape, and motility. These observations suggest that spines are essential and integral components of synaptic regulation and cognitive processes.

Consistent with their role in synaptic and cognitive regulation, both human and animal studies have suggested that spines may be a structural target of various mental disorders and neurological diseases. For example, morphological studies on patients with mental retardation (MR) revealed profound deficits in spine properties (e.g., reduction in spine density and abnormal spine morphology) in the absence of gross changes in the CNS anatomy. In addition, animal models of MR and drug addiction exhibit changes in spine development, maturation, and morphogenesis. Although it is not clear whether spine deficits are a primary cause or a secondary consequence of these mental disorders, human molecular genetic studies support the hypothesis that spines are among the main targets of genetic abnormalities. For example, an increasing number of MR genes, including the LIMK-1 gene, have been identified as encoding putative proteins potentially involved in the signal transduction pathways. These are mediated by the Rho family small GTPases, which are central mediators of actin dynamics and cell morphology. Given the predominant role of the actin cytoskeleton in the structural properties of the spine, it is likely that MR gene mutations result in abnormal Rho signaling that directly targets spines.

LIM Kinase 1 and Actin

The LIMK family is a unique group of serine/threonine/tyrosine protein kinases with two N-terminal LIM domains, a PDZ (PSD-95, Dlg, ZO-1) domain, and a C-terminal kinase catalytic domain. Both LIM and PDZ domains have been found in various proteins that are believed to mediate protein–protein interactions, but the role of these protein modules associated with LIMK has not been clearly defined. Although two members of the LIMK family (LIMK-1 and LIMK-2) have been identified and found to be expressed in the mammalian CNS, most studies related to neuronal structures and functions have focused on LIMK-1. However, because of their

Figure 1 Regulation of spines and synaptic function by LIMK-1: (a) cultured hippocampal neurons stained with the F-actin dye phalloidin (red) and an antibody against microtubule-associated protein (MAP)2 (green), showing mushroom-shaped spines (arrows) with intense F-actin presence but a lack of microtubules; (b) cultured hippocampal neurons transfected with green fluorescent protein (GFP), showing similar spine morphology as revealed in (a) by phalloidin staining; (c) representative dendritic branch of cultured hippocampal neurons prepared from wild-type (WT) mice, showing distinct spine heads with significantly higher F-actin staining than adjacent dendritic shafts; (d) representative dendritic branch of cultured hippocampal neurons prepared from LIMK-1 knockout ($KI^{-/-}$) littermates, showing a lack of distinct spine heads and abnormal accumulations of F-actin in the dendritic shaft; (e) a hypothetical model for LIMK-1 regulation of spine morphology and synaptic function. In this model, the protein level or the activity of LIMK-1 can be regulated by various signals, including synaptic activity. For example, LIMK-1 could be reciprocally regulated by LTP and LTD induction. High LIMK-1 during LTP results in spine F-actin accumulations and spine enlargement, whereas low LIMK-1 causes actin depolymerization and spine shrinkage. ADF, actin depolymerization factors; BDNF, brain-derived neurotrophic factor; GTPase, guanosine-5′-triphosphate binding protein; LIMK, LIM kinase; LTP, long-term potentiation; PAK, p-21 activated kinase; PSD, postsynaptic density; ROCK, Rho kinase.

similar biochemical properties and regulation, it is expected that at least some of the known neuronal functions found in LIMK-1 studies can also be extended to LIMK-2.

Consistent with cell line studies, LIMK-1 is a potent regulator of the actin cytoskeleton in the mouse CNS. Thus, the disruption of LIMK-1 causes profound deficits in actin properties. In mature pyramidal neurons, actin is the predominant cytoskeletal protein in the dendritic spine. Therefore, cycling between polymerized actin filaments (F-actin) and monomeric actin (G-actin) is the key determinant of a stable spine structure as well as its dynamic changes, including spine motility and plasticity. As shown in Figure 1(a), the F-actin dye phalloidin staining (red) is extremely intense in the spine, which essentially lacks microtubules (green) that are abundant in the dendritic shaft. The importance of the actin cytoskeleton in neuronal structure and function has been demonstrated in numerous studies. Direct perturbations of actin dynamics using pharmacological reagents significantly affect a wide range of neuronal properties, including spine formation, synaptogenesis, spine motility, and synaptic plasticity. Although not clearly defined in molecular organization and functional significance, spine F-actin appears to exist in

at least three forms, each apparently associated with distinct spine compartments or organelles. First, a network of actin filaments is present throughout the spine head, some of which are in contact with a distinct electron-dense region called the postsynaptic density (PSD). This fraction of actin filaments may serve as a major structural component of the spine and is probably critical for proper spine morphology. Second, a pool of F-actin is physically contained in the PSD, possibly serving as anchoring proteins for the PSD components, including glutamate receptors. For example, NMDA receptors can directly interact with the actin-binding protein α-actinin, which may stabilize the former by linking them to the actin cytoskeleton. In addition, this pool of actin may directly participate in the regulation of the channel properties of the receptors and their signaling to the spine cytosol. Finally, a more stable class of actin filaments are found along the neck of the spine. LIMK-1 appears to be particularly important for the first two pools of F-actin because LIMK-1 knockout neurons display a significant reduction in the amount of F-actin at the spine head but not at the neck of the spine. In fact, abnormal accumulations of F-actin clusters in knockout mice are significantly enhanced, both at the base of the spine neck and in adjacent dendritic shafts. It is possible that separate signaling processes independent of LIMK-1 are responsible for maintaining dendritic actin filaments. These results suggest that LIMK-1 is of special significance to the regulation of actin reorganization in response to spine and synaptic activities.

LIM Kinase 1 and Spine Morphogenesis

In accordance with its regulation of spine actin, perhaps the most clearly demonstrated role of LIMK-1 is the regulation of spine structure, specifically the morphology of the spine. Although spines are very heterogeneous in size and shape, as well as being highly dynamic (they can be easily altered by additional factors, including experimental conditions and the age of spine development), most of them have an enlarged head and a thin constrictive neck (i.e., mushroom-shaped; **Figure 1(a)**). This shape is well conserved both in cultured neurons and in the *in vivo* brain and appears to require functional LIMK-1. Thus, hippocampal pyramidal neurons from LIMK-1 knockout mice exhibit filopodium-like spine morphology without a distinct spine head. These types of spines are also characteristic of developing or immature neurons, suggesting that LIMK-1 is required for spine maturation or maintenance. Conversely, increasing LIMK-1 expression leads to a significant enlargement of the spine heads. Therefore, LIMK-1 appears to be specific and sufficient to govern bidirectional regulation in spine morphogenesis or spine maturation. Consistent with its role in spine regulation, LIMK-1 potently affects the postsynaptic structure. Mammalian asymmetric excitatory synapses are characterized by the presence the PSD and an opposing presynaptic terminal containing numerous vesicles. Although these structures are clearly discernible in LIMK-1 knockout mice, the size of PSD is significantly reduced compared to that of the wild-type animals. The correlated reductions in spine and synapse sizes are consistent with the idea that proper spine morphology or maturation is critical for normal synaptic structure. These structural deficits probably contribute to the deficits in synaptic transmission and plasticity associated with the LIMK-1 knockout mice.

LIM Kinase 1 and Synaptic Regulation

LIMK-1 appears to be important for both basal synaptic transmission and synaptic plasticity. For example, LIMK-1 knockout mice exhibit elevated levels of basal excitatory synaptic responses in the CA1 region of the hippocampus. These changes appear to be inconsistent with structural alterations that predict a reduction in synaptic response. However, it remains to be investigated if the molecular compositions of the spine and synapse (such as synaptic glutamate receptors) are affected in the knockout mice. Other factors, including presynaptic neurotransmitter release, may also contribute to the changes observed in the basal synaptic strength of knockout mice. In support of this possibility, several important studies showed that perturbations of actin dynamics affect the release of both the readily releasable and more distal reserve pool of synaptic vesicles. The effect of LIMK-1 on long-lasting synaptic plasticity is also complex. In the CA1 region of the hippocampus, brief high-frequency tetanic stimulation (e.g., 5–100 Hz) induces a persistent increase in the excitatory synaptic transmission or LTP. CA1-LTP is of particular interest and is functionally significant compared to other forms of synaptic plasticity because it shares some of the important properties with learning and memory, including associativity and specificity, therefore providing a potential mechanism for information processing and storage. Although much remains to be investigated regarding the molecular mechanisms underlying CA1-LTP, it is generally agreed that the tetanic stimulations (or other conditioning protocols) transiently activate NMDA receptors, resulting in a significant increase in Ca^{2+} ions in the postsynaptic spine. A series of signaling processes are then initiated, which eventually lead to enduring enhancements of synaptic responses

predominantly mediated by AMPA receptors. In addition, at least two distinct phases of LTP can be generated depending on the induction protocols: an early phase (E-LTP) that is induced by a relatively short and weak induction protocol and thought to be accomplished by modifications of existing synapses, such as increased numbers and/or channel conductance of synaptic AMPA receptors, and a late phase (L-LTP) that is produced by a more sustained conditioning (e.g., multiple trains of 100 Hz stimulation) and believed to require new gene expression, protein synthesis, and, ultimately, the formation of new spines and synapses. E-LTP and L-LTP are functionally important because they are thought to underlie short- and long-term memory, respectively. LIMK-1 regulation of CA1-LTP appears to be both phase- and frequency-dependent. For example, applications of 5–10 Hz stimulations are able to induce a form of E-LTP in wild type but not in LIMK-1 knockout mice. On the other hand, E-LTP induced by a stimulation protocol of one train of 100 Hz is dramatically enhanced in the knockout mice compared to wild-type controls. Interestingly, LTP induced by multiple trains of 100 Hz stimulation exhibits a faster decay in the knockout mice, suggesting a deficit in L-LTP. Although these results indicate that LIMK-1 regulates multiple forms of LTP, the underlying mechanisms may be completely related to actin and spine properties. It is possible that changes in spine morphology may have nonspecific effects on the molecular composition (e.g., glutamate receptors) and the signaling processes of the spine that can, in turn, influence LTP. For example, spines with a small head may reach critical Ca^{2+} concentrations more easily, and therefore, LTP could be induced more readily in these spines. It has been shown that spine Ca^{2+} compartmentalization and diffusion to the dendritic shafts are related to the spine shape. It is therefore important to study basal and activity-dependent Ca^{2+} dynamics in LIMK-1 knockout neurons. In addition, changes in the amount of F-actin may directly affect LTP processes independent of spine morphology. For example, protein trafficking at the synapse, a key mechanism thought to be responsible for changing the number of synaptic glutamate receptors during, E-LTP, is regulated by actin dynamics. Finally, deficits in actin dynamics may prevent structural reorganization, including the formation of new spines and synapses thought to be critical for L-LTP.

LIM Kinase 1 and Cognition

The significant role of LIMK-1 in cognitive processes is evident in that LIMK-1 knockout mice exhibit altered performances in several learning and memory tasks. For example, in a fear-conditioning paradigm based on electric foot shocks (which provides a robust associative learning test in mice), the LIMK-1 knockout mice show elevated and more persistent freezing responses in both cued and contextual tests 24 h following training, suggesting enhanced performances in these tasks. However, in a water maze test designed to evaluate spatial learning and memory in rodents, although LIMK-1 knockout mice were comparable to controls in initial learning acquisitions, they were significantly impaired in locating the platform in a reverse learning paradigm (a further test following the initial learning that alternates the locations of the platform during training). Although these results clearly indicate abnormalities in at least certain aspects of cognitive processes in LIMK-1 knockout mice, further behavioral analyses are needed to determine what specific forms of learning and memory are affected. For example, although LIMK-1 knockout mice display an increased amount of freezing 24 h following training, it is not known whether such an enhancement occurs immediately after training and how long it persists. Given the deficits in actin properties and E-LTP, it is possible that these mice have impairments in longer-term memory in which structural changes are considered to be critical. Further assessment of other behavioral responses in LIMK-1 knockout mice is therefore important.

It is known that one copy of the LIMK-1 gene, along with several others, is deleted in patients with Williams syndrome, a developmental condition with an intriguing cognitive profile, including severe deficits in visual-spatial cognition in the presence of well-developed language and social skills. The role of LIMK-1 in various aspects of this mental disorder is unclear, although the results from the LIMK-1 knockout mice are consistent with the hypothesis that dysfunctional LIMK-1 contributes to the cognitive deficits of this disease.

Molecular Mechanisms Underlying LIM Kinase 1 Actions

The most extensively studied molecular targets of the LIMK family are members of the actin depolymerization factors (ADF)/cofilin family. These are actin-binding proteins whose functions include severing actin filaments and promoting actin depolymerization by binding to the pointed end of F-actin. The activity of ADF/cofilin is stringently regulated by protein phosphorylation on serine 3. Thus, in vertebrates, serine 3 phosphorylation inactivates ADF/cofilin proteins and completely abolishes their ability to bind to and disassemble actin filaments. Only

recently, the specific protein kinases that are responsible for ADF/cofilin phosphorylation have been revealed to be LIMK-1. Although additional proteins have since been identified that are also capable of phosphorylating ADF/cofilin, LIMK-1 is perhaps the predominant protein in phosphorylating and regulating ADF/cofilin activity in the mammalian CNS. Thus, the phosphorylated forms of ADF/cofilin are diminished in LIMK-1 knockout brain tissues and neurons. Furthermore, LIMK-1 appears to be a key mediator of activity-dependent changes in ADF/cofilin phosphorylation and dephosphorylation cycling. In brain slices and neurons, the amount of phosphorylated ADF/cofilin undergoes rapid alterations in response to a wide range of external stimuli, including neurotrophic factors and the activation of glutamate receptors. In the absence of LIMK-1, these stimulus-induced changes in phosphorylated ADF/cofilin are no longer present. For example, glutamate treatment of hippocampal slices or cultured hippocampal neurons causes a rapid reduction in the amount of phosphorylated ADF/cofilin without changes in total ADF/cofilin protein level, and this reduction is abolished in LIMK-1 knockout mice. Given the importance of ADF/cofilin in regulating actin dynamics, it is likely that the effects of LIMK-1 on the actin cytoskeleton and structural properties are mediated by changes in ADF/cofilin activity. In agreement with this possibility, several recent studies have shown that direct manipulations of ADF/cofilin perturb both basal and activity-dependent bidirectional changes in spine morphology as well as synaptic plasticity.

In addition to ADF/cofilin, a number of additional synaptic proteins have been shown to directly interact with LIMK-1, and therefore potentially mediate the effects of LIMK-1. These include protein kinase C (PKC), neuregulins, and cyclic adenosine-3′, 5′-monophosphate (cAMP) responsive element-binding protein (CREB). Although all these proteins are known to directly regulate various aspects of synaptic transmission and plasticity, the functional significance of their interactions with LIMK-1 remains to be elucidated. For example, are the activities of these proteins regulated by LIMK-1? It is important to emphasize that LIMK-1 knockout mice are significantly impaired in L-LTP, where the transcription factor CREB is thought to be critical in promoting activity-dependent gene expression. The activity of CREB is regulated by protein phosphorylation at serine 133 by multiple protein kinases, including LIMK-1. Therefore, it is possible that LIMK-1 regulates L-LTP through phosphorylating and activating CREB. It is of considerable interest to determine whether CREB activity or distribution is altered in LIMK-1 knockout mice.

Significance of LIM Kinase Signaling

Among synaptic proteins, the Rho family GTPases (RhoA, Rac1, and Cdc42) are regarded as the central regulators of actin dynamics in response to various stimuli, including neuronal activities. They are small guanine nucleotide-binding proteins that function as molecular switches cycling between an active GTP-bound state and an inactive GDP-bound state. The relative ratios of these two states dictate the activity of the Rho GTPases, and they are regulated by multiple proteins, including GAPs (GTPase activating protein) and GEFs (guanine nucleotide exchange factors), many of which have been found to interact with and to be regulated by various receptor proteins. The critical role of Rho signaling in spine and synaptic regulation is supported by many recent studies in which manipulations of Rho proteins or their regulators drastically affected spine development and morphogenesis, synaptic plasticity, and memory formation. Although the effects of Rho proteins (including those on spine properties) have been shown to be diverse and complex, it is generally thought that these effects are achieved through changes in the actin cytoskeleton and that LIMK-1 provides an important molecular link between Rho activation and actin. At least two families of protein kinases, p-21 activated kinases (PAKs) and Rho kinases (ROCKs), have been identified and shown to interact with active forms of Rho GTPases. Significantly, both PAKs and ROCKs can directly phosphorylate and stimulate the kinase activity of the LIMK family. Therefore, a sequential protein phosphorylation pathway consisting of PAK/ROCK-LIMK-ADF/cofilin has been proposed as a key signaling mechanism between the Rho GTPases and actin dynamics (Figure 1(e)). Consistent with this model, manipulations of LIMK-1 have shown to be able to block various effects on actin and structural properties induced by Rho activation in neurons and other cell types. Because Rho proteins can be regulated by many channels and receptors, including glutamate receptors, LIMK-ADF/cofilin may serve as a common molecular target for a variety of stimuli to regulate the actin network.

Because LIMK-1 is also a potential target of other synaptic proteins that have no apparent involvement in Rho signaling, it may also be responsible for Rho-independent actin reorganization at the synapse. As discussed earlier, both PKC and neuregulins interact with LIMK-1, and therefore some of their synaptic functions, particularly those related to the actin cytoskeleton, could be mediated by LIMK-1. Consistent with this possibility, the effect of PKC activators on

synaptic responses is dramatically reduced in LIMK-1 knockout mice, indicating that LIMK-1 is required for at least some of the actions of PKC. Further dissection of the effects of PKC mediated by LIMK-1 is required.

Finally, changes in LIMK-1 protein level may be responsible for a wide array of activity- or experience-dependent structural changes. For instance, a recent study demonstrated that a brain-specific microRNA (miR-134) negatively regulates the size of dendritic spines and this regulation is mediated by inhibiting the dendritic translation of LIMK-1 mRNA. Thus, overexpression of miR-134 results in a reduction of both the amount of the LIMK-1 protein and spine volume. Conversely, the inhibition of endogenous miR-134 leads to a significant increase in both the LIMK-1 protein and spine size. Moreover, this miR-134-regulated LIMK-1 protein synthesis appears to be responsible for the effect of brain-derived neurotrophic factor on spine development and maturation. Changes in LIMK-1 protein levels have also been found to be associated with other conditions, including drug administration and learning experience.

Concluding Remarks

Accumulating evidence indicates that LIMK-1 is a key synaptic molecule in regulating spine and synaptic properties. Although LIMK-1 appears to mainly target the actin cytoskeleton through directly phosphorylating and inactivating ADF/cofilin, a number of other synaptic proteins have been shown to interact with LIMK-1. It is important to investigate the significance and underlying mechanisms of these protein interactions and to determine their relative contributions to spine and synaptic regulation. Studying the molecular details of LIMK-1 regulation is expected to greatly contribute to the better understanding of the fundamental mechanisms responsible for synapse formation and function.

Lipids and Membranes in Brain Aging

Introduction

Biological membranes have multiple roles in cells. At a macro level, the membrane acts as a barrier between the cell interior and extracellular environment and between the cytoplasm and intracellular organelles. Viewed at the molecular level, membranes are composed of lipids and proteins and in some instances are in dynamic interaction with each other. How membranes are organized has evolved from the early notion in the 1850s describing the membrane as a relatively thin ion-impermeable layer covering cells and subsequent work showing that such a membrane contains lipids based on lipid solubility experiments. Later evidence in the 1920s suggested a bilayer of lipids with a hydrophobic interior and hydrophilic part of the lipid in contact with the extracellular and intracellular aqueous environment. The idea that proteins may be associated with the membrane was introduced in the 1930s, and later work introduced the concept that the membrane was a single lipid layer with proteins or what was referred to as the unit membrane model. In 1972, Singer and Nicolson proposed the fluid mosaic model of membranes, with lipids and proteins randomly distributed with lateral and rotational diffusion. Being a major component of the membrane, lipids were viewed as being important in maintaining the fluidity of the bilayer. An optimal fluidity was thought to be required for numerous membrane functions, such as transport, signal transduction, exocytosis, and endocytosis. Changes in lipid composition, such as an increase in cholesterol content, would reduce fluidity and alter activity of membrane function, which could be detrimental to the cell. That the state of the membrane was important to cell function has been proposed to be a factor in several different pathophysiological conditions ranging from alcoholism to Zellweger's syndrome. Changes in membrane fluidity and lipid composition have previously been proposed to be major contributors to cellular dysfunction observed with increasing age. This article critically examines aging and brain membranes from the perspectives of changes in fluidity, lipid composition, and membrane domains and identifies areas in which further study is needed.

Brain Membrane Fluidity

Fluidity is a broad term used to describe the lateral motion of lipids in membranes. Several studies have reported a reduction in fluidity of brain membranes with increasing age. However, reduced membrane fluidity in aged membranes has not been consistently observed. The lack of consistency in membrane fluidity and aging studies could possibly be attributable to different techniques (electron spin resonance, fluorescence spectroscopy, and nuclear magnetic resonance), probes residing in different membrane locations (DPH, pyrene, 5-doxyl stearic acid), purity of the membrane preparation (whole brain homogenate, synaptosomes, synaptic plasma membranes in different brain regions), and different species used. Regardless of whether there are aged differences in membrane fluidity, one conclusion regarding the extant studies on fluidity of brain membranes and aging is that most have been limited in their technological sophistication and precision. For example, fluidity actually consists of two components which have been characterized as rate of motion, a dynamic component, and the extent of motion, a static component. Parameters such as limiting anisotropy and order parameter refer to static components, whereas rotational correlation time and rotational rate denote dynamic components. Studies examining brain membrane fluidity in aged organisms have not distinguished between dynamic and static components. Furthermore, the majority of studies on fluidity of brain membranes of aged organisms have used techniques which provide an estimate of the overall average fluidity of the membrane in contrast to more circumscribed areas of the membrane. There may be specific differences in fluidity of the aged brain membrane which would not be detected by conventional techniques, and this issue is discussed later. Another limitation of studies on membrane fluidity and aging is that changes in fluidity on membrane and cell functions in general are not well understood.

Brain Membrane Cholesterol Levels

Lipids are a major contributor to the fluidity of membranes, and this has been demonstrated experimentally in both biological and model membranes. Cholesterol, which accounts for more than 25% of the total lipid of synaptic plasma membranes (SPMs), is a key factor in determining membrane fluidity. Above the phase transition of the lipid environment, reducing membrane cholesterol increases fluidity, whereas the opposite

effect is observed when membrane cholesterol levels are increased. Age differences in brain membrane cholesterol levels have not been consistently observed. This observation applies to both human and animal studies. Even in those studies reporting an increase in cholesterol levels with increasing age, the mechanism for such an increase has not been forthcoming. The biosynthesis of cholesterol requires more than 30 enzymes and several cofactors. To date, there has been very little work on the brain cholesterol synthetic pathway in aging organisms.

Cholesterol is derived from mevalonate, which is also the precursor of various compounds including isoprenoids. There is great interest in the role of isoprenoids such as geranylgeranyl pyrophosphate (GGPP) and farnesyl pyrophosphate (FPP), which prenylate various small GTPases, such as Rho, Rac, and Ras. These proteins are involved in a variety of cell signaling functions. GGPP and FPP levels have not been reported in brain, but an isoprenoid whose abundance has been reported is dolichol. Dolichols are long-chain polyisoprenoids derived from FPP. These compounds are ubiquitous among body organs, with the highest levels observed in testis, kidney, brain, and various exocrine glands. Dolichol can be in a free form or phosphorylated. Dolichol phosphates are intermediates in the synthesis of oligosaccharide groups of glycoproteins. The cellular function of free dolichols is not known. Free dolichol increased fluidity of SPMs, and it has been detected in membranes in which it might function to regulate membrane fluidity. There is a marked increase of free dolichol in human brain tissue with aging and in SPMs of aged mice compared to younger mice. Increased free dolichol content has also been observed in brain tissue from individuals with Alzheimer's disease and individuals with neuronal lipofuscinosis. The precise function of free dolichol and the consequences of elevated dolichol levels observed with increasing age and certain neurodegenerative diseases have not been established.

Brain Membrane Phospholipids and Fatty Acids

In order of abundance, the membrane phospholipids in brain are phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylinositol (PI), and cardiolipin (CL). Neural membranes are also enriched in ether phospholipids (i.e., phospholipids with alkyl or alkenyl linkage in the *sn*-1 position). Whereas most diacyl-type phospholipids are synthesized in the endoplasmic reticulum, ether phospholipids are synthesized in peroxisomes and changes in levels of ether lipids are associated with peroxisomal disorders. Cardiolipin, an unusual phospholipid with two glycerol backbones and four fatty acids, is exclusively present in the mitochondrial membrane. Cardiolipin plays an important role in regulating respiratory chain activity in mitochondria. Phospholipids in brain membranes are enriched in plasmalogens of the ethanolamine type (alkenyl-acyl-gly cerophosphoethanolamine(PEpl)). PEpl is especially enriched in myelin, comprising more than 60% of total ethanolamine phospholipids. Plasmalogens may act as endogenous antioxidants. Although phosphatidylinositol (PI) comprises only 4% of total phospholipid, it is metabolically active and is converted to phosphatidylinositol-4-phosphate (PIP) and phosphatidylinositol-4,5-bisphosphates (PIP2) by kinases. PIP2 plays an important role in the stimulus–signal coupling reactions that lead to generation of second messengers. Stimulation of many G-protein-coupled receptors (GPCRs) leads to activation of phospholipase C (PLC), which hydrolyzes PIP2 to form diacylglycerol (DG), a second messenger for activation of protein kinase C (PKC) and inositol trisphosphate (IP3), a second messenger for mobilization of intracellular Ca^{2+} stores. Another PI kinase, PI3K, adds a phosphate group to the third position of PIP2 to form PIP3. Activation of PI3K by tyrosine kinase and/or kinases associated with GPCRs has been implicated in signaling pathways associated with cell growth, proliferation, survival, and plasticity.

Fatty Acids of Brain Phospholipids

Phospholipids in neural membranes are enriched in polyunsaturated fatty acids such as 20:4n-6 (AA) and 22:6n-3 (DHA). Each type of phospholipid is composed of unique patterns of acyl or alkenyl groups, and these patterns may vary depending on their subcellular localization. For example, myelin is known for its high content of PEpl, and this phospholipid is enriched with monounsaturated fatty acids such as 18:1 and 20:1. In fact, 20:1 is an unusual fatty acid almost exclusively found in the myelin membrane. On the other hand, fatty acids of PEpl in the nerve ending fraction (synaptosome) are enriched in 20:4n-6 and 22:6n-3. Earlier studies showed an age-dependent increase in monounsaturated fatty acids (e.g., 18:1 n-9 and 20:1 n-9 (~43%)) and a decrease in polyunsaturated fatty acids (e.g., 22:6 n-3 (~14%)) in mouse brain PE between 3 and 26 months of age. Similar changes are found in PE in the brain of rhesus monkey. Studies on the glutathione redox state in mouse brain showed an age-dependent decrease in the ratio of reduced to oxidized glutathione (GSH/GSSG) between 3 and 21 months of age. Whether the age-dependent decrease in polyunsaturated fatty acids is

associated with the decrease in GSH remains to be investigated. Since levels of PEpl and 22:6n-3 decrease with normal aging and with memory impairment, considerable interest has focused on whether dietary supplementation of fish oil which is enriched in n-3 fatty acids may help to reverse the age-related deficits and improve memory and cognitive functions.

The fatty acid profile of PS is enriched in 22:6 n-3, which is predominantly coupled with 16:0 in the *sn*-1 position. On the other hand, fatty acids in PI, as well as poly-PI are enriched in 20:4 n-6, which is linked to 18:0 in the *sn*-1 position. Consequently, when PIP2 is hydrolyzed by PLC to form DG and IP3, the fatty acid of this DG pool is enriched in 18:0/20:4 and is different from the DG pools associated with PL biosynthesis. Unlike fatty acids of phospholipids in other organs, brain fatty acids have low levels of 18:2 n-6, although this fatty acid is enriched in CL. The unique presence of CL in mitochondria suggests its role in mitochondrial membrane function. There is evidence that in cerebral ischemia, CL in mitochondria decreases together with release of cytochrome c. Because these anionic phospholipids are present in minute amounts in the brain, little is known about age-dependent changes of these phospholipids.

Enzymes Regulating Membrane Phospholipids

Fatty acids in the *sn*-2 position of phospholipids are maintained in a dynamic equilibrium, regulated by phospholipases A_2 (PLA_2) and lysophospholipid acyltransferases, constituting the deacylation–reacylation cycle. It is important to note that whereas hydrolysis of fatty acids by PLA_2 releases fatty acids from phospholipids, the reacylation process involves ATP-dependent conversion of a fatty acid to its acyl-CoA and transfer of acyl-CoA to lysophospholipids. Although the number of studies on the structure and function of different types of PLA_2 has increased considerably in the past decade, studies regarding lysophospholipid acyltransferases are still lacking. Besides PLC, phospholipids are also hydrolyzed by phospholipase D (PLD), resulting in formation of phosphatidic acid (PA). In the presence of ethanol, PLD may mediate transphosphatidylation of PC to form phosphatidylethanol, which is a marker of ethanol metabolism.

Turnover of fatty acids among different phospholipids is dependent not only on the type of phospholipids but also on the types of membranes in different cell types. Thus, it is conceivable that fatty acids in myelin phospholipids undergo slower turnover compared to synaptic membranes. Age-related decrease in turnover of fatty acids in SPM phospholipids may provide an explanation for the decrease in synaptic functions during aging.

Phospholipase(s) A_2

PLA_2s are enzymes for cleaving fatty acids in the *sn*-2 position of phospholipids. These enzymes are ubiquitous in mammalian cells. Besides their role in maintenance of cell membrane phospholipids, they also play an important role in providing lipid mediators such as arachidonic acid (AA), which serves as the precursor for synthesis of a number of eicosanoids. Hydrolysis of phospholipids by PLA_2s also produces lysophospholipids which possess detergent-like properties and can alter membrane micro domains. Among more than 20 different types of PLA_2s, studies have focused on three groups, namely the calcium- and kinase-dependent group IV cytosolic PLA_2 ($cPLA_2$), the Ca^{2+}-independent group VI PLA_2 ($iPLA_2$), and the Ca^{2+}-dependent secretory PLA_2 ($sPLA_2$).

$cPLA_2$ is composed of three isoforms: α, β, and γ. In brain, most studies have focused on $cPLA_2$-α, an 85-kDa protein comprising a Ca^{2+} binding C2 domain and a catalytic domain with several putative phosphorylation sites for mitogen-activated protein kinase (MAPK), PKC, and Ca^{2+}/calmodulin-dependent protein kinase II. Upon binding with Ca^{2+} and phosphorylation by protein kinases, $cPLA_2$-α is translocated to the membrane and targets phospholipids, especially those containing AA. Consequently, $cPLA_2$-α is activated by metabotropic and ionotropic receptors and releases AA for biosynthesis of eicosanoids. However, the mechanism for the coupling between $cPLA_2$ and cyclooxygenases (COX) remains a subject for further investigation. $cPLA_2$s have been shown to target a number of intracellular membranes, including the Golgi complex, plasma membranes, and nuclear membranes. The putative pleckstrin homology (PH) domain in $cPLA_2$ suggests possible interaction with acidic phospholipids such as PIP2 which are localized in plasma membranes. There is evidence that the translocation process may involve binding to cytoskeletal proteins and intermediate filaments such as vimentin and actin.

Secretory PLA_2s are low-molecular-weight proteins ($\sim$14 kDa). More than ten subtypes of $sPLA_2$s are present in the mammalian system, including the brain. In recent years, considerable attention has been given to the $sPLA_2$-IIA in the cardiovascular system because of its association with inflammatory responses in diseases such as arthritis, atherosclerosis, and sepsis. Indeed, $sPLA_2$ is an independent risk factor for cardiovascular diseases. Although studies have implicated the increase in $sPLA_2$-IIA in reactive astrocytes in response to cerebral ischemia, studies demonstrating $sPLA_2$ in human brain and in relation with other neurodegenerative diseases have not been forthcoming. In astrocytes, mRNA expression for $sPLA_2$-IIA along with COX-2 and inducible nitric oxide synthase are stimulated by

proinflammatory cytokines (tumor necrosis factor-α, interleukin-1β, and interferon-γ) and lipopolysaccharides, and the increase in inflammatory response is coupled with production of prostaglandin E_2 and nitric oxide.

Since $sPLA_2$-IIA is induced by proinflammatory cytokines, it needs to be determined whether its release from glial cells can cause neuronal damage. Studies using extracellular forms of $sPLA_2$ have clearly demonstrated the ability of $sPLA_2$-IIA to cause neuronal excitotoxicity and apoptosis by enhancing the ionotropic receptor and Ca^{2+} channel activities. Other studies have shown that secreted $sPLA_2$-IIA can perturb cellular membranes, especially those undergoing apoptosis. In PC12 cells, lysophospholipids produced by $sPLA_2$-IIA were shown to enhance neurite outgrowth, further implicating an important role of this enzyme in neurodegenerative diseases.

$iPLA_2$ consists of two major subtypes, VIA and VIB. $iPLA_2$-VIA comprises 85–88 kDa proteins with three splice variants – VIA-1, VIA-2, and VIA-3 – all containing multiple ankyrin domains, suggesting its ability to interact with other proteins. $iPLA_2$-VIA shows no apparent specificity for the fatty acids in the *sn*-2 position or the type of phospholipid headgroups. This enzyme can efficiently hydrolyze oxidized phospholipids. In agreement with its major role in maintenance of membrane phospholipid homeostasis, $iPLA_2$ activity is frequently proportional with the level of lysoPC upon inhibition by BEL, a hydrophobic serine-reactive inhibitor specific for $iPLA_2$. Nevertheless, there is increasing evidence that this enzyme may also play a role in stimulus–response coupling activity and in the release of AA for prostaglandin biosynthesis.

Oxidative Stress, Aging, and Membrane Phospholipids

Due to the high oxygen consumption, the enrichment of polyunsaturated fatty acids, and the relatively low activity of antioxidative defense enzymes, cells in brain are highly susceptible to oxidative insults, which are important underlying factors for the pathogenesis of a number of age-related neurodegenerative diseases. Several cellular enzymes, including enzymes in the respiratory chain in mitochondria, xanthine/xanthine oxidase, myloperoxidase, cytochrome P450 in cell cytoplasm, monoamine oxidases, cyclooxygenases, and NADPH oxidase, can catalyze molecular oxygen to produce reactive oxygen species (ROS) such as superoxide anion (O_2^-) and H_2O_2. In the presence of metal ions, Fe^{2+}, and Cu^{2+}, H_2O_2 can be further converted to hydroxyl radical (OH) through the Fenton reaction. Hydroxyl radicals can react with polyunsaturated fatty acids in membrane phospholipids forming peroxyl radical (ROO) and propagate the chain reaction of lipid peroxidation. External factors such as radiation, drugs, and disease states can upset the oxidative–antioxidative equilibrium, rendering cells to become pro-oxidative. More studies should be directed at examining the mechanism(s) leading to the increase in oxidized lipids in brain, especially under pathological conditions.

Among the phospholipids, plasmalogens appear to be most susceptible to oxidative stress. There is considerable evidence that production of ROS and lipid peroxidative products in brain increases with age and that the age-related increase in oxidative stress may enhance neuroinflammatory responses in the aged population. An obvious decrease in plasmalogens was observed in Alzheimer's brain and the decrease could be detected even at early stages of the disease. Lipid peroxidation products such as 4-hydroxynonenal (HNE) can form adducts with proteins and cause neurotoxicity. Thus, the increase in HNE has been regarded as an important contributor to the pathogenesis of many neurodegenerative diseases, including Alzheimer's disease and stroke.

Brain Lipid Domains

The preceding discussion examined membranes from the perspective of broad changes in fluidity and lipid composition in contrast to specific areas or domains of membranes. Bretscher and others in the 1970s postulated and demonstrated that the two leaflets which form the bilayer are asymmetric in their lipid distribution. Figure 1(a) is a model of SPM and it can be seen that the outer or exofacial leaflet is enriched in phosphatidylcholine and sphingomyelin. In contrast, the inner or cytofacial leaflet is enriched in phosphatidylethanolamine, phosphatidylserine, phosphatidylinositol, and cholesterol. This lipid asymmetry confers differences in the charge properties and fluidity of the two leaflets. The exofacial leaflet is considered to be neutral or zwitterionic, whereas the cytofacial leaflet is more negatively charged due to the enrichment of the anionic phospholipids phosphatidylserine and phosphatidylinositol. Mechanisms involved in the maintenance of phospholipid asymmetry are not completely understood. There is evidence that at least three different proteins may be involved in promoting phospholipid asymmetry: an ATP-dependent transporter (flippases) directed at the cytofacial leaflet, an ATP-dependent transporter (floppase) directed at the exofacial leaflet, and an ATP-independent transporter (scramblase) interacting with both leaflets. Phospholipid asymmetry is thought to be important in such cell signaling functions as Ca^{2+} homeostasis and receptor-mediated signal transduction. A loss of phospholipid asymmetry has been observed in sickle cell anemia,

Figure 1 Plasma membrane domains. (a) The two leaflets of the plasma membrane showing the asymmetric distribution of cholesterol and phospholipids. Large globular structures represent proteins. Cholesterol (denoted by yellow structure), phosphatidylinositol (PI), phosphatidylethanolamine (PE), and phosphatidylserine (PS) are enriched in the cytofacial leaflet. Phosphatidylcholine (PC) and sphingomyelin (SM) are in abundance in the exofacial leaflet, and there is some PC in the cytofacial leaflet. A lipid raft is denoted in the exofacial leaflet (a) containing a glycosylphosphatidyl inositol-anchored protein (GPI). (b) A model of caveolae enriched in cholesterol, sphingolipids, and caveolin. Reproduced from Wood WG, Igbavboa U, Eckert GP, and Müller WE (2007) Cholesterol – a Janus faced molecule in the central nervous system. In: Lajtha A (ed.) *Handbook of Neurochemistry and Molecular Neurobiology*, 3rd edn., pp. 151–170. Heidelberg, Germany: Springer. With kind permission of Springer Science and Business Media.

sperm cell maturation, and apoptosis. In human aging erythrocytes whose life span in the body is approximately 120 days, phospholipid asymmetry is reduced. There have been a few reports on phospholipid asymmetry in brain membranes whose distribution is similar to that of nonbrain membranes, but there have been no reported studies on phospholipid asymmetry in brain membranes of aging organisms.

Exofacial and Cytofacial Leaflet Fluidity

There is a major difference in fluidity of the exofacial leaflet compared to the cytofacial leaflet. The exofacial leaflet is markedly more fluid, as determined by limiting anisotropy and rotational relaxation time of DPH in SPM, and is more easily perturbed than is the cytofacial leaflet. For example, 25 mM ethanol significantly increased fluidity of the exofacial leaflet but had no effect on the cytofacial leaflet even with an ethanol concentration as high as 400 mM. Chronic ethanol consumption reduced fluidity of the SPM exofacial leaflet producing resistance to ethanol perturbation, demonstrating cellular membrane tolerance. The asymmetry in fluidity of the two leaflets is diminished with increasing age in mouse SPM. In mice 3 or 4 months old, the exofacial leaflet was 21% more fluid than the cytofacial leaflet; in mice 14 or 15 months old, it was 9% more fluid; and in mice 24 or 25 months old, differences between the two leaflets in fluidity were indistinguishable.

Transbilayer Cholesterol Distribution

The major difference in fluidity between SPM exofacial and cytofacial leaflets is associated with the transbilayer cholesterol distribution (TCD). Figure 1(a) shows that cholesterol is asymmetrically distributed between the two leaflets. In young mice, approximately 15% of SPM cholesterol resides in the exofacial leaflet and the remaining 85% in the cytofacial leaflet. TCD is not static but, rather, can be altered by different treatment conditions. Chronic ethanol consumption, apolipoprotein E (APOE) and its isoforms, and HMG-CoA reductase inhibitors (statins) all have been shown to alter TCD. Increasing age had a striking effect on SPM TCD. The exofacial leaflet of aged mice (24 or 25 months old) showed a twofold increase in cholesterol compared to that of younger mice. Mice 14 or 15 months of age were intermediate in their cholesterol distribution with respect to the young and aged mice. Interestingly, the increase in exofacial leaflet cholesterol of the aged mice was not the result of an increase in total SPM cholesterol. There were no significant differences in total SPM

cholesterol among the three age groups. A valuable conclusion which can be drawn from this study is that striking changes in neuronal membrane cholesterol homeostasis can occur in the absence of changes in total membrane cholesterol levels.

The mechanism for maintaining TCD is not well understood. Several potential candidates have been proposed, including APOE, the low-density lipoprotein receptor (LDLR), sterol carrier protein-2 (SCP-2), polyunsaturated fatty acids, fatty acid-binding proteins (FABPs), and caveolin. However, it is worth mentioning that even when some of these potential mechanisms are experimentally altered, the cytofacial leaflet continues to maintain the greater amount of cholesterol compared with the exofacial leaflet. From these results, one conclusion is that there may be multiple mechanisms which are involved in the regulation of TCD. These mechanisms might involve multiple sites, such as the surface of the exofacial leaflet (APOE, LDLR, and caveolin), within the plasma membrane (fatty acid composition) and cytofacial leaflet interaction with intracellular proteins (SCP-2 and FABPs). A question which has not been addressed is the functionality of changes in TCD. In the case of chronic ethanol consumption, the redistribution of cholesterol may be adaptive and diminish partitioning of ethanol into the cell, in turn altering cell function. With respect to the redistribution of cholesterol in aged SPM, it is not known if such changes are adaptive or have pathophysiological consequences.

Lipid Rafts and Caveolae

Two other lipid domains which have received substantial attention are lipid rafts and caveolae. In this discussion, lipid rafts refer to structures enriched in cholesterol, glycosphingolipids, and glycosylphosphatidylinositol-anchored proteins and not containing the caveolae protein, caveolin, as shown in Figure 1(a). Other names for lipid rafts include detergent-insoluble glycolipid-enriched membranes and detergent-resistant membranes. Caveolae as seen in Figure 1(b) are defined as membrane invaginations containing the protein caveolin and are enriched in cholesterol and glycosphingolipids. There has been considerable interest in these lipid domains, and several reviews have been published. In contrast, there has been very little advancement in the aging field regarding brain lipid rafts and caveolae. Levels of the lipid raft markers flotillin-1 and flotillin-2 did not differ in brain lipid rafts prepared from a whole brain homogenate of young and aged rats. In contrast, a reduction of flotillin-1 levels as well as alkaline phosphatase activity was observed with increasing age in synaptosomal lipid rafts of aged mice expressing human apoE3 and apoE4 compared with young apoE3 mice. Lipid rafts of young apoE4 mice were more similar to those of older mice compared to young apoE3 mice for flotillin-1 levels and alkaline phosphatase activity. Cholesterol and sphingomyelin levels of lipid rafts did not differ between the young apoE3 and apoE 4 mice, but levels of those lipids did increase with age. Both increasing age and the apoE4 genotype are risk factors for Alzheimer's disease, and both have similar effects on brain lipid raft protein markers. There is evidence that lipid rafts may play a role in the processing of amyloid β-protein, which is thought to be a causal factor in the pathophysiology of Alzheimer's disease.

Superoxide dismutase-1, which is associated with membrane caveolae, was found to be reduced in aortic tissue of aged rats compared to younger animals. Caveolin-1 is a major protein of caveolae, and it has been demonstrated that the life span of caveolin-1 null mice is reduced by approximately 50% compared with wild-type mice and caveolin-1 heterozygous (+/−) mice. Brain caveolin-1 levels were found to be decreased in aged rats compared to younger rats.

The concept of lipid rafts, like that of the membrane, has been evolving. At a Keystone Symposium on Lipid Rafts and Cell Function in 2006, a consensus was reached that the term 'lipid rafts' should be changed to 'membrane rafts' recognizing the role of raft proteins, and that caveolae should be considered a membrane raft. Another issue which was discussed at that meeting and that has been proposed by others was that some membrane rafts may be transient with a lifetime of milliseconds or less, in contrast to a static structure. Such a short lifetime could pose problems for isolation of rafts as commonly done using density gradient centrifugation. An understanding of membrane rafts in aging organisms will require conceptual and technological approaches which are state of the art in the membrane raft field.

Conclusions

A broad conclusion which can be reached is that studies on age differences in membrane organization have mostly been approached from the standpoint of the Singer–Nicolson fluid mosaic membrane model. However, modification of this model has been proposed by different groups suggesting a more mosaic-like structure which is heterogeneous, with lipid–lipid, protein–protein, and lipid–protein interactions, in contrast to a fluid membrane in which proteins are unrestricted in their lateral movement. The majority of studies on age differences in membranes, whether fluidity or lipid composition, have examined bulk changes in the membrane. Although this approach provides an

overview of the membrane environment, it does not address the vast heterogeneity of the membrane. There is a need to study both macro and micro membrane domains in aging organisms and the functional consequences of membrane domains on cellular function.

Introduction

Lipofuscin is a pigmented oxidized protein–lipid compound, stored in a granulum or residual body in the cells of the nervous system, also called the 'wear-and-tear' pigment. Its chemical composition is ill-defined, since it is cell-type dependent, but the oxidation of its polyunsaturated lipids is well understood. Lipofuscin's presence starts around the first year, is already substantial around the sixth year of life, is further increasing in quantity during lifetime, and is abundantly present in neurons during aging. Remarkably, lipofuscin is found in autonomic ganglia during the fetal period.

Lipofuscin granula are concentrated in special compartments in most types of neurons (Figure 1), and its presence is accentuated by various stainings. A lipofuscin granule has a yellow reddish/brownish appearance, is capable of auto-fluorescence, (Figure 2), and contains several substances, for example, fat, carbohydrates (sometimes disputed), and proteins.

Lipofuscin is also present in other parts of the body (e.g., liver, digestive tract, and heart), but this is beyond the scope of this article.

History

From the earliest moment that fixed nervous tissue could be studied, lipofuscin was recognized and distinguished from the black pigment neuromelanin (for a review see Usunoff et al. (2002)), although both substances were placed in the group of fuscins.

The first description of pigments is by Purkyně (1837). Within the dorsal root ganglion cells he described a pigment, now known as lipofuscin and in the substantia nigra the black pigment neuromelanin (Purkyně's figure (Figure 1) shows the lipofuscin pigments, however, in multipolar cells). One year later, Remak (1838) published a book on sympathic ganglia and also indicated a pigment in these cells. Presumably the pigments could be detected due to the achromatic microscope that was first used by both authors. Eventually, the human, autogenous pigments were divided by Sachs (1943) into fuscin and melanin. Fuscins could fluoresce in ultraviolet light (Figure 2); neuronal melanin required oxidation before fluorescence occurred. Around the previous centennial, within a decade (1895–1905), a series of publications appeared studying lipofuscin, proposing that lipofuscin is the expression of a degenerative process, that starts early in life, but this degeneration can be arrested due to the compensatory capacity of the neuronal cytoplasm. Reduction of this compensatory capacity slowly leads to death of the neuron (Mühlmann, 1901). So, lipofuscin is considered a 'sign or marker', in the form of a storage (end) product of a 'cellular process' (degeneration, nowadays aging). This basic view has not been changed up till now.

Relation to Homologous Substances

Since lipofuscins, also called chromolipoids, are mainly or partially derived from lipid precursors, they are easily related to other lipid pigments: haemofuscins, cytolipochrome, ceroids, pseudomelanosis pigment, iron-containing lipid pigment, and lipochrome. The original lipid is colorless until it contains dissolved carotenoids and is oxidized to an insoluble, colored product. Strong variability exists as to the type of cell, the amount of protein involved, and whether the constituting amino acids are either oxidized or not (Pearse, 1985).

The degree of autoxidation as studied by different coloring techniques shows increasing oxidation for different types of polyunsaturated lipids: early oxidation as in apocrine globules and macrophage lipids can be distinguished from ceroid pigments. Ceroids are in a further stage of oxidation, and in turn lipofuscins can be noted by an even stronger oxidation. The melanin, hemosiderin, heamatoidin, and chromaffin granules are easily recognized by their black color and/or iron-containing properties (Pearse, 1985).

Enzymes

A few enzymes are localized in lipofuscins: nonspecific esterases, acid phosphatases, and proteases. Due to the increase in volume of the amount of granula, they displace cytoplasm that contains oxidative enzyme activity, resulting in empty zones for these enzymes in the cells. Some enzymes are noted near lipofuscin granula. A 'striking' increase was noted for glucose-6-phosphate dehydrogenase in the sites of lipofuscin accumulation. In general, nerve cells with a highly active respiratory apparatus seem to accumulate more lipofuscin than cells with a low oxidative metabolism (Friede, 1966).

Figure 1 (a) Original picture of Purkyně (1837), indicating pigment in multipolar neurons. (b) Area taken from a horse dorsal root ganglion colored with methylene blue. Pigment is in brown color. Note that all neurons accumulated lipofuscin. (c) Three different horse dorsal root ganglion neurons (type I and II; upper one shows type I, lower figures show type II) colored with methylene blue. Pigment is restricted to certain compartments of the cytoplasm. A section through such a cytoplasmatic area shows the whole soma loaded with pigment granula. Pigment accumulation is cell-type independent in dorsal root ganglia. (d) Median section through a human neuron of Onuf's nucleus. Compartmentalization and strong accumulation of lipofuscin granula can be noted. Cytoplasm area is $\pm 1500\,\mu m^2$. (b, c) From Dogiel AS (1908) Der Bau der Spinalganglien des Menschen und der Säugetiere. Gustav Fischer Verlag: Jena.

Staining

Lipofuscin is stained by several lipid-staining methods: Sudan III and oil red. It gives acid-fast coloration with carbol fuchsin. It stains with ferric ferricyanide (Schmorl method I), methyl green, and the periodic acid-Schiff (PAS) reaction.

The reason for the PAS-positive reaction in only the intermediate stages of oxidation of lipids is unclear. "It certainly does not mean, as many authors have concluded, that the lipid concerned belongs to the carbohydrate containing glycolipid (cerebroside) group. Pearse says, Aldehydes can be produced from non-carbohydrate-containing unsaturated phosphatides by the action of periodic acid. However, "It is more likely that 1,2-glycols are formed by the hydroxylation of epoxides engendered in the earliest stages of lipofuscin formation and be converted to Schiff-positive dialdehydes by oxidation with periodate". The J-band effect stain for lipofuscins is recommended by Pearse, and in his *Histochemistry*, volume 2, other staining methods can be consulted.

Nile blue staining is used for the differentiation of melanin and lipofuscin, and silver nitrate–gold

chloride demonstrates lipofuscin granules as small distinct dots, surrounded by a halo (Gurr, 1962).

The Masson–Fontana ammoniacal silver technique, previously thought to be specific for neuromelanins, because it is a strong argentaffin reactive pigment, also stains lipofuscin (Usunoff et al., 2002).

Based on a series of studies on the common histochemical properties of neuromelanin and lipofuscin, Barden (1969) insisted that neuromelanin is melanized lipofuscin.

Braak et al. (1988) developed a silver impregnation method for neurofibrils in which counterstaining with crotonaldehyde fuchsin followed by performic acid oxidation demonstrates lipofuscin in human pathological brains. This technique is highly recommended for human lipofuscin brain studies.

Figure 2 (a) Lipofuscin granula are present in both light and dark cells of human neurons of Onuf's nucleus (±500×). (b) Auto fluorescence of trigeminal mesencephalic nucleus neurons. A clear fluorescent halo is present. Long diameter of neurons is 45–60 μm. (c) Enlargement of lipofuscin granula in a neuron of the human nucleus of Onuf (±30 000×). Biochemistry

X-ray absorptions show 56% by weight of dry substance in lipofuscin, indicating that a high content of solid material is present. Ultraviolet absorption indicates the presence of pterins or aromatic amino acids. More recent studies show that lipofuscin granula from the eye showed a 44% protein and 50% lipid content (Warburton et al., 2005). Results from other areas can range from 30% to 70% protein content. The same, but inverse to protein, variability is noted for lipids. Using lectins, mannose was detected to be the dominant sugar residue, but also acetylglucosamine, acetylgalactosamine, sialic acid, galactose, and fucose are detected in human neuronal lipofuscin (Monserrt et al., 1995). Lipofuscins are also enriched in Al, Cu, and Fe, and in dolichols, the essential cofactor for the *N*-glycosylation of membrane proteins (Harman, 1989).

Lipofuscins originate from oxidation of polyunsaturated lipids. However, cellular protein catabolism is also proposed. The transition from propigment (ceroids) into lipofuscin is hard to indicate.

Electron Microscopy

Ultrastructure of the lipofuscin granula is demonstrated in this part by human material of a 75-year-old man, in which Onuf's nucleus was studied (Figure 2) and rat aged striatal neuron (Figure 3). Lipofuscin granula (diameter can go up to 2.5–3 μm) contain one or more translucent vacuoles. Around them, an electron denser substance or a matrix adheres, in which electron black spongy or black granular material is present. Trilinear

Figure 3 Striatal neuron from an aged rat (2.1 year). Arrows indicate lipofuscin granula. Note the heterogeneous matrix of the lipofuscin granula as compared to human ones in Figure 2(c) (±30 000×). From Itzev D, Lolova I, Lolov S, and Usunoff KG (2001) Age-related changes in the synapses of the rat's neostriatum. *Archives of Physiology and Biochemistry* 109: 80–89.

(Man) and/or pentalinear (other mammals) structures can be discerned in the pigment matrix (Boellard et al., 2004). The whole granulum is surrounded by a unit membrane. Translucent areas between the membrane, the vacuoles, and dense substance are found (Figure 2).

The lipofuscin granula are different in the hippocampal CA1 and CA3/4 areas in man. The hippocampal lipofuscin granula are totally different from those in the neocortex of man. Moreover, species-specific differences are found electron microscopically (cf. Figures 2(c) and 3).

Lysosomal Origin

Lipofuscin granula are thought to develop from lysosomes (Essner and Novikoff, 1960). Its origin therefore is intracellular. In short, autophagosomes fuse with a so-called dense body or lysosome to produce a secondary lysosome or residual body. Extra lipid and/or tyrosine phenol uptake will result into a residual body containing lipofuscin. The accumulating heme compounds contribute to the oxidation process and this theory also explains the presence of the type of enzymes in lipofuscin granula; for example, acid phosphatase is the marker enzyme for lysosomes.

The other studies state that the lipid pigments are derived from mitochondria (Duncan et al., 1960), while the bridge between both theories is that lipofuscin granula occur due to the incomplete lysosomal degradation of damaged mitochondria (Gray and Woulfe, 2005).

Peroxisomes are also involved in lipid breakdown; however, their granulum volume hardly increases, as occurs in lipofuscin lysosomes, and their marker enzymes are catalase and urate oxidase. Using differential centrifugation peroxisomes can be distinguished from lysosomes.

Manipulation of Lipofuscin Content

Vitamin D deficiency is responsible for an abundant increase in lipofuscin granula (Menken et al., 1986). Administration of vitamin E (α-tocopherol) diminishes the proliferation of lipofuscin granula. Vitamin A-deficient rats contained less lipofuscin in their retinal pigment epithelium.

Carotenoid pigments are related to vitamin A. Beta-carotene by the uptake of water produces two molecules of vitamin A. Moreover, rhodopsin is a carotenoid complex. Carotenoids are extremely soluble in fat, but once dissolved they are insoluble in water, glycerol, or formalin, and then held responsible for the lipofuscin color. Increase in lipofuscin granula in the pigment layer of the eye is supposed to be related to vitamin A autoxidation. Reduction of this autoxidation by vitamin E should explain the reduction of lipofuscin content. This is a debated issue.

Topography

Within the 'normal' nervous system, not all neurons develop lipofuscin granula. Good examples are the hypothalamic nuclei in man, especially the supraoptic and paraventricular nuclei, and also the type III cells in the claustrum (Braak and Braak, 1982). On the other hand, various types of neurons accumulate severely lipofuscin granula, called lipophilic, and others only few, called lipophobic (Obersteiner, 1903). Brain regions can also be called lipophobic (e.g., hippocampal CA1) or lipophilic (e.g., hippocampal CA3/4).

The distribution and amount of granula is different in nervous system areas; for example, the distribution of lipofuscin in the magnocellular nuclei in the basal forebrain shows for large multipolar neurons: 10% of these cells are lipofuscin-loaded in the medial septal and vertical limb nucleus of the diagonal band of Broca, 36% in the horizontal limb of the Broca band and anteromedial subnucleus of the basal nucleus, and 54% in the posterolateral subnucleus of the basal nucleus. The number of these multipolar lipofuscin-loaded neurons is more pronounced in Parkinson's disease (Ulfig et al., 1981).

Lipofuscin granula are also found in glia, epithelia of the choroids plexus, meninges, phagocytes, perivascular spaces, and the pigmented epithelium of the eye.

It is only possible to give short remarks on lipofuscin brain topography here. Lipophobic nuclei are nucleus tractus solitarius, the colliculus inferior, and the nucleus interpeduncularis. Lipophilic nuclei are all the cranial and spinal motor nuclei, large cells of the reticular formation, Deiter's neurons, neurons of the mesencephalic trigeminal nucleus, red nucleus, many thalamic nuclei, and cortical pyramidal cells. Good overviews can be found by Obersteiner, Altschul (1938, 1943), and Wolf and Pappenheimer (1945). One should especially consult the topographic articles of Braak and Braak, since a systematic atlas of their findings is missing.

Theories

Several theories are developed concerning lipofuscin granula. An incomplete enumeration follows here:

1. *The degeneration or aging theory.* See start of this article and Porta (2002) for an overview on aging.
2. *The proteolysis theory.* Nonenzymatic oxidation of proteins of the outer-segment components in the eye is involved in lipofuscin production (Katz, 1989).

3. *Removal theory.* Lipofuscin is produced in order to package and remove it from the neurons into macrophages and blood vessels (Gless et al., 1986).
4. *Myelination theory.* The greater the degree of myelinization and the less intense the pigmentation are, the more resistant a given projection neuron is to oxidative stress as well as to the development of Alzheimer's disease-related neurofibrillary changes and vice versa (Braak and Braak, 1999, 2000).
5. *Scavenger receptor theory.* A series of scavenger receptors is capable to recognize and internalize modified lipoproteins, making them susceptible to degeneration. The theory tries to explain several diseases (Zingg et al., 2000).
6. *The oxidation theory.* There is an increasing oxidation level from polyunsaturated lipids, via ceroids, lipofuscins, and perhaps even to the neuromelanins.
7. *The respiration chain theory.* High respiration activity is related to high lipofuscin accumulation.

Lipofuscinosis

The disease (also called Batten's disease and grouped under the neural lipidoses) was ill-defined and different illnesses on first sight were grouped to it. This was because the sign (accumulation of lipofuscin) was considered and not the deterioration of the cellular process underlying the occurrence of high concentrations of lipofuscin granula.

Modern genetic and molecular biology changed that view. Recently the neuronal (ceroid) lipofuscinoses are all considered an inherited neurodegenerative disorder (Goebbles et al., 1999; Haltia, 2003; Santavuori, 1988). Mutations in the *CLN* genes (locus name for the neuronal ceroid lipofuscinoses) are held responsible for this disease. Several of the genes are coded for and the modern nomenclature now is: *CLN 1*, infantile precocious form (called still Santavuori–Haltia disease); *CLN 2*, retarded infantile form (Janski– Bielschowsky disease); *CLN 3*, juvenile form, called the Spielmeyer–Vogt or the infantile Batten's disease; *CLN 4*, adult form, known as Kufs disease; *CLN 5*, variable form of CLN 2, also called Lake and Cavanagh disease or juvenile precocious form Finnish variant; and *CLN 8*, recently described form Turkish variant, starting early in infancy (Ranta et al., 1999).

The basic disturbed proteins and gene codes are known for most *CLN* types:

1. *CLN 1.* Localized at 1p32, coding for a glycoprotein of 37 kDa called palmyltoyl thioesterase. This is a lysosomal enzyme.
2. *CLN 2.* Localized at 11p15, coding for a lysosomal peptidase.
3. *CLN 3.* Localized at 16p, coding for a lysosomal transmembrane protein.
4. *CLN 4.* Gene not localized.
5. *CLN 5.* Localized at 13q22, coding for a transmembrane protein with unknown function.
6. *CLN 8.* Localized at 8p23, coding for a transmembrane protein, present in the endoplasmic reticulum.

One should note that the substances accumulated are different for the various lipofuscin diseases due to the different mutated enzymes. The disease can be related to a severe astrocyte gliosis coinciding with neuronal atrophy, for example, in the cortex and cerebellum. Especially astrocyte surcharging of substances is found in the hippocampus, the brain structure related to epileptic seizures.

Symptoms of the disease are blindness or visual disturbances, ataxia, mental retardation, dementia, myoclonus, choreoathetosis, and (epileptic) seizures.

A family history of lipofuscinosis indicates inherited autosomal recessive traits.

Based on all the evidence available nowadays, the neurolipofuscinoses are grouped under the heading hereditary lysosomal storage diseases, as first proposed by Koenig (1969).

Liprins, ELKS, and RIM-BP Proteins

S Schoch, T Mittelstaedt, and M Zürner, University of Bonn, Bonn, Germany

Introduction

Exocytosis of neurotransmitter-filled synaptic vesicles is temporally and spatially highly coordinated. The docking, priming, and fusion of vesicles takes place at a specialized area of the presynaptic plasma membrane, called the active zone (AZ). A proteinaceous network, the cytomatrix at the active zone (CAZ), is involved in the different steps of the synaptic vesicle cycle. Several large multidomain proteins that do not contain transmembrane domains have been identified as being enriched at the active zone and interacting with one another in various combinations. Three of these protein families, ELKS, liprins, and Rab3-interacting molecule (RIM) binding proteins (RIM-BPs), are the focus of this article.

ELKS/CAST/ERC Proteins

ELKS/CAZ-associated structural protein (CAST)/ERC proteins were identified in several independent screens and therefore are known under a variety of names. They were first described as part of a gene rearrangement with the receptor tyrosine kinase RET and named ELKS due to their high content in the amino acids glutamate (E), leucine (L), lysine (K), and serine (S). Oligomerization of the chimeric ELKS-RET protein via the N-terminus has been shown to lead to its transformation into an oncoprotein and cause papillary thyroid carcinomas. Furthermore, ELKS has been described as being an essential regulatory subunit of the IκB kinase (IKK) complex in the nuclear factor (NF)-κB signaling cascade. It was also isolated as Rab6-interacting protein 2 (Rab6IP2B) and implicated as acting together with the small guanosine triphosphatase (GTPase) Rab6 in Golgi transport. ELKS were identified as components of the presynaptic cytomatrix (CAZ) independently in a biochemical screen for proteins enriched in the postsynaptic density fraction as CAST (CAZ-associated structural protein) and in a yeast two-hybrid screen for binding partners of the active zone protein RIM as ERC (ELKS/Rab6-interacting protein/CAST).

Gene Structure

Mammals contain two inordinately large *ELKS* genes, *ELKS1* (= ERC1/CAST2) and *ELKS2* (= ERC2/CAST), in which exons are separated by introns of more than 100 kb. The ELKS gene structure exhibits an unusual organization in that most exons are in-frame, allowing for alternative splicing. Whereas one short homologous sequence (SLTS) is variably inserted in ELKS1 and ELKS2, two separate interior sequences are alternatively spliced in either ELKS1 or ELKS2. Most strikingly, alternative splicing of the ELKS1 (but not the ELKS2) C-terminus results in two isoforms with diverging tissue distributions and biochemical properties. The two ELKS1 C-termini are coded for by distinct exons that are separated by a large intron. Whereas ELKS1A encompasses a longer sequence with no homologies to other known proteins, the shorter C-terminus in ELKS1B is almost identical to ELKS2 (Figure 1).

Expression and Localization

ELKS1A is expressed exclusively outside the brain beginning early during development. By contrast, the expression of ELKS1B and ELKS2 is restricted to the brain and becomes detectable at embryonic day (E) 14.5, when most synaptic proteins are synthesized. During the first postnatal days, the mRNA of both isoforms is widely expressed in the brain; however, in the adult brain ELKS1B mRNA is mainly detected in the hippocampus and cerebellum, whereas ELKS2 is abundantly expressed in the forebrain, including the hippocampus, cortex, olfactory bulb, and thalamus. Of the three ELKS proteins, only ELKS2 is insoluble, enriched in the postsynaptic density fraction, and exclusively localized at the presynaptic AZ. By contrast, ELKS1B is enriched in the synaptic plasma membrane but is also soluble and present at the AZ as well as in the cytoplasm. ELKS1A is largely cytosolic. In immunoelectron microscopy, ELKS2 can be detected only in the presynaptic nerve terminal, with symmetrical synapses exhibiting weaker labeling than asymmetrical synapses. In the ribbon synapses of the retina, ELKS2 was shown to localize to the base of ribbons, whereas ELKS1B was detected around the ribbons.

Protein Interactions

The amino acid sequences of ELKS1 and ELKS2 are highly homologous to one another and conserved in human, mouse, and rat. ELKS1B and -2 are 120 kDa proteins that are composed of four coiled-coil domains with no homology to other proteins and a C-terminal consensus-binding motif (IWA) for binding the PDZ (Psd-95, Dlg, and ZO1) domains of RIM1α, RIM2α/β, and syntenins (Figures 1 and 2(a)). Whereas the interaction of the ELKS1B/2 C-terminus with the RIM–PDZ domain is highly specific in that it is

Figure 1 Domain structure of ELKS, RIM binding protein (RIM-BP), and liprin protein families. ELKS proteins are composed of highly homologous coiled-coil domains (homology regions are highlighted in yellow boxes) and an isoform-specific C-terminus, which in ELKS1B and ELKS2 contains the RIM-PDZ-binding motif (pink box). RIM-BPs consist of three homologous SH3 domains and three contiguous fibronectin type III domains. Liprins contain N-terminal coiled-coil domains and three C-terminal SAM domains. Within the liprin subfamilies, isoforms exhibit a high degree of homology. abolished even by conservative substitutions, the binding to syntenin is affected only by one mutation in the last four residues of ELKS (GIWA, -B, -C, and -D) out of five mutations tested. ELKS proteins can form hetero- and homooligomers through their N- and C-terminal domains. The central region of ELKS interacts with the C-terminal region of Bassoon and Piccolo. Although the binding of ELKS with Bassoon

or Piccolo is mutually exclusive, ELKS can interact simultaneously with Bassoon/Piccolo and RIM. Moreover, ELKS proteins interact with all four liprin-α isoforms, and ELKS1A/B bind to the small GTPase Rab6. In cultured neurons, it was shown that ELKS2 is localized to synapses through its N-terminal half (including the 1 and 2 coiled-coil domains) independently of its interaction with RIM. In the same system, overexpression of ELKS2 promotes the synaptic clustering of liprins-α and syntenin-1 and is involved in, but not essential for, the localization of RIM at the AZ. However, ELKS is not required to target Bassoon to synapses.

Function

To study the role of ELKS in the regulation of synaptic vesicle fusion, superior cervical ganglion neurons (SCG) were microinjected with peptides of fusion proteins that interfered with the binding of ELKS to either RIM or Bassoon. The inhibition of both interactions resulted independently in an impairment of synaptic transmission 70 min after the microinjection of the peptides.

ELKS function has also been studied outside the nervous system. ELKS1 is expressed in pancreatic β-cells and was shown to play a role in insulin exocytosis from these cells. Introduction of the Bassoon-binding region of ELKS1 into pancreatic β-cells led to a reduction in the docking and fusion of insulin granules. Furthermore, knockdown of ELKS1 by siRNA resulted in a decrease of docked granules and glucose-evoked insulin release. PC12 cells also express ELKS1, and overexpression of ELKS1 enhanced stimulated exocytosis of human growth hormone (hGH) from PC12 cells. The binding of ELKS1 to RIM2 as well as to Bassoon was necessary to observe this increase.

Caenorhabditis elegans ELKS

A single ELKS homolog was detected in *C. elegans* that resembles mammalian ELKS weakly throughout the protein but exhibits patches of strong similarity mainly in the C-terminus, which is identical to ELKS1B/2. It was shown that the direct interaction between RIM and ELKS is conserved for the *C. elegans* proteins. RIM and ELKS are co-localized in the *C. elegans* nervous system, and the localization of both proteins is independent of the kinesin motor protein unc-104. Moreover, animals devoid of ELKS have a normal RIM staining pattern and vice versa, suggesting that in *C. elegans* this interaction is not necessary to localize RIM or ELKS to the synapse. However, expression of the soluble PDZ domain of RIM interferes with ELKS AZ targeting and truncated RIM (consisting of the PDZ and C2A domain) targets release sites in an ELKS-dependent manner, suggesting a tight association of the two proteins *in vivo*. In addition, worms deficient for ELKS display normal behaviors and are not resistant to the acetylcholine esterase (AChE) inhibitor Aldicarb. Accordingly, an electrophysiological analysis did not reveal any synaptic phenotype. Therefore, ELKS is a component of the *C. elegans* AZ, but is not a critical part of the release machinery.

Drosophila Bruchpilot

Interestingly, the recently identified *Drosophila* protein Bruchpilot (BRP) contains in its N-terminus short stretches of up to 67% identity with mammalian and *C. elegans* ELKS. However, the C-terminal coiled-coil domain has no direct vertebrate homolog and does not contain the PDZ-binding motif (IWA) of ELKS1B/2 and *C. elegans* ELKS (Figure 1). Instead, this sequence exhibits homology to large cytoskeletal proteins such as plectin and myosin heavy chain and encompasses two leucine zipper domains and a glutamine-rich C-terminus. The expression of BRP is restricted to the nervous system, and there is no nonneuronal isoform. An elegant analysis using stimulated emission depletion fluorescence microscopy (STED) showed that BRP is localized in donut-shaped structures centered at AZs of neuromuscular synapses.

An analysis of mutant flies in which nearly the entire open reading frame was deleted revealed that these animals exhibited slightly smaller neuromuscular junctions (NMJs), with fewer individual synapses, whereas the individual receptor fields were enlarged. Strikingly, the dense-core projections at the AZs (T-bars) were completely missing. At the NMJ of BRP mutant larvae, the amplitudes of excitatory junctional currents (eEJC) were drastically decreased, the nerve-evoked responses were less synchronized, and the initial release probability was reduced. Furthermore, the density of Ca^{2+}-channel clusters was severely decreased over the entire NMJ.

Liprins

Liprins are a family of multidomain scaffolding proteins that are highly evolutionarily conserved from *C. elegans* to humans. Liprins-α were first described as cytoplasmic-binding partners for the leukocyte common antigen-related (LAR) receptor protein tyrosine phosphatase (RPTPase). Several recent studies have identified liprins-α as components of the presynaptic CAZ and as part of the proteinaceous network present in dendritic spines. Furthermore, there is accumulating evidence for an integral role of liprins-α in diverse neuronal processes.

Gene Structure

The liprin protein family is composed of two subfamilies, named liprins-α and liprins-β (Figure 1). Whereas in *C. elegans* and *Drosophila* a single liprin-α gene is found, syd-2 and Dliprin, respectively, mammalian genomes contain four liprin-α isoforms (liprin-α1, -α2, -α3, and -α4). The liprin-β family consists of two genes in mammals, liprin-β1 and -β2, and one in invertebrates, celiprin-β in *C. elegans* and Dliprin-β in *Drosophila*. Liprins are composed of several N-terminal coiled-coil domains and three C-terminal sterile alpha motif (SAM) domains (Figure 1). Only liprins-α1–3 have an additional PDZ-domain binding motif at their C-terminus. The domain structure is highly homologous among the individual subfamilies. In particular, the individual domains exhibit a high degree of identity between the invertebrate and mammalian isoforms.

Expression and Localization

The different members of the liprin gene family show diverging expression patterns. Of the four mammalian liprins-α, the mRNA expression of liprin-α2 and liprin-α3 is restricted to the nervous system. By contrast, liprin-α1 mRNA is found in most tissues and liprin-α4 mRNA can be detected in the brain, heart, and muscle, although at very low levels. Whereas liprin-β2 expression is ubiquitous, liprin-β1 mRNA is mainly expressed in the heart and to a much lesser extent in the brain, liver, placenta, lung, muscle, kidney, and pancreas.

Studies in primary neuronal cultures showed a punctate staining pattern for liprins-α that co-localize extensively but not exclusively with markers for the presynaptic active zone and the postsynaptic density (PSD). Furthermore, liprin-α labeling could be detected at the excitatory and inhibitory synapses. However, liprins-α are also distributed to various nonsynaptic structures in the axons, dendrites, and soma. Ultrastructural analysis by electron microscopy has revealed a pre- and postsynaptic localization of liprins-α. Moreover, liprins-α were preferentially present in the proximity of the pre- and postsynaptic membrane, whereby the lateral distribution along the length of the AZ and the PSD appeared uniform. In subcellular fractionation analyses, liprins-α were tightly associated with the PSD fraction, lending further support to an enrichment of liprins-α in the proteinaceous network at the AZ and the PSD. In *Drosophila,* Dliprin expression has been shown to be restricted to the central nervous system and muscle. However, at *C. elegans* synaptic junctions, syd-2 is strictly localized at presynaptic terminals and tightly associated with the electron-dense specializations within the active zone.

Protein Interactions

The domain structure of liprins-α suggests that they can engage in multiple protein–protein interactions and, fittingly, a large number of binding partners for liprins-α have been isolated in recent years (Figure 2(b)). Within the N-terminal coiled-coil regions of liprins-α, separate binding domains for the presynaptic AZ proteins RIMs and ELKS, as well as for G-protein-coupled receptor kinase-interacting protein (GIT), a GTPase activating protein for the family of adenosine diphosphate (ADP)-ribosylation factor GTPases, have been characterized. Liprins-α bind to the C-terminal C2B domain of RIMs, to the N-terminal coiled-coil domain of ELKS, and to the C-terminal G-protein-coupled receptor kinase-binding (GRKBD) domain of GIT. Furthermore, liprins-α interact indirectly via GIT with another component of the presynaptic CAZ, named Piccolo. The liprin-α region, comprising the interaction sites for ELKS and GIT, mediates binding to the motor protein kinesin family member (KIF)1A. Several binding partners have also been identified for the C-terminal three SAM domains. Liprins-α (but not liprins-β) interact via the SAM domains with the catalytically inactive D2 domain of the receptor protein tyrosine phosphatases LAR, PTPδ, and PTPσ. A recent report described the binding of the first SAM domain of liprin-α2 to the N-terminus of calcium/calmodulin-dependent serine protein kinase (CASK), thereby linking liprins-α to the evolutionarily conserved tripartite complex consisting of CASK, Mint-1, and veli/MALS (lin-7–lin-10–lin-2) and via CASK to the cell-adhesion molecules neurexins and SynCAMs. However, the interaction of liprins-α and Mint-1 with CASK seems to be mutually exclusive. So far, only the multi-PDZ domain-containing protein glutamate receptor interacting protein (GRIP) has been shown to bind with PDZ6 to the C-terminal PDZ-binding motif of liprins-α. Interestingly, homo- and heterodimerization has been observed within the liprin protein family. The α- and β-subfamilies form homodimers via their N-terminal coiled-coil domains and heterodimers through the SAM domains. Considering all the protein interactions that have been reported for the various domains of liprins-α, it seems very likely that they are part of various multiprotein complexes; for example, liprins-α were found in one complex with GRIP, glutamate receptor (GluR)2/3, and GIT and in another with ELKS, Piccolo, and GIT.

Function

The first investigations into the function of liprins-α were carried out in the nematode *C. elegans*. The liprin-α homolog syd-2 was identified in a screen for

mutants affecting the localization of the synaptic vesicle protein synaptobrevin. Mutant animals expressing low levels of a short truncated syd-2 protein suffered from reduced locomotion and defective egg laying and exhibited a degree of resistance to aldicarb comparable to worms deficient for rab3 and aex-3 and indicative of a defect in synaptic transmission. The overall morphology of motor neurons was unaltered; however, presynaptic proteins such as syntaxin, rab3, and synaptotagmin were diffusely localized. An ultrastructural analysis of synapses at the NMJ revealed that the length of the presynaptic active zones was increased. The phenotype of the mutant animals could be fully rescued by the presynaptic overexpression of full-length syd-2. The deletion of the SAM domains reduced the rescuing ability of overexpressed syd-2. Taken together, these results provided the first evidence for a role of liprins-α in the organization of presynaptic active zone ultrastructure.

This hypothesis was further substantiated by studies at the NMJ junction of Dliprin-deficient flies. In mutant flies, the NMJ exhibited a decrease in branch complexity and a reduction in the number of boutons formed per NMJ. Electron micrography of individual synapses revealed that the size and shape of the AZ was dramatically altered in Dliprin-deficient flies compared to wild-type flies. On average, the total AZ area was increased by 2.4-fold. Furthermore, synaptic transmission at the NMJ was impaired because evoked excitatory junctional potentials were reduced by 36%. These results strongly imply that Dliprin is a requisite structural component of the AZ. Interestingly, the phenotype of animals deficient for Dlar, the *Drosophila* homolog of the LAR RPTP, with regard to synaptic ultrastructure is very similar to the one observed in the Dliprin mutant flies, indicating that Dliprin and Dlar act in the same pathway. However, Dlar-deficient flies show an additional defect in axon guidance at the NMJ that is not replicated in Dliprin mutants. Recent data suggest that Dliprin, together with Dlar and N-cadherin, is required for photoreceptor target selection in *Drosophila*. Furthermore, Dliprin has been described as a downstream effector of a ubiquitin ligase named the anaphase-promoting complex/cyclosome (APC/C). It has been suggested that APC/C regulates synaptic size in neurons and synaptic transmission in muscle via control of local ubiquitin-mediated protein degradation.

Dliprin has further been implicated in the trafficking of synaptic vesicles (Figure 3). Dliprin mutants showed abnormal punctate accumulations of the synaptic vesicle protein synaptotagmin along the axon and a lower density of synaptic proteins at the NMJ. Ultrastructural analysis revealed an increase in the number of clear-core vesicles in mutant axons in the absence of ectopic presynaptic specializations. Even though no change in the total flux of synaptic vesicle precursors (SVPs) was observed, the loss of Dliprin resulted in a significant decrease of the transport of SVPs in the anterograde direction with a concomitant increase in retrograde flux. It was hypothesized that in the absence of Dliprin, anterograde traffic is disrupted by decreasing the processivity of transport and increasing the initiation of retrograde movement. Dliprin interacts with the *Drosophila* kinesin-1 (khc-1), in analogy to the binding of mammalian liprin-α to the motor protein KIF1A that mediates long-range transport of AZ components in neurons along microtubuli. Studies in primary neuronal cultures showed liprins-α and KIF1A to be co-localized in various subcellular regions. Therefore, Dliprin/liprins-α could potentially function as a linker between KIF1A and its cargo or directly promote kinesin activity (Figure 3). Liprins-α have also been linked to postsynaptic transport processes. The ternary complex of GluR2/3–GRIP–liprin-α–GIT has been shown to be involved in the dendritic targeting

Figure 3 Role of liprins-α in neuronal transport processes: (a) in axons; (b) in dendrites. Kinesin motor proteins traveling along microtubuli toward the synapse are in yellow. GIT, G-protein-coupled receptor kinase-interacting protein; GluR, glutamate receptor; GRIP, glutamate receptor interacting protein; Kif, kinesin family member.

of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPARs) . Both inhibition of the interaction between GRIP and liprins-α and the one between GIT and liprins-α results in a decrease of AMPAR clustering and surface expression. In addition, overexpression of liprin-α1 that is unable to bind to GRIP reduces the density of dendritic spines. It was proposed that AMPARs are transported to synapses and dendritic spines by a mechanism that requires liprins-α and their interaction with GRIP, GIT, and LAR-RPTPs. Furthermore, the binding between liprin-α and GIT may either facilitate the physical retention of AMPARs at the surface membrane or might actively inhibit the endocytosis of AMPARs. Liprins-α have also been shown to participate in localizing the scaffolding protein veli/MALS to synapses. Synaptic localization of liprins-α, in turn, seems to be partially dependent on their interaction with the AZ protein ELKS.

In summary, liprins-α engage in multiple protein–protein interactions and thereby are components of several large protein complexes/networks. There is accumulating evidence that they are critically involved in the organization and maintenance of the synaptic ultrastructure, the transport of pre- and postsynaptic cargo, and the target selection of specific axons.

RIM Binding Proteins

RIM-BP1/2 were isolated in a yeast two-hybrid screen with the C-terminus of the RIM. The human isoform of RIM-BP1 had been previously described as a protein binding to the peripheral benzodiazepine receptor and named peripheral benzodiazepine receptor-associated protein 1 (PRAX-1/bzrap1).

Gene Structure

The mammalian genome contains three RIM-BP genes, whereas a single gene has been identified in *Drosophila* and *C. elegans*. RIM-BPs are large multimodular proteins and are composed of an N-terminal Src homology 3 (SH3) domain, three central contiguous fibronectin type III (FNIII) repeats, and two tandem SH3 domains at the C-terminus (Figure 1). The amino acid sequences of the SH3 domains as well as the FNIII repeats are rather untypical but highly conserved between the individual RIM-BPs. The flanking regions are more divergent among the different isoforms and are rich in arginine, lysine, glutamic acid, and leucine. RIM-BP1 contains three proline-rich regions with a proline content around 30% and strings of charged residues with up to 13 consecutive glutamic acid residues. However, RIM-BP2 and-BP3 share only one proline-rich region with RIM-BP1, which is located downstream of the FNIII repeats. The long strings of glutamic acid residues are not conserved in RIM-BP2 and -BP3.

Expression and Localization

Expression of RIM-BP1 and RIM-BP2 is mainly restricted to the brain. A pan-RIM-BP antibody raised against the C-terminal SH3 domains of chicken RIM-BP2 resulted in an extensive and almost uniform neuronal labeling in the chicken brain. The protein could be detected pre- and postsynaptically. In cultured dorsal root ganglion neurons from chicken, a punctate distribution was observed that partially overlapped with the labeling of the synaptic vesicle protein SV2A but was also extrasynaptic. Subcellular fractionation revealed that RIM-BPs co-purify with components of the presynaptic cytomatrix and postsynaptic density proteins. Furthermore, it was shown that RIM-BPs are localized at active zones of hair cells and ribbon synapses. Interestingly, chicken RIM-BP2 expressed in human embryonic kidney (HEK) cells is diffusely distributed in the cytoplasm. However, co-expression with the Ca^{2+} channel Cav1.3 results in a clustered distribution. Immunocytochemical staining of rat brain sections with anti-RIM-BP1 antibody (raised against a peptide localized in the C-terminus of human RIM-BP1) revealed neuron-specific labeling that was intense in the cell cytoplasm and in the proximal axonal segments.

Protein Interactions

So far, protein interactions have been described only for the RIM-BP SH3 domains. The second SH3 domain of RIM-BPs binds to a proline-rich sequence in the C-terminus of RIMs. Furthermore, all SH3 domains of RIM-BP2 have been shown to interact with L-type Ca^{2+} channel Cav1.3 and N-type Ca^{2+} channel Cav2.2 (Figure 2(a)). RIM-BP SH3 domains bind to class I ligand consensus sites, +XϕPXϕP (in which + is a basic residue, usually arginine; X is any amino acid; and ϕ is a hydrophobic residue). The Cav1.3 interaction motif, RLLPPTP, fits the consensus sequence for class I ligands, differing only by a nonhydrophobic threonine residue in the sixth position. This threonine is conserved in the PXXP motifs of Cav2.2, Cav2.1 (RQLPQTP), and Cav1.4 (RLLPPTP). Therefore, RIM-BPs could interact with various Ca^{2+} channel α subunits in the brain. Interestingly, RIM-BPs can bind to Ca^{2+} channels and RIMs simultaneously. Also, the binding to the last 14 amino acids of the peripheral benzodiazepine receptor is mediated by the RIM-BP C-terminus, containing the last two SH3 domains. However, to obtain a high level of binding, it was necessary to use three copies of the 14-amino-acid sequence separated by glycines.

Function

So far, the role of RIM-BPs in the regulation of secretion has been studied only in PC12 cells. In this system, depolarization-induced secretion was enhanced by the overexpression of fusion proteins that interfered with the interactions of RIM-BP with either RIMs or Ca^{2+} channels. These results led to the hypothesis that RIM-BPs repress RIMs and Ca^{2+} channels. However, no effect on secretion was observed by overexpressing the full-length RIM-BP2. This might be due to the fact that all endogenous binding sites in RIMs and Ca^{2+} channels are already occupied. However, the ability of RIM-BPs to bind to RIMs and Ca^{2+}channels simultaneously, as well as their potential to interact with additional proteins, points to a role as a linker among the site of Ca^{2+} influx, the priming machinery, and synaptic vesicles.

Introduction

The pattern of development of the human cerebral cortex is complex and leads to the unique diversity of cognitive functions that makes us human. Many advances have been made by studying the variations from the basic pattern of forebrain organization in different vertebrates. The mammalian cerebral cortex, a patterned structure, is divided into anatomically distinct and functionally specialized areas leading to a species-specific map. Mature cortical areas differ by their location within the cortex, molecular properties, histological organization, patterns of connectivity, and function. Within the neocortex, rostral regions regulate motor and executive functions whereas caudal regions process somatosensory, auditory, and visual inputs. These different cortical areas have a precise connectivity, particularly with nuclei within the dorsal thalamus, which provides some of the principal inputs to the cerebral cortex. Although many of these areas can be related to each other during vertebrate evolution and share common features of cortical development, many other aspects remain poorly understood. Proliferation, migration, differentiation, and survival of neuronal precursors have been modified during brain evolution to allow for the development of the highly organized primate neocortex. Whenever one of these mechanisms, and in particular neuronal migration, is disrupted or its delicate balance is perturbed, neocortical disorders may arise and lead to different forms of mental retardation or cognitive disabilities and severe epilepsy.

Lissencephaly (LIS) is one of the best characterized and studied human genetic malformations of the cerebral cortex (MCCs). The primary defect underlying the smoothening of the brain of lissencephalic patients (Figure 1) is defective neuronal migration. The inability of postmitotic neurons to reach their final destination and correctly populate the cortical plate of the cerebral cortex consequently leads to abnormal cortical thickness and reduced or absent gyri and sulci of its surface. Neuronal migration is driven by complex mechanisms that are orchestrated by many proteins that interact mainly, but not exclusively, to promote the recruitment, organization, stability, movement and function of microtubules. Scientific understanding of the molecular mechanism and the genetic interactions that form the basis of neuronal migration has been aided by the analysis of spontaneous and engineered mouse models, and the gene function of some of the key regulatory proteins has been elucidated. The ability to study the migration features of such mouse models has been greatly facilitated by the development of *in vivo* time-lapse microscopy methods for the imaging of migrating cells. Although our knowledge of neural migration and neocortical development has been partially clarified, the mechanisms and pathways controlling these processes are far from being fully elucidated, and many questions remain unanswered.

Human Genetic Malformations

The development of the cerebral cortex is characterized by three main steps: (1) proliferation and differentiation of the neuronal stem cells into neuroblasts and glia cells, (2) migration of neuronal precursors toward the cortical plate by either radial or tangential movements, and (3) cortical organization into six layers associated with synaptogenesis and apoptosis. These processes are dynamic and occur simultaneously during the different stages of development, and perturbation of these steps leads to MCCs and malfunction. Defects occurring during the early phases of proliferation are usually associated with altered differentiation of both neuroblasts and glia cell precursors, while defects affecting neuronal migration are characterized by malpositioning of neurons along the six layers of the developing cortex. The genetic study of cerebral cortical malformations in humans has identified several genes playing crucial roles during neocortical development. Malformations due to defective neuronal migration include periventricular nodular heterotopia, classical LIS, subcortical band heterotopia (SBH), and Zellweger syndrome. Malformations due to abnormal cortical organization, also called proliferation and patterning disorders, include polymicrogyria and schizencephaly. More-detailed information regarding MCCs may be found in recent reviews. Migration is not the only process responsible for MCCs; proliferation, maturation, and survival of neurons may be critical as well for a proper cortical development. Abnormalities of the brain associated with an impaired proliferation capacity of multipotent stem cells and neuronal precursors may be responsible for microcephaly, a condition characterized by a smaller size of the brain. Compound brain phenotypes may also occur, such as the case of microlissencephaly or the cerebral

Figure 1 Brain MRI scan, coronal section passing through the hippocampus. The lissencephalic brain (right) shows diffuse cortical thickening (about 1 cm vs. 4 mm of the normal cortex, left) with simplified gyral pattern, especially in the brain convexity. The cortical sulci are shallow, and the number of convolutions is reduced. Courtesy of Dr. Renzo Guerrini, Department of Pediatric Neurosciences, Pediatric Hospital A Meyer and University of Florence, Firenze, Italy.

abnormalities associated with Neu–Laxova syndrome, in which cell survival seem to play and important role. MCCs may be associated with epilepsy that typically tends to be severe, although its incidence and type vary in different malformations; it has been estimated that $\leq$40% of children with drug-resistant epilepsy have a cortical malformation. Some of the causative genes for MCCs have been identified, but most remain unknown; only a dozen or so genes have been found causing epilepsy, and about 400 unbalanced chromosome rearrangements are associated with epilepsy syndromes, thus suggesting that a large number of dosage sensitive genes remain to be discovered.

Neuronal Migration

The mammalian neocortex is organized into six distinct cortical layers, each with distinct neuronal morphology and functions. The distribution of neuronal cells during cortical development occurs mainly by radial and tangential movements. In the neocortex, most neurons and glia arise from radial glia progenitor cells. Radial migration represents the predominant direction and type of movement for the positioning of most neurons in the neocortex departing from the ventricular zone (VZ), where postmitotic neuroblasts arise from radial glia progenitor cells and migrate toward the pial surface. This type of migration is characteristic of the dorsal telencephalon giving rise to the excitatory glutamatergic projection neurons of the cerebral cortex, which sequentially reach the different layers of the cortex. Tangential migration, on the other hand, occurs mainly from progenitors arising in the ventral telencephalon, generating γ-aminobutyric acid (GABA)ergic inhibitory neurons, including basal ganglia neurons, as well as interneurons that migrate tangentially to contribute to the formation of the cortex and to reach the olfactory bulb by following the rostral migratory stream. Cortical layering occurs in the mouse between days 11 and 18 during embryogenesis and in the human between 6 and 20–24 weeks. The generation of the six layers occurs in an inside-out fashion: early migrating neurons will populate the deeper level of the cortex, and later migrating neurons the more superficial ones. The first postmitotic neurons produced in the VZ migrate to form a subpial preplate or primitive plexiform zone. Subsequently, later migrating neurons will form the cortical plate by migrating into the preplate to split it into the superficial molecular layer (or layer I or marginal zone containing Cajal–Retzius neurons) and the deep subplate. The different waves of migrating neurons will pass the subplate and end their migration below layer I, forming cortical layers VI, V, IV, III, and II in an inside-out fashion. Radial migration occurs either by locomotion, in which neurons migrate along the processes of radial glia cells (progenitors guiding migration), or by nuclear translocation, in which migrating neurons extend their leading process toward outer levels of the cortex, to be followed by centrosome–nuclear movement. The two types of radial migration are dynamically different and occur at different times during neocortical development; moreover, recent observations suggest that neuronal migration displays different and complex patterns characterized by spatially and temporally distinct changes in the direction of movement and speed of migration for both pyramidal cells and interneurons.

Time lapse imaging studies using cortical slice cultures have demonstrated that neurons generated in the VZ at later stages of development pass through

a series of distinct stages of migration characterized by changes in cell shape, direction of movement, and speed of migration as they move to the cortical plate. According to these observations, radial migration does not occur directly to the cortical plate but is divided into four different phases. During phase 1, newly generated neurons at the ventricular surface move radially from the VZ to the subventricular zone (SVZ). At this point, phase 2, they pause at the border of the intermediate zone (IZ) with the SVZ and acquire a multipolar stage. This morphological change provides cells with a dynamic capability to change polarity, extending and retracting processes to move within the SVZ. Consequently, they do not appear to depend on radial glia fibers for their movement, as demonstrated by their ability to move tangentially. Most of the neurons go through a third phase characterized by a bipolar state, in which they extend processes toward the VZ, followed by retrograde translocation of the cell body. In the fourth phase, neurons reverse polarity and extend a pial-directed leading process, take on the bipolar morphology of migrating neurons, and begin radial migration to the cortical plate. Some neurons, however, after pausing in the SVZ, do not proceed through phase 3 with a retrograde motion toward the ventricle but instead progress directly from phase 2 to phase 4.

It is interesting that these four distinct phases of neuronal migration may be relevant to partially explain the generation of human migration disorders. For instance, in SBH a band of cortical neurons fails to migrate fully into the cortex and collects in the subcortical white matter. It is possible that these neurons fail to migrate because they are not able to make the transition from phase 2 to phase 3 of migration and therefore remain as immature multipolar neurons in the subcortical white matter. Similarly, periventricular nodular heterotopia may reflect a failure of neurons to transit from phase 3 to phase 4 of migration or inappropriate migration backward toward the ventricular surface. In this regard, *in utero* electroporation experiments indicate a cellular role of filamin A in exit from the multipolar stage; indeed, excess expression of the rodent filamin A or RNAi of Filip1 (which encodes a filamin A-binding protein that targets filamin for degradation) reduces the number of multipolar cells in the SVZ and IZ. By contrast, overexpression of Filip1 and the resulting decrease in Flna expression causes accumulation of cells in the multipolar stage. Filamin A is thus required for migration within the multipolar stage and for the transition into bipolar modes of migration. LIS1 knockdown (see the section titled 'LIS: clinical aspects and molecular genetics') causes accumulation in the VZ and SVZ of multipolar cells that have reduced capacity for migration. Doublecortin (DCX) knockdown in rats (see below) causes cells to accumulate in the multipolar stage in the IZ. Overexpression of DCX, by contrast, causes cells to adopt a highly bipolar morphology. Therefore, similar to FLNA, DCX loss of function and gain of function cause increases and decreases, respectively, in the number of cells in the multipolar stage. Overall, these observations suggest that the multipolar stage is a point of vulnerability to disruption that will require further investigation.

Molecular Pathways of Neuronal Migration

During the past decade, several molecules have been identified that participate in the control of neuronal migration, and several of the mechanisms driving neuronal movement have been partially clarified. The cloning of human disease genes and the study of genetically modified mouse models have helped in the understanding of the function of these gene products. Four main categories can be distinguished in triggering initiation, progression, modulation, and termination of neuronal migration. Filamin-A (an actin-binding protein) and Arfgef2 (or adenosine diphosphate–rybosylation factor GEF2 involved in vesicle trafficking) seem to play an important role in the initiation of migration, whereas DCX, a microtubule-associated protein (MAP), and LIS1, a MAP and dynein regulator, are involved in the regulation of its progression, and mutation of these genes results in slow or delayed migration. Other molecules (MAP1B, MAP2, and Tau) have been described and associated with migration defects, although not yet with human disorders. A second category includes proteins that play a role in lamination, such as reelin (a glycoprotein of the extracellular matrix), Dab1 (an adaptor protein), two reelin receptors (apolipoprotein E receptor 2 (ApoER2), and very low-density lipoprotein receptor (VLDLR)), p35 (an activator of cyclin-dependent kinase 5 (Cdk5), Cdk5 (a serine-serine-threonine kinase), and Brn1/Brn2 (transcriptional activators of Cdk5 and Dab1). Disruption of each of these proteins results in cortical layer inversion. A third category of molecules includes modulators of glycosylation that likely provide stop signals for migrating neurons. These molecules include protein O-mannosyltransferase, protein O-mannose b-1, 2-*N*-acetylglucosaminyltransferase, fukutin (a putative glycosytransferase), and focal adhesion kinase. The last group of molecules acts as modulators of neuronal migration and may be trophic factors such as brain-derived neurotrophic factor and thyroid hormones or neurotransmitters like glutamate and γ-aminobutyric acid.

One molecular pathway important for the progression of neuronal migration ultimately leads to the regulation of dynein motor function via LIS1. A plausible simplified model for this pathway has been proposed regulating nucleokinesis during neuronal migration through the regulation of dynein motor function (Figure 2). RELN binds to the VLDLR–ApoER2 complex to activate mDab1. Activated mDab1 associates with cAbl and activates cables. Cables has been identified as a potential link between the RELN pathway and Cdk5. Cables activates Cdk5 through interaction with cAbl and mDab1, bridging the RELN and Cdk5 pathways. Activated Cdk5 then phosphorylates NDEL1 (and perhaps NDE1), and P-NUDEL binds to 14-3-3ε to protect it from phosphatase attack. A LIS1–NudE homolog complex then positively regulates dynein motor function through direct association with CDHC and dynein LC. It appears that Cdk5, LIS1, NDEL1, NDE1, and 14-3-3ε regulate dynein motor function in a positive fashion, since decreasing the activity, decreasing the amount, or eliminating these proteins completely results in decreased dynein motor function and mislocalization of dynein components and centrosomal proteins. Thus, the apparent function of the LIS1 pathway is to activate dynein motors and place them in the proper cellular location for function. This model is undoubtedly an oversimplification of what is likely to be a process that is regulated in a highly ordered and complicated fashion. There may be many branch points to and from this basic backbone, and much of the cross-talk between pathways remains to be identified.

LIS: Clinical Aspects and Molecular Genetics

Classical LIS, or 'smooth brain,' represents a pathological condition of the brain characterized by a simplified pattern or the absence of the normal pattern of

Figure 2 A simplified molecular pathway of the regulation of neuronal migration. The disruption of both actin filaments and microtubule dynamics can inhibit neuronal migration. The molecular cascade is initiated by the binding of reelin to its receptors. The stabilization of microtubules via mitogen-activated proteins (MAPs) and the activation of the dynein motor complex play a critical role in the nucleus–centrosome coupling and nucleokinesis. See text for details. ApoER2, apolipoprotein E receptor 2; Cables, a potential link between the RELN pathway and Cdk5; Cdk5, cyclin-dependent kinase 5; Dab1, an adaptor protein; DCX, doublecortin; CDHC, cytoplasmic dynein heavy chain; CDLC, cytoplasmic dynein light chain; Cdc42, cell division cycle 42; Rho, Rho family GTPase; PP2A, protein phosphatase 2A; VLDLR, very low-density lipoprotein receptor.

gyri and sulci, resulting in a reduction of the cortical surface with abnormal thickness and layer organization (**Figure 1**). This disorder affects about one in 40 000 individuals and is inherited as either an autosomal or an X-linked dominant disorder. Typically, LIS, diagnosed through magnetic resonance imaging, is associated with severe mental retardation and intractable epilepsy that consequently lead to a shortened life span. Syndromes related to LIS include Miller–Dieker syndrome (MDS; a severe form of LIS); double cortex syndrome, or SBH (a less severe condition); and LIS with cerebellar hypoplasia, polymicrogyria, and cobblestone with associated congenital muscular dystrophy and eye disease. In LIS, neurons migrate only partially toward their proper cortical destination so that in the mature cortex, gyri and sulci fail to form. SBH is a disorder in which bilateral bands of grey matter are interposed in the white matter between the cortex and the lateral ventricles. Two major forms of LIS have been differentiated, classical LIS (type I) and cobblestone (type II), although careful delineation of syndromes has revealed multiple forms of LIS.

Two genes have been associated with classical LIS and SBH. The first gene, LIS1 (Online Mendelian Inheritance in Man (OMIM) database number 601545), on chromosome 17p13.3, is responsible for the autosomal form of LIS, while the second gene, DCX (or XLIS, OMIM 300067), is X-linked. Although mutations in either gene can result in either LIS or SBH, the majority of cases of classical LIS are due to deletions or mutations of the LIS1 gene, whereas the majority of cases of SBH are due to mutations of the DCX gene. The most important characteristics of LIS in patients with LIS1 mutations are the very thick (10–20 mm) cortex, gyral malformations that are more severe in posterior than anterior brain regions, and a prominent cell-sparse zone in the cortex, whereas DCX mutations result in LIS more severe in anterior brain regions.

Mouse knockouts for *Lis1* with graded reduction of the protein level displayed a severe developmental brain disorder as the result of an abnormal neuronal migration. Mice with 50% of LIS1 protein displayed cortical, hippocampal, and olfactory bulb disorganization resulting from delayed neuronal migration. Mice with further reduction (35% of LIS1 protein) displayed a more severe brain disorganization, as well as cerebellar defects. These results suggested that *Lis1* has an essential and dosage-sensitive role in neuronal migration during brain development. Reduction of *Lis1* levels has been shown to have a pleiotrophic effect involving interkinetic nuclear migration, neuroblast proliferation, and survival.

Patients with LIS and deletions of 17p13.3 (MDS) have more-severe LIS than do patients with isolated LIS sequence (ILS) in addition to facial abnormalities, thus suggesting that at least a second gene in the deleted region may contribute to the migration defects during cortical development. MDS is always associated with LIS grade 1 (essentially complete agyria), while ILS has been associated with a more variable LIS phenotype ranging from grade 2 to grade 4, in which pachygyria is most frequently observed. The definition of the deleted region in MDS patients (about 400 kb) suggested that 14-3-3ε was the best candidate gene contributing to the severity of phenotype. Indeed, mouse knockouts for *14-3-3ε* displayed abnormal cortical development due to a reduced capacity of neurons to migrate and populate the upper level of the cortex. In addition, double heterozygote mouse mutants for *Lis1* and *14-3-3ε* displayed increased severity of cortical migration defects and hippocampal disorganization compared with the single heterozygotes. The finding of slower migration in the cortex and hippocampus of double heterozygotes, compared with single heterozygotes and wild-type mice, strongly suggested a genetic interaction between *Lis1* and *14-3-3ε* during brain development and neuronal migration, thus partially clarifying the phenotype differences between MDS and ILS patients.

LIS1 encodes a protein that is similar to the β subunit of heterotrimeric G-proteins and has two functions: a regulatory subunit of platelet-activating factor acetylhydrolase (PAF-AH), an enzyme that degrades the bioactive lipid PAF, and a dynein regulator. The importance of LIS1 as part of PAF-AH in neuronal migration is unclear. LIS1 protein has been shown to co-localize with microtubules and to promote their stabilization, and an ortholog of LIS1 in *Aspergillus nidulans*, nudF, mediates nuclear translocation by interacting with microtubules and dynein. Thus, LIS1 exerts its effects on migration through regulating dynein function and microtubule stability. The gene is expressed in neural progenitors within the VZ as well as in differentiated neurons, suggesting a function during multiple stages of neural development. The interaction between LIS1 and dynein is critical for the binding of microtubules to the cell cortex and generation of cellular machinery for neuronal division. LIS1 binds cytoplasmic dynein and dynactin and localizes to the cell cortex and to mitotic kinetochores. It has been demonstrated that the perturbation of LIS1 in cultured cells interferes with mitotic progression and leads to spindle disorientation. The use of *in utero* electroporation of *Lis1* small interfering RNA and dominant-negative forms of LIS1 or dynactin allowed the first real-time imaging of cortical cell progenitors lacking LIS1 or dynactin function. These experiments resulted in the perturbation of the progression of neural progenitors through

the cell cycle in the VZ, causing a reduction of proliferation and the block of postmitotic precursors through the SVZ, leading to the accumulation of multipolar progenitor cells within the SVZ. Additional insights into the role of LIS1 in cortical development are coming from the analysis of human neural precursors isolated from a 33-week postmortem fetus with MDS. This study provides evidence of disruption in cell proliferation, in addition to migration, and suggests that this process might have an important role in the development of LIS.

DCX is a MAP that stabilizes actively polymerized microtubules and is expressed in newly postmitotic migrating neurons in both the central and the peripheral nervous systems. *Dcx* heterozygote and hemizygote knockout mice showed remarkably normal overall brain morphology, with six layers of the cerebral cortex. In contrast to the normal cerebral cortex, however, the hippocampal formation was malformed, affecting the CA fields in both genotypes. The anatomical abnormalities of the hippocampus were shown to be associated with learning and memory deficits. The central role of DCX in neuronal migration, through the organization and stability of microtubules, and the previous finding of LIS1 effects on microtubules, suggest that microtubule regulation is a key component of neuronal migration in the cerebral cortex. In fact, manipulation studies of LIS1, DCX, dynein, and microtubules have demonstrated that LIS1 and DCX mediate nucleus-centrosome coupling in migrating neurons through dynein, and overexpression of either one enhances migration and rescues the reduced nucleus-centrosome distances. Recent data have shown that DCX is also expressed in tangentially migrating neuroblasts in the rostral migratory stream and that it is an important regulator of both radial and tangential migration. Moreover, DCX hemizygosity was responsible for a branched phenotype in neurons that failed to migrate, thus suggesting an additional role of DCX in maintaining the bipolar morphology of migrating neurons, together with its involvement in nuclear translocation.

Conclusion

In the past 10 years, major progress has been made in the diagnostic recognition of MCCs, especially through the use of magnetic resonance imaging. Variations in distribution and depth of cortical sulci, cortical thickness, boundaries between grey and white matter, and signal intensity allow recognition of different malformation patterns. Sophisticated brain imaging techniques in the emerging field of behavioral neurogenetics allow the precise identification of these malformative patterns, greatly contributing to the selection of patients with similar or identical phenotypes. In turn, the improved selection of patients facilitates the analysis and the discovery of the genetic causes for these conditions. The study of patients with LIS has provided an entry point to the molecular pathways governing neocortical development and neuronal migration in particular. Although the basic mechanisms driving the movement of neurons are becoming clearer, many questions remain to be answered, and most likely other pathways remain to be uncovered. Migration is obviously the driving major force for cortical organization, but the importance of proliferation of neuronal precursors and the survival of postmitotic neurons are events that need to be further investigated. One possibility for improving the body of knowledge is to further investigate the molecules or pathways and binding partners that have already been discovered by means of either transgenic mice or sophisticated *in vivo* technologies. An alternative approach would be to identify new candidate genes with positional cloning methods by screening patients with cortical abnormalities and testing these genes with functional tools. Techniques such as RNA interference and the *in vivo* imaging of neurons using slice cultures will be useful for testing new genes and potentially detecting novel players on the migration pathways.

Introduction

The cortex, or pallium, comprises several subdivisions. In mammals, these functionally distinct regions include the hippocampus, parahippocampal areas, neocortex, entorhinal cortex, olfactory cortex, claustrum, and olfactory bulb. The remarkable conservation of the pattern of areal divisions within a given species suggests a highly conserved and rigidly regulated regional specification program that controls their development. Neocortical regional specification depends on interactions between intrinsic properties of cortical cells with input from subcortical structures.

The development of the human cerebral cortex is a dynamic process that can be divided into partially overlapping stages that occur during several gestational weeks. During the first stage, stem cells proliferate and differentiate into young neurons or glial cells deep in the forebrain, in the ventricular and subventricular zones lining the cerebral cavity. After their final mitotic division, cortical neurons migrate away from their place of origin in a radial fashion along the radial glial fibers from the periventricular region or tangentially, primarily from the ganglionic eminences, toward the pial surface, where each successive generation passes one another and settles in an inside-out pattern within the cortical plate. In a third phase, cortical organization into six layers occurs, associated with synaptogenesis and apoptosis (Figure 1). In humans, the proliferation stage ranges from prenatal weeks 5–6 to weeks 16–20, migration from prenatal weeks 6–7 to weeks 20–24, and organization from week 16 until well into postnatal life. When migration is complete, the cortex is a six-layered structure, with each layer comprising different types of neurons that form discrete connections within the central nervous system (CNS) and performing distinct functions. When neurons reach their destination, they stop migrating and order themselves into specific architectonic patterns. Mechanisms by which cell migration into the cortical plate stops at the appropriate location have been elucidated through the characterization of the *Reeler* mutant mouse. In this animal model, the cortical pattern is the opposite of the normal inside-to-outside development of the cerebral cortex. These data suggest *Reln* is required for the normal inside-to-outside positioning of cells as they migrate from the ventricular zone, a first component of a signaling pathway guiding cells to the correct location in the cerebral cortex.

Genetic studies of cerebral cortex development and neuronal migration have been remarkably successful over the past few years, uncovering several genes that, when mutated, cause disorders of neuronal migration in mice and in humans. Cell migration has been implicated in many disorders; however, lissencephaly (LIS) and periventricular heterotopia (PVH) are the only disorders that are clearly pathogenetically proven to be cell-migration defects.

Lissencephaly Type 1

Definition and Histopathology

Lissencephaly (LIS) (derived from the Greek words *lissos,* meaning smooth, and *enkephalos,* meaning brain) is a neuronal migration disorder characterized by absent (agyria) or decreased (pachygyria) convolutions, producing a smooth cerebral surface. Several different types of LIS have been recognized. The most common type, known as classical LIS or type 1 LIS, features a very thick 10–20 mm cortex and no other major brain malformations.

The cytoarchitecture consists of four primitive layers, including an outer marginal layer, which contains Cajal-Retzius neurons (layer 1); a superficial cellular layer, which contains numerous large and disorganized pyramidal neurons (layer 2) corresponding to the true cortex; a variable cell sparse layer (layer 3); and a deep cellular layer composed of medium and small neurons, which extends to more than half the width of the mantle (layer 4) (Figure 2). The white matter, which is severely reduced in volume, occasionally contains individual neurons or a collection of neurons forming the heterotopia.

Subcortical band heterotopia (SBH) is a related disorder in which there are bilateral bands of gray matter found interposed in the white matter between the cortex and the lateral ventricles. SBH may appear as a solid band of heterotopic tissue or as numerous islands of radially oriented gray matter separated by white matter. Pyramidal cells in the heterotopic band may appear smaller than normal (i.e., those in the overlying cortex, which is usually structurally normal with the exception of shallow sulci).

Genetics

Two genes have been associated with classical LIS and SBH. The *LIS1* gene (Online Mendelian Inheritance in Man (OMIM): *601545) on chromosome 17p13.3

Figure 1 Normal cortical development: (a) preplate stage; (b) cortical-plate stage; (c) adult stage. The preplate stage (a) is marked by the formation of the preplate (PP), a plexiform layer that forms around embryonic day (E)10–12 in mice and embryonic week 8–9 in humans. The cortical-plate stage (b) is marked by the proliferation of neuroblasts in the ventricular zone (VZ) (indicated by mitotic spindles) and the migration of these cells along radial glial fibers (brown processes). Migrating neurons penetrate the preplate, split the preplate into the subplate (SP) and the marginal zone (MZ), and deposit in the cortical plate (CP). Neurons generated later must pass through the SP and pass previously deposited neurons to reach the outer limits of the developing CP (indicated by the progressively lighter shades of green in more-superficial CP neurons). The cortical-plate stage lasts from E10 to E17 in mouse and embryonic week 10–18 in humans. The adult stage (c) is marked by the lamination of the CP into a six-layered structure. IZ, intermediate zone; V, ventricle; WM, white matter. Figure 2 Coritcal layering: (a) normal cortical laminar organization (six layers); (b) cortical layering in classical lissencephaly (four nonorganized layers); (c) histopathological section from a patient with lissencephaly. Adapted from Golden JA and Harding BN (2004) *Pathology & Genetics: Developmental Neuropathology*. Basel: ISN Neuropath Press, with permission from Blackwell Publishing.

is responsible for the autosomal form of LIS, whereas the double-cortin gene (*DCX* or *XLIS*) (OMIM: *300121) is X-linked. Although mutations in either gene can result in either LIS or SBH, most cases of classic LIS are due to deletions or mutations of *LIS1*, whereas most cases of SBH are due to mutations of *DCX*. *LIS1* mutations result in more severe LIS in the posterior brain regions (posterior (p) > anterior (a) gradient), whereas *DCX* mutations result in more severe LIS in the anterior brain regions (a > p gradient) (Figure 3). Among all the patients with isolated LIS, 40% exhibit a deletion involving the entire *LIS1* gene, and 25% show an intragenic mutation (4% gross rearrangement, 17% deletion/truncating mutations, and 4% missense mutations). Patients with missense mutations generally have less severe malformations and may accordingly present with milder motor and cognitive impairment. Severe truncating

Figure 3 Brain MRI scan; axial section: (a) classical lissencephaly in a boy with *LIS1* gene mutation; (b) lissencephaly in a girl with *DCX* mutation. In (a), there is a typical posterior > anterior malformative gradient with relative preservation of the gyral pattern and cortical thickness in the anterior brain; cortical thickness is around 6 mm in the frontal lobes (two black arrowheads; normal cortical thickness = 4 mm) and around 3 cm in the posterior brain (white arrow). In (b), there is a typical anterior > posterior malformative pattern; cortical thickness is around 2 cm in the frontal lobes (white arrow) and around 4 mm in the posterior brain (two white arrowheads).

mutations cause severe LIS, whereas milder mutations, usually missense mutations, cause pachygyria and rare cases of SBH. Mosaic mutations of *LIS1* also cause SBH in the posterior brain.

DCX mutations classically cause the striking SBH phenotype, in which a second band of cortical neurons exists within the white matter, below the true cortex (Figure 4). Women with *DCX* mutations have an anteriorly predominant band/pachygyria. However, rare carrier women have been described who harbor missense mutations but have normal brain magnetic resonance imaging (MRI), due to either favorable X-inactivation skewing or to mutations having mild functional consequences. Mutations of the coding region of *DCX* have been found in all reported pedigrees, including families in which females have SBH and males have LIS, and in approximately 80% of sporadic females and 25% of sporadic males with SBH. Genomic deletions of the *DCX* gene have been identified in females with sporadic SBH and in males with X-linked lissencephaly. Maternal germ-line or mosaic *DCX* mutations may occur in approximately 10% of cases of either SBH or XLIS. Hemizygous males with *DCX* mutations have classic lissencephaly, but rare boys with missense *DCX* mutations with an anteriorly predominant SBH have also been described.

Recently, it has been demonstrated that a mutation in the guanosine triphosphate (GTP) binding pocket of a-1 tubulin (*Tuba1*) generates a mutant mouse with abnormalities in the laminar architecture of the hippocampus and cortex, accompanied by impaired neuronal migration. Mutations in the human homolog of *Tuba1*, *TUBA3*, were subsequently identified in two patients with LIS. The first patient presented classic LIS with a thick disorganized cortex, epilepsy, severe mental retardation, and motor impairment. The second patient showed a less severe phenotype, with pachygyria in the temporal regions and around the Rolandic sulcus, accompanied by abnormal organization of the hippocampus.

Figure 4 Brain MRI scan; coronal section of a young woman with a missense mutation of the *DCX* gene. The gyral pattern of the cortex looks normal, but beneath the cortex, and separated from it by a thin layer of white matter, is present a subcortical laminar (band) heterotopia (black arrows) showing the same signal intensity as the cortex. The thickness of the heterotopic band is variable from approximately 3 mm to 1 cm.

Experimental Models and Pathogenesis

LIS1 encodes a 45 kDa protein (PAFAH1B1), which is similar to the α subunit of heterotrimeric G-proteins and functions as a regulatory subunit of platelet-activating factor acetylhydrolase (PAF-AH), an enzyme that degrades the bioactive lipid PAF. PAFAH1B1 homozygous mutant mice die at the trophoblast stage, whereas heterozygous mice are grossly normal but show a dose-dependent histopathological disorganization of cortical lamination, as well as hippocampal and cerebellar cortical defects. A reduction in the migration of *in vitro* cerebellar granule cells occurred on treatment with a PAF agonist, implying that the LIS1 protein function in PAF-AH is related to its essential role in migration. The LIS1 protein has been shown to co-localize with microtubules and promote their stabilization. Proper nuclear migration in the *Aspergillus nidulans* depends on NudF, an ortholog of LIS1. The human homolog of NudC, which associates with NudF in yeast, in conjuction with LIS1 regulates dynein activity during mitosis in vertebrate cells, suggesting that classic LIS is caused by a loss of dynein function, which is required for nuclear translocation. This hypothesis is supported by the demonstration that LIS1 also interacts with NUDEL and mNudE to regulate cytoplasmic dynein motor function and location within the cell. Loss of function of either NUDEL, LIS1, or of dynein impact on the microtubule network that couples the centrosome and nucleus, leads to a defect in nuclear translocation, cell migration, and positioning during cortical development. The LIS1–NUDEL pathway has also been linked to the Reelin–/Cdk5–p35 pathway. The phosphorylation of NUDEL by Cdk5 appears to control its cellular localization and probably influences dynein motor function (Figure 5). Thus, the LIS1 protein probably exerts its effects on migration through microtubules.

Figure 5 Lis1 and Reln signaling pathways for neuronal migration. Extracellular Reln binds to one of three receptors complexes: cadherin-related neuronal receptor (CNR), VLDLR/ApoER2 or 3β-integrin. This binding activates mDab1, which can activate Cdk5/p35. Cdk5 can phosphorylate many intracellular targets, including Nudel. Phosphorilated Nudel forms a complex with Lis1, mNudE, dyneins, and microtubules. This complex is necessary for cell migration and nuclear positioning. Dcx is also believed to interact with Lis1 and modulate microtubule function. In addition, RELN binding to the VLDLR and ApoER2 causes src-family kinase (SFK) activation and Dab1 phosphorylation. Upon Reelin stimulation, phosphorylated Dab1 interacts with Lis1. Lis1 also binds the catalytic subunits of the Pafah1b complex (α1 and α2) as well as components of the cytoplasmic dynein complex. The α1 and α2 subunits also bind to VLDLR and compete with Dab1 for receptor occupancy. The binding of catalytic Pafah1b subunits to VLDLR may displace P-Dab1 and promote its interaction with Lis1. ApoER2, apolipoprotein E receptor 2; VLDLR, very low density lipoprotein receptor. Adapted from Golden JA and Harding BN (2004) *Pathology and Genetics: Developmental Neuropathology*. Basel: ISN Neuropath Press, with permission from Blackwell Publishing.

DCX encodes for a 40 kDa microtubule-associated protein (DCX) that is expressed in migrating neuroblasts exclusively in the fetal brain, including the forebrain and cerebellum. The DCX protein contains two tandem evolutionarily conserved repeats (doublecortin domain) that form a b-grasp superfold. Each of the repeats binds to tubulin but not to microtubules; so both repeats are necessary for microtubule polymerization and stabilization. DCX was disrupted in mice using targeted mutagenesis. However, these mice did not have a cortical defect. More recently, using the RNA interference method, Dcx function was reduced in a rat model that resulted in SBH resembling that seen in humans. This model made it possible to directly examine the role of DCX in radial migration and associated cellular morphogenesis through cortical development. In particular, DCX is required for all radial migrating neocortical neurons to enter the cortical plate from the interventricular zone.

Lis1 and Dcx display overlapping localization and may interact. Dcx and Lis1 co-immunoprecipitate from brain lysate, and purified Dcx and Lis1 bind cooperatively to microtubules. Studies on mouse cerebellar granule neurons demonstrated that Lis1 and Dcx interact with dynein to mediate nucleus–centrosome coupling in neuronal migration, suggesting that proper coupling may be critical in neuronal migration. In addition, LIS1 and DCX interact physically, both *in vivo* and *in vitro*, suggesting that the addition of DCX and LIS1 to tubulin enhances polymerization in an additive fashion. In *in vitro* competition assays, when LIS1 is added first, DCX competes with LIS1 in its binding to microtubules, but when DCX is added prior to the addition of LIS1 it enhances the binding of LIS1 to microtubules. LIS1 and DCX cross-talk is important to microtubule function in the developing cerebral cortex. The interaction of both DCX and LIS1 with microtubules may explain the striking similarities between the lissencephalic phenotypes that result from mutations in either gene.

Epidemiology and Clinical Features

Classical lissencephaly is rare with a prevalence of 11.7 per million births. All patients have early developmental delay, early diffuse hypotonia, later spastic quadriplegia opisthotonus, and eventual severe or profound mental retardation. Rare patients with pachygyria may have moderate mental and motor impairment. Some children with LIS live more than 20 years, although anecdotal experience suggests that the life span is less than 10 years in most patients. Seizures occur in over 90% of children, with onset before 6 months in approximately 75%. Approximately 80% of children have infantile spasms, although the electroencephalogram (EEG) does not show typical hypsarrhythmia. Later, most children have mixed seizure disorders. Because most clinical and neurophysiological studies on children with LIS were conducted before a genetic distinction was made between XLIS and LIS1, it is unknown whether these two forms have distinctive electroclinical patterns.

Genetic Counseling

All reported *LIS1* mutations are *de novo*. Nevertheless, if an *LIS1* mutation is found, it is correct to perform mutation analysis on both parents. Given the theoretical risk of germ-line mosaicism in either parent (which has never been demonstrated for *LIS1*), a couple with a child with LIS is usually given a 1% recurrence risk.

When a mutation in the *DCX* gene is found in a boy with LIS, the mutation analysis of *DCX* should be extended to the mother, even if her brain MRI is normal. If the mother is a mutation carrier, the mutation will be transmitted according to Mendelian inheritance. If the mother is not a carrier, she can still be at risk for germ-line mosaicism; the risk of transmitting the mutation might be roughly estimated at around 5%. For this reason, a prenatal diagnosis is indicated in every pregnancy of a woman who has a child with features of X-linked LIS with a *DCX* mutation.

Miller–Dieker Syndrome

Miller–Dieker syndrome (MDS) is caused by a contiguous gene deletion. Classic LIS is accompanied by distinct dysmorphic facial features, including a prominent forehead, bitemporal hollowing, flattened ear helices, mild hypertelorism, epicanthic folds, a short nose and anteverted nares, prominent lateral nasal folds, and a round philtrum. Additional malformations can be observed. Affected children have severe delay, epilepsy, and feeding problems. Deletions of 17p13.3, including the *LIS1* gene, are found in almost 100% of patients. The deletion of two additional genes, *CRK* and *14-3-3ε* telomeric to LIS1, may contribute to the most severe LIS grade and dysmorphic features observed in MDS.

X-Linked Lissencephaly with Corpus Callosum Agenesis and Ambiguous Genitalia

X-linked lissencephaly with absent corpus callosum and ambiguous genitalia (XLAG) is a severe malformation syndrome that is observed only in boys. The anatomoclinical spectrum includes LIS with a posterior-to-anterior gradient and an only moderate increase of the cortical thickness (only 6–7 mm in XLAG, vs. 15–20 mm in classic LIS) (Figure 6), an absent corpus callosum; poorly delineated and cavitated basal

Figure 6 Brain MRI scan; axial section of a 1-year-old boy with X-linked lissencephaly, with corpus callosum agenesis and ambiguous genitalia due to the mutation of the ARX gene. Note the absence of the corpus callosum with ventriculomegaly and lissencephaly.

ganglia; postnatal microcephaly; neonatal-onset epilepsy; hypothalamic dysfunction, including deficient temperature regulation; chronic diarrhea; and ambiguous genitalia with micropenis and cryptorchidism. Early death is not uncommon. Brain neuropathology reveals an abnormally laminated cortex containing exclusively pyramidal neurons, with a pattern suggesting the disruption of both tangential and radial migration, dysplastic basal ganglia, hypoplastic olfactory bulbs and optic nerves, abnormal gliotic white matter containing numerous heterotopic neurons, and complete agenesis of the corpus callosum without Probst bundles.

Mutations of the X-linked *aristaless*-related homeobox gene (*ARX*) (OMIM: *300382) were identified in individuals with XLAG and in some female relatives. Females carrying *ARX* mutations usually have normal cognition and may either have a normal brain MRI scan or show partial or complete agenesis of the corpus callosum. However, mild mental retardation and epilepsy have been reported in rare carriers. Mouse *Arx* and human *ARX* are expressed at high levels in both dorsal and ventral telencephalon, including the neocortical ventricular zone and germinal zone of the ganglionic eminence, with less intense signals in the subventricular zone, cortical plate, hippocampus, basal ganglia, and ventral thalamus. The murine *Arx* gene is specifically expressed in the γ-aminobutyric acid (GABA)ergic neural lineages both during development and in adulthood. *Arx*-deficient mice show deficient tangential migration and abnormal differentiation of interneurons containing GABA(GABAergic interneurons) in the ganglionic eminence and neocortex. These findings suggest that the different *ARX* mutations may affect in different grades the overall GABAergic system functionality, leading to the clinical features of XLAG in humans, and might account for the severe neonatal epileptic encephalopathy with suppression-burst EEG that is often observed in affected boys. The mutations of the *ARX* gene in XLAG patients are predominantly premature termination mutations. Missense mutations are less common and are located essentially in the homeobox domain. Patients carrying nonconservative missense mutations within the homeodomain showed less severe XLAG, whereas conservative substitution in the homeodomain causes Proud syndrome (agenesis of the corpus callosum (ACC) with abnormal genitalia). A nonconservative missense mutation near the C-terminal aristaless domain causes unusually severe XLAG with microcephaly and mild cerebellar hypoplasia.

Autosomal Recessive Lissencephaly with Cerebellar Hypoplasia

An autosomal recessive form of LIS associated with severe abnormalities of the cerebellum, hippocampus, and brain stem was mapped to 7q22, and mutations were identified in the *RELN* gene (OMIM: *600514). Patients presented dysmorphic facial features, including bitemporal hollowing, sloping forehead, widely set eyes, and prominent nasal bridge. A similar phenotype had previously been described as the Norman–Roberts syndrome. *RELN* encodes a large (388 kDa) extracellular matrix protein that acts on migrating cortical neurons by binding to the very low-density lipoprotein receptor (VLDLR), the apolipoprotein E receptor 2 (ApoER2), α3-β1 integrin, and cadherins-related receptors (CNRs). In mice, *Reln* mutations cause cerebellar hypoplasia, abnormal cerebral cortical neuronal migration, and abnormal axonal connectivity. Neurons in affected mice fail to reach their correct location in the developing brain, disrupting the organization of the cerebellar and cerebral cortices and other laminated regions. In this animal model, the cortical layering appears inverted. Thus, Reln is thought to control cell–cell interactions critical for cell positioning in the brain. Binding of Reln to the α3-β1 functions as a stop signal after neuronal migration; however, the downstream components within the cells that regulate the migration stop are not known. Interactions between the Reln and Lis1 signaling pathways have been demonstrated. The interaction of Reln with the CNRs phosphorylates the cytoplasmic messenger mDab1, possibly through the

VLDLR. Phosphorylated mDab1 can interact with a variety of proteins, including Src, which is involved in the cytoskeletal remodeling, or the protooncogene c-Abl. Once activated, c-Abl phosphorylates and activates Cdk5. Cdk5 and p35 (another activator of Cdk5) have also been implicated in directing neurons to the appropriate location within the cerebral cortex. The interaction between Lis1 and Dab1 has also been demonstrated. This interaction takes place when Dab1 is phosphorylated on tyrosine residues in response to Reln. In addition, it has been demonstrated that both the α subunits of the Pafah1b bind the VLDLR, suggesting that the Pafah1b complex modulates the Reln pathway. The binding of catalytic Pafah1b subunits to the VLDLR may displace phosphorylated Dab1 and promote its interaction with Lis1 (Figure 5).

Nine additional phenotypes have been also associated with the LIS–SBH spectrum, although they do not belong to the subgroup of the type 1 LIS. Clinical features and associated genes or loci, if identified, are reported in Table 1.

Periventricular Nodular Heterotopia

Definition and Histopathology

PNH, most often bilateral, consists of nodules of gray matter located along the lateral ventricles with a total failure of migration of some neurons. PNH can be highly variable in extent, ranging from isolated single nodules to confluent bilateral lesions. PNH is most common near the angle of the lateral ventricles and around the temporal horns. The cortex overlying PNH often shows macroscopic abnormalities, most commonly polymicrogyria. Nodules of PNH may sometimes show some rudimentary lamination, and its neurons show changes in size consistent with developmental age. A variety of neuronal types are present, including small neurons that express parvalbumin, calretinin, or neuropeptide Y (NPY). Decreased expression of the *N*-methyl-D-aspartate (NMDA) receptor and its signaling pathway has been reported in PNH nodules and overlying dysplastic cortex.

Early fluorodeoxyglucose-positron emission tomography studies showed that heterotopia has the same

Table 1 Additional phenotypes associated with the lissencephaly–SBH spectrum but not belonging to the subgroup of the type 1 lissencephalies

Syndrome	*Clinical features associated with lissencephaly/pachigyria*	*Locus (gene)*	*OMIM accession number*
Baraitser–Winter syndrome	Eye coloboma, ptosis, hypertelorism, epicanthic folds, broad nasal bridge, long philtrum, thin upper lip, telechantus, short stature	Possibly autosomal recessive	
Walker–Warburg syndrome (HARD +/− E syndrome)	Congenital muscular dystrophy, congenital retinal nonattachment with or without microophthalmia and persistent hyperplastic primary vitreous	9q34.1 (*POMT*1), 14q24.3 (*POMT2*)	236670
Muscle–eye-brain disease (MEB)	Congenital muscular dystrophy, congenital hypotonia and muscle weakness, severe visual failure, uncontrolled eye movements, myopia	19q13.3 (*FKRP*), 1p34–p33 (*POMGNT1*)	253280
Fukuyama congenital muscular dystrophy (FCMD)	Generalized muscle weakness, hypotonia, speech defect	9q31 [*fukutin* (*FCMD*)]	253800
Lissencephaly and bone dysplasia	Craniofacial edema and arthrogryposis; epiphyseal stippling of cervical vertebrae, feet, and sacrum; shortened metacarpal bones and hypoplastic phalanges	Supposed autosomal recessive	601160
Neu-Laxova syndrome (NLS)	Severe subcutaneous edema, atrophic muscles, camptodactyly, syndactyly of toes and fingers, hypoplastic genitalia, hypertelorism, protruding eyes	Unknown	256520
Lissencephaly with cleft palate and cerebellar hypoplasia	Cleft palate	Unknown	604382
Craniotelencephalic dysplasia	Frontal bone protrusion, encephalocele, craniosynostosis, septooptic dysplasia	Unknown	218670
Muscular dystrophy with severe central nervous system atrophy and absence of large myelinated fibers	Hypertelorism, telecanthus, small and posteriorly angulated ears, micrognathia and high-arched palate, severe hypotonia, muscle weakness	Unknown	601170

OMIM, Online Mendelian Inheritance in Man; SBH, subcortical band heterotopia.

metabolic activity as normal gray matter. Functional MRI studies indicated that PNH can also be functionally integrated in the motor circuits, suggesting that neurons that have failed to migrate have maintained the information that allows them to assemble in functionally active aggregates and to participate in integrated networks.

Although most patients with PNH come to medical attention because they have epileptic seizures, there is a wide spectrum of clinical presentations with some correlation between the size of PNH and the likelihood of concomitant structural abnormality of the cortex and clinical severity.

Genetics

PNH occurs much more frequently in women as an X-linked trait (Figure 7), which is associated with high rates of prenatal lethality in male fetuses and a 50% recurrence risk in the female offspring of affected women. Almost 100% of families with X-linked bilateral PNH and approximately 26% of sporadic patients harbor mutations of the *filamin A* gene (*FLNA*) (OMIM: +300017). The low percentage of *FLNA* mutations in sporadic cases might be explained by somatic mosaicism. Heterozygous females have normal to borderline intelligence and epilepsy. Coagulopathy and cardiovascular abnormalities have been observed in some patients. A few living male patients with bilateral PNH due to *FLNA* mutations are on record. Mild missense mutations or mosaic mutations, probably causing a limited functional defect of the *FLNA* protein, account for the survival of affected males, who can, in turn, transmit their genetic defect to their daughters. Rare patients of both genders with *FLNA* mutations had unilateral PNH or classic bilateral PNH associated with Ehlers–Danlos syndrome.

Figure 7 Brain MRI scan; axial section of a typical, classic bilateral periventricular nodular heterotopia in a woman with a missense mutation of the *FLNA* gene. The bilateral nodules of subependymal heterotopia are contiguous and rather symmetric, extensively lining the ventricular walls (white arrows). Patients with periventricular heterotopia different from the kind reproduced in this picture have very low chances of carrying a mutation on the *FLNA* gene.

Mutations in other genes can cause PNH. A rare recessive form due to mutations of the adenosine diphosphate-ribosylation factor guanine nucleotide exchange factor 2 (*ARFGEF2*) (OMIM: *605371) has been reported in two consanguineous pedigrees. This gene encodes for the protein brefeldin A-inhibited GEF2 (BIG2), which is required for vesicle and membrane trafficking from the *trans*-Golgi network. Impaired vesicle trafficking prevents transport to the cell surface of polarized molecules, such as E-cadherin and β-catenin, thereby disrupting proliferation and migration during cortical development. Affected children have microcephaly, severe delay, and early-onset seizures, including infantile spasms. PNH may also be observed in patients with chromosomal rearrangements, such as duplication of 5p15.1 or 5p15.33. PNH has also been associated with hydrocephalus, frontonasal malformation, severe mental retardation and syndactyly, Ehlers–Danlos syndrome, fragile X syndrome, and nephrosis. Whether each of these variants represents a truly distinct compound disorder with a specific genetic mechanism remains to be determined. In some such syndromes, the malformation can result from small chromosomal rearrangements involving the *FLNA* gene and other unknown genes.

FLNA mutations have also been associated with four additional multiorgan syndromes: otopalatodigital syndrome type 1 and 2 (OPD1 and OPD2), frontometaphyseal dysplasia (FMD) and Melnick–Needles syndrome. In contrast to the loss-of function *FLNA* mutations seen in PNH patients, these four syndromes appear to involve gain-of-function *FLNA* mutations.

Experimental Models and Pathogenesis

FLNA maps to Xq28 and codes for the F-actin-binding cytoplasmic cross-linking phosphoprotein Filamin A (FLNA), composed by three major functional domains: (1) a tandem N-terminal calponin-homology domain (CHD1 and CHD2), conferring F-actin binding properties; (2) 15 + 8 internally homologous Ig-like

repeats separated by a short run with an unique sequence (hinge 1), important for flexibility; and (3) a second short run (hinge 2) followed by the C-terminal repeat 24, which is important for binding to a wide range of proteins and for dimerization. The N-terminal actin-binding domain displays strong structural and functional similarity to the N-terminal domains of dystrophin, α-actin, and β-spectrin. The 24th repeat is truncated, allowing dimerization of two *FLNA* molecules at the C-terminus. FLNA dimers bind membrane-associated proteins such as b1 and b2 integrins, tissue factor, and presenilin1. FLNA can also bind other membrane-associated molecules, such as glycoprotein Ib-α, through repeats further from the C-terminus. The specific roles of FLNA and its association with pathological conditions are yet to be fully understood. Additional functional complexity is conferred by the existence and by the time/tissue-specific expression of the two human paralogous genes, *Filamin B* and *Filamin C*. The Y-shaped homodimerized FLNA promotes the organization of actin filaments in orthogonal networks of the cytoskeleton. A similar mechanism might also be hypothesized for Filamin B and C, even though their heterodimerization has been demonstrated only *in vitro*. In addition, Filamin A and Filamin B co-localize within neuronal precursors, and the heterodimerization of these two isoforms has been hypothesized. Interactions of the dimer with integrin receptors, transmembrane proteins, and several signaling proteins are believed to integrate extracellular and cytoplasmic signals with cellular cytoskeleton rearrangements and membranes reshaping. Filamin homologs have been shown to be implicated in the regulation of cell stability, protrusion, and motility across various biological systems. The mouse *Filamin A* ortholog was abundantly expressed in the cell soma and leading processes of migratory neurons, and it is widely distributed across the cortical mantle, reaching the highest levels in the ventricular zone within the cortex during neurogenesis. FLNA probably influences neuroblast migration during cortical development in vertebrates, and PNH in humans probably results from the disruption of this process. A model of *FLNA* function postulates that, in *FLNA*-deficient neurons, part of the essential migratory motor is defective and that these defective neurons are incapable of migration. An alternative model proposes that FLNA acts earlier in development, as a component of a switch that is required for a neuron to become competent for subsequent migration. In the latter model, FLNA still functions by structuring actin networks at the cell periphery but, instead of acting at the leading edge of the migrating neuron, FLNA maintains a static focal contact between a stationary neuron and a neighboring radial glial cell. FLNA also promotes orthogonal branching of actin filaments and is important for coagulation and vascular development. These coagulation and vascular-related functions of FLNA might account for the prenatal male lethality observed in most pedigrees, a hypothesis supported by the birth of a male infant to a mother with PNH, who shared her affected haplotype and who died postnatally of severe widespread hemorrhage. Cardiovascular or gut malformations might also account for prenatal male lethality. The complete loss of Flna in mice results in embryonic lethality with severe cardiac structural defects involving the ventricles, atria, and outflow tracts, as well as widespread aberrant vascular patterning. Despite these widespread developmental defects, the migration and motility of many cell types, including Flna-deficient neural crest cells, do not appear to be affected. Moreover, Flna-null vascular endothelial cells display defects in cell–cell contacts, suggesting cell motility-independent functions of FLNA in cell–cell contacts and adherens junctions during the development of many organs.

Genetic Counseling

Genetic counseling is relatively easy in familial cases with a clear X-linked pattern of inheritance. Classic PNH with cerebellar hypoplasia and no dysmor phic features is much more frequent in women and more likely to be due to *FLNA* mutations than in atypical cases. Among carrier women, approximately half have *de novo* mutations of *FLNA*, whereas the remaining half have inherited mutations. Although maternal transmission is much more likely, father-to-daughter transmission is possible, implying that either parent can transmit the mutation to a female proband. If neither parent has epilepsy or cognitive impairment, the proband's mother should be studied first to confirm the mutation or the brain abnormality. If the mother is mutation-negative and the proband is a female, the father should also be studied. Given that the germ-line mosaicism of *FLNA* has never been reported, the recurrence risk (for other children) seems to be very low when a mutation is found in the proband but neither parent is a carrier.

Localizing Signal Sources

G M Klump, Universität Oldenburg, Garching, Germany

© 2009 Published by Elsevier Ltd.

In animal communication, it is advantageous for the receiver to locate the source of a signal (i.e., the sender) that it has detected and possibly recognized. For example, if the sender is a territorial competitor, a territory holder as the receiver would benefit by being able to pinpoint the competitor's location and to evaluate whether this competitor already intruded into the territory. In many behavioral contexts, such as in the case of searching for a mate or searching for food, the response of the receiver will be an approach toward the source that also requires localization (a response that is composed of orienting toward the signal source and the approach movement is termed 'taxis'). Even in the case that fleeing rather than approaching the source of a signal is the adaptive response, a receiver may benefit by choosing a direction of the escape route away from the signal source that minimizes its risk.

Localizing a signal source in three dimensions in general requires being able to determine the direction from which a signal emanated. Directional information can be separated into azimuth (angle on the horizontal plane) and elevation (angle on the vertical plane). If the location of the origin of a signal has to be determined on the spot, it is also necessary to obtain a measure of the distance between the receiver and the signal source. Alternatively, a receiver may combine the information on the direction with an approach to the signal source that finally leads it to its location. Which strategy for localizing the signal source will be more advantageous will depend on (among other factors) the modality of the signal, the physical effects of the environment on the signal when being transmitted from the sender to the receiver, and the representation of the directional cues in the sensory organs and the neural system of the receiver. Furthermore, senders of communication signals are not necessarily stationary but can move while signaling. The trajectories of a moving sender should also be evaluated when locating the signal source.

This article focuses on the localization of sound signals and only briefly discusses the localization of optical and chemical signals. Some aspects (e.g., the short-distance localization of signal sources in the perception of electrical signals by fish) will not be discussed.

Evaluating Cues for Localizing the Signal Source

Visual Signals

The physical characteristics of the signals and the receiver's sensory organs will determine which cues can be used for localization of communication signals. Eyes often can provide information on azimuth and elevation simply as a result of the physical projection of the image on a surface of receptors that forms a retina. Light from different locations in the environment surrounding the receiver will excite different spots on the retina (or the compound eye of an insect), and the position of the source of a visual signal in the environment can be determined by the place of excitation on the retina. Determining the distance of a signal source for an optical signal requires the evaluation of additional information. Stereo vision is one mechanism for distance (i.e., depth) perception exploiting the disparities of the projection of the images on the retinae of the two eyes. Another possibility to infer the distance of a stationary visual object is to make use of the information of motion parallax and the visual flow field that is generated by movement of the receiver. Objects close to the receiver will elicit a larger shift of the image on the retina and a faster optical flow than objects at a greater distance. This cue can also be used in monocular vision. Finally, previously acquired knowledge about the object can be used to infer the distance. For example, if the size of the object is known, then the distance can be estimated based on the size of the projection on the retina.

Acoustic Signals

Unlike for localization of visual targets, there is no direct spatial representation of the environment in each receiving sensory organ that can be exploited to localize the source of acoustic communication signals. Characteristics of acoustic signals, such as the overall intensity, spectral composition, time of arrival, or other features, will vary depending on the azimuth and elevation of the sound source or its distance from the receiver. In general, the auditory system infers azimuth and elevation of a signal source by comparing the input to two receiving sensory organs – that is, the ears. However, some sound-receiving organs can also encode directional information about the sound source directly without requiring a comparison between two sound-receiving organs.

Spectral composition of the signals at the two ears is one cue that may be exploited to infer the source location. Due to the physical characteristics of the

outer ear and the immediate surround created by the head, body, etc., differences between the ears in signal amplitude at the various frequencies comprising a specific signal (i.e., the amplitude spectrum) can change systematically with sound source azimuth or elevation. The amount of amplitude change that occurs for signals with a different frequency composition impinging on the two acoustically separated ears will depend on the wavelength of the signal and the dimensions of the structure carrying the ears (mostly the head). If the wavelength is similar to the size of the head (or other structure), it can provide a sound shadow that generates interaural intensity differences that change systematically in relation to the azimuth and elevation of the sound source. Many mammals use ultrasonic communication signals with frequencies above 20 kHz (and wavelengths below 2 cm) that will generate interaural intensity differences that are sufficiently large for localization. If the wavelength of the sound is much larger than the diameter of the head (e.g., 10 times larger), interaural intensity differences are rather small (not more than 1 or 2 dB) and accurate sound localization based on intensity differences is compromised. A minimum interaural intensity difference of 1 dB is needed to perceive a change in the angle of sound incidence. However, in many land vertebrates with small heads and a small interaural distance that use low-frequency communication signals with a wavelength that is much larger than their head diameter, an acoustic coupling between the middle ear cavities or an acoustic connection of other inputs to the middle ear cavity (e.g., in many frogs) can be observed. This acoustic coupling allows interference between inputs reaching both sides of the tympanum of each ear, thus producing a pressure gradient that can enlarge interaural intensity differences. A similar mechanism based on acoustic interference of sound impinging on the inside and outside of a tympanum is also found in some insects and can create a large variation of the sound intensity experienced at the ears when the azimuth angle of sound incidence changes.

So far, interaural intensity differences have been discussed without a specific reference to the overall spectrum of the sound. However, the overall shape of the spectrum of a broadband sound also provides important cues for localization. Changes in the shape of the spectrum of a sound may be created by the pinna or other structures of the ear (e.g., the coupled middle ear cavities) that will enhance or reduce the amplitude of frequencies in the spectrum of an incoming sound. In mammals and other vertebrates, the physical filter characteristics of the ear will lead to specific notches in the spectrum of a sound. These notches play an important role in sound source localization. They aid the auditory system in computing the elevation of a sound source or resolve front/back errors in localization (there are multiple sites in space that will produce similar interaural time and intensity differences at the two ears).

The second cue used by the auditory system for localizing signal azimuth is the interaural time difference that is due to the different travel times of the sound from the source to the two ears if the source is located somewhat to the side of the head. Interaural time differences (ITDs) relate to the angle of sound incidence θ as given by

$$\mathrm{ITD} = \frac{ar}{c}\sin(\theta) \qquad [1]$$

where a is a constant factor, r is the head radius, and c is the speed of sound.

According to Kuhn, at low frequencies (i.e., if the product of wave number and the head radius is smaller than approximately 2), it is more appropriate to calculate ITDs with a value of 3 for the factor a, and at higher frequencies it is better to set the factor a to the value of 2. The minimum ITD that can be perceived by a land vertebrate auditory system is on the order of 10–50 μs. In an absolute localization task involving low-frequency sounds (e.g., 1 kHz), this ITD threshold translates to an accuracy of between 4° and 27° for a head diameter of 2.5 cm (e.g., a gerbil) and between 1° and 7° for a head diameter of 15 cm (e.g., a human). Psychophysical measurements of the localization accuracy are consistent with the results of these calculations.

The ITD may be weighted differently at various times after the start of the signal. If the signal has sharp onset transients, these transients arriving at the ear first may be, at least in mammals, quite prominent in determining the perceived location of the signal source. Transients in signals that are due to reflections on surfaces that arrive 10 ms or more later than the primary signal traveling on the direct path from the source to the ears do not strongly contribute to the perceived location of the source (i.e., the primary signal takes precedence). If no strong transients are provided by the signal or if the signal is relatively long, ongoing time differences are also important. For signals composed of low frequencies (i.e., below 2 or 3 kHz in general) that allow the encoding of signal phase by the auditory system (the barn owl may be an exception, with excellent phase locking up to 9 kHz), ITDs may also be derived from the ongoing time differences and not predominantly from transients.

It is obvious from the previous discussion that signals with wavelengths that are much larger than the dimensions of the head (or other parts of an

animal body) separating the ears will only provide minute interaural time and intensity difference cues. A typical example is the acoustic signals used for mate attraction in the green tree frog (*Hyla cinerea*). Female green tree frogs approach males for mating that are advertising their location by high-level calls with peak frequencies of 900 and 3000 Hz (with corresponding wavelengths of 38 and 11 cm, respectively). If the ears of a female with a typical head diameter of 1.2 cm would operate as two separate pressure receivers, the maximum ITD given by eqn [1] is only 52 μs. The available ITD between the ears corresponding to the female green tree frogs' localization accuracy of approximately 20° is 18 μs. However, the related time difference observed in the firing of action potentials of the auditory nerve of the green tree frog for the same change in the frontal angle of sound incidence is approximately a factor of 10 larger (and can be as large as 1.3 ms when the sound is coming from the side). This discrepancy suggests that in this species the ears are not completely decoupled but, rather, may form a pressure gradient receiver system that can provide much larger interaural time and intensity differences than those found in the sounds impinging on the ears. Physical measurements of the acoustic directionality of the frog ear suggest that a number of different sound inputs contribute to the pressure gradient system in the green tree frog and other species.

A small parasitoid fly, *Ormia ochracea*, with two sound-receiving membranes separated by a mere 0.5 mm has evolved another solution to localizing calling crickets that produce signals in the frequency range of 5 kHz (i.e., with a wavelength that is two orders of magnitude larger than the distance between the fly's 'ears'). The localization accuracy in the fly has been described as being so high that it would require a detection of ITDs on the order of 50 ns (i.e., three orders of magnitude higher than that discussed previously). Also in this small fly, the two eardrums are functionally coupled, and the specific anatomy underlying the coupling results in the generation of receptor spike time differences that vary by 3.5 μs per degree change in the angle of sound incidence. The fly's localization accuracy suggests that it can distinguish differences in the timing of the action potentials as small as 7 μs. This task probably requires combining the information from many receptors since the jitter in the timing of the action potentials of individual receptors is an order of magnitude larger than the threshold deduced from the fly's behavioral performance.

So far, we have only considered localization of signal sources using sound pressure or pressure differences. Another cue is provided by the movement of particles that are oscillating back and forth around their resting position at the frequency of the sound driving the movement. Velocity receptors such as the tiny hairs in an arthropod cuticula or the hair cells in the sacculus of the inner ear of a fish can register the particle movement, which is directional. It occurs in the direction of the pressure wave originating from the sound source and opposite this direction (i.e., the particles move on a line pointing to the source). If velocity receptors can respond differentially to the particle movement related to the various angles of sound incidence, this feature can be used to localize a sound source. Afferent neurons innervating the hair cells in the sacculus of a fish, for example, have a distinct polarity that results in a large response along one directional axis and a small response in the direction perpendicular to this axis. Using a population of such directionally selective afferent neurons from the right and left sacculus, the brain can evaluate the location of the source in relation to the body axis of the fish. It has been suggested that this may explain the behavioral observation that fish exhibit differential responses in relation to underwater sound sources placed in different directions.

Chemical Signals

As in the case of auditory localization, localizing sources of chemical signals over a distance by the sense of smell also requires computations by the neural system since the receptor organ does not provide immediate directional cues. Due to the nature of the olfactory signals in the environment of an animal, however, these computations may involve the input from other sensory modalities or require considerable integration of information from the sensory input over extended time periods. Starting at the source of an odor, the turbulent flow of the medium transporting the odor signal (air or water) leads to a breaking up of the odor plume into a patchy landscape of odor eddies. These provide intermittent signals to the receptor organ that are analyzed to localize the odor source. Various mechanisms have been suggested for localizing the source, and some have been tested by implementing these mechanisms in a robot and comparing the robot's behavior to that of an animal such as a lobster. In animals with spatially separated bilateral odor receptor organs, such as the lobster with its lateral antennular flagellum on each side, bilateral comparisons of odor concentrations can be exploited in source localization. Observations in the lobster suggest that its path is continuously affected by the bilateral odor pulse input resulting in eddy chemotaxis. Information about the flow of the medium from the mechanoreceptors is frequently integrated with information on the concentration of the odor:

The animal moves against the current while responding to the odor plume (i.e., it performs an eddy rheo-chemotaxis). A number of variants of these mechanisms have been proposed, and most animals that rely on olfactory cues for their orientation have developed specific behavioral strategies for tracking the source of an odor.

Strategies for Localizing Sources

Two major strategies have been identified for localizing the source of a communication signal. The first, the open-loop strategy, makes use of the input to the receptor organs to calculate the corresponding direction of the signal source instantaneously. Localization ability must be absolute – that is, the receiver must be able to infer the source location in space and it is not sufficient for localizing the signal source if the receiver can only perceive a change in source location (which is termed 'relative localization'). To be useful, this strategy requires the ability for a rather accurate localization based on the available cues since the estimate of the location of the signal source relies on a single brief measurement. The sound localization of barn owls (*Tyto alba*) responding to a brief transient signal such as a short rustling noise created by a mouse moving through leaf litter is an example of such open-loop localization. Upon hearing the stimulus, the owl will initiate a saccadic head movement that continues past the end of the stimulus and positions the head so that it faces the direction from which the sound emanated. The dynamic movement of the head during the saccade follows a stereotyped pattern. When the endpoint of the movement is reached after the stimulus has ended, no further corrective movements are made (if the stimulus continues, another saccade may be initiated). The advantage of the open-loop localization strategy is that it allows a fast response since no integration of information takes place over an extended time period.

The second strategy, called a closed-loop strategy, acquires information about the location of a source by making sequential comparisons. Applying this strategy, the animal integrates the information on the location of the signal source during its own movements. The ability to lateralize (i.e., to perceive whether the sound source is left or right of the body axis) is sufficient for acoustic closed-loop localization. If, for example, an animal first perceives a sound from the right and then turns rightward until the sound is being perceived from the left, it will have crossed the line pointing to the sound source. Many animals appear to exploit such a strategy to localize a signaling mating partner during a phonotactic approach. The green tree frog female, for example, follows a zigzag path when approaching a calling male. If she points to the left of the male, she will turn and jump to the right and vice versa. The advantage of this strategy is that she can reliably find the calling male in a chorus based only on acoustic cues, although her localization accuracy at best is only approximately 20 °. Closed-loop strategies with an integration of information over an extended time period are especially suitable to locate a signal source if the relevant cues vary considerably over time and a single estimate of a source location from one isolated measurement is unreliable. A typical example of coping with such a variable cue is the localization of odor sources. The odor eddies that are generated by turbulences in the medium transporting the odor stimulus lead to a highly variable stimulation of the receptors, making each single estimate of the source direction unreliable.

Long-Term Depression (LTD): Endocannabinoids and Cerebellar LTD

D M Lovinger, National Institutes of Health, Rockville, MD, USA

Published by Elsevier Ltd.

Endocannabinoid-Dependent Long-Term Depression Is a Form of Synaptic Plasticity

Glutamatergic synapses are capable of long-lasting changes in their ability to communicate. These enduring changes in efficacy are often referred to as long-term plasticity. Long-term depression (LTD) a long-lasting decrease in synaptic efficacy, occurs at glutamatergic synapses throughout the brain. Subtypes of LTD with different mechanisms have been identified. One recently discovered form of LTD involves endogenous fatty acid derivates that are agonists for cannabinoid receptors (called endocannabinoids). Endocannabinoid-dependent LTD (eLTD) is widespread in the forebrain. This form of plasticity has been observed at the following glutamatergic forebrain synapses:

- Glutamatergic synapses between deep-layer cortical projection neurons and striatal medium spiny projection neurons.
- Glutamatergic synapses on medium spiny projection neurons in the nucleus accumbens.
- Glutamatergic synapses between pairs of layer 5 thick-tufted neurons in the primary visual cortex.
- Glutamatergic synapses between layer 4 neurons and layer 2/3 neurons in the whisker barrel field sensory cortex.

A form of eLTD induced by the application of the addictive drug amphetamine has been observed at glutamatergic inputs to neurons in the lateral amygdala. The synapses that exhibit LTD in this case arise from extrinsic cortical inputs to the amygdala. In addition, eLTD has been described at γ-aminobutyric acid (GABA)ergic inhibitory synapses in other brain regions, including the basolateral amygdala and hippocampus. It is likely that this form of plasticity will be found elsewhere in the nervous system in the coming years. A form of LTD found within the cerebellum also has mechanistic similarities to eLTD (see the section titled 'Cerebellar long-term depression').

Endocannabinoids

Endocannabinoids are fatty acid analogs that are metabolites of membrane lipids. These compounds are formed inside of neurons as a result of lipid breakdown catalyzed by phospholipases. There are two major endocannabinoids in the body: arachidonylethanolamide (AEA, also known as anandamide) and 2-arachindonyl glycerol (2-AG). Increases in intracellular calcium play a prominent role in endocannabinoid formation because they stimulate the enzymes necessary for biosynthesis of the compounds.

The biological actions of endocannabinoids are produced via interactions with several target proteins, the most prominent of which are the cannabinoid receptors. Cannabinoid receptors were originally discovered as targets for Δ9-tetrahydrocannabinol (Δ9-THC), the psychoactive ingredient in marijuana and other drugs derived from the *Cannabis sativa* plant. These receptors couple to G-proteins and activate biochemical signals inside cells. In the brain, the CB1 type of cannabinoid receptor (CB1R) is the major endocannabinoid target. AEA and 2-AG act as agonists at the CB1R. Most CB1Rs in the brain are located on presynaptic terminals of GABAergic and glutamatergic synapses. The CB1Rs generally couple to $G_{i/o}$-type G-proteins. They usually inhibit neurotransmitter release.

Induction and Expression Mechanisms of eLTD

eLTD is initiated by the coactivation of presynaptic glutamatergic afferents and the postsynaptic neuron. Experiments designed to elicit eLTD usually involve electrical stimulation of afferent fibers and electrophysiological recording from inside the postsynaptic neuron in brain-slice preparations. However, eLTD can also be induced in dual recordings from a single presynaptic neuron that forms a glutamatergic synaptic connection with a single postsynaptic neuron. The patterns of activation necessary for eLTD induction differ at different synapses. Induction protocols range from one-to-one pairing of pre- and postsynaptic action potentials (called spike timing-dependent synaptic plasticity (STDP)) at low frequencies of activation, to high-frequency afferent activation paired with postsynaptic depolarization.

There are several general features of eLTD at different synapses and variants that are specific to a given synapse. The induction of eLTD involves a sequence of events that starts with presynaptic activation. Repetitive activation of excitatory glutamatergic synapses stimulates postsynaptic signals that are involved in the induction of most forms of eLTD. The sequence of events involved in eLTD induction is:

1. Presynaptic glutamate release.
2. Depolarization leading to the activation of voltage-gated calcium channels and a rise in

postsynaptic calcium concentration (these steps are not required for eLTD of inhibitory synapses in the basolateral amygdala and hippocampus).
3. Activation of metabotropic glutamate receptors (mGluRs), leading to phospholipase activation.
4. Formation and release of endocannabinoids from the postsynaptic neuron.
5. Activation of presynaptic CB1Rs.

The initial postsynaptic depolarization necessary for most forms of eLTD arises from the activation of alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type glutamate receptors subsequent to the presynaptic release of glutamate. The rise in postsynaptic calcium can come from several sources. In most forms of eLTD a voltage-gated calcium channel is activated by depolarization, and this allows calcium influx to the postsynaptic neuron. In the case of eLTD in striatum, an L-type calcium channel plays this role. A T-type channel appears to be the predominant calcium channel involved in eLTD induction in the whisker barrel cortex, with L-type channels playing a lesser role at this synapse. Activation of mGluRs can also contribute to the rise in postsynaptic calcium. These receptors activate the enzyme phospholipase C, which catalyzes the breakdown of phosphatidylinositol into diacylglycerol (DAG) and inositol trisphosphate (IP3). The IP3 generated by this reaction acts on receptors that release calcium from intracellular stores, and this is another source of calcium that can contribute to endocannabinoid production and eLTD induction. The DAG formed by mGluR activation of phospholipase C can also contribute to endocannabinoid formation. The enzyme known as DAG lipase catalyzes the formation of 2-AG. Inhibitors of DAG lipase prevent eLTD at several synapses, suggesting that 2-AG is a retrograde signal in this form of plasticity. The key role of mGluRs in eLTD is underscored by the fact that the application of mGluR agonists can produce such plasticity at several synapses.

In contrast to several other forms of long-term synaptic plasticity, eLTD usually does not require activation of *N*-methyl-D-aspartate (NMDA)-type glutamate receptors. The exception is eLTD in the cortex (Figure 1).

Endocannabinoids formed in the postsynaptic neuron traverse the synapse in a retrograde direction (post-to-presynaptic) and activate CB1Rs. The retrograde signal appears to be restricted to presynaptic terminals impinging on the postsynaptic neurons that produce the endocannabinoids. This finding is consistent with the idea that endocannabinoids do not diffuse more than 10–20 μm from their site of release. The CB1Rs activated by endocannabinoids then initiate molecular events leading to a long-lasting decrease in the probability of neurotransmitter release. Synergistic effects of CB1Rs and other receptors may be required for eLTD induction at many synapses. For example, eLTD at synapses in visual cortex requires the activation of NMDA-type glutamate receptors, most likely presynaptic receptors that contain the NR2B subunit. Activation of a presynaptic NMDA receptor has also been implicated in eLTD at synapses in the whisker barrel cortex. Expression of eLTD becomes independent of CB1R activation within minutes after the induction paradigm (Figure 2). Thus, the expression mechanism is set into motion by CB1R activation, but eLTD persists well beyond the brief initial period of receptor activation. It is not yet clear which endocannabinoid acts as the retrograde signal, but studies in the hippocampus and sensory cortex suggest a role for 2-AG based on the fact that an inhibitor of the DAG lipase enzyme prevents eLTD induction. The molecular mechanisms underlying sustained eLTD expression are poorly understood at present.

The induction of eLTD can also be modulated by neurotransmitters other than those directly involved in induction or expression. For example, in dorsal striatum dopamine acts on D2-type receptors to increase the likelihood that LTD will be initiated. However, recent evidence indicates that the D2 receptor is not strictly necessary for eLTD induction or expression because the receptor can be bypassed, for example, by combined depolarization and activation of postsynaptic mGluRs. A similar role for dopamine is probably involved in amphetamine-induced eLTD in the amygdala.

As mentioned previously, the expression of eLTD has been observed at both excitatory glutamatergic and inhibitory GABAergic synapses in different brain regions. However, even in cases in which the depression is expressed as a decrease in GABAergic transmission, the initiation process usually involves glutamatergic transmission that activates mGluRs.

Cerebellar LTD

The LTD observed at parallel fiber (PF) inputs to cerebellar Purkinje cells (PCs) was the first form of LTD characterized in the brain. Theoretical models of cerebellar function predicted that LTD at this synapse might have a crucial role in motor learning and that the coactivation of PFs and climbing fibers (CFs) would activate this type of plasticity. Consistent with these predictions, it has been found that paired PF and CF activation at low frequencies does indeed produce a long-lasting decrease in the efficacy of synaptic transmission at the PF–PC synapse. This form of LTD has been shown to occur *in vivo* and has also been found in brain slices and in single Purkinje

Figure 1 Induction mechanisms of four types of eLTD: (a) homosynaptic LTD; (b) heterosynaptic LTD; (c) spike timing LTD; (d) cerebellar LTD. The diagrams show the molecular mechanisms proposed to participate in initiation of eLTD at the striatal neocortical and cerebellar glutamatergic synapses (a, c), and amygdala and hippocampal GABAergic synapses (b). Note that eLTD expression is probably presynaptic in the amygdala, hippocampus, neocortex, and striatum but postsynaptic in the cerebellum. eLTD in the neocortex and striatum is homosynaptic, whereas in the amygdala and hippocampus it is heterosynaptic. Cerebellar LTD requires pairing of afferent inputs. 2-AG, 2-arachindonyl glycerol; AC, amygdala complex; AEA, arachindonylethanolamide; AMPAR, alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor; AP, action potential; cAMP, cyclic adenosine-3′,5′-monophosphate; CB1R, CB1 receptor; CF, climbing fiber; DAG, diacylglycerol; DGL, lower layer of the dentate gyrus; eCB, endocannabinoid; eLTD, endocannabinoid-dependent long-term depression; GABA, γ-aminobutyric acid; Glu, glutamate; LTD, long-term depression; mGluR, metabotropic glutamate receptor; NAT, *N*-acetyltransferase; NMDAR, *N*-methyl-D-aspartate receptor; NOS, nitric oxide synthase; PF, parallel fiber; PKA, protein kinase A; PLC, phospholipase C; TBF, theta-burst frequency. neurons grown in cell culture. In the cell culture preparation, the activation of afferent inputs can be replaced by the application of receptor antagonists to induce LTD and examine mechanisms of expression.

A large array of molecules has been implicated in cerebellar LTD, including many that also participate in eLTD. There is consensus about the involvement of the following mechanisms:

- Presynaptic release of amino acid transmitters from CFs and PFs.
- Postsynaptic depolarization and activation of voltage-gated channels, including calcium channels.
- Activation of AMPA-type glutamate receptors and receptors containing the glutamate $\delta 2$ subunit.
- Activation of type I mGluRs.
- Increased postsynaptic intracellular calcium and sodium.
- Activation of G-proteins and phospholipases.
- Protein phosphorylation/dephoshorylation, involving the activation of enzymes such as protein kinase C (PKC), cyclic guanosine monophosphate (cGMP)-dependent protein kinase and protein phosphatases PP1 and PP2A. The AMPA receptor itself is an important target for phosphorylation.

Figure 2 Time course of endocannabinoid release and CB1 activation during striatal LTD. Expression of LTD is prevented when CB1 antagonist is applied 1 min after high-frequency stimulation (HFS) but not when application begins 10 min after induction. Results with application at 3 min are intermediate. Calibration = 100 pA, 25 ms. EPSC, excitatory postsynaptic current; LTD, long-term depression. Reproduced from Ronesi J, Gerdeman GL, and Lovinger DM (2004) Disruption of endocannabinoid release and striatal long-term depression by postsynaptic blockade of endocannabinoid membrane transport. *Journal of Neuroscience* 24: 1673–1679, copyright 2004 by the Society for Neuroscience, with permission.

- Internalization of GluR2-containing AMPA receptors.
- Transcription and translation (in late-phase LTD).

Other molecular mechanisms have been implicated in the induction of cerebellar LTD, but they may play modulatory roles or may represent alternative pathways for activating the molecular mechanisms involved in LTD induction. For example, activation of nitric oxide synthase, leading to formation of the gaseous messenger nitric oxide (NO), has been implicated in cerebellar LTD induction. However, NO is not necessary for LTD in the cell culture preparation. This is most likely due to the fact that LTD in cell culture results from the strong activation of phosphorylation by the PKC pathway. In the slice preparation, NO released from stellate-type interneurons in response to glutamate activation of NMDA receptors appears to participate in LTD induction by the activation of guanylate cyclase, leading to the formation of cGMP. This intracellular second messenger, in turn, stimulates cGMP-dependent PKC to phosphorylate a substrate that inhibits the activity of the protein phosphatases PP1 and PP2A. Phosphatase inhibition presumably stabilizes GluR2 in the phosphorylated state and promotes AMPA receptor internalization.

Expression of cerebellar LTD almost undoubtedly involves postsynaptic mechanisms. Decreased AMPA receptor-mediated responses are observed that are tightly coupled to LTD expression. No reliable evidence of a presynaptic change associated with cerebellar LTD has yet been observed. The predominant cellular mechanism believed to be important for the expression of this form of LTD is the internalization of AMPA receptors at PF–PC synapses. Phosphorylation of the AMPA receptor itself, most likely via PKC-mediated transfer of phosphate to serine 880 on the GluR2 subunit, is a key step in this process. Phosphorylation at this residue enhances protein interacting with C kinase 1 (PICK1) binding to GluR2, and this protein–protein interaction results in the subsequent internalization of GluR2-containing AMPA receptors by a process of endocytosis involving the coating of the vesicles by the molecule clathrin. Reduction in the number of synaptic AMPA receptors leads to the reduction in the amplitude of the PF synaptic responses.

It has also been suggested that the activation of CB1Rs plays a role in cerebellar LTD. Postsynaptic mGluR activation and increases in intracellular calcium stimulate endocannabinoid production in Purkinje neurons and the subsequent activation of

Figure 3 Extinction of aversive memories is impaired in the CB1 receptor knockout mouse: (a) after 1 day of conditioned freezing; (b) after 6 days of conditioned freezing; (c) pain thresholds; (d) unconditioned freezing; (e) open arm entries in the elevated plus maze; (f) horizontal open-field locomotion; (g) stronger conditioning regimen. Conditioned freezing extinguishes over several trials in $CB1^{+/+}$ but not in $CB1^{-/-}$ mice after 1 day (a) or 6 days (b) of conditioning. Pain thresholds, unconditioned freezing, open arm entries in the elevated plus maze, and horizontal open-field locomotion do not differ across the different mouse lines. In (g), some extinction is observed in $CB1^{-/-}$ mice with a stronger conditioning regimen, but extinction was still slower and less complete in comparison to $CB1^{+/+}$ mice. Black symbols indicate $CB1^{-/-}$ mice; white symbols indicate $CB1^{+/+}$ mice. CS, conditioned stimulus. presynaptic CB1Rs. A recent study suggested that these molecular events take place during the induction of cerebellar LTD. The presynaptic CB1 activation leads to the release of another factor, possibly NO, that then acts on the postsynaptic neuron to induce LTD.

Other forms of synaptic plasticity occur in the cerebellum that can interact with PF LTD. The CF synapses are capable of expressing LTD when activated by sustained 5 Hz electrical stimulation in cerebellar slices. CF LTD may also involve a postsynaptic expression mechanism and may be involved in pruning back excessive innervation by this powerful synaptic input. Recent studies have characterized a form of long-term potentiation (LTP) that reverses PF LTD. This form of LTP is activated by sustained low-frequency PF input in

the absence of CF coactivation. It is expressed postsynaptically and involves phosphatase activation.

Functional Roles of eLTD

The roles played by eLTD in the function of neural circuits and in behavior are not yet fully understood. The suppression of inhibitory transmission produced by eLTD at GABAergic synapses produces a long-lasting increase in the potential for excitation of the postsynaptic neuron by glutamatergic synaptic inputs. In the hippocampus, this can lead to the priming of LTP at glutamatergic synapses to CA1 pyramidal neurons. The suppression of inhibition allows for greater excitation of the postsynaptic neuron in response to the activation of glutamatergic inputs. This increases the likelihood of NMDA receptor activation and thus enhances the probability of LTP induction.

Roles for eLTD in learning and memory have been postulated, as is the case for other forms of persistent synaptic plasticity. The only example to date in which eLTD has been linked to a specific form of learning is in the extinction of fear conditioning. The basolateral amygdala (BLA) is one site of information storage important for forming conditioned fear responses to previously neutral stimuli by pairing them with aversive stimuli. Endocannabinoids in the BLA appear to play a role in this extinction, and eLTD at GABAergic synapses within this brain region is a candidate mechanism for the decrease in efficacy of inhibitory transmission thought to underlie extinction (Figure 3).

The discovery that eLTD accounts for spike timing-dependent, long-lasting depression of excitatory transmission in the visual cortex suggests a role for this plasticity in cortical development and information storage. Plasticity at cortical glutamatergic synapses is thought to shape patterns of information flow through cortical circuitry during development by setting relative efficacies of thalamocortical and cortico-cortical synapses. These efficacies are shaped by sensory experience. For example, ocular dominance plasticity is a well-characterized change in cortical neuron responses to visual input. Visual experience, including deprivation, alters the strength of neuronal responses from the different eyes, and these experience-dependent changes may involve eLTD and other forms of synaptic plasticity. Within the rodent whisker barrel field sensory cortex, eLTD may also play roles in information storage related to tactile stimuli, as well as in synaptic development. A form of LTD that shares expression mechanisms with eLTD occurs during deprivation of sensory input from facial whiskers, although it is still to be determined if this LTD requires endocannabinoids or the CB1R.

Endocannabinoids and cannabinoid receptors are implicated in neural responses to drugs of abuse, including not only cannabis-based drugs but other addictive substances. Reducing CB1R activity with either antagonists or gene-targeted knockout reduces the self-administration of a variety of drugs of abuse. It has been suggested that eLTD might play a role in neuroadaptations to drugs and drug-related conditioning and that these processes might contribute to addiction. In the nucleus accumbens, eLTD is lost following chronic exposure to Δ9-THC. The loss of plasticity in this case is most likely a consequence of a drug-induced decrease in the number of CB1Rs (receptor downregulation). The loss of eLTD may contribute to behavioral tolerance to cannabinoid drugs. The eLTD induced by amphetamine in the lateral amygdala could play a role in drug-related conditioning, such as conditioned place preference.

Cerebellar LTD is thought to be part of an error-adaptation system involved in motor learning in which PF synapses activated during incorrect performance are depressed based on feedback from the CF inputs. This can come into play during fine-tuning of the vestibulo-ocular reflex. Cerebellar LTD may also play roles in Pavlovian eyeblink conditioning and locomotor adaptation.

Long-Term Depression (LTD): Metabotropic Glutamate Receptor (mGluR) and NMDAR-Dependent Forms

How Is LTD Induced?

Although *N*-methyl-D-aspartate receptor (NMDAR-) and metabotropic glutamate receptor (mGluR-) long-term depression (LTD) can both be elicited *in vivo*, the mechanisms of LTD have been best studied in the acute brain-slice preparation, where it can be induced with a number of protocols. At most synapses, NMDAR-LTD is induced by a modest activation of NMDARs, whereas stronger activation leads to long-term potentiation (LTP). Exceptions to this rule may apply to the parallel fiber (PF)–Purkinje cell synapse in the cerebellum.

Activity-Dependent Induction

For NMDAR-LTD, prolonged low-frequency afferent stimulation (e.g., 900 stimuli at 1–5 Hz) has proven to be very efficient. Brief low-frequency afferent stimulation coupled to weak postsynaptic depolarization to –40 mV (to promote a modest relief of the Mg block of the NMDAR) can also efficiently induce NMDAR-LTD. In addition, NMDAR-LTD can be induced by the correlated activation of the pre- and postsynaptic neuron in many systems in which the firing of the postsynaptic neurons precedes the presynaptic action potential (AP) that releases the glutamate. The proposed mechanism to explain this spike timing-dependent LTD is that the AP in the postsynaptic cell back-propagates to the synapse, relieving the Mg block of the NMDAR. If the back-propagating AP precedes the release of glutamate, a low level of NMDAR activation is generated that leads to LTD.

To induce mGluR-LTD, a wide variety of stimulation protocols have been used. Typically mGluR-LTD requires a higher stimulation frequency than NMDAR-LTD (up to 300 Hz) or burst firing (e.g., several repetitions of five stimuli at 66 Hz), most likely due to the extrasynaptic location of mGluRs. In the hippocampus, a typical induction protocols consists of stimulation at 5 Hz for 3 min or the delivery of pairs of presynaptic APs in rapid succession.

Chemical Induction

Because activity-dependent LTD is generally specific to the small fraction of synapses that receive that activity, there has also been interest in chemical induction of LTD with receptor-selective agonists. This approach is particularly useful for studying the mechanisms underlying both NMDAR-LTD and mGluR-LTD because such treatment uniformly changes transmission in the majority of synapses.

NMDAR-LTD can be chemically induced by the exposure of a slice with NMDA for a few minutes. This chemically induced NMDAR-LTD occludes with NMDAR-LTD that is induced by synaptic stimulation, suggesting that the two overlap substantially. Similarly, mGluR-LTD can be induced by bath application of the drug dihydroxyphenylglycol (DHPG), a selective agonist of group I mGluRs. As with NMDAR-LTD, mGluR-LTD induced chemically occludes with mGluR-LTD induced by synaptic activity.

What Receptors Are Involved in the Induction of LTD?

An interesting idea, introduced about 6 years ago, is that the subunit composition of activated NMDARs determines whether LTD or LTP is elicited. Based on the use of subtype-selective NMDAR antagonists, it has been reported that the NR2A-containing NMDARs selectively elicit LTP but not LTD, whereas NR2B-containing receptors selectively elicit LTD but not LTP in both the hippocampus and cortex. However, results from genetic manipulations suggest that NR2B can contribute to LTP. Several studies have also failed to replicate the reported NMDAR-subtype dependence of LTP or LTD in the hippocampus. LTD is, similarly, not obviously subunit-dependent in the anterior cingulate cortex.

mGluR-LTD requires the activation of mGluRs, but there are several mGluR subtypes (mGluR1–8) and the particular mGluR leading to LTD appears to depend on the preparation in which it is induced. DHPG, a selective agonist of group I mGluRs (mGluR1 and mGluR5) elicits mGluR-LTD, which occludes with synaptically induced plasticity in many different systems, suggesting that in most cases mGluR-LTD is mediated by mGluR1, mGluR5, or both. The selective mGluR1 antagonist CPCOOEt blocks synaptically induced mGluR-LTD in the ventral tegemental area (VTA), and mGluR1 is also implicated in LTD in the cerebellum and neostriatum. mGluR5, on the other hand, has been shown to be the principal receptor responsible for mGluR-LTD in the hippocampus, cortex, and nucleus accumbens, although recent data in knockout mice indicate that the two

receptors may work in synergy. The activation of group II mGluRs (mGluR2 and mGluR3) has also been implicated in the CA3 and dentate gyrus of the hippocampus, as well as some regions of the cortex and the amygdala.

Intracellular Events Triggered by the Induction of LTD

The crucial event triggered by NMDAR activation during NMDAR-LTD is calcium influx (see Figure 1). The requirement for modest, but not strong, NMDAR activation suggests that a modest increase in calcium can lead to NMDAR-LTD, whereas strong increases give rise to NMDAR-LTP. This notion is supported by manipulations of intracellular calcium in which weak and prolonged calcium stimuli lead to LTD, whereas rapid and robust calcium stimuli lead to LTP. The exact determinants of the time course and spatial extent of the calcium signal still have to be worked out, and it remains unclear whether [Ca] levels alone are sufficient to determine whether LTP or LTD is induced. However, an attractive explanation for the bidirectional effects of calcium is that the calcium-dependent effectors that are required for NMDAR-LTD are very sensitive to calcium, whereas the effectors for NMDAR-LTP are less so.

Figure 1 Schematic of intracellular signaling pathways involved in postsynaptic NMDAR-LTD and mGluR-LTD. Both forms of LTD involve the phosphorylation of ser-880 on the C-terminal tail of GluR2, which eventually increases endocytosis of mobile AMPARs. Mobility is conferred by exchanging GRIP/ABP for PICK1. NMDAR-LTD is, in addition, associated with a dephosphorylation of ser-845 on the C-terminal tail of GluR1, leading to decreased conductance and recycling. AKAP regulates the balance between constitutive PKA phosphorylation and activity-driven dephosphorylation of ser-845. AKAP, A-kinase associating protein; GRIP/ABP, glutamate receptor interacting protein/AMPA receptor binding protein; mGluR, metabotropic glutamate receptor; NMDAR, *N*-methyl-D-aspartate; receptor; NSF, *N*-ethylmaleimide sensitive factor; PICK1, protein interacting with C kinase 1; PKA, protein kinase A; PKC, protein kinase C; PSD, postsynaptic density protein; SAP, synapse-associated protein; ser, serine.

Consistent with this line of reasoning, NMDAR-LTD requires the calcium/calmodulin-dependent phosphatase calcineurin, which has a very high affinity for calcium-bound calmodulin (~100 pM). The protein phophatase 1 (PP1) is also required for at least some forms of NMDAR-LTD. NMDAR-LTD leads to a dephosphorylation of ser-845 of the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor (AMPAR) subunit GluR1. Thus, NMDAR activation leads to the activation of PPs, which leads to AMPA receptor dephosphorylation. A caveat, however, is that there is much yet to be understood regarding how phosphatase activity is required for NMDAR-LTD; activity-dependent NMDAR-LTD requires both calcineurin and PP1, but chemically induced NMDAR-LTD does not appear to require PP1. Moreover, the phosphatase that actually directly targets GluR1 has not yet been identified.

mGluR-LTD depends on the activation of G-proteins of the pertussis-toxin-insensitive G_q and $G_{\alpha 11}$ family (see Figure 1). Group I mGluRs couple to phosphoinositide signaling via G_q. G_q seems to predominate in mGluR-LTD at most synapses, including in area CA1 of the hippocampus and at cerebellar PF synapses, where LTD was strongly reduced in $G_q^{-/-}$ mice, whereas in $G_{\alpha 11}^{-/-}$ mice the reduction was much smaller.

The events that happen downstream of G_q activation, however, are less clear. G_q is coupled to phospholipase C (PLC), which triggers the synthesis of inositol triphosphate (IP_3) and protein kinase C (PKC). This ultimately leads to release of calcium from intracellular stores. PKC is clearly involved in mGluR-LTD in the cerebellum and the VTA, but in the hippocampus mGluR-LTD seems not to require PKC or even PLC. The involvement of several other signaling pathways has been suggested, including p38 mitogen-activated protein (MAP) kinase, the extracellular signal-regulated kinase, tyrosine phosphatases, and phosphoinositide-3-kinase. Further study to define the intracellular cascades activated by mGluRs in the hippocampus will be of interest.

Expression Mechanisms Underlying NMDAR- and mGluR-Dependent LTD

There is a general agreement that at least some forms of NMDAR-LTD and mGluR-LTD are expressed as a postsynaptic reduction in AMPAR function, and evidence suggests that both forms of LTD act primarily via the clathrin-mediated endocytosis of AMPARs. However, there are several differences between these two types of LTD, and a number of significant questions remain to be addressed.

AMPAR Trafficking

The first evidence that NMDAR-LTD was due to a withdrawal of AMPARs from the cell surface came from a series of studies demonstrating that NMDAR activation could lead to the internalization of AMPARs in cultured hippocampal neurons and that NMDAR-LTD in hippocampal slices was blocked by disrupting interactions between key components of the endocytic machinery (the proteins amphiphysin and dynamin). LTD is abolished by blocking the interactions between AMPAR subunits and the AP-2 complex, which links to clathrin and is involved in the formation of endocytic-coated pits. In addition, LTD is impaired by viral transfections of the dominant-negative form of the small GTPase Rab5, which is thought to be involved in the trafficking of vesicles between the plasma membrane and endosomal compartments. Thus, NMDAR-LTD requires several components of endocytotic machinery at different stages of the endocytic pathway, and NMDAR activation leads to the withdrawal of AMPARs from the cell surface.

Some evidence also implicates receptor endocytosis in mGluR-LTD, although the issue has received less direct experimental attention. In the cerebellum, the postsynaptic infusion of peptides that interfere with the amphphysin–dynamin interaction blocks mGluR-dependent LTD. Activation of group I mGluRs has also been found to cause a reduction in AMPAR clustering at synapses in hippocampal cell cultures that is, again, blocked by interfering with the amphiphysin – dynamin interaction. Thus, mGluR-LTD appears to lead to loss of synaptic AMPARs via receptor internalization. However, not all data are readily compatible with this model. NMDAR-LTD leads to a reduction in postsynaptic responsiveness to exogenous agonists, as does mGluR-LTD in the cerebellum. Surprisingly, however, mGluR-LTD induced by DHPG application in the hippocampus does not. One possible explanation is that in the hippocampus, mGluR-LTD leads to a selective internalization or dispersion of synaptic AMPARs while leaving extrasynaptic AMPARs unaffected. In fact, with both types of LTD the time course and location of endo- and exocytosis remains to be fully identified. In hippocampal neuronal cultures, NMDAR activation induces a rapid lateral movement that precedes internalization at extrasynaptic sites.

Several studies also implicate a presynaptic reduction of transmitter release probability in mGluR-LTD, particularly in hippocampus. It remains unclear whether mGluR-LTD has both presynaptic and postsynaptic components that operate in tandem, or whether AMPAR loss preferentially affects synapses which have a high release probability.

AMPAR Subunits and LTD

Because AMPARs are heteromultimeric complexes that can be composed of any of four different subunits, GluR1–4, there has been considerable emphasis on the possible differential involvement of specific AMPAR subunits in the expression of LTD.

GluR2 The extreme C-terminus of GluR2 and GluR3 contains a postsynaptic density protein (PSD-) 95, Dlg, and ZO1 (PDZ) ligand sequence that is recognized by several proteins with PDZ domains (the glutamate receptor interacting protein (GRIP), the AMPA receptor binding protein (ABP), and the protein interacting with C kinase 1 (PICK1)). The binding of GluR2 to GRIP/ABP appears to be important in stabilizing AMPARs at the synapse and may also be involved in retaining AMPARs in intracellular pools. Blocking the interaction between GluR2 and PICK1 blocks the removal of GluR2 from the plasma membrane and recent data suggest a model in which the binding of PICK1 allows the mobility of AMPARs. The GluR2/PICK1 complex can be disassembled by ATPase activity of the *N*-ethylmaleimide sensitive factor (NSF), which binds to GluR2 (but not GluR3) at a site upstream of the PDZ ligand.

In addition to binding with GluR2, PICK1 also binds to the α isoform of PKC and to GRIP/ABP. This complex of PICK1, PKC, and GRIP/ABP recruits PKCα to synapses. GluR2 has a PKC phosphorylation site (serine 880 (ser-880)) that is near the PDZ ligand sequence, and the phosphorylation of GluR2 at ser-880 disrupts the interaction between GluR2 and GRIP/ABP but not the interaction between GluR2 and PICK1. Thus, a simple model is one in which LTD induction activates PKCα, leading to the PICK1-mediated targeting of PKCα to synapses. This would promote phophorylation of ser-880 on GluR2, causing GluR2 to release GRIP/ABP and bind to PICK1, promoting lateral diffusion and ultimately internalization.

An elegant series of studies suggest that just such a mechanism accounts for the mGluR-dependent LTD in the cerebellum. Cerebellar LTD requires PKC, and in particular PKCα. LTD induction leads to the phosphorylation of ser-880, and genetic manipulations that disrupt the PKC consensus site on GluR2, as do disruptions of the PDZ ligand site on PKCα that mediates its interaction with PICK1.

PDZ domain-mediated interactions among GluR2, PICK1, and PKCα also appear to be required for cerebellar LTD. Peptides that disrupt the PDZ interactions between GluR2 and PICK1 attenuate cerebellar LTD without affecting basal transmission. Cerebellar LTD is also abolished in knockout mice lacking either GluR2

or PICK1. More specific evidence of the necessity for GluR2–PICK1 interaction is provided by the observation that cerebellar LTD is also impaired by genetic manipulations that disrupt the PDZ ligand on GluR2 or the PDZ domain on PICK1.

Finally, interactions between NSF and GluR2 appear to be essential for the synaptic incorporation of AMPARs that are competent to undergo cerebellar LTD. Transfection of GluR3 into Purkinje cells from GluR2 knockout mice does not rescue cerebellar LTD, nor is the transfected GluR3 incorporated into synapses. However, a mutated version of GluR3 that contains the NSF binding site of GluR2 is incorporated into Purkinje cell synapses from GluR2 knockout mice, and these synaptically incorporated AMPARs are competent to undergo cerebellar LTD.

Do similar mechanisms account for mGluR-LTD observed at other synapses or for NMDAR-LTD? It is clear that at least some synapses express a form of mGluR-LTD that cannot occur via a loss of GluR2-containing AMPARs – at excitatory synapses on to dopamine cells in the VTA, for example, mGluR-LTD causes a shift in the biophysical properties of the AMPAR excitatory postsynaptic current (EPSC) that suggests a selective loss of AMPARs that lack the GluR2 subunit.

At first glance, NMDAR-LTD also seems unlikely to act via similar mechanisms because NMDAR-LTD does not require PKC activity. However, NMDAR-LTD can lead to PKC-independent phosphorylation of ser-880 through an as yet unidentified kinase, raising the possibility that a similar mechanism can be engaged by the same phosphorylation mediated by a different kinase. Moreover, peptides that interfere with the interaction between GluR2 and PDZ domain-containing proteins do impair LTD, although there is disagreement about whether GRIP/ABP or PICK1 is the essential mediator of these effects. Peptides that disrupt the interaction between GluR2 and NSF have also been observed to cause a rundown of synaptic transmission and a concomitant impairment of LTD.

However, a few notes of caution are in order. The NSF binding site on GluR2 overlaps substantially with a binding site for the AP-2 adaptor complex that links to clathrin and is involved in the formation of endocytic-coated pits. This AP-2 binding site is also present in GluR1 and GluR3, and the peptides used in initial studies of the NSF–GluR2 interaction also disrupt the interaction between AMPARs and AP-2. Experiments with more selective peptides suggest that AP-2 interactions with AMPARs are required for NMDAR-LTD, whereas NSF–GluR2 interactions are required for the rundown of basal transmission. Mutated versions of GluR2 in which the interactions with GRIP, ABP, and PICK1 are abolished can still undergo normal NMDA-induced internalization in hippocampal cultures, and a mutated version of GluR2 in which the phosphorylation of ser-880 is disrupted is still competent to undergo LTD in hippocampal slices, albeit less efficiently than wild-type GluR2.

More decisively, NMDAR-LTD is unaffected in GluR2 knockout mice, and it is actually enhanced in GluR2–GluR3 double-knockout mice. This makes it difficult to argue that either GluR2 or GluR3 is a critical component of NMDAR-LTD. One possible explanation is that the peptides used to selectively interfere with GluR2 function are not as specific as previously thought. This possibility is supported by the difficulties in distinguishing between NSF and AP-2 interactions with GluR2 and also by the observation that the peptides that interfere with GluR2–PDZ domain interactions can also impair PDZ domain interactions with distantly related kainate receptor subunits.

GluR1 An alternative subunit-selective mechanism for NMDAR-LTD is suggested by the observations that the ser-845 residue on GluR1 is dephosphorylated by exogenous NMDA in cell culture or by more conventional LTD induction in hippocampal slices. Ser-845 is constitutively phosphorylated by protein kinase A (PKA), and PKA activation has little effect on AMPAR function under basal conditions, presumably because of basal phosphorylation. However, the inhibition of PKA can depress AMPAR-mediated synaptic transmission and occlude LTD. PKA and calcineurin are colocalized by the A-kinase associating proteins (AKAPs), which are targeted to synapses by interactions with the scaffolding proteins PSD-95 and synapse-associated protein (SAP-)97. An accumulating body of evidence suggests indicates that AKAPs are dynamically regulated during LTD to shift the equilibrium between PKA and calcineurin localization at synapses. This determines the phosphorylation state of ser-845, and manipulations that interfere with PKA binding to AKAPs cause a depression of AMPAR-mediated transmission that occludes LTD. Further experiments to selectively examine the role of ser-845 in NMDAR-LTD will be of interest.

How might ser-845 dephosphorylation be involved in LTD? Phosphorylation of ser-845 can enhance AMPAR function by increasing the peak open probability of the channel, so calcineurin-mediated dephosphorylation of GluR1 could directly contribute to LTD expression even in the absence of changes in receptor trafficking. However, dephosphorylation of ser-845 appears to be downstream of receptor internalization and prevents the recycling of AMPARs after they have been internalized. Thus, current evidence suggests that the dephosphorylation of GluR1 is a

fairly late event in the mechanisms underlying LTD that may have more to do with preventing AMPAR reinsertion than with the withdrawal of AMPARs from the synapse.

Maintenance of LTD

The previous section focused on the mechanisms by which AMPAR function is depressed during LTD. We now turn our attention to the mechanisms that allow the depression to persist long after the induction event is over. The answers to this question are still largely unknown, although the available data are sufficient in some cases to draw some surprising conclusions that deserve mention.

In the case of NMDAR-LTD, some evidence is consistent with the idea that LTD is maintained by the change in phosphorylation of the AMPAR itself. As discussed previously, dephosphorylation at ser-845 on GluR1 prevents internalized AMPARs from recycling back to the synapse, suggesting that the phosphorylation state of this site may determine whether LTD persists; consistent with this idea, PKA activation can lead to a reversal of LTD following the stable induction of LTD, as can synaptic activity. Synaptically induced de-depression can be reduced by the inhibition of PKA, providing further evidence for dephosphorylation of PKA targets as a mechanism that is responsible for the maintenance of NMDAR-LTD.

However, it need not be the case that NMDAR-LTD is maintained by the duration of modifications to AMPARs. An alternative is that the number of AMPARs at the synapse is limited by proteins that tether the AMPAR at the postsynaptic density; a decrease in the amount of this tether would preclude AMPAR reinsertion at synapses following LTD induction even if the AMPARs were recycled to the cell surface because there would be no mechanism to hold them at the synapse. The protein PSD-95 has many properties that are consistent with such a tether. Manipulations that increase or decrease PSD-95 expression cause parallel changes in the synaptic AMPAR-mediated response. This may be relevant to the maintenance of NMDAR-LTD, because NMDA applied to hippocampal neurons in culture leads to the ubiquitination and subsequent proteosomal degradation of PSD-95. This loss of PSD-95 is dependent on calcineurin and blocked by PKA activation, similar to LTD; moreover, the inhibition of proteosome function prevents the NMDA-induced reduction in surface expression of GluR1 and GluR2. NMDA also actively recruits proteosomes to dendritic spines. Further characterization of this potential mechanism for LTD maintenance will be of interest.

In the case of mGluR-LTD, it has long been known that the LTD induced by DHPG can be reversed long after stabilization by the application of group I mGluR antagonists. This indicates, surprisingly, that the expression mechanisms underlying mGluR-LTD are maintained by constitutive activation of an mGluR following LTD induction; in the absence of mGluR activity, the depression is quickly reversed.

An alternative model that has some experimental support is that mGluR-LTD might be maintained by the synthesis of new proteins that stabilize LTD expression. Both LTD and the internalization of AMPAR subunits are blocked by inhibitors of mRNA translation. This potential link between translation of new proteins and mGluR-LTD became a source of considerable excitement when it was found that mice lacking the fragile X mental retardation protein (FMRP) have enhanced mGluR-LTD in both the hippocampus and cerebellum.

The loss of function of FMRP is responsible for the fragile X syndrome in humans, an X-linked form of mental retardation. FMRP is an RNA-binding protein, although it remains a topic of debate whether FMRP represses or stimulates translation. Regardless of the precise action of FMRP on translation, the observation that FMRP enhances mGluR-LTD seemed at first to clearly indicate a role for changes in protein synthesis as an essential part of mGluR-LTD. Surprisingly, however, subsequent analysis of FMRP knockout mice indicated that mGluR-LTD in these mice is not only enhanced but also independent of protein synthesis. Similarly, the inhibition of proteosome function has recently been found to block mGluR-LTD in wild-type mice but not in FMRP knockout mice. These results are difficult to reconcile with an integral role for protein synthesis or degradation in mGluR-LTD, and further study will be of interest.

Long-Term Depression: Cerebellum

M Ito, RIKEN Brain Science Institute, Wako, Japan

© 2009 Elsevier Ltd. All rights reserved.

Long-term depression (LTD) is a type of synaptic plasticity in which the efficacy of signal transmission across a synapse continuously decreases after a certain triggering activity. LTD in the cerebellum was proposed as a theoretical possibility around 1970 and was discovered a decade later. Thus far, several subtypes of LTD, varying in cellular and molecular mechanisms, have been found in the cerebellum, hippocampus, neocortex, striatum, and amygdala in vertebrate brain and also in molluscan ganglia. LTD may occur in synapses that have received a triggering activity (homosynaptic LTD) or in those that have not received a triggering activity (heterosynaptic LTD). Some temporal phases of LTD have been distinguished (short, long, and late phases). LTD occurs not only in excitatory synapses, but also in inhibitory synapses. LTD may weaken or functionally interrupt useless or erroneous synaptic connections between neurons, providing a mechanism synergistic with long-term potentiation (LTP) in various forms of learning and memory.

Induction and Observation of LTD

In Cerebellum and in a Cerebellum-Like Structure

In the cerebellar cortex, each Purkinje cell forms two distinct types of excitatory synapses, one from parallel fibers and the other from a climbing fiber. LTD occurs when these two types of synapses are activated repeatedly in approximate synchrony, leading to a continuous decrease in the synaptic strength of parallel fibers. In *in vitro* cerebellar slices, LTD is typically induced by the conjunctive stimulation of parallel and climbing fibers at 1 Hz for 5 min (300 stimuli), which decreases transmission efficacy by 30%. A repetitive stimulation of parallel fibers followed by the stimulation of climbing fibers (a few times) is also effective in inducing LTD. Such LTD can be observed by electrical recording from individual Purkinje cells, and also by optical imaging of the surface of the cerebellum using voltage-sensitive dyes. LTD is robust in the sense that its induction does not critically depend on the timing between climbing fiber stimulation and parallel fiber stimulation. In inducing LTD, climbing fiber stimulation is often replaced by current-induced membrane depolarization that enhances the influx of Ca^{2+} into Purkinje cell dendrites, as in the case of climbing fiber stimulation.

LTD induced by the conjunctive stimulation of parallel fibers and a climbing fiber is represented by a decrease in parallel-fiber-evoked excitatory postsynaptic potential (EPSP) or current (EPSC), which usually fully develops gradually over 30–60 min. In contrast, LTD induced by parallel fiber stimulation in combination with depolarizing pulses develops faster (in 5–10 min). The difference between these two types of LTD indicates the fast phase of LTD that follows parallel fiber stimulation–depolarization conjunction, but not parallel fiber–climbing fiber conjunction. LTD can be observed to continue for 1–3 h without any signs of recovery. Under the influences of protein synthesis inhibitors, previously developed LTD declines over 1 h, revealing the protein-synthesis-dependent slow phase of LTD.

Strong stimulation of parallel fibers causes homosynaptic LTD in Purkinje cells. This is because a sufficiently large influx of Ca^{2+} occurs in strongly activated Purkinje cell dendrites. Conjunctively induced LTD is accompanied by LTD in neighboring synapses that are located within a distance of 100 μm and are not involved in conjunctive stimulation. Nevertheless, such LTD occurs in only neighboring synapses that are active even at a very low rate of discharge (~0.2 Hz), indicating a weak temporal relationship with climbing fiber activity. Thus, the input specificity of LTD still holds in a wider sense. An input-non-specific LTD occurs in inhibitory synapses that Purkinje cells supply to cerebellar nuclear neurons. In this case, repetitive stimulation of a portion of inhibitory synapses leads to LTD in this portion as well as in other, unstimulated portions.

The brains of certain fish species contain a cerebellum-like structure that lacks climbing fibers. LTD occurs in Purkinje cell-like neurons in parallel-fiber-evoked EPSPs when EPSPs repeatedly precede postsynaptic spikes by 60 ms, at the most.

In Hippocampus and Neocortex

In pyramidal cells of the hippocampal CA1 region, a low-frequency stimulation (LFS) of a bundle of presynaptic fibers (1 Hz for 5–15 min) typically induces LTD, whereas a high-frequency stimulation (five stimuli at 100 Hz repeated at 200 ms intervals for 2 s) induces LTP. LFS-induced LTD also occurs in layer III neurons of the visual cortex following the stimulation of the white matter or layer IV. LTD has also been observed in the sensorimotor and prefrontal cortex.

An associative stimulation of presynaptic fibers with postsynaptic membrane depolarization (5 Hz for 16 s) also induces LTD or LTP, depending on the time from pre- to postsynaptic activities. Repetitive postsynaptic spiking within a time window of 20 ms after presynaptic activation results in LTP, whereas

postsynaptic spiking within a window of 20 ms before a repetitive presynaptic activation leads to LTD. A significant LTP occurs only at synapses with a low initial strength, whereas the extent of LTD does not show obvious dependence on the initial synaptic strength. LTD occurs in stimulated (homosynaptic LTD) and unstimulated (heterosynaptic LTD) synapses, whereas LTP occurs only homosynaptically. As revealed in a triple chain of cultured hippocampal neurons, the induction of associative LTD in a synapse is accompanied by a back-propagated induction of LTD in a synapse of a presynaptic cell. Through this induction, temporal information coded in the timing of individual spikes may be converted into spatially distributed patterns of continuous synaptic modifications in a neural network. In fact, it has been shown that the receptive fields of superior colliculus neurons are modified through a temporary exposure to patterns of visual stimuli.

Associative LTP or LTD is also induced in the hippocampus and neocortex, when presynaptic stimulation is paired with membrane depolarization. A strong membrane depolarization induces LTP, whereas a weak membrane depolarization causes LTD. This dichotomy depends on the amount of Ca^{2+} influx evoked by the depolarization.

In Amygdala, Striatum, and Molluscan Ganglia

LTD occurs in the basolateral amygdala, following a LFS (1 Hz/900 pulses) of the mouse lateral amygdala of an *in vitro* slice preparation. In slices from 2-week-old mice, interneurons express pronounced LTD, in contrast to those in slices from adult mice (2–4 months old). Principal neurons show only a weak LTD. In the basolateral nucleus of the amygdala, γ-aminobutyric acid (GABA)-ergic interneurons and serotonergic afferents appear to play a pivotal role in the induction of LTD.

The corticostriatal glutamatergic synapses in the striatum exhibit LTD in a high percentage of medium spiny neurons. D2 receptors mediate this LTD induction. However, the medium spiny neurons form two groups. Only one group, striatopallidal neurons, expresses D2 receptors, whereas the other group, striatonigral neurons, expresses D1 receptors. A recent study suggests that the D2 receptor-mediated dopaminergic control of LTD induction is not directly exerted on the corticostriatal synapses, but that it is mediated by cholinergic interneurons that express D2 receptors; D2 receptor-mediated LTD in these interneurons leads to reduction of M1 receptor tone at corticostriatal synapses.

Invertebrate central synapses also possess the capacity for LTD. For example, activation of sensory neurons at 2 Hz for 15 min induces LTD of isolated *Aplysia* sensorimotor synapses in cell culture.

Signal Transduction Underlying LTD

Conjunctively induced LTD is a purely postsynaptic event, whereas other LTD subtypes include presynaptic factors. Postsynaptic signal transduction processes have been analyzed in synaptically induced LTD and in various reduced forms of LTD induced with a chemical or by an electrical stimulation of neurons in place of synaptic activation. The analytical methods have been improved using various pharmacologically specific antagonists and genetic manipulation. More than 30 molecules have been identified in the signal flow map underlying conjunctively induced LTD (Figure 1).

Receptors

LTD in excitatory synapses is, at least in part, caused by a reduction in the number of functional α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor molecules in the postsynaptic membrane. Other types of receptors play roles in eventually inducing this change. The activation of *N*-methyl-D-aspartate (NMDA) receptors is required for LTD induction in excitatory synapses but not in inhibitory synapses of hippocampal neurons. Even though NMDA receptors are not functional in adult Purkinje cells, the activation of NMDA receptors present in other cells, probably in stellate cells, is required for the induction of conjunctive LTD in Purkinje cells. Parallel fiber synapses on Purkinje cells contain, besides AMPA receptors, type 1 metabotropic glutamate receptors (mGluR1s) and δ2 glutamate receptors, whereas climbing fiber synapses contain AMPA receptors, type 1 corticotropin-releasing factor receptors (CRFR1s), and type 1 insulin-like growth factor receptors (IGF1Rs). The δ2 receptor is an orphan receptor with a still unknown function. The mGluR1s, CRFR1s, and IGF1Rs are associated with G-proteins which are coupled with certain second messenger processes. Because the inhibition of any of these receptors results in the blockage of LTD, a concerted activation of all these receptors leads to the conjunctive induction of LTD (Figure 1).

Calcium Entry and Release from Intracellular Stores

The conjunctive induction of LTD requires an increase in $[Ca^{2+}]_i$, because LTD is blocked by the injection of a Ca^{2+} chelator (ethylene glycol tetraacetic acid; EGTA) into Purkinje cells. Climbing fiber impulses evoke Ca^{2+} influx into dendrites of Purkinje cells through voltage-sensitive Ca^{2+} channels. As in underlying homosynaptic LTD, Ca^{2+} influx also occurs in association with parallel-fiber-induced EPSPs, when the EPSPs are sufficiently large to

activate voltage-sensitive Ca^{2+} channels. Ca^{2+} is also released from intracellular stores in the endoplasmic reticulum, when inositol trisphosphate (IP_3; also $Ins(1,4,5)P_3$) or ryanodine receptors on the reticulum are activated. The inhibition of IP_3 receptors, the depletion of Ca^{2+} stores, or the genetically induced loss of the endoplasmic reticulum in dendritic spines results in the blockade of conjunctively induced LTD. A double-shock stimulation of parallel fibers at 50–60 ms intervals induces an optimal activation of Ca^{2+} release from the endoplasmic reticulum, and therefore induces LTD effectively.

In hippocampal and neocortical neurons, LTD induction depends on membrane potential (see earlier), which determines the influx of Ca^{2+} ions into neurons through cation channels associated with NMDA receptors. These channels are normally blocked by Mg^{2+} that is removed at a depolarized membrane potential. Modest and strong activations of NMDA receptors lead to LTD and LTP, respectively. Inhibition of postsynaptic Ca^{2+} influx by a partial blockade of NMDA receptors shifts LTP to LTD. LTP is also shifted to LTD by injecting EGTA into neocortical neurons. Induction of homosynaptic and heterosynaptic

LTDs in the hippocampus requires functional ryanodine and IP_3 receptors, respectively. A functional blockade or the genetic deletion of type 1 IP_3 receptors leads to a shift of LTD to LTP and the inhibition of heterosynaptic LTD, whereas the blockade of ryanodine receptors inhibits only homosynaptic LTD. In mouse amygdala slices, Ca^{2+} influx via NMDA receptors is essential in triggering LTD; loading single neurons with the calcium chelator 1,2-bis(*o*-aminophenoxy)ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid (BAPTA) (30 mM) does not decrease the EPSC following LFS, and the induction of LTD is suppressed by a competitive NMDA receptor antagonist. Calmodulin kinase II (CamKII) plays a role in amygdala LTD because the application of a specific CamKII antagonist, KN-62, blocks LFS-induced LTD.

Metabotropic Glutamate Receptor-Driven Processes

The activation of mGluR1s in Purkinje cells results in the activation of phospholipase C (PLC), which generates IP_3 (see earlier) and diacylglycerol (DAG) from membrane phospholipids. DAG activates protein kinase C (PKC). The mGluR1s can also be coupled to phospholipase A_2 (PLA_2), which produces arachidonic acid and oleic acid from membrane phospholipids. The inhibition of mGluR1, PKC, PLA_2, or IP_3 receptors prevents LTD induction, indicating that these molecules are involved in LTD induction. The application of an mGluR5 agonist, dihydroxy propoxy methyl guanine (DHPG), effectively induces a continuous decrease in EPSPs in hippocampal CA1 neurons, which has been studied as a reduced form of hippocampal LTD. In amygdala slices, LTD is blocked by a metabotropic glutamate receptor antagonist and by 5-hydroxytryptamine (5-HT) via the activation of 5-HT(1A) receptors. Moreover, blocking $GABA_A$ receptor-mediated synaptic transmission with bicuculline or picrotoxin inhibits LTD induction. GABAergic interneurons and serotonergic afferents may play roles in amygdala LTD induction.

Nitric Oxide and cGMP

Cerebellar granule cells contain a neuronal-type nitric oxide synthase (nNOS), and parallel fiber terminals release NO upon stimulation. NO then diffuses into Purkinje cells and activates guanylate cyclase to increase the level of cyclic guanosine monophosphate (cGMP). cGMP in turn activates a cGMP-dependent protein kinase (PKG). The role of NO in the conjunctive induction of LTD is evident because such induction is blocked when an inhibitor of NO synthase, N^{ω}-monomethyl-L-arginine (L-NMMA), or hemoglobin, which absorbs NO, is applied to cerebellar slices. Furthermore, sodium nitroprusside, which releases NO, or a membrane-soluble derivative of cGMP induces an LTD-like phenomenon when applied to cerebellar slices together with AMPA.

Protein Kinases and Phosphatases

The conjunctive induction of cerebellar LTD requires the activities of PKC, PKG, protein tyrosine kinase (PTK), and mitogen-activated protein kinase (MAPK), but not that of PKA. PKC phosphorylates serine 880 of AMPA receptors, and PTK interacts with PKC. PKG acts on a PKG-specific substrate, G-substance, which is abundant in Purkinje cells. The phosphorylated G-substrate becomes a potent inhibitor of protein phosphatases, presumably type 2A (PP2A). Specific inhibitors of PP2A block LTD induction.

PKC and PTK, but not PKA, are involved in mGluR-induced LTD in neurons of the hippocampal dentate gyrus. A Ca^{2+}/calmodulin-dependent protein phosphatase, calcineurin (or PP2B), mediates LTD induction in the hippocampus and visual cortex because a calcineurin inhibitor, FK506, blocks LFS-induced LTD. Mice deficient in the calcineurin catalytic unit B1 exhibit significantly suppressed LFS-induced LTD in the hippocampus. This is in contrast to the finding in Purkinje cells in which the inhibition of PP2A causes LTD. Calcineurin is also involved in LTD induction, downregulating $GABA_A$ receptors in inhibitory synapses of the hippocampus.

Protein Synthesis

Protein synthesis plays roles in hippocampal neuronal processes because a translational inhibitor blocks the late phase of LFS-induced LTD as well as the entire course of DHPG-induced LTD. Translational inhibitors suppress the late phase of LTD in cultured Purkinje cells, but they entirely block LTD in cerebellar slices. Studies using 5 min pulses of translational inhibitors revealed that the synthesis of a protein with a rapid turnover is required for LTD induction only during the 15 min period from the onset of conjunctive stimulation. A 5 min pulse application of transcriptional inhibitors also effectively blocks LTD induction with a delay of 30 min.

Mutant mice lacking the fragile X mental retardation type 1 *FMR* gene show abnormally slender dendritic spines and exhibit an abnormally enhanced LTD in the visual cortex and cerebellum. *FMR1* encodes an RNA-binding protein that acts as a negative translational regulator. Studies of *FMR1* demonstrated the importance of local protein synthesis within a neuron as a determinant of normal synaptogenesis and development of cognitive abilities.

Phosphorylation and Internalization of AMPA Receptors

Of the subunits constituting AMPA receptors, GluR2 subunits are predominant in parallel fiber–Purkinje cell synapses. Evidence indicates that at the late phase of the conjunctive induction of cerebellar LTD, GluR2 is phosphorylated at its serine 880 anchorage to glutamate receptor-interacting protein (GRIP), and free AMPA receptors are removed from the postsynaptic membrane by internalization via endocytosis. A similar mechanism is considered applicable to associative LTD in hippocampal neurons.

Cannabinoid

It has recently been revealed that transmitter release at parallel fiber–Purkinje cell synapses is regulated through the activation of presynaptic cannabinoid receptors by endogenous cannabinoids that are released as retrograde messengers from Purkinje cells. This retrograde regulation occurs in response to the activation of postsynaptic mGluR1s. It accounts for the short-term depression of parallel fiber–Purkinje cell transmission that follows a brief tetanic stimulation of parallel fibers.

Molecular Organization of LTD

Of the more than 30 molecules involved in LTD induction, some may serve as mediators that are indispensable for LTD induction, whereas others may serve as modulators of the functions of the mediators. The lack of a mediator should always lead to the blockade of LTD, but that of a modulator would not necessarily block LTD induction. For example, the NO–cGMP pathway is required for LTD induction in cerebellar slices, but not for the induction of the reduced form of LTD in isolated Purkinje cells. Because climbing fiber activation can be replaced by current-evoked depolarization in LTD induction, AMPA receptors activated together with the activation of voltage-gated Ca^{2+} channels should normally be a mediator, whereas mGluR1s, CRFR1s, and IGF1Rs at climbing fiber synapses should be modulators. This view is also supported by the observation that LTD can be induced in tissue-cultured Purkinje cells lacking climbing fibers, using depolarization pulses. Thus far, parallel fiber–AMPA receptors coupled with voltage-gated Ca^{2+} influx, and parallel fiber–mGluR1 receptors coupled with intracellular Ca^{2+} release, are thought to constitute duplicated mediators; either one can mediate LTD.

The signal flow map shown in Figure 1 should also include a coincidence-detector mechanism by which multiple signals that coincide within a short time window induce a supralinear effect, that is, LTD. The first candidate for such a coincidence detector is IP_3 receptors on the endoplasmic reticulum, activated via mGluR1s in parallel fiber synapses. The activation of climbing fiber synapses evokes the influx of Ca^{2+}, which sensitizes IP_3 receptors. The coincidence of these two events leads to increases 8.2 times larger than the linear sum of the increases induced by a separate stimulation of parallel fibers and a climbing fiber.

The second candidate for the coincidence detector is voltage-gated Ca^{2+} channels in dendritic spines. These channels are activated superlinearly by parallel-fiber-evoked EPSPs and climbing-fiber-evoked EPSPs; the increase in $[Ca^{2+}]_i$ so induced is 4.5 times larger than the linear sum of the increases induced by individual stimulation.

The high $[Ca^{2+}]_i$ that results from coincidence detection in either or both of the two mediator pathways leads to the next stage of signal transduction on the way to LTD. This is the phosphorylation and internalization of AMPA receptors, and this is carried out by the phosphorylation–dephosphorylation system (see preceding sections, 'Phosphorylation and internalization of AMPA receptors' and 'Cannabinoid'). The possible operation of the entire multiple molecular signal transduction underlying LTD has been reproduced by kinetic simulation.

Functional Roles of LTD

In the cerebellum-like structure in fish, LTD plays a distinct role in attenuating the effects of sensory inputs coinciding with command signals to allow only unpredicted sensory inputs to predominate, thus forming an adaptive sensory processor. The involvement of LTD in certain forms of cerebellar learning has been demonstrated using pharmacological or genetic manipulations that impair LTD. Applying an NO scavenger or transfecting a pseudoinhibitor of PKC to the cerebellum abolishes the adaptive change in the vestibuloocular reflex (VOR). An NO scavenger or an NOS inhibitor also blocks the adaptive change that occurs in the smooth pursuit eye movement during repeated sudden increases in the velocity of a moving spotlight. Mice deficient in the glial fibrillary acidic protein or phospholipase C β4 lack LTD and do not exhibit the classical conditioning of eye blinking. A walking cat or mouse can normally adapt to a sudden change in running belt conditions, but cannot under the influence of an NO scavenger or an NOS inhibitor or when it has mGluR1 deficiency, which blocks LTD. Mice in which hippocampal LTD is suppressed because of a

conditional knockout of calcineurin are specifically impaired in working memory and episodic-like memory tasks, including a delayed matching-to-place task and a radial maze task.

LTD as Memory Trace

LTD can be observed continuously for 1–3 h, after which long-term depressed synapses may disappear, because, after repeated VOR adaptations, a decrease in the number of synapses occurs in parallel fiber–Purkinje cell synapses, or the long-term depressed synapses may be maintained as silent synapses, structurally unchanged but functionally silent. This unexpected possibility has recently been indicated by three observations. First, up to 80% of parallel fiber–Purkinje cell synapses are silent or have a very low transmission efficacy. Second, in a sagittal slice of the rat cerebellum, parallel fiber stimulation excites an area of 380 μm^2 covering 1140–2660 parallel fiber–Purkinje cell synapses, but evokes EPSCs 5- to 30-fold larger than those evoked by a unitary parallel fiber synaptic current (12 pA). Hence, the electric stimulation of parallel fibers in a small dendritic area of a Purkinje cell activates at most 2.6% (30/1140) of the parallel fiber–Purkinje cell synapses located within the area. Third, in the forelimb area of the C3 zone, each Purkinje cell responds, via parallel fibers, to stimulation in only one of the 30–40 types of receptive fields that cover the forelimb skin in its entirety. The receptive fields of Purkinje cells vary even between neighboring Purkinje cells located along the same parallel fiber bundle. Thus, effective parallel fiber inputs to a Purkinje cell can be only about 3% of the total number of cutaneously activated parallel fibers forming synaptic contacts with the cell.

Surprisingly, an electric burst stimulation of parallel fibers (100 Hz burst of 15 pulses every 3 s for 5 min), unpaired with climbing fiber activity, induces a very large, long-lasting increase in the receptive field size of Purkinje cells over 2–6 h. On the other hand, the stimulation of parallel fibers, paired with climbing fiber activity, reverses the changes in the size of the receptive field. On the basis of these findings, Ekerot and Jörntell suggest that silent synapses are produced functionally by LTD, and that learning converts silent synapses to active synapses, or vice versa, by LTP or LTD induction. The finding on silent synapses opens a new aspect of the cerebellar microcomplex mechanism. The relationships of silent synapses with synaptic plasticity and their significance in information processing should be investigated further.

Another intriguing issue concerning LTD as a memory process is whether the cerebellar cortical network permanently stores memory via LTD, or whether memory is transferred to cerebellar or vestibular nuclei to be consolidated. Relevant to this issue, two phases, fast and slow, of VOR adaptation have recently been distinguished. LTD in floccular Purkinje cells accounts for the memory of fast-phase VOR or optokinetic response (OKR) adaptation, which develops during continuous rotation for about 1 h. This was demonstrated by blocking such adaptation by injecting a localized anesthetic, lidocaine, into the flocculus. In contrast, the slow-phase VOR or OKR adaptation, established by repeated trials of screen rotation for 1 week, continues after the flocculus is injected with an AMPA/kainate receptor blocker, 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) or lidocaine. Nevertheless, the slow-phase OKR adaptation is suppressed by an NOS inhibitor that blocks LTD, or by a lesion in the inferior olive. Therefore, LTD in the flocculus is required for the development of the fast and slow phases of OKR adaptation, but not for the maintenance of the previously formed, slow-phase adaptation. Underlying the slow-phase OKR adaptation, an increase in vestibular nerve-induced activity occurs in vestibular relay neurons. This indicates that non-input-specific plasticity in vestibular nuclei accounts for the slow-phase OKR adaptation. In the eye blink conditioning, information on the magnitude of the eye blink reflex has been assumed to be stored in the anterior interpositus nucleus, whereas information on the timing of the eye blink reflex is stored in the cerebellar cortex. In this case as well, plasticity changes occur in cellular excitability that lacks input specificity. It is important to define the capacity of memory storage in nuclei differently from that in the cerebellar cortex, in light of the elaborateness of the neuronal network structures, and, accordingly, of the capabilities of processing and retaining spatiotemporal-patterned information.

Other issues to be addressed are whether information acquired through synaptic plasticity is eventually stored at the level of modified molecules, such as altered genes, and whether new proteins produced by these genes are carriers of memory traces. The involvement of the immediate-early genes *JunB* and c-*Fos* in LTD induction and the involvement of CamKIV and cAMP response element-binding (CREB) protein in the late phase of LTD have been suggested, but these experiments lasted no more than 2 h.

Summary

Investigations during the past 25 years have established LTD as a major type of synaptic plasticity that plays roles in various forms of learning and memory. Complex molecular mechanisms underlying

LTD induction have been revealed. It will be a future task to confirm whether LTD is converted to a permanent memory, and, if so, by what mechanism. We should also determine the specific functional roles of LTD in individual forms of learning and memory.

Long-Term Potentiation (LTP)

Synaptic Plasticity and Memory

The particular circuits and neuronal connections that underlie most forms of mammalian learning and memory are mysterious at present. There is little understanding of the means by which complex memories are stored and recalled at the neural circuit level – this is a very important avenue of modern research.

This article focuses on long-term potentiation (LTP), a phenomenon that is currently the best candidate for a cellular mechanism contributing to learning and memory in the mammalian central nervous system (CNS). LTP has been extensively studied and is the best-understood form of synaptic plasticity at the molecular level. Moreover, it is a specific candidate cellular mechanism for mediating certain forms of associative learning, spatial learning, and adaptive change in the CNS, in particular in the amygdala, hippocampus, and cerebral cortex, respectively.

Learning and memory manifest themselves as a change in an animal's behavior, and scientists capitalize on this to study these phenomena by observing and measuring changes in an animal's behavior in the wild or in experimental situations. However, all the behavior exhibited by an animal is a result of activity in the animal's nervous system. The nervous system comprises many kinds of cells, but the primary functional units of the nervous system are neurons. Because neurons are cells, all of an animal's behavioral repertoire is a manifestation of an underlying cellular phenomenon. By extension, changes in an animal's behavior, such as those that occur with learning, must also be subserved by an underlying cellular change.

By and large, the vast majority of the communication between neurons in the nervous system occurs at synapses. Because synapses mediate the neuron–neuron communication that underlies an animal's behavior, changes in behavior are ultimately subserved by alterations in the nature, strength, or number of interneuronal synaptic contacts in the animal's nervous system. The capacity for alterations of synaptic connections between neurons is referred to as synaptic plasticity, and one of the great unifying theories to emerge from neuroscience research in the last century was that synaptic plasticity subserves learning and memory. LTP (of some sort, at least) is the specific form of synaptic plasticity that is the leading candidate for the mechanism subserving behavior-modifying changes in synaptic strength that mediate higher-order learning and memory in mammals.

One of the pioneers who advanced the idea that changes in neuronal connectivity are a mechanism for memory was the Canadian psychologist Donald Hebb, who published his seminal formulation as what is now generally known as Hebb's postulate:

> When an axon of cell A . . . excites cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells so that A's efficiency as one of the cells firing B is increased. (Hebb, 1949; p. 62)

A Breakthrough Discovery – LTP in the Hippocampus

LTP, a cellular phenomenon with the attributes predicted by Hebb's postulate, has been most widely studied in the hippocampus, an area of the CNS widely documented as being important for memory information. As a young postdoctoral researcher, Tim Bliss set out to find a long-lasting form of synaptic plasticity in the hippocampus, and after teaming up with Terje Lomo in Per Anderson's laboratory in Oslo, he did just that. The seminal 1973 report by Bliss and Lomo describing a phenomenon they termed "long-term potentiation" of synaptic transmission set the stage for what is now over three decades of progress in understanding the basics of long-term synaptic alteration in the CNS.

In their experiments, Bliss and Lomo recorded synaptic responses in the dentate gyrus, stimulating the perforant path inputs from the entorhinal cortex. They used extracellular stimulating and recording electrodes implanted in the animal, and the basic experiment was begun by recording the baseline synaptic transmission in this pathway. They discovered that a brief period of high-frequency (100 Hz tetanic) stimulation led to a robust increase in the strength of synaptic connections between the perforant path inputs from the entorhinal cortex to the dentate granule neurons in the dentate gyrus (Figure 1). They also observed an increased likelihood of the cells firing action potentials in response to a constant synaptic input, a phenomenon they termed E-S (excitatory postsynaptic potential (EPSP)-to-spike) potentiation.

Figure 1 Bliss and Lomo's first published long-term potentiation (LTP) experiment, in which Tim Bliss and Terje Lomo demonstrated the LTP of synaptic transmission at perforant path inputs into the dentate gyrus (see Figure 4). Arrows indicate the delivery of high-frequency synaptic stimulation, resulting in LTP. Filled circles are responses from the tetanized pathways; open circles are a control pathway that did not receive tetanic stimulation. The bar, where no data points are available, indicates a period of time when Bliss fell asleep. Data acquisition in this era involved the investigator directly measuring by hand synaptic responses from an oscilloscope screen. Moreover, it was not unusual for experiments to extend overnight due to the long time involved in preparing the rabbit for the experiment, implanting the electrodes into the brain, and establishing a stable recording configuration. EPSP, excitatory postsynaptic potential. Reproduced from Bliss TV and Lomo T (1973) Long-lasting potentiation of synaptic transmission in the dentate area of the anaesthetized rabbit following stimulation of the perforant path. *Journal of Physiology* 232: 331–356, with permission from Elseiver.

These two phenomena together were termed LTP. LTP lasted many, many hours in this intact rabbit preparation. The appeal of LTP as an analog of memory was immediately apparent – it is a long-lasting change in neuronal function that is produced by a brief period of unique stimulus, exactly the sort of mechanism that had long been postulated to be involved in memory formation. This pioneering work of Bliss and Lomo set in motion a several-decades-long pursuit by numerous investigators geared toward understanding the attributes and mechanisms of LTP.

The Hippocampal Circuit and Measuring Synaptic Transmission in the Hippocampal Slice

Bliss and Lomo did their experiment using the intact rabbit, stimulating and recording in the anesthetized animal using implanted electrodes. In recent times, this preparation has been largely supplanted by the use of recordings from hippocampal slices maintained *in vitro* (see Figures 2 and 3). Most experiments on the basic attributes and mechanisms of LTP have been studies of the synaptic connections between axons from area CA3 pyramidal neurons that extend into area CA1. These are the synapses onto CA1 pyramidal neurons that are known as the Schaffer collateral inputs.

In a popular variation of the basic LTP experiment, extracellular field potential recordings in the dendritic regions of area CA1 are used to monitor synaptic transmission at Schaffer collateral synapses (see Figures 3 and 4). A bipolar stimulating electrode is placed in the stratum radiatum subfield of area CA1, and electrical stimuli are delivered. Stimuli delivered in this fashion stimulate the output axons of CA3 neurons that pass nearby, causing action potentials to propagate down these axons. Cellular responses to this stimulation are recorded using extracellular or intracellular electrophysiological recording techniques.

The typical waveform in an extracellular recording consists of a fiber volley, which is an indication of the presynaptic action potential arriving at the recording site, and the EPSP itself. The EPSP responses are a manifestation of synaptic activation (depolarization) in the CA1 pyramidal neurons. For measuring field (i.e., extracellularly recorded EPSPs), the parameter typically measured is the initial slope of the EPSP waveform (see Figure 3). Extracellular field recordings measure responses from a population of neurons, so EPSPs recorded in this fashion are referred to as population EPSPs (pEPSPs).

As a prelude to starting an LTP experiment input–output (I/O) functions for stimulus intensity versus EPSP magnitude are recorded in response to increasing intensities of stimulation (see Figure 4). Baseline synaptic transmission at this constant test-stimulus intensity is usually monitored for a period of 15–20 min to assure a stable response.

Once the health of the hippocampal slice is confirmed, as indicated by a stable baseline synaptic response, LTP can be induced using any one of a wide variety of different LTP induction protocols. Many

popular variations include a single or repeated period of 1 s 100 Hz stimulation (with the delivery of the 100 Hz trains separated by 20 s or more) in which stimulus intensity is at a level necessary for approximately half-maximal stimulation (see Figure 4). This protocol gives robust LTP that lasts for essentially as long as the researcher can keep the hippocampal slice alive.

N-Methyl-D-Aspartate Receptor-Dependence of LTP

In 1983, Graham Collingridge made the breakthrough discovery that induction of these tetanus-induced forms of LTP are blocked by a blockade of a specific subtype of glutamate receptor, the *N*-methyl-D-aspartate (NMDA) receptor. Collingridge's fascinating discovery was that the glutamate analog amino-phosphono-valeric acid (APV), an agent that selectively blocks the NMDA subtype of glutamate receptor, can block LTP induction while leaving baseline synaptic transmission entirely intact.

This was the first experiment to provide a specific molecular insight into the mechanisms of LTP induction. The properties of the NMDA receptor that allow it to function in this unique role as a trigger of LTP are important (see later in this article). For our purposes right now, suffice it to say that pharmacological blockers of NMDA receptor function have allowed the definition of different types of LTP that can be selectively induced with various physiological stimulation protocols. For example, subsequent work has shown that an NMDA receptor-independent type of LTP can be induced in area CA1 and elsewhere in the hippocampus (mossy fibers to be precise), as well as other parts of the CNS.

Figure 3 Recording configuration and typical physiological responses in a hippocampal slice recording experiment. Electrode placements and responses from the stratum pyramidale (cell body layer) and stratum oriens (dendritic regions) are shown. In addition, the typical waveform of a population EPSP is illustrated, showing the stimulus artifact, fiber volley, and population EPSP. EPSP, excitatory postsynaptic potential. Early studies of LTP used mostly high-frequency (100 Hz) stimulation in repeated 1 s-long trains as the LTP-inducing stimulation protocol. Although these protocols are still widely used to good effect, it is clear that such prolonged periods of high-frequency firing do not occur physiologically in the behaving animal. LTP can also be induced by stimulation protocols that are much more like naturally occurring neuronal firing patterns in the hippocampus. To date, the forms of LTP induced by these types of stimulation have all been found to be NMDA receptor-dependent in area CA1. Two popular variations of these protocols are based on the natural occurrence of an increased rate of hippocampal pyramidal neuron firing while a rat or mouse is exploring and learning about a new environment. Under these circumstances, the hippocampal pyramidal neurons fire bursts of action potentials at approximately 5 bursts per second, or 5 Hz. This is the hippocampal theta rhythm that has been described in the literature. One variation of LTP-inducing stimulation that mimics this pattern of firing is referred to as theta-frequency stimulation (TFS) and consists of 30 s of a single stimulus delivered at 5 Hz. Another variation, theta-burst stimulation (TBS) consists of three trains of stimuli delivered at 20 s intervals, each train composed of 10 stimulus bursts delivered at 5 Hz, with each burst consisting of four pulses at 100 Hz. It is worth noting that these patterns of stimulation, which are based on naturally occurring firing patterns *in vivo*, lead to LTP in hippocampal slice preparations as well.

Pairing LTP

Of course, there are much more sophisticated electrophysiological techniques than extracellular recording that we can use to monitor synaptic function. Intracellular recording and patch clamp techniques that measure electrophysiological responses in single neurons have also been used widely in studies of LTP. In these recording configurations, we can induce synaptic potentiation using tetanic stimulation or

theta-pattern stimulation, and we can measure LTP as an increase in postsynaptic currents through glutamate-gated ion channels or as an increase in postsynaptic depolarization when monitoring the membrane potential.

Control of the postsynaptic neuron's membrane potential with cellular recording techniques also allows for some sophisticated variations of the LTP induction paradigm. In one particularly important series of experiments, it was discovered that LTP can be induced by pairing repeated single presynaptic stimuli with postsynaptic membrane depolarization, called pairing LTP.

The basis for pairing LTP comes from one of the fundamental properties of the NMDA receptor. The NMDA receptor is both a glutamate-gated channel and a voltage-dependent one. The simultaneous presence of glutamate and a depolarized membrane is necessary and sufficient (when the co-agonist glycine is present) to gate the channel. Pairing synaptic stimulation with membrane depolarization provided via the recording electrode (plus the low levels of glycine always normally present) opens the NMDA receptor channel and leads to the induction of LTP.

How is it that the NMDA receptor triggers LTP? The NMDA receptor is a Ca^{2+} channel, and its gating leads to elevated intracellular Ca^{2+} in the postsynaptic neuron. It is this Ca^{2+} influx that triggers LTP. The molecular processes triggered by this Ca^{2+} influx are quite complex and involve many of the basic molecular processes underlying synaptic transmission, including presynaptic functions such as glutamate release and postsynaptic functions such as neurotransmitter receptor regulation. A brief listing of some of the molecular sites subject to modification in LTP is given in Figure 5.

The gating of the NMDA receptor/channel involves a voltage-dependent Mg^{2+} block of the channel pore. Depolarization of the membrane in which the NMDA receptor resides is necessary to drive the divalent Mg^{2+}cation out of the pore, which then allows Ca^{2+} ions to flow through. Thus, the simultaneous occurrence of both glutamate in the synapse and a depolarized postsynaptic membrane is necessary to open the channel and allow LTP-triggering Ca^{2+} into the postsynaptic cell.

These properties, glutamate dependence and voltage dependence, of the NMDA receptor allow it to function as a coincidence detector. This is a critical aspect of NMDA receptor regulation, and this allows for a unique contribution of the NMDA receptor to information processing at the molecular level. Using the NMDA receptor, the neuron can trigger a unique event, Ca^{2+} influx, specifically when a particular synapse is both active presynaptically (glutamate is present in the synapse) and postsynaptically (when the membrane is depolarized).

This confers a computational property of associativity on the synapse. This attribute is nicely illustrated by pairing LTP, as already described, when low-frequency synaptic activity paired with postsynaptic depolarization can lead to LTP. The associative property of the NMDA receptor allows for many other types of sophisticated information processing as well, however. For example, activation of a weak input to a neuron can induce potentiation, provided a strong input to the same neuron is activated at the same time. These particular features of LTP induction have stimulated a great deal of interest because they are reminiscent of classical conditioning with depolarization and synaptic input roughly corresponding to unconditioned and conditioned stimuli, respectively.

Figure 5 Potential sites of synaptic modification in LTP. AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; Glu, glutamate; LTP, long-term potentiation. Figure by J. David Sweatt and Sarah E. Brown. Reproduced from Sweatt D (2003) *Mechanisms of Memory*. London: Elsevier, with permission from Elsevier.

LTP Can Be Divided into Phases

Contemporary models divide very long-lasting LTP (i.e., LTP lasting in the range of 5–6 h) into at least two phases. LTP comprising both phases can be induced with repeated trains of high-frequency stimulation in area CA1, and the phases are expressed sequentially over time to constitute what we call LTP. Late LTP (L-LTP) is hypothesized to be dependent for its induction on changes in gene expression, and this phase of LTP lasts many hours. Early LTP (E-LTP) is probably subserved by persistently activated protein kinases; it starts at around 15 min or less posttetanus and is over after approximately 2–3 h.

E-LTP and L-LTP refer to different temporal phases of LTP. These two phases are subserved by different maintenance mechanisms of different time courses and durations. Maintenance, or more specifically a maintenance mechanism, refers to the persisting biochemical signal that lasts in the cell. This persisting biochemical signal acts on an effector, for example, a glutamate receptor or the presynaptic release machinery, resulting in the expression of LTP. In contrast, induction refers to the transient events serving to trigger the formation of LTP.

It is important to keep in mind that, depending on the design of the experiment, induction, maintenance, and expression can be differentially inhibited (see Figure 6). The simplest type of experiment does not do this. For example, if we apply an enzyme inhibitor (or knock out a gene) before, during, and after the period of LTP-inducing high-frequency stimulation, this manipulation may block LTP; however, this does not distinguish whether the missing activity is required for the induction, the expression, or the maintenance of LTP. To distinguish among these possibilities, imagine instead that we apply the inhibitor selectively at different times during the experiment. If inhibitor is applied only during the tetanus and then is washed out and it blocks the generation of LTP, we can conclude that the enzyme is necessary for LTP induction. If the inhibitor is applied after the tetanus and it reverses the potentiation, it may be blocking either the maintenance or expression of LTP. Transient application of an inhibitor after tetanus may block synaptic potentiation, but the potentiation recovers after removal of the inhibitor. This is a blockade of LTP expression. However, if the inhibitor causes the potentiation to be lost irreversibly, the inhibitor has then by definition blocked the maintenance of LTP.

LTP outside the Hippocampus

The abundance of literature dedicated to studying LTP in the hippocampus might lead a newcomer to the field to suppose that LTP is somehow restricted to these synapses. However, plasticity of synaptic function, including phenomena such as LTP and long-term depression (LTD), is the rule rather than the exception for most forebrain synapses. LTP outside the hippocampus has been studied mostly in the cerebral cortex and the amygdala. The likely functional roles for LTP at these other sites are quite diverse, but two specific examples are worth highlighting. LTP-like processes in the cerebral cortex play a role in the activity-dependent development of the visual system and other sensory systems. LTP in the amygdala has received prominent attention as a mechanism contributing to cued fear conditioning.

Figure 6 The different experimental approaches to dissecting the effects on the biochemical mechanisms subserving LTP induction, maintenance, or expression. EPSP, excitatory postsynaptic potential; LTP, long-term potentiation. Reproduced from Sweatt D (2003) *Mechanisms of Memory*. London: Elsevier, with permission from Elsevier.

The role of LTP in amygdala-dependent fear conditioning, in fact, is the area for which the strongest case can be made for a direct demonstration of a behavioral role for LTP. It is important to bear in mind that cortical LTP and amygdalar LTP probably exhibit some mechanistic differences from the NMDA receptor-dependent LTP that we are focusing on.

Depotentiation and LTD

If synapses can be potentiated and this potentiation is very long-lasting, over time the synapses will be driven to their maximum synaptic strength. In this condition, there is no longer synaptic plasticity and no further capacity for that synapse to participate in synaptic-plasticity-dependent processes. Worse, over the lifetime of an animal synapses will by random chance experience LTP-inducing conditions (presynaptic activity coincident with a postsynaptic action potential, for example) numerous times. If LTP is irreversible, ultimately every synapse will be maximally potentiated – obviously not a desirable condition vis-à-vis memory storage.

Consideration of this conundrum raises two implications. First, synapses that are involved in lifelong memory storage must be rendered essentially aplastic. In order to have good fidelity of memory storage over the lifetime of an animal, a synapse involved in permanent memory storage must be rendered immutable to a change in synaptic strength due to the random occurrence of what would normally be LTP-inducing stimulation.

But what about synapses such as those in the hippocampus that are not sites of memory storage but, rather, whose plasticity is part of the active processing of forming new long-term memories? In order to retain their plasticity and, hence, their capacity to contribute to memory formation, their potentiation must be reversible. Schaffer collateral synapses can undergo activity-dependent reversal of LTP, a phenomenon termed depotentiation (see Figure 7). Another activity-dependent way to decrease synaptic strength is LTD, the mirror image of LTP. LTD is a long-lasting decrease of synaptic strength below the baseline. Using logic similar to that of the first paragraph of this section, the phenomenon of dedepression of synaptic transmission is implied, although this has not been widely studied at this point.

As a practical matter, it is often difficult to separate depotentiation from LTD experimentally. For example, a baseline response in hippocampal slices or *in vivo* probably is a mixture of basal synaptic activity and activity at previously potentiated synapses. Moreover, for the most part the stimulation protocols used to induce depotentiation are variations of the protocols used to induce LTD. Nevertheless, mechanistic investigations have made clear that depotentiation and LTD use different mechanisms and thus must be considered distinct processes.

Physiological LTD (and depotentiation) induction protocols generally involve variations of repetitive 1-Hz stimulation. A common protocol is to deliver 900 stimuli at 1 Hz, but there are also LTD protocols that use random small variations in frequency in the 1-Hz region and variations that use paired-pulse stimuli delivered at 1 Hz. Synaptic depression appears to be fairly robust *in vivo*, but it is quite difficult to induce in hippocampal slices from adult animals. LTD *in vitro* is almost always studied using slices from immature animals or cultured immature neurons, and it is possible that LTD as it is currently studied *in vitro* is largely a manifestation of what is normally a developmental mechanism.

One ironic aspect of the LTP/LTD story is that both phenomena at Schaffer collateral synapses can be blocked by NMDA receptor antagonists. This suggests that Ca^{2+} influx triggers both processes, and indeed current models of LTD induction hypothesize that LTD is caused by an influx of Ca^{2+} that achieves a lower level than that needed for LTP induction. This lower level of Ca^{2+} is hypothesized to selectively activate protein phosphatases and, by this mechanism, lower synaptic efficacy.

Another very different type of LTD is cerebellar LTD. Cerebellar LTD occurs at synapses on Purkinje neurons in the cerebellar cortex. Cerebellar LTD is a very interesting phenomenon because its behavioral role is much better understood than the hippocampal plasticity phenomena. Among other things, cerebellar LTD is involved in associative eyeblink conditioning, a cerebellum-dependent classical conditioning paradigm. Considerable progress has been made in investigating the roles and mechanisms of cerebellar LTD as well.

Summary

Like learning, LTP can be defined as a long-lasting change in output in response to a transient input. The persistence of this effect has been demonstrated to extend many hours *in vitro* and several weeks *in vivo*. We do not know how LTP relates to memory, and there is evidence for and against the hypothesis that hippocampal LTP is involved in memory. Regardless, it is the best-understood example of long-lasting synaptic plasticity in the mammalian CNS, and it is a model for how long-lasting memory-associated changes are likely to occur in the CNS. Studying LTP has yielded valuable insights into the mechanisms of plasticity that underlie learning and memory in

Figure 7 Depotentiation and LTD: (a) LTP, depotentiation, LTD, de-depression, and combinations of these; (b) LTD and depotentiation in hippocampal neurons, shown in simultaneous recording of slices receiving baseline stimulation (control, open circles) and 1-Hz stimulation (closed circles); (c) LTD, depotentiation, and dephosphorylation. In (b), regulation of distinct AMPA receptor phosphorylation sites during bidirectional synaptic plasticity is shown. In (c), homosynaptic LTD in CA1 is associated with dephosphorylation of GluR1 at a PKA site (ser (S)845); depotentiation gives dephosphorylation at a CaMKII/PKC site (S831). the brain. The bona fide changes in neuronal connections that occur *in vivo* may or may not be identical to LTP as it is presently studied in the laboratory, but this does not diminish its utility as a cellular model system for studying lasting neuronal change in the mammalian CNS.
