Long-Term Potentiation (LTP): Mossy Fiber cAMP-Dependent Presynaptic LTP

A Contractor, Northwestern University Feinberg School of Medicine, Chicago, IL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Mossy fiber synapses in the hippocampus are formed by the axons of the granule cells and their postsynaptic targets in the hilar and CA3 regions of the hippocampus. The excitatory synapses formed with the principal pyramidal neurons exhibit a number of unique structural and functional properties, including a distinctive form of long-term potentiation (LTP) that is expressed in the presynaptic terminal and is dependent on cyclic adenosine monophosphate (cAMP) signaling. Here the current state of our understanding of this form of synaptic plasticity is reviewed.

The Mossy Fiber Synapse

The hippocampus is a widely studied structure because of its well-described involvement in memory processing and formation. The circuitry of excitatory synaptic connections in this structure is relatively simple with an almost linear progression in connectivity, and therefore information flow, between the granule neurons in the dentate gyrus, which receive the largest proportion of extrinsic connections from the cortex, through the CA3 and CA1 regions and outputting to the subiculum and cortex. However, this simplified scheme in reality is somewhat more complex; in the CA3 region in particular, extensive axon collaterals of the pyramidal neurons make synapses onto other pyramidal neurons and local circuit interneurons. Neurons in the CA3 also receive a direct perforant path connection from the cortex. While the absolute number of collateral synapses per pyramidal neuron is much greater, the connection between the granule cell axons, termed the mossy fibers, and the CA3 pyramids has the greatest impact on CA3 pyramidal excitability. The mossy fiber axons extend from the dentate gyrus traversing through the hilus and projecting through the stratum lucidum. This long axonal projection (upwards of 3 mm in the rat) forms en passant connections in the CA3 with the proximal dendrites of the pyramidal neurons and the local circuit interneurons. In a stunning example of target cell-specific synaptic segregation, the connections to the pyramidal neuron and interneuron have completely divergent functional properties. Connections onto the pyramidal neurons are formed by large mossy fiber boutons that are typically 2–8 μm in diameter. From these large synaptic terminals, filopodial extensions reach out tens of micrometers to form synaptic contact exclusively with interneurons. The main mossy fiber bouton apposes complex, multi-headed spines, termed thorny excresences, which extend from the proximal dendrites of the CA3 pyramidal neurons; each terminal contains multiple release sites that are apposed to multiple postsynaptic densities on the same spine. This article focuses almost exclusively on the mossy fiber connection to the principal CA3 pyramidal neurons.

Expression Mechanisms of Mossy Fiber LTP

Long-term potentiation (LTP) was first described in the hippocampus in pioneering work from Tim Bliss and Terje Lømo in the early 1970s. These seminal studies quickly led to a large and sustained effort to describe a synaptic phenomenon that is now widely believed to be a cellular correlate of memory formation. LTP at the mossy fiber to CA3 pyramidal neuron synapse was described a decade after these initial findings and soon proved to be mechanistically distinct from LTP in the CA1 region of the hippocampus and the dentate gyrus. Several important findings about the induction of mossy fiber LTP were described in these early studies. For instance, several groups found that *N*-methyl-D-aspartate (NMDA) receptor activation, a defining characteristic of LTP at most other synapses, was not required for the induction of mossy fiber LTP. Whereas some aspects of mossy fiber LTP remain controversial, in particular the requirement of postsynaptic Ca^{2+} signaling for induction, other aspects, such as the expression mechanisms, are more firmly established. Several coincident lines of evidence have confirmed that mossy fiber to CA3 pyramidal neuron LTP is expressed in the presynaptic terminal as a long-lasting increase in glutamate release probability. Among these analyses are clear reductions in paired pulse ratio, increased rate of open channel block of NMDA receptors, and quantal variance analysis, which strongly support an increase in transmitter release probability following induction of LTP.

Involvement of cAMP Signaling in Mossy Fiber LTP

A complete description that incorporates all the published findings for the expression mechanisms of

mossy fiber LTP has not been established, and it seems likely that a consensus on a simple unitary model is likely to be elusive because several parallel pathways may underlie mossy fiber LTP. Despite this, the involvement of several molecules has been firmly established using molecular/genetic techniques and more acute pharmacological manipulation. A major signaling pathway that has overwhelming evidence supporting its involvement in the expression of mossy fiber LTP is the cAMP cascade resulting in the activation of the cAMP-dependent protein kinase PKA. The earliest evidence that cAMP might be involved in mossy fiber LTP came from pharmacological manipulations. Application of the diterpene forskolin, which directly activates adenylyl cyclase to elevate cAMP, produces a long-lasting enhancement of mossy fiber transmission. Similarly, analogs of cAMP also potentiate mossy fiber transmission. Forskolin potentiation and activity-induced LTP mutually occlude one another, suggesting, but not implicitly confirming, that elevation of cAMP is involved in mossy fiber LTP. Further support for a role of cAMP elevation in mossy fiber LTP comes from studies in knockout mice. Evidence suggests that elevations in presynaptic Ca^{2+} are required for the LTP cascade, specifically through the activation of presynaptic R-type voltage-dependent Ca^{2+} channels. Therefore, the focus has been on Ca^{2+}-activated forms of adenylyl cyclase as the effectors of this rise in cAMP. There are two Ca^{2+}-sensitive adenylyl cyclases expressed in the central nervous system (CNS): adenylyl cyclase 1 (AC1) and adenylyl cyclase 8 (AC8). Knockout mice for either one of these proteins show impaired mossy fiber LTP, further supporting the role of cAMP signaling at this synapse.

Downstream Targets of cAMP

Elevations in cAMP may have several potential downstream targets that could mediate changes in release probability. At the mossy fiber synapse, the emphasis has been on the cAMP-dependent protein kinase PKA; however, it is also worth mentioning the other potential effectors that might be involved. At the neuromuscular junction of both crayfish and *Drosophila*, cAMP elevation potentiates transmitter release by acting directly on presynaptic hyperpolarization-activated cyclic nucleotide-gated channels that underlie the hyperpolarization-activated cation channel (*I*h). A similar role for presynaptic *I*h in mossy fiber LTP is controversial. Incubation of ZD7288, an *I*h channel blocker, reduces LTP and forskolin-mediated potentiation of mossy fiber transmission. However, the interpretation of this finding is complicated, as ZD7288 was found to have nonspecific actions on synapses and by itself causes a robust depression of mossy fiber basal synaptic transmission. Presynaptic *I*h therefore is unlikely to play a substantive role in mossy fiber LTP.

Recently there has been considerable interest in another downstream target of cAMP: the cAMP-sensitive guanine nucleotide exchanging factor (GEF) Epac. This GEF has been implicated in synaptic potentiation at the medial nucleus of the trapezoid body (MNTB) neurons in the brain stem and also in potentiation of transmission at the *Drosophila* neuromuscular junction. Epac is expressed at high levels in the hippocampus; however, thus far there has not been any suggestion that it plays a role in transmitter release or potentiation at any hippocampal synapse, including at mossy fibers.

The more commonly accepted downstream target of cAMP is PKA, and, as alluded to earlier, there is substantial evidence that this kinase plays a central role in mossy fiber LTP. Inhibitors of PKA block mossy fiber LTP, and targeted mutation of either regulatory or catalytic subunits of PKA has specific effects on mossy fiber LTP. While it is commonly assumed that PKA in the presynaptic terminal plays a critical role, it is worth noting that inclusion of PKA inhibitory peptide in the postsynaptic cell can also block the establishment of mossy fiber LTP, possibly suggesting a more complex scheme in which both pre- and postsynaptic PKA activity is required for the full expression of mossy fiber LTP.

Potential Substrates of PKA Involved in Elevation of Transmitter Release

All available evidence seems to suggest that PKA is central to mossy fiber LTP; therefore, there has been a concerted effort to uncover the molecular substrates of this enzyme that could underlie the sustained increase in transmitter release. Two molecules that have received particular scrutiny for their role in mossy fiber LTP are Rab3a and RIM1α. Rab3a is a vesicle-associated GTPase which has been implicated in vesicle fusion. Rab3a is not itself a substrate of PKA, at least in *in vitro* assays, but it interacts with other synapse-associated proteins that are. RIM1α is an active zone protein which is thought to be a presynaptic scaffold. The involvement of both these molecules in mossy fiber LTP has been determined using examination of knockout mice. The model that has emerged from these studies suggests that phosphorylation of RIM1α and its interaction with Rab3a are required for the long-lasting increase in neurotransmitter release. While the exact roles of

these proteins are still unknown, the clear impairment in mossy fiber LTP in knockout mice put these two molecules at the center of efforts to uncover the molecular basis for plasticity at this synapse. However, several observations suggest that this model may be somewhat simplistic. One assumption from this model might be that if PKA and Rab3a converge upon RIM1α, raising cAMP with forskolin would abrogate the synaptic potentiation observed with this diterpene in RIM1α knockout mice. However, normal forskolin-mediated potentiation is observed, suggesting that other parallel mechanisms may in fact mediate cAMP signaling. While it remains unclear what the precise nature of this mechanism might be, several potential PKA substrates have been excluded as mediators of mossy fiber plasticity. Knockout mice in which synapsin I and II or rabphilin are ablated express normal mossy fiber LTP, suggesting that these three PKA substrates play no role. Therefore, while there is evidence that activation of PKA phosphorylates RIM1α and possibly facilitates an interaction with the vesicle-associated protein Rab3a resulting in a sustained increase in transmitter release, this model does not integrate all the available data from mechanistic studies and is likely to undergo further revision as additional studies uncover more information about how PKA exerts its actions in mossy fiber LTP.

State-Dependent cAMP Signaling at Mossy Fiber to Interneuron Synapses

As noted previously, the mossy fiber axons make contact onto both pyramidal neurons and stratum lucidum interneurons in the CA3 region. These two synaptic connections demonstrate a remarkable segregation in their functional properties. High-frequency stimulation of mossy fibers, which causes LTP at pyramidal cell synapses, actually depresses mossy fiber interneuron synapses through activation of presynaptic metabotropic glutamate receptor 7 (mGluR7) and protein kinase C (PKC) signaling. Naive interneuron synapses are not potentiated by elevating cAMP by application of forskolin, suggesting that these synapses are under regulation by fundamentally different mechanisms despite being formed by the same axons and being closely spatially arranged (filopodial synapses onto interneurons emanate from the main mossy fiber boutons that form the synapses onto the pyramidal neuron). However, one interesting recent report demonstrated that activation of mGluR7 and depression of the mossy fiber interneuron synapse uncovers a subsequent sensitivity to cAMP-dependent potentiation. This state-dependent responsiveness to cAMP suggests that this signaling pathway is more ubiquitous in mossy fibers than was originally thought.

Mossy Fiber LTD cAMP Dependency

The functional inverse of LTP is long-term depression (LTD) of synaptic transmission. A simplistic view of LTD is that it should also engage the same molecular machinery as LTP, but in reverse. While it turns out that things are usually more complicated, there are many examples of molecules that have central roles in both LTD mechanisms and LTP. At the mossy fiber to pyramidal cell synapse, LTD involves cAMP signaling and therefore may engage at least some of the same machinery as LTP. Mossy fiber LTD can be induced by long trains of low-frequency stimulation or by the application of group II mGluR agonist combined with activity. LTD at this synapse is blocked by inhibitors of PKA. In initial studies it was also reported that LTD was absent in Rab3a knockout mice. These results had established a model that seemed to involve the same molecular players as mossy fiber LTP. However, later studies by the same group could not replicate this finding in Rab3a knockout mice, bringing this model into some doubt. Examination of knockout mice for the other prominent player in mossy fiber LTP, RIM1α, is also consistent with a separate molecular pathway for LTD. In fact, the magnitude of mossy fiber LTD in RIM1α knockout mice is enhanced, possibly due to a masked potentiation occurring in parallel with LTD with low-frequency stimulation at some synapses. Therefore, it seems that LTD of mossy fiber to pyramidal cell synapses, while involving cAMP signaling, is unlikely to be an inverse process of LTP, but instead involves an alternate pathway whose components are still unknown.

Comparison with Other cAMP-Dependent Forms of LTP

Three other synapses have been demonstrated to have forms of LTP similar to that at the mossy fiber pyramidal cell synapse. Corticothalamic fibers originating in layer VI of the neocortex form synapses onto neurons in the ventrobasal thalamus. LTP at corticothalamic synapses is NMDA receptor independent and expressed presynaptically. These synapses are also subject to forskolin potentiation, and LTP can be blocked by PKA inhibitors. Beyond these initial finding it is not clear whether corticothalamic synapses utilize the same molecular machinery as mossy fibers for the expression of LTP.

In the cerebellum, parallel fiber axons of the granule cells form synapses onto Purkinje cell dendrites in

the molecular layer. Parallel fiber transmission is potentiated by forskolin, which occludes subsequent LTP. Further, parallel fiber LTP induction is blocked by inhibitors of PKA and is almost absent in RIM1α knockout mice, further suggesting that parallel fibers and mossy fibers utilize similar LTP mechanisms. In a reduced co-culture system, reintroduction of RIM1α rescued parallel fiber LTP, but expression of a mutant of a putative phosphorylation site of RIM1α (serine 413) did not rescue and itself acted as a dominant negative to block LTP in wild-type cultures. These experiments have further reinforced the central role of phosphorylation of RIM1α in the expression of presynaptic cAMP-dependent forms of LTP.

A final example of presynaptic LTP that is dependent on cAMP signaling is at the corticoamygdala synapse. Although the mechanisms underlying this form of LTP are likely to be different than those at mossy fiber synapses (for instance, NMDA receptor activation is required for induction), some similarities exist. Synaptic transmission is potentiated by forskolin, and this occludes subsequent LTP induction, and PKA inhibitors also block LTP. Interestingly, corticoamygdala LTP is impaired in Rab3a knockout mice but is not significantly impaired in RIM1α knockouts, perhaps suggesting a different signaling pathway through a different, as yet unidentified, PKA substrate.

Outstanding Questions

While evidence from numerous studies has begun to dissect the molecular pathways that underlie LTP at mossy fiber synapses, it seems we are some way from consolidating all the available evidence into a single model. There is strong evidence that cAMP signaling plays a central role in the expression mechanisms; however, it is possible that it exerts its effects through multiple pathways. Evidence from knockout studies has demonstrated the importance of Rab3a and RIM1α, the putative downstream substrate of PKA, in mossy fiber LTP; however, unpredictably, forskolin potentiation is still observed in these mice. The role of presynaptic *I*h has been disputed at mossy fiber synapses, but at least at other synapses it does play a role in regulating transmitter release. Similarly, many of the early studies have relied upon inhibitors whose specificity is somewhat unreliable. There are numerous inconsistencies in the literature regarding the induction and expression of mossy fiber LTP. Among these is the finding that postsynaptic mechanisms may play a role in the induction process. Recently there has been evidence that ephrin signaling is also required for mossy fiber LTP. It remains to be determined whether a consensus can be established and whether in fact mossy fiber LTP might turn out to be more complex than first thought.

Long-Term Potentiation (LTP): NMDA Receptor Role

A J Doherty, S M Fitzjohn, and G L Collingridge, University of Bristol, Bristol, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The subtype of glutamate receptor known as the *N*-methyl-D-aspartate (NMDA) receptor is the trigger for both long-term potentiation (LTP) and long-term depression (LTD) at the majority of synapses in the central nervous system (CNS), where long-lasting synaptic plasticity has been observed. The role of NMDA receptors (NMDARs) in synaptic plasticity was first identified, and has been most extensively studied at, the synapses made between CA3 and CA1 pyramidal neurons in the hippocampus, the Schaffer collateral–commissural pathway. While most is known about LTP at these CA1 synapses, it seems that the principles discovered here apply elsewhere in the brain. The following discussions pertain to LTP at CA1 synapses.

Glutamate Receptors and Synaptic Transmission

It is commonly considered that α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPARs) mediate synaptic transmission and NMDARs trigger alterations in synaptic efficiency. However, the reality is more complex. AMPARs do indeed mediate the majority of the response to low-frequency stimulation. However, NMDARs contribute significantly to high-frequency synaptic transmission. Given that in the conscious animal CA3 neurons often discharge in high-frequency bursts, then NMDARs are likely to play a major role in the transmission of synaptic information within the CA1 area. It is also sometimes mistakenly considered that only AMPARs mediate the response that is modified during LTP. While it is true that it is often the AMPAR-mediated response that is studied, it is equally true that the NMDAR-mediated component of synaptic transmission has the capacity to undergo LTP.

NMDAR Properties Govern Their Role in Synaptic Transmission

The NMDAR has unique properties that govern its role in synaptic processing. First, it is strongly antagonized by micromolar concentrations of Mg^{2+}. Second, this block is highly voltage dependent. Third, the NMDAR-mediated conductance has slow kinetics, compared with the AMPAR-mediated response. Fourth, the NMDAR not only passes monovalent cations but also has a significant permeability to Ca^{2+}.

During low-frequency transmission there is rapid activation of AMPARs. However, while L-glutamate binds to NMDARs, they are largely blocked by Mg^{2+}, which is present in the synaptic cleft at around 1 mM (Figure 1). This prevents NMDARs from contributing appreciably to the synaptic response. During high-frequency transmission there is a sustained depolarization, due in part to the temporal summation of AMPAR-mediated excitatory postsynaptic potentials (EPSPs), and this alleviates the voltage-dependent Mg^{2+} block to enable NMDARs to contribute to the synaptic response. Since they have a slow decay phase, the NMDAR-mediated EPSPs summate very effectively.

Induction of LTP

Induction by High-Frequency Stimulation

Conditions that enable the activation of NMDARs can result in the induction of LTP. The most commonly used induction stimulus is a continuous high-frequency train (tetanus), sometimes delivered more than once. This provides the depolarization to transiently relieve the Mg^{2+} block of NMDARs. The Ca^{2+} that then enters the neuron through the NMDARs provides the initial trigger for the plastic change. Although a tetanus typically comprises 100 stimuli or more (e.g., 100 Hz, 1 s), far fewer stimuli can induce LTP, provided that they are appropriately timed. One such protocol is the delivery of brief high-frequency bursts (e.g., four shocks at 100 Hz) with an interburst frequency of around 5 Hz (i.e., an interburst interval of 200 ms). This pattern of activity mimics the physiological activity that occurs during the theta rhythm, a frequency of activation observed in the electroencephalogram (EEG) when animals are exploring their environment. The minimal induction protocol is the delivery of a single priming stimulus followed approximately 200 ms later by a single burst (which could comprise as few as two stimuli, though typically four are used). Thus, under optimal conditions LTP can be induced by three to five stimuli.

Induction by Pairing

LTP can also be induced by pairing. This is achieved by maintaining low-frequency stimulation but depolarizing the neuron artificially by injecting current through

Figure 1 *N*-Methyl-D-aspartate receptors (NMDARs) are activated by high-frequency stimulation. Under basal conditions, NMDAR activity is blocked due to voltage-dependent binding of Mg^{2+} ions. A single stimulus results in the release of L-glutamate and activation of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPARs) but does not provide sufficient depolarization to repel the Mg^{2+} ions. High-frequency stimulation results in a more sustained depolarization of the postsynaptic terminal, leading to the release of the Mg^{2+} block and an increase in cytosolic Ca^{2+} ions. The rise in Ca^{2+} concentration may be localized to the activated synapse, ensuring that only the activated synapse undergoes long-term potentiation.

the recording electrode. Typically, approximately 50 pairings of low-frequency stimulation and depolarization are employed. LTP can also be induced by the pairing of appropriately timed presynaptic and postsynaptic action potentials. The common feature of all of these induction protocols is that they enable sufficient depolarization to transiently relieve the Mg^{2+} block of NMDARs. Once this occurs, it enables Ca^{2+} to enter the synapse through the NMDARs in sufficient amounts to trigger the biochemical cascades that result in enhanced synaptic transmission.

NMDAR Activation without LTP

However, activation of NMDARs does not necessarily induce LTP. Under conditions whereby the LTP process has been saturated (by prior periods of LTP induction), protocols that normally induce LTP result in no change in synaptic strength. In addition, certain patterns of activation can activate NMDARs but induce long-term depression rather than LTP. If a pathway has already undergone LTP, then these same patterns of activation may induce depotentiation (DP) of the potentiated response. Typically, NMDAR-dependent LTD and DP are induced by prolonged periods of low-frequency stimulation (1–3 Hz). Finally, an intermediate frequency (e.g., 5 Hz) will neither induce LTP nor LTD, while still activating NMDARs.

Features of NMDAR-Dependent LTP

Input Specificity

NMDAR-dependent LTP has several hallmark features. Input specificity refers to the property that if two inputs are activated and converge on a population of neurons, or indeed a single neuron, but an induction protocol is delivered to just one of the inputs, then only that input will undergo LTP. The other input typically will not change its efficiency of transmission, or under certain circumstances may be depressed via a process known as heterosynaptic depression. Input specificity is an important property. It means that the unit of modification is the activated input, not the entire neuron. This implies that the unit of information storage can be as small as a single synapse. Input specificity is due to the requirement for L-glutamate to activate NMDARs and the fact that the Ca^{2+} that permeates NMDARs does not spread very far. Therefore, when a neuron is sufficiently depolarized, those synapses that are activated by synaptically released L-glutamate can undergo LTP. Nearby neighbors may also undergo LTP if either the synaptically released L-glutamate 'spills over' in sufficient amounts to activate enough NMDARs or if the Ca^{2+} spreads beyond the activated spine. In its purest form, LTP is restricted to the activated inputs.

Cooperativity

Cooperativity refers to the need to stimulate multiple afferent fibers to induce LTP. Experimentally this is observed as the failure of a 'weak tetanus' to induce LTP, while a 'strong tetanus' that activates more fibers is able to induce LTP. Cooperativity can be explained by the need for multiple inputs to be activated around the same time to provide sufficient depolarization to remove enough of the Mg^{2+} block to enable the induction of LTP. This property provides a threshold of activity that has to be exceeded for synaptic plasticity to occur. CA3 neurons typically fire in brief, synchronous bursts and this is presumably to exceed the cooperativity threshold to enable LTP to occur at CA1 synapses.

Associativity

Associativity is an extension of cooperativity, but whereby the 'strong tetanus' is delivered to an independent input. There is a critical timing window in which the strong input can be delivered after the weak input and still be effective. Associativity is explained by the weak input providing the necessary L-glutamate but insufficient depolarization, whereas the 'strong input' provides the (additional) depolarization to sufficiently alleviate the Mg^{2+} block. The associative depolarization could be provided by a second glutamatergic input or by a different neurotransmitter system that provides or enables depolarization at the critical time. Experimentally, the depolarization can be provided by the recording electrode (in a pairing experiment) and this can permit a single input onto a single neuron to undergo LTP. Thus the requirement for synchronous activity to induce LTP is to provide sufficient depolarization. In conclusion, the Mg^{2+} block and Ca^{2+} dependence of the NMDAR explain the properties of input specificity, cooperativity, and associativity.

Role of γ-Aminobutyric Acid Inhibition in LTP

Role of Postsynaptic γ-Aminobutyric Acid Receptors

γ-Aminobutyric acid (GABA) inhibition plays a pivotal role in LTP. When several afferents are activated at a low frequency the EPSP is mediated essentially exclusively by AMPARs. This is only because of synaptic inhibition, which is also activated via the excitation of feed-forward interneurons. If GABA receptors are blocked pharmacologically, then the AMPA-mediated EPSP is prolonged and NMDARs contribute much more substantially to the later part of a composite EPSP. Thus, it is the hyperpolarization by GABA to maintain, and indeed intensify, the Mg^{2+} block that prevents NMDARs contributing to any appreciable extent during low-frequency transmission. Thus, blocking GABA inhibition can facilitate the induction of LTP. However, the inhibition of GABA is not just some pharmacological curiosity. During the more physiological patterns of induction (priming and theta) there is an activity-dependent depression of GABA inhibition that is required to enable sufficient activation of NMDARs. This activity-dependent depression is mediated largely by the activation of a presynaptic $GABA_B$ autoreceptor.

Role of $GABA_B$ Autoreceptors

During low-frequency stimulation, GABA is released and evokes a biphasic inhibitory postsynaptic potential (IPSP), mediated by $GABA_A$ and $GABA_B$ receptors, to restrict the synaptic activation of NMDARs (Figure 2). Some of the GABA that is released activates a presynaptic $GABA_B$ autoreceptor, which inhibits subsequent GABA release. During low-frequency transmission this has no effect on GABA transmission, since the effect fully recovers within a second or so. But during high-frequency transmission the autoreceptor mechanism leads to a depression in GABA inhibition. The maximum effect occurs after around 200 ms, which explains the effectiveness of this interval for theta and priming-induced LTP. The $GABA_B$ autoreceptor mechanism is essential for the induction of LTP under these conditions, since antagonizing this receptor completely blocks priming-induced LTP. However, the depression of synaptic inhibition only occurs for a few stimuli as the synapse undergoes an activity-dependent facilitation, and, when sufficient stimuli are delivered, a depolarizing potential is generated. Therefore when more artificial induction protocols are used, such as tetanus, blocking $GABA_B$ autoreceptors has no effect on the induction of LTP. Given that in the exploring animal there are brief periods of synchronized high-frequency activity occurring at the theta frequency, it is likely that $GABA_B$ autoreceptors are critically involved in the induction of LTP *in situ*.

Signaling Mechanisms Involved in LTP

The induction of LTP requires an elevation of postsynaptic Ca^{2+}. This Ca^{2+} enters the synapse via the activated NMDARs, where the Ca^{2+} signal may be greatly magnified by Ca^{2+}-induced Ca^{2+} release from intracellular stores. It then activates various kinases. Several protein kinases have been implicated in the induction of LTP. These include Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII), protein kinases A and C (PKA, PKC), protein tyrosine kinase (PTK), mitogen-activated protein kinase (MAPK), and

Figure 2 Role of γ-aminobutyric acid (GABA ergic) inhibition in the induction of long-term potentiation. (a) Activation of glutamatergic inputs onto CA1 hippocampal neurons is accompanied by the activation of inhibitory GABAergic interneurons. These in turn provide an inhibitory input onto the pyramidal cells. GABA release is delayed with respect to glutamate release, as there are two synapses for the signal to pass through, rather than one. This results in a rapid depolarization due to α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor (AMPAR) activation followed by a rapid inhibition due to GABA$_A$ receptor (GABA$_A$R) activation, ensuring the maintenance of the Mg^{2+} block. Sustained inhibition is then maintained by activation of postsynaptic GABA$_B$Rs. Simultaneously, activation of presynaptic GABA$_B$ autoreceptors results in a temporary inhibition of GABA release (EPSP, excitatory postsynaptic potential). (b) A burst of high-frequency stimulation while GABA release is reduced (200 ms after the priming stimulus) results in sustained postsynaptic depolarization, overcoming the weakened inhibitory inputs. This sustained depolarization results in the release of Mg^{2+} from the *N*-methyl-D-aspartate receptor (NMDAR) and the influx of Ca^{2+} ions, leading to the induction of long-term potentiation.

phosphatidylinositol 3-kinase (PI3K). Why the need for multiple kinases? It seems that different kinases may be important at different developmental stages and for different phases of LTP. A full understanding of how kinases lead to persistent alterations in synaptic strength during LTP is far from complete.

Expression Mechanisms Involved in LTP

Phases of LTP

Numerous studies have attempted to determine how AMPAR-mediated synaptic transmission is enhanced in LTP, and multiple mechanisms have been identified.

It is clear that different mechanisms occur at different stages of the LTP process. For example, the earliest phase of LTP, often referred to as short-term potentiation (STP) and most prevalent when a high-frequency tetanus is used to induce the process, probably involves an increase in L-glutamate release. The next phase, commonly referred to as early-phase LTP (E-LTP), most probably involves an alteration in AMPAR number or properties. A similar alteration in AMPAR function may also account for the next, protein synthesis-dependent phase of LTP, known as late-phase LTP (L-LTP). However, the expression mechanisms of LTP seem also to be developmentally regulated, with presynaptic mechanisms appearing to play a more important role in E-LTP within the first week of life.

Mechanisms of LTP Expression

Two ways in which AMPARs function at synapses may be directly altered during LTP have been identified. There can be an increase in the number of receptors or an increase of the efficiency of the receptors (Figure 3). In the latter case, the mechanism involves an increase in the single-channel conductance of the receptors, so that they pass more current in unit time. The extent to which this results from a modification of receptors already inserted in the synapse – for example, by phosphorylation, or by the exchange of high- for low-conductance receptors – is not yet known. One idea is that AMPARs lacking the GluR2 subunit can be transiently inserted during LTP. This has the effect of both increasing single-channel conductance and providing an activity-dependent Ca^{2+} signal, by permeation through the now Ca^{2+}-permeable AMPARs. This Ca^{2+} signal might then drive the insertion of additional Ca^{2+}-impermeable AMPARs.

A number of proteins that interact directly with AMPARs have been found to affect their targeting and stabilization at synapses, or their functional properties. These include two membrane-associated guanylate kinases (MAGUKs) – synapse-associated protein 97 (SAP97) and postsynaptic density-95 protein (PSD95), the latter of which binds to an accessory AMPAR protein known as a transmembrane AMPA receptor protein (TARP). Another protein that binds to AMPARs and may be involved in LTP is PICK1 ('protein interacting with C kinase 1'). Elucidating how these and other interacting proteins, together with small guanosine triphosphatases (GTPases) and protein kinases, function to regulate AMPARs during LTP is the focus of much current interest.

Metaplasticity

Metaplasticity is a term that is used to refer to the plasticity of synaptic plasticity. With respect to NMDAR-dependent LTP this can be manifest in several ways. For example, a stimulus protocol (e.g., continuous low-frequency stimulation) that has no effect on baseline transmission can cause LTD of synaptic transmission following the induction of LTP. When the depression is conditional on prior LTP it is referred to as depotentiation. Two forms of depotentiation have been identified; one is dependent on the activation of NMDARs and the other is dependent on activation of metabotropic glutamate receptors (mGluRs). Similarly, two forms of LTD of baseline transmission (sometimes referred to as *de novo* LTD)

Figure 3 Expression of long-term potentiation. There are multiple mechanisms that result in the long-term increase in synaptic strength that come under the umbrella of long-term potentiation. The number of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPARs) present in the postsynaptic membrane may be increased by exocytosis from an intracellular pool, or the activity of those AMPARs already present may be modified by, for example, phosphorylation. Additional mechanisms include the increase in glutamate release (NMDAR, *N*-methyl-D-aspartate receptor).

have been identified that are dependent on activation of NMDARs or mGluRs. The induction of LTP, while enabling depotentiation, can also inhibit the induction of NMDAR-dependent *de novo* LTD. The induction of NMDAR-dependent LTP can be affected by the prior history of synaptic activity. For example, prior activity at NMDARs can result in inhibition of subsequent LTP, while prior activity of mGluRs can result in facilitation of LTP. Finally, it should be noted that the NMDAR-mediated component of synaptic transmission is itself plastic – both LTP and LTD have been demonstrated.

Introduction

It has been more than 50 years since Donald Hebb proposed that associative learning might be accomplished by increasing the strength of synaptic connections between neurons whose activity is correlated. Since the discovery of long-term potentiation (LTP) and long-term depression (LTD) more than 30 years ago, a great deal of experimental and theoretical evidence has accumulated lending support to the hypothesis that these forms of Hebbian synaptic plasticity might underlie numerous forms of experience-dependent plasticity, including learning, memory, and activity-dependent development. This article focuses on the phenomenon of experience-dependent development and plasticity of sensory systems and addresses how LTP and LTD mechanisms at excitatory synapses might be used to mediate such changes.

Mechanisms of LTP and LTD

LTP and LTD are nearly ubiquitous phenomena, having been observed at almost every excitatory synapse studied. Their mechanisms of induction and expression and their functions, however, are subjects of much debate and likely depend on which synapses, which neural circuits, and what stage of development are involved. Much of the characterization of how LTP and LTD are induced and expressed has come from studies examining excitatory synapses in hippocampal slice preparations. These synapses, like most excitatory synapses in the mammalian brain, communicate through the release of glutamate onto postsynaptic α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPARs), whose strength and number determine the efficacy of synaptic transmission. Although there is still debate over the precise molecules and pathways involved in synaptic plasticity, one of the most common forms depends on postsynaptic activation of the *N*-methyl-D-aspartate type of ionotropic glutamate receptors (NMDARs). NMDARs serve as molecular coincidence detectors in that they are active only when the synaptic membrane is depolarized and glutamate is bound to the receptor, thereby satisfying Hebb's rule of correlated presynaptic and postsynaptic activity. In addition, NMDARs conduct calcium ions, which can activate a variety of second messenger pathways. In the simplest models, a large calcium influx through NMDARs triggered by strong synaptic activation can activate kinases such as calcium/calmodulin-dependent protein kinase II (CaMKII) and protein kinase A (PKA). These kinases then lead to LTP either by trafficking new AMPARs to activated synapses or by acting on the biophysical properties of existing AMPARs via posttranslational modifications. Conversely, a smaller calcium influx through NMDARs triggered by weak synaptic activation will recruit phosphatases that can lead to LTD via the opposite mechanisms.

Detailed mechanistic studies of hippocampal LTP and LTD have shown how the history and pattern of synaptic activity necessary for a certain level of NMDAR activation can regulate LTP and LTD and also how modulating specific biochemical signaling pathways can influence their expression. Many of these mechanisms are known to be shared by excitatory synapses outside the hippocampus, including those in the sensory neocortex.

Sensory Maps, Critical Periods, and Experience-Dependent Plasticity

Sensory systems are typically organized in a precise topographic manner, such that neurons that respond to nearby locations in the sensory periphery are also physically located closest to each other in the brain. Examples of such topography are the retinotopic map and the map of eye preference (ocular dominance) in the primary visual cortex (V1), which simultaneously preserves visuotopic order while separating the contralateral and ipsilateral eye inputs originating from the two eyes. In a qualitatively similar manner, the somatosensory cortex of rodents contains individual 'barrels' that represent input from single facial whiskers on the snout while preserving somatotopic order across the entire whisker field. Analogously, in the auditory cortex, there is a tonotopic organization of neurons that respond best to different audible frequencies.

One of the salient features of these maps is that they are not entirely static in adults but undergo plastic changes in response to sensory manipulations and behaviorally relevant experience throughout life. In the somatosensory cortex of adult monkeys, for example, there is a topographic representation of the body surface. This somatotopic map can be manipulated in an experience-dependent manner, as amputation of

digits from the hand results in the loss of cortical responsiveness to the amputated digits, accompanied by an increase in cortical representation to the neighboring spared digits.

Early in life, at a time when the development and refinement of these maps is ongoing, plasticity is particularly dramatic during a 'critical period,' a narrow time window in which changes in sensory activity can have permanent anatomical and physiological effects. For example, in the rat auditory system, the development of a precise tonotopic map involves a sharpening of tone-evoked receptive fields such that cortical neurons progressively respond to a more and more narrow range of audible frequencies. This refinement is dependent on auditory experience as presentation of pulsed monotone frequencies during the critical period results in an overrepresentation of the pulsed frequency at the expense of other frequencies. When rats are presented with pulsed white noise during the critical period, which serves to synchronize all the auditory inputs to the cortex, there is also a severe impairment of the developmental refinement of auditory receptive fields and tonotopicity. These results suggest that the temporal pattern of activity provides an instructive signal for sensory map refinement and that activity-dependent competition between inputs is required for experience-dependent plasticity.

At the cellular level, sensory experience can also be used to shape the physiological responses of single neurons in a Hebbian manner. In another example from the auditory system, pairing tones with either depolarizing or hyperpolarizing current injected into auditory cortex neurons results in responses to tones paired with depolarized cells being significantly increased relative to responses to tones paired with hyperpolarizing current. These results support a classical Hebbian model of experience-dependent plasticity in the auditory system, and indeed, associative LTP has been observed at auditory cortical synapses *in vitro*.

A definitive causal or mechanistic link between Hebbian synaptic plasticity (LTP and LTD) and experience-dependent map plasticity is difficult to demonstrate empirically. There is, however, a set of criteria to support this causal relationship. It should be noted that even these criteria do not prove causality but serve only as the essential correlations necessary to examine further whether a causal relationship does indeed exist:

1. Synaptic plasticity (LTP and LTD) must exist at the same connections that display experience-dependent plasticity.
2. Manipulations that block synaptic plasticity should impair map plasticity.
3. Experience-dependent plasticity should induce the same cellular and molecular changes observed during synaptic plasticity.
4. Experience-dependent plasticity should occlude further synaptic plasticity.

Although map plasticity has been reasonably well characterized in the auditory cortex, the underlying synaptic or circuit mechanisms in this system remain unclear. In contrast, a more convincing link between experience-dependent plasticity and synaptic plasticity exists in the visual and somatosensory systems.

Synaptic Plasticity during Experience-Dependent Plasticity in the Visual System

One of the most informative model systems for studying experience-dependent plasticity has been the system of ocular dominance columns in V1. In monkeys, the thalamic projections representing inputs from the two eyes remain segregated in the cortex and, when visualized with anatomical techniques, form an array of alternating stripes or ocular dominance columns. In a series of classic studies, David Hubel and Torsten Wiesel discovered that in response to one eye's deprivation of visual input (monocular deprivation) during a critical period of development, the ocular dominance columns of the deprived eye shrink, while those of the spared eye expand (Figure 1). Physiologically, Hubel and Wiesel also showed that there is a functional depression of responses in cortical neurons to stimulation of the deprived eye and a commensurate increase in responses to the spared eye following monocular deprivation. It is important to note that these functional changes occur only during an early critical period of development.

These studies laid the groundwork for examining the role of neural activity in shaping functional connectivity in the developing and adult visual system. A large body of work across multiple model systems has confirmed the requirement for retinal activity during ocular dominance plasticity. In the cat visual cortex, ocular dominance plasticity is associated with distinct anatomical changes, as geniculocortical axons rapidly retract their branches in response to either brief or prolonged monocular deprivation, while an expansion of the axonal projections from the nondeprived eye occurs only after prolonged deprivation. Subsequent experiments in the mouse visual cortex showed that physiological changes involve both a rapid depression of the deprived eye response and a slower potentiation of the spared eye response, consistent with the distinct anatomical signatures of monocular deprivation found in the cat.

Mechanisms of Hebbian plasticity have been widely hypothesized to mediate this global plasticity

Figure 1 Ocular dominance columns and the effects of monocular deprivation in macaque monkey. Using a radioactive marker injected into one eye, sections of primary visual cortex can be subsequently visualized for the marker using a technique called autoradiography. (a) An example of such an image, with white areas corresponding to the injected eye and dark areas corresponding to the noninjected eye. In normal animals such as these, the projections from the two eyes segregate in layer 4 of the cortex into stripes, or 'ocular dominance columns,' which occupy a similar area of visual cortex. (b) An example from a monocularly deprived animal, in which the marker was injected into the spared, open eye. As a result of deprivation, the area occupied by the spared eye increases, while the area devoted to the deprived eye shrinks dramatically. The dots represent the position of six lesions made through an electrode during electrical recordings from this animal. The arrows show the location of the two penetrations made with the electrodes. Reproduced from Hubel DH and Wiesel TN (1977) Ferrier lecture: Functional architecture of macaque monkey visual cortex. *Proceedings of the Royal Society of London, Series B: Containing Papers of a Biological Character* 198: 1–59, with permission from The Royal Society.

since they provide a natural mechanism to mediate competition among inputs. Modeling studies support this hypothesis by showing how a greater amount of coincident activity between spared inputs and cortical neurons can result in a greater functional representation of spared inputs relative to deprived inputs via a Hebbian synaptic learning rule (Figure 2).

During the past 20 years, a great deal of experimental evidence has accumulated to support these theories. For example, binocular deprivation during the critical period does not induce ocular dominance plasticity, and reversing a preexisting deprivation produces functional and anatomical recovery. In addition, alternating monocular deprivation between the two eyes results in a decrease in the number of binocularly responsive neurons. Finally, when cortical activity is suppressed pharmacologically, not only is ocular dominance plasticity prevented in response to monocular deprivation, but there is actually a shift in favor of deprived-eye responses when measured physiologically and anatomically. This 'reverse plasticity' results in a greater representation of deprived eye columns over spared eye columns. These results confirm the role of coincident pre- and postsynaptic activity during experience-dependent plasticity, as predicted by Hebbian learning rules, and also strongly suggest a role for competitive mechanisms of synaptic plasticity between inputs from the two eyes as a substrate for experience-dependent plasticity (Figure 3).

Direct tests of Hebbian mechanisms in V1 come from studies recording intracellularly from cortical neurons *in vivo*. Pairing depolarizing, excitatory current injections into cortical neurons with visual stimuli from one eye (positive pairing) results in a long-lasting increase in visual response, while pairing hyperpolarizing current with visual stimuli from the

Figure 2 Diagram depicting how Hebbian learning rules could underlie ocular dominance plasticity. The cells represent groups of layer 4 neurons in the visual cortex, which receive thalamic input representing each eye. During monocular deprivation, the inputs from the spared eye have much greater activity than do those from the deprived eye and are therefore better able to drive activity in the postsynaptic neurons. Based on mechanisms of Hebbian synaptic plasticity, these activity correlations would result in the strengthening of synapses associated with the spared eye. The inputs from the deprived eye, meanwhile, have greatly reduced activity and are therefore unable to influence postsynaptic activity. These synapses are therefore gradually weakened and eventually eliminated. Reproduced from Purves DA, Augustine GJ, Fitzpatrick D, Katz LC, LaMantia AS, and McNamara JO (eds.) (1997) *Neuroscience*. Sunderland, MA: Sinauer, with permission from Sinauer Associates, Inc.

other eye (negative pairing) results in a long-lasting decrease in visual response. Similar reinforcement studies were used to test plasticity of orientation preference, and positive pairings consistently resulted in a potentiation of responses to the paired orientation relative to negative pairings. These results were most robust during the critical period for experience-dependent plasticity, suggesting a correlation between the cellular mechanisms of response potentiation and map plasticity.

More direct evidence of a role for synaptic plasticity during map plasticity comes from *in vitro* experiments in slices of rodent visual cortex. In accordance with the stipulations described above, both LTP and LTD of visual cortical neurons were observed during the critical periods. Both high-frequency stimulation, which should provide a robust postsynaptic calcium profile, and pairing presynaptic stimulation with postsynaptic current injection reliably induced LTP, satisfying Hebb's rule for associative potentiation. It is interesting that the capacity for synaptic plasticity is greatest between postnatal days (P) 14 and 21 and subsequently decreases with age, therefore demonstrating a critical period similar to that of experience-dependent map plasticity (Figure 4(c)). This synaptic plasticity is also regulated by visual experience, as dark-reared animals show increased LTP and reduced LTD (Figure 4(d)). These results suggest that synaptic plasticity mechanisms themselves are regulated by sensory experience through a 'sliding threshold' for synaptic plasticity, or a 'metaplasticity' that could underlie activity-dependent modifications in the visual system. This 'Bienenstock, Cooper, and Munro theory' of synaptic plasticity proposes that the history of activity at any given synapse can regulate the capacity for further plasticity at that synapse. Synapses would have a variable modification threshold, and if their responses are previously potentiated, then their capacity for further LTP is decreased, and vice versa. These theories also predict that sensory experience can regulate plasticity in a bidirectional manner, and therefore that homosynaptic LTD might underlie the loss of visual responsiveness due to monocular deprivation. Homosynaptic LTD is in fact observed at visual

Figure 3 Competition between afferents serving the two eyes drives ocular dominance. In these experiments, all activity in the eyes was blocked by chronic injections of tetrodotoxin, a sodium channel blocker that prevents action potential firing. Recordings were subsequently made in the visual cortex to determine the ocular dominance index of each cell, in which a score of 1 indicates that the cell responds exclusively to stimulation of the ipsilateral eye and a score of 7 indicates response only to stimulation of the contralateral eye. (a) The activity patterns of each eye were synchronized by direct electrical stimulation of the optic nerves. The result of this manipulation is that most visual cortical neurons come to respond to stimulation of either eye. (b) In contrast, asynchronous stimulation was applied to the nerves. Under these conditions, the ocular dominance profile is highly segregated, indicating that most cortical neurons respond only to stimulation of one or the other eye. As described in the article, alternating monocular deprivation results in an ocular dominance profile similar to that shown in (b). These results support the hypothesis that activity-dependent competition between the thalamic inputs of each eye is responsible for ocular dominance plasticity in the visual cortex. Reproduced from Purves DA, Augustine GJ, Fitzpatrick D, Katz LC, LaMantia AS, and McNamara JO (eds.) (1997) *Neuroscience*. Sunderland, MA: Sinauer, with permission from Sinauer Associates, Inc.

cortical synapses *in vitro*, and monocular deprivation serves to induce homosynaptic LTD of deprived eye responses *in vivo*. Furthermore, this depression is not observed after monocular inactivation due to tetrodotoxin injections, confirming a necessity for presynaptic activity for experience-dependent LTD and strengthening a metaplastic model for visual cortical plasticity.

If synaptic plasticity mechanisms mediate experience-dependent plasticity, manipulations that block it should also block map plasticity. Numerous studies have shown that ocular dominance plasticity is blocked by applying NMDAR antagonists to the visual cortex, a manipulation known to prevent LTP *in vitro*. Repeated presentation of a single orientation also results in the selective potentiation of responses to that orientation in mouse and cat V1. This stimulus-selective response potentiation is blocked by both NMDAR antagonists and the injection of peptides that interfere with AMPAR trafficking, both of which are known to be required for cortical LTP.

The molecular and functional changes that are associated with homosynaptic LTD are also observed after monocular deprivation. Decreases in AMPAR subunit phosphorylation and AMPAR surface expression are observed after deprivation, in addition to a decrease in synaptic transmission. Prior monocular deprivation also occludes subsequent induction of LTD, offering further proof that the two are mechanistically related. In combination, these results from the visual system satisfy all the stipulations outlined above for consistency with a causal relationship between Hebbian LTP, LTD, and experience-dependent plasticity.

Synaptic Plasticity during Experience-Dependent Map Plasticity in the Somatosensory Cortex

Even more compelling evidence for a role of LTP and LTD in experience-dependent plasticity comes from studies in the barrel cortex of the rodent somatosensory system. Barrels are clusters of cells located in layer 4 (L4) of the cortex that receive topographic input from individual vibrissae located on the snout. This input is relayed through the ventrobasal thalamus. Excitatory neurons in each barrel then project up to L2/3 neurons in the same column, maintaining

Figure 4 Synaptic plasticity in the visual cortex is regulated by age and sensory experience. The data shown here depict the effect of theta-burst stimulation (TBS) in white matter on the amplitude of extracellularly recorded field potentials in L2/3 of rat visual cortex slices. (a) TBS stimulation induces a robust LTP during the critical period for visual cortical plasticity. (b) After the critical period, however, TBS fails to induce LTP. (c) The developmental regulation of TBS-induced LTP in visual cortical slices. (d) In addition to age, LTP is regulated by sensory experience. In dark-reared animals, the capacity for LTP is much greater than in normal, light-reared animals. Field potential amplitudes were normalized to the time from TBS onset, and each time point was averaged across animals and plotted as the mean ± SEM. These results suggest that visual experience might induce LTP *in vivo*, and therefore that the induction of further LTP is occluded by a 'sliding threshold' model (see the section titled 'Synaptic plasticity during experience-dependent plasticity in the visual system' for explanation). Reprinted by permission from Macmillan Publishers Ltd: [Nature] Kirkwood A, Lee HK, and Bear MF (1995) Co-regulation of long-term potentiation and experience-dependent synaptic plasticity in visual cortex by age and experience. *Nature* 375: 328–331, copyright (1995).

strong feed-forward excitation from the 'principal whisker.' Experience-dependent plasticity is robust in this system and has been observed at multiple points along the sensory pathway. Cortical organization at the level of the thalamocortical barrel map is particularly sensitive to early experience, as manipulations in whisker activity can induce rapid and long-lasting anatomical map plasticity. In response to whisker trimming or deprivation, the cortical area devoted to the deprived whisker will shrink, and the areas representing neighboring whiskers will expand into the deprived territory (Figure 5(b)). In L4 of rodents, this plasticity obeys a strict critical period during development as barrel map cytoarchitecture remains nearly static after the first postnatal week (Figure 5(c)). Physiologically as well, responses to deprived whiskers are reduced in the corresponding barrel, while thalamocortical input from neighboring spared whiskers is functionally increased. Outside L4 in the cortex (L2/3, 5, and 6), anatomical and functional plasticity decreases with age, but significant residual plasticity remains in the adult.

LTP- and LTD-like phenomena are likely to contribute at least in part to this experience-dependent plasticity. After whisker deprivation, the resulting anatomical rearrangements in barrels are prevented with selective administration of glutamate receptor antagonists to the cortex. Functionally as well, cortical activity blockade serves to prevent the potentiation of spared whisker responses and the depression of deprived whisker responses. These results support a model in which postsynaptic activity is required for map plasticity, consistent with Hebbian synaptic plasticity.

The initial development of the barrel map is also thought to rely on activity-dependent mechanisms like LTP and LTD. Coinciding with the critical period for L4 map plasticity, there is a critical period for synaptic plasticity of thalamocortical afferents to L4; not only does thalamocortical synaptic plasticity exist during the periods of map formation, but the

Figure 5 There is a critical period for barrel map plasticity in the rodent somatosensory cortex. Staining for cytochrome oxidase (CO) activity in thin brain sections can reveal the pattern of thalamic afferent clustering into barrels in the somatosensory cortex of rodents. In response to cauterization, or removal, of the entire 'c' row of whiskers from one side of the snout early in development, the contralateral hemisphere shows robust map plasticity. This involves both a shrinkage of area devoted to the deprived whiskers and an expansion of the neighboring barrels, as shown in (b). (a) is the control, ipsilateral hemisphere. This map plasticity has a strict critical period, and if cauterization is performed at postnatal day (PND) 5, no thalamic rearrangements are observed, as shown in (c). Scale bar = 500 μm.

ability to induce LTP decreases during the same period that the ability to induce experience-dependent plasticity decreases (Figure 6). Moreover, blocking or disrupting NMDAR activity prevents the proper formation of the barrel map, fulfilling the first two stipulations described above.

Perhaps the most direct evidence for the involvement of LTP in barrel cortex plasticity comes from experiments showing that whisker experience can drive AMPARs into synapses, a process that mimics the increase in synaptic strength that occurs during LTP *in vitro*. Furthermore, manipulations that block AMPAR trafficking into synapses also prevent the synaptic potentiation that is normally observed following experience-dependent plasticity. These observations provide direct support for a causal relationship between LTP and experience-dependent plasticity in the somatosensory barrel map system.

Since experience-dependent plasticity in the barrel cortex involves both a selective increase in response to salient inputs and a decrease in response to deprived or unused inputs, the expression of thalamocortical LTD would also theoretically be necessary. Indeed, NMDAR-dependent LTD has been observed at thalamocortical synapses in L4, and it is important to note that this LTD is also developmentally regulated. The magnitude of thalamocortical LTD is greatest during the critical period for map plasticity, suggesting a mechanistic link.

Layer 2/3 of barrel cortex is also susceptible to map plasticity in response to whisker deprivation, and these same sensory manipulations induce LTD of layer 2/3 synapses *in vitro*. In addition, this whisker deprivation-induced LTD occludes the induction of further LTD *in vitro* when compared with nondeprived synapses. These results suggest that map plasticity shares the same cellular mechanisms as synaptic plasticity and strengthens the causal link between the two phenomena.

Spike Timing-Dependent Plasticity during Experience-Dependent Plasticity

In addition to the learning rules already described, another form of Hebbian synaptic plasticity that has received a great deal of attention over the past two decades depends on the temporal order of activity between pre- and postsynaptic cells. Referred to as spike timing-dependent plasticity (STDP), this learning rule has proved to be an effective means of inducing experience-dependent plasticity in neural circuits. The typical STDP rule predicts that presynaptic activity preceding postsynaptic spiking within approximately 10 ms will lead to synaptic strengthening (LTP), while the reverse spiking order will lead to weakening (LTD). Initially described in cerebellar-like structures, STDP has been observed in numerous brain areas across many different species, underscoring its potential importance in mediating normal development and learning.

STDP learning rules are naturally associated with experience-dependent plasticity and have been implicated in sensory map plasticity in many different systems. In the barrel cortex, STDP is observed at L4 to L2/3 synapses *in vitro*, and as described above, whisker deprivation produces a long-lasting depression at these same synapses. It is interesting that L4 cells consistently fire before L2/3 cells in normal animals when whisker-evoked spiking responses are measured *in vivo*. After whisker deprivation, however, this firing order is reversed, suggesting that a spike timing-dependent learning rule mediates synaptic depression at this synapse.

Figure 6 Thalamocortical long-term potentiation (LTP) has a critical period similar to that of barrel map plasticity. Date collected from P 3-7 animals are shown as black dots, and date from p 8-14 animals are shown as white dots. (a) LTP and long-term depression (LTD) at thalamocortical synapses in the barrel cortex are easily induced during the first week after birth. Here, LTP in an *in vitro* brain slice preparation is produced by pairing postsynaptic depolarization with presynaptic stimulation, conditions that mimic Hebbian plasticity. The same pairing protocol is incapable of inducing plasticity in animals more than 1 week old. (b) The amount of LTP decreases gradually with age over the first postnatal week at thalamocortical synapses in rodent barrel cortex, paralleling the decline in *in vivo* barrel map plasticity. EPSP slopes were normalized to the time from pairing onset, and each time point was averaged across animals and plotted as the mean ± SEM. Date collected from P3-7 animals are shown as black dots, and data from P8-14 animals are shown as white dots. Reprinted by permission from Macmillan Publishers: Nature Crair MC and Malenka RC (1995) A critical period for long-term potentiation at thalamocortical synapses. *Nature* 375: 325–328, copyright (1995).

In the visual system, STDP has been implicated in several different experience-dependent modifications. Receptive fields of neurons in the visual cortex of the rat, for example, can be modified by pairing visual stimulation with spiking in the cortical neuron. If the visual stimulation precedes the spiking, the response is enhanced to stimulation from that area, and the converse is observed when the order of activation is reversed. In the developing tadpole optic tectum, STDP learning rules serve to rapidly shift the visual receptive fields either toward or away from any given area in the visual field, depending on the relative timing of postsynaptic spiking.

The development of direction sensitivity in the developing tadpole tectum has also been attributed to a form of STDP learning rule. By presenting bars at specific speeds, tectal neurons can be trained to become selective for the direction of movement when allowed to spike. Further studies confirm that the speeds that are effective for this induction produce temporal patterns of synaptic activation that are consistent with a spike-timing learning rule and indeed are able to induce the required synaptic modifications.

Finally, the development of orientation selectivity in the visual system is also modulated by sensory experience and regulated by an STDP learning rule. For example, orientation maps in the visual cortex of cats rapidly degrade during the critical period when deprived of visual experience. If the animal is reared under conditions that limit its exposure to just one orientation during the critical period, however, the cortex comes to respond preferentially to that orientation and not to others. At the same time, pairing visual stimuli of specific orientations with spikes in cortical neurons can lead to a shift in orientation preference toward the paired orientation if the stimuli preceded the spike. Consistent with an STDP learning rule, the response to the presented orientation is diminished when it is presented after the spiking. Together, these results highlight the importance of

spike timing-dependent synaptic plasticity in mediating the experience-dependent plasticity of sensory systems, during both development of cortical maps and adult learning.

Synaptic Homeostasis during Experience-Dependent Plasticity

It is now clear that neural activity can play an instructive role in regulating the functional connectivity of neural circuits through various mechanisms of LTP and LTD induction. These Hebbian changes, however, are inherently unstable and can lead to the runaway excitation or depression of a subset of synapses when left unchecked. For example, if LTP is based on the ability of a presynaptic neuron to fire a postsynaptic neuron effectively, then the resulting potentiation will subsequently increase the capacity of that connection to induce firing again in the future, thereby resulting in even greater LTP. This cycle will continue again and again and eventually can cause a destabilizing effect on the circuit. For this reason, Hebb-based models for experience-dependent development and plasticity of neural circuits typically require some type of homeostatic rules to constrain synaptic strength within certain physiological limits.

In the last decade, a number of elegant studies have been performed to investigate homeostatic mechanisms that can permit selective changes at appropriate synapses without degrading the function of the entire neural circuit. In cortical and hippocampal cultures, for example, individual neurons dynamically adjust the strength of all their excitatory synapses during different levels of input activity in order to maintain a target firing rate. In response to a global reduction in afferent activity, excitatory synapses will increase their strength, whereas a global increase in activity will induce an overall reduction in synaptic strength. These results suggest there are cell-autonomous mechanisms that not only can detect the overall level of activity in individual neurons but that are also capable of modulating the strength of all the synapses onto that neuron when firing rates fall out of specific target limits.

One of the mechanisms that may mediate this type of homeostasis is termed 'synaptic scaling.' In synaptic scaling, the distribution of amplitudes of excitatory currents at all the synapses onto a neuron (the miniature excitatory postsynaptic current (mEPSC)) increases in response to reduced activity and decreases in response to increased activity. These distributions are scaled up or down in a proportional manner, thereby preserving the relative differences in synaptic weights among all the synapses onto any given neuron. This synaptic scaling allows for competition among inputs that undergo Hebbian synaptic plasticity during experience-dependent modifications. If a subset of inputs has been recruited for potentiation, then the overall level of activity will increase in that neuron, and scaling mechanisms will result in a proportional decrease in strength of all synapses. In this case, the weakest inputs will be selectively eliminated, and the strongest (and presumably most salient) inputs will be selectively maintained.

It is worth noting that synaptic scaling has been observed in the developing visual system. As described above, monocular deprivation results in a number of physiological and anatomical changes in the primary visual cortex. In the rodent, 2 days of monocular deprivation results in an increase in the amplitude of mEPSCs onto pyramidal neurons in the deprived hemisphere relative to the control hemisphere. These changes are consistent with the observations of synaptic scaling described in culture and are reversed with subsequent visual experiences. This suggests that synaptic scaling mechanisms are recruited by changes in sensory experience, and that synaptic homeostasis, in addition to Hebbian LTP and LTD, is important for regulating the experience-dependent plasticity and development of neural circuits.

Alternative Mechanisms of Experience-Dependent Plasticity

Although the evidence presented above is compelling for a role of Hebbian LTP and LTD in various forms of experience-dependent plasticity, the criteria listed in the section titled 'Sensory maps, critical periods, and experience-dependent plasticity' are by nature correlative and do not prove causality. Indeed, there is evidence that suggests manipulations that block LTP and LTD do not always interfere with experience-dependent plasticity. For example, a number of signaling molecules downstream of NMDAR activation are required for *in vitro* LTP, including PKA and CaMKII. In slices of visual cortex, genetically disrupting PKA signaling prevents the expression of pairing-induced LTP and LTD in some cortical neurons. These same genetic manipulations, however, do not prevent the emergence of ocular dominance plasticity in response to monocular deprivation, suggesting a dissociation between experimentally observed forms of homosynaptic plasticity and *in vivo* circuit changes. This dissociation can be explained on a number of levels, including cell-autonomous molecular and genetic compensation in disrupted cortical neurons, or circuit-level compensation by separate neural circuits whose capacity for plasticity remains intact.

What alternative mechanisms exist that could underlie the changes induced by sensory experience?

Instead of long-term changes in synaptic efficacy, changes in short-term plasticity and short-term synaptic dynamics could play a role. Indeed, it might be more efficient for neural circuits to take advantage of subtle and cumulative changes to adapt their functions rather than employing energetically costly forms of large changes in synaptic efficacy.

In addition, the balance of excitation and inhibition could be regulated to mediate the changes observed during experience-dependent plasticity. The critical period for ocular dominance plasticity, for example, has been shown to depend on the onset of inhibition within the primary visual cortex. In mice that have been genetically modified to lack functional γ-aminobutyric acid (GABA) release, ocular dominance plasticity is prevented but can be rescued by pharmacologically restoring GABA function. It is interesting that this rescue can occur at any age, suggesting that the emergence of inhibitory circuits is an important determining factor in critical period onset.

Concluding Remarks

Over the past 30 years, a great deal of experimental evidence has emerged supporting a role for Hebbian LTP and LTD in mediating a large range of functions, including activity-dependent development, sensory map plasticity, and learning and memory. A combination of *in vivo* and *in vitro* studies from the visual and somatosensory systems supports the hypothesis that mechanisms of synaptic plasticity contribute at least in part to various types of experience-dependent plasticity. These studies have shown that sensory experience can both induce and occlude synaptic plasticity, and those manipulations that block synaptic plasticity *in vitro* can also block experience-dependent plasticity *in vivo*. Although no direct causal link has emerged, and may never emerge, a continued examination of the mechanisms responsible for synaptic learning rules and synaptic homeostasis during the formation and plasticity of neural circuits will prove to be an effective means of examining how our brains are capable of adapting to changes in the myriad forms of information we experience during our lifetimes.

Lysosomal System

Introduction

The lysosomal storage diseases (LSDs) are a clinically heterogeneous group of inherited disorders associated with the accumulation of incompletely degraded substrates within membrane-bound bodies (the lysosome), usually due to deficiency in the activity of a specific enzyme/hydrolase (Figure 1). The clinical manifestations associated with distinct LSDs reflect the cellular sites of substrate storage and resultant organ dysfunction. In contrast to peroxisomal disorders, which are often associated with severe developmental malformations in the early-onset forms, the LSDs involve tissues and organs that develop normally but subsequently malfunction. Table 1 provides a summary of the features that may be helpful in distinguishing the lysosomal storage group of disorders from defects involving other cellular organelles, such as the peroxisome or mitochondria.

In contrast to defects of small molecules that involve amino acids, organic acids, or simple sugars (e.g., phenylketonuria, methylmalonic acidemia, and galactosemia, respectively), analysis of metabolites that accumulate in patients with LSD is not practical or readily available, except for examination of the pattern of urinary mucopolysaccharide (glycosaminoglycans)/oligosaccharide excretion in the mucopolysaccharidoses (MPSs) or oligosaccharidoses, respectively. Even in the latter cases, it is necessary to obtain biochemical confirmation of the diagnosis in every patient for accurate prognostication, management, and genetic counseling.

Except for Fabry disease, Hunter syndrome (MPS-II), and Danon disease, which are inherited in an X-linked recessive fashion, the LSDs are transmitted as autosomal recessive traits. Prenatal diagnosis is possible for almost all LSDs, based on analysis of enzymatic activity, molecular genetic testing, and/or ultrastructural examination for inclusion bodies in cells from cultured chorionic villi or amniocytes.

The Lysosome and Its Contents

The lysosome is a membrane-bound intracytoplasmic vacuole that contains several enzymes required for the degradation of complex lipids, protein, and nucleotides. It is an organelle that maintains an acidic milieu (pH $\sim$ 5.4), necessary for the optimal activity of the enclosed enzymes and their cofactors/activators. There are over 40 different lysosomal diseases (with a combined incidence of $\sim$1:5000 births), classified according to the metabolites that are stored within the various organs/tissues involved (Table 2) or, more recently, by the nature of the molecular defect (see later, section 'Pathophysiology and diagnosis').

The trafficking of most lysosomal hydrolases is mediated by a mannose-6-phosphate (M-6-P)-dependent pathway, in which asparagine-linked oligosaccharides on newly synthesized lysosomal hydrolases are modified in a two-step process to contain a terminal M-6-P moiety. The initial step in posttranslational M-6-P modification is catalyzed by the enzyme uridine diphosphate (UDP)-*N*-acetylglucosamine-1-phosphotransferase, and involves the transfer of *N*-acetylglucosamine (GlcNAc)-1-phosphate from UDP-GlcNAc to specific 1,2-linked mannoses on lysosomal hydrolases. The second step involves the enzyme *N* -acetylglucosamine-1-phosphodiester-*N*-acetylglucosaminidase, which facilitates the removal of the covering GlcNAc and generates the terminal M-6-P. Lysosomal enzymes bearing the M-6-P modification then bind to one of two M-6-P-receptors in the *trans*-Golgi and are transferred to the lysosome. Failure to make these modifications results in the enzymes entering the secretory pathway followed by inappropriate secretion from the cells, and the accumulation of various incompletely metabolized substances within the lysosome as a consequence of the intracellular deficiencies.

The enzyme *N*-acetylglucosamine-1-phosphotransferase has been found to be composed of three subunits ($\alpha_2\beta_2\gamma_2$) coded for by two different genes (α and β by one gene on chromosome 4q21-q23, and γ by another gene on chromosome 16p). Mucolipidosis types II (I-cell disease) and IIIA (pseudo-Hurler polydystrophy) are due to allelic defects in the $\alpha\beta$ gene, whereas mucolipidosis IIIC results from a defect specifically in the gene coding for the γ subunit.

Patients with I-cell (Leroy) disease present in early infancy with coarse facial features, and develop severe psychomotor retardation and joint contractures. Pseudo-Hurler polydystrophy can be distinguished from the 'classic' Hurler syndrome (α-L-iduronidase deficiency) because of its slower progression, the absence of organomegaly, and absence of mucopolysaccharidurie. Typical clinical findings include stiffness of the hands and shoulders, claw-hand deformity, scoliosis, short stature, coarse facies, and mild mental retardation. Radiographically, severe dysostosis multiplex of the hip is characteristic and frequently disabling. The clinical diagnosis of I-cell disease and pseudo-Hurler

Figure 1 Lysosomal storage disease (LSD) mechanisms of pathogenicity. Disorders of lysosomal storage cause acute or chronic progressive diseases, characterized at the cellular level by a metabolic gridlock usually resulting from either a deficiency of a catabolic enzyme or a defect in vesicular transport.

Figure 2

polydystrophy can be confirmed indirectly by finding elevated serum lysosomal enzyme levels and/or decreased lysosomal enzyme levels in cultured fibroblasts. Alternatively, GlcNAc-phosphotransferase can be directly assayed in cultured fibroblasts, or the responsible gene can be screened for mutations.

Unlike the related diseases, mucolipidosis II and IIIA, the enzyme affected in mucolipidosis IIIC (*N*-acetylglucosamine-1-phosphotransferase), also known as variant pseudo-Hurler polydystrophy, retains full transferase activity on synthetic substrates but lacks activity on lysosomal hydrolases. The defect may lie in failure of lysosomal hydrolase recognition.

Pathophysiology and Diagnosis

The progressive intralysosomal accumulation of the incompletely degraded, complex substrates represents the initial and possibly major insult to the cells. Lysosomal storage diseases can occur through various means, including (1) a primary deficiency of a specific hydrolase (e.g., Tay–Sachs, Gaucher, and

Fabry diseases); (2) deficiency of either a 'protective protein' that aids in the lysosomal targeting and prevention of premature degradation of the enzyme (e.g., galactosialidosis), or an 'activator protein' necessary for enzyme–substrate interaction and degradation (GM2 gangliosidosis, AB variant); (3) abnormal enzyme processing by the required enzymes in the endoplasmic reticulum (e.g., multiple sulfatase deficiency); and (4) failure to attach the appropriate targeting signals (M-6-P) in the Golgi apparatus (e.g., I-cell disease). More recently, it has been shown that LSDs can also result from defects in the removal or transport of the substrate from lysosomes (e.g., Niemann–Pick type C and sialic acid storage diseases) or defects in an integral membrane protein of endosomal–lysosomal membranes, leading to abnormalities in endocytosis, vesicle fusion, or the internal endosomal or lysosomal environment (e.g., Danon disease).

Figure 3

As noted, besides the single enzyme deficiency diseases, LSDs can also arise secondary to multiple enzyme deficiencies. Unlike the peroxisomal disorders, wherein multiple enzyme deficiencies result from a defect of peroxisomal membrane assembly and/or targeting, this subgroup of LSDs arise from either (1) a defect of posttranslational modification involving the glycosylation (mucolipidosis II and IIIA) or sulfation (multiple sulfatase deficiency) of the enzyme/protein product or (2) absence of a protective protein (galactosialidosis I and II).

Multiple sulfatase deficiency (Austin disease) is a rare disease characterized by coarse facial features, hepatosplenomegaly, and skeletal changes in association with progressive neurodevelopmental deterioration and peripheral neuropathy. The disease results from deficiencies of several enzymes (i.e., arylsulfatases A, B, and C, and mucopolysaccharide sulfatase) that normally require the conversion of a specific cysteine thiol residue to an aldehyde to function properly. The defect in the posttranslational modification of these enzymes leads to loss of their catalytic activity, and the accumulation of mucopolysaccharides and steroid sulfates.

Galactosialidosis results from a deficiency of a protective protein/cathepsin A that prevents the intralysosomal degradation of β-galactosidase and sialidase, leading to a combined deficiency of these two enzymes. Galactosialidosis is characterized by coarse facial features, a cherry-red retinal spot, myoclonus, and cerebellar ataxia.

Rare variants of certain sphingolipid storage disorders result from a defect in the enzyme cofactor/activator rather than a primary hydrolase defect.

Table 1 Features helpful in distinguishing lysosomal storage disorders from other organelle diseases

Lysosomal	*Peroxisomal*	*Mitochondrial*
Oligosystemic (RES, CNS)	Multisystemic	Multisystemic
Acute and chronic course	Hypotonia	Lethargy
Behavioral changes	Spatic paraparesis, leukodystrophy (XL-ALD)	Failure to thrive
Seizures (late)		Cerebral dysgenesis
Leukodystrophy		Sensorineural hearing loss
Cerebellar atrophy	Neuronal migration defects (ZS)	Ophthalmoplegia
Macular cherry-red spot		Retinitis pigmentosa
Lung involvement (interstitial disease)	Developmental delay	Cardiomyopathy
	Failure to thrive	Myopathy
Hepatosplenomegaly	Abnormal craniofacies	Diabetes mellitus
Skin lesions (angiokeratoma)	Rhizomelic short stature	
Bone disease (dysostosis multiplex)	Cerebral dysgenesis	
	Sensorineural hearing loss	
	Hepatocellular dysfunction	
	Adrenal dysfunction	

RES, reticuloendothelial system; CNS, central nervous system; XL-ALD, X-linked adrenoleukodystrophy; ZS, Zellweger syndrome.

Table 2 Lysosomal storage disease substrates, enzyme deficiencies, and gene loci

Stored substrate	*Disease*	*Enzyme deficiency*	*Gene locus*
A. Sphingolipids			
GM2 gangliosides, glycolipids, globoside oligosaccharides	Tay–Sachs, GM2 gangliosidosis (three types)	α Subunit β-hexosaminidase	15q23-q24
GM2 gangliosides, oligosaccharides	Sandhoff disease, GM2 gangliosidosis	β Subunit β-hexosaminidase	5q13
GM2 gangliosides, glycolipids	GM2 gangliosidosis	GM2 activator	5q32–33
GM1 gangliosides, oligosaccharides, keratan sulfate, glycolipids	GM1 gangliosidosis (three types)[a]	β-Galactosidase	3p21–3pter
Sulfatides	Metachromatic leukodystrophy (MLD)	Arylsulfatase A (galactose-3-sulfatase)	22q13.31-qter
GM1 gangliosides, sphingomyelin, glycolipids, sulfatide	MLD variant	Saposin B activator	10q21
Galactosylceramides	Krabbe disease	Galactocerebrosidase	14q31
α-Galactosyl-sphingolipids, oligosaccharides	Fabry disease	α-Galactosidase A	Xq22
Glucosylceramide, globosides	Gaucher disease (GD) (three types)[a]	β-Glucosidase	1q2l
Glucosylceramide, globosides	GD (variant)	Saposin C	10q2l
Ceramide	Farber disease (seven types)	Acid ceramidase	8p22-p21.2
Sphingomyelin	Niemann–Pick disease, types A and B	Sphingomyelinase	11p15.1-p15.4
B. Mucopolysaccharidoses (glycosaminoglycans)			
Dermatan sulfate (DS) and heparan sulfate (HS)	Mucopolysaccharidose (MPS) I, Hurler, Scheie	α-L-Iduronidase	4p16.3
DS and HS	MPS II, Hunter	Iduronate-2-sulfatase	Xq27.3-q28
HS	MPS IIIA, Sanfilippo A	Sulfamidase	17q25.3
HS	MPS IIIB, Sanfilippo B	α-*N*-Acetylglucosaminidase	17q21.1
HS	MPS IIIC, Sanfilippo C	Acetyl-CoA:α-glucosaminide-*N*-acetyltransferase	–
HS	MPS IIID, Sanfilippo D	*N*-Acetylglucosamine-6-sulfatase	12q14
Keratan sulfate (KS)	MPS IVA, Morquio A	Galactosamine-6-sulfatase	16q24.3
KS	MPS IVB, Morquio B	β-D-Galactosidase	3p21.33
DS	MPS VI, Maroteaux-Lamy	*N*-Acetylgalactosamine-4-sulfatase	5q13-q14
DS and HS	MPS VII, Sly	β-D-Glucuronidase	7q21.1-q22
Hyaluronan	MPS IX	Hyaluronidase	3p21.3
C. Glycogen			
Glycogen	Pompe, glycogen storage disease (GSD) IIA	α-D-Glucosidase	17q23
Glycogen	Danon disease	Lysosomal-associated membrane protein 2 (LAMP-2)	Xq24–25
D. Oligosaccharides/glycopeptides			
α-Mannoside	α-Mannosidosis	α-mannosidase	19p13.2-q12
β-Mannoside	β-Mannosidosis	β-Mannosidase	4q22-q25
α-Fucosides, glycolipids	α-Fucosidosis	α-Fucosidase	1p34.1-p36.1
α-*N*-Acetylgalactosaminide	Schindler disease	α-*N*-Acetylgalactosaminidase	22q13.1-q13.2
Sialyloligosaccharides	Sialidosis	α-Neuraminidase	6p21.3
Aspartylglucosamine	Aspartylglucosaminuria	Aspartylglucosaminidase	4q34-q35
E. Multiple enzyme deficiencies			
Glycolipids, oligosaccharides	Mucolipidosis II (I-cell disease)	*N*-Acetylglucosamine-1-phosphotransferase	4q21-q23
Sulfatides, glycolipids, glycosaminoglycans	Multiple sulfatases	SUMF-1	3p26
F. Lipids			
Cholesterol esters	Wolman disease, cholesteryl ester storage disease (CESD)	Acid lipase	10q23.2-q23.3

Continued

Table 2 Continued

Stored substrate	*Disease*	*Enzyme deficiency*	*Gene locus*
Cholesterol, sphingomyelin	Niemann–Pick disease type C	NPC1; HE1	18q11-q12; 14q24.3
G. Monosaccharides/amino acid/monomers			
Sialic acid, glucuronic acid	Salla, infantile sialic acid storage disease (ISSD)	Sialin	6q14-q15
Cystine	Cystinosis	Cystinosis	17p12
H. Peptides			
Bone proteins	Ycnodysostosis	Cathepsin K	1q21
I. S-Acylated proteins			
Palmitoylated proteins	Infantile neuronal ceroid lipofuscinosis (NCL)	Palmitoyl-protein thioesterase	1p32
Pepstatin-insensitive lysosomal peptidase	Late-infantile NCL	Pepstatin-insensitive lysosomal peptidase	11p15

[a]Three types imply infantile, childhood, and adulthood presentations.

Figure 4

There are two categories of sphingolipid activators, one representing the GM2 activator and a second group of four molecules (saposins A, B, C, and D) derived by proteolytic cleavage of a common precursor, prosaposin, encoded by a gene localized to chromosome 10. Deficiency of the GM2 activator results in the so-called AB variant of GM2 gangliosidosis. Saposin B activates arylsulfatase A; its deficiency gives rise to a variant of metachromatic leukodystrophy (MLD). Saposin C activates glucocerebrosidase and β-galactocerebrosidase; its deficiency leads to a clinical picture often referred to as an atypical form of Gaucher disease (GD; primarily due to glucocerebrosidase deficiency) because of overlap in the clinical features observed in GD patients with the type 3 variant (subacute neuropathic GD). Disorders resulting from cofactor deficiencies are characterized by normal enzymatic activities *in vitro* when using the synthetic (artificial) substrate; thus, the diagnosis can be missed by routine biochemical testing unless the study is performed using the natural glycosphingolipid substrate. Alternatively, molecular analysis may reveal the presence of mutations in the relevant encoding genes.

A few LSDs result from transport defects, including Salla disease and the severe infantile form (ISSD), cystinosis. Salla disease and ISSD are allelic autosomal recessive disorders resulting from a defective gene *SLC17A5* (sialin), an anion/cation symporter, mapped to chromosome 6q14-q15. Both conditions are neurodegenerative disorders characterized by hypotonia, cerebellar ataxia, and mental retardation, with large amounts of sialic acid excreted in the urine. ISSD is further characterized by the presence of visceromegaly and coarse facial features.

Cystinosis is characterized by the accumulation of cystine crystals in lysosomes and principally affects the kidneys. It has been attributed to defects in cystinosin (mapped to chromosome 17p12), an integral lysosomal membrane protein with structural similarities to other membrane transporters. This autosomal recessive disorder comprises three allelic clinical forms, varying in severity and age of onset. The infantile form

generally appears at 6–8 months of age with a proximal renal tubulopathy which, in the absence of renal transplantation, can lead to death by 10 years of age due to renal failure. Other clinical signs include retinal blindness, hypothyroidism, diabetes mellitus, swallowing difficulties, and neurological deterioration. The juvenile form is characterized by glomerular renal damage, which manifests at around 10–12 years of age and slowly progresses to glomerular insufficiency and photophobia due to corneal cystine-crystal deposits. Finally, the ocular nonnephropathic form is solely characterized by a mild photophobia but no renal anomalies.

Unlike the small-molecule diseases (i.e., defects of organic and amino acid metabolism) that lead to acute neurotoxicity, LSDs are often associated with a clinical picture consistent with chronic or subacute encephalopathy. Myoclonic seizures are seen in the following disorders: GM2 gangliosidosis, sialidosis type 1, Schindler disease (α-*N*-acetylgalactosaminidase deficiency), Gaucher disease types 2 and 3, and fucosidosis. However, it should be noted that there are certain subtypes – for example, Gaucher disease type 1, Scheie syndrome (MPS-IS), mild Hunter syndrome (MPS-II), Morquio syndromes A (MPS-IVA) and B (MPS-IVB), Maroteaux–Lamy (MPS-VI), and cystinosis – that are not associated with primary central nervous system involvement.

As a group, the various LSDs are characterized by multisystemic involvement and wide heterogeneity in clinical presentation. Although visceromegaly (e.g., hepatosplenomegaly) is a typical manifestation, there are several exceptions (Table 3). Varying disease severity has been attributed to different mutations that produce a protein with differing residual enzyme activities and potential patient-specific differences in substrate flux (i.e., cellular toxicity is hypothesized to occur when the substrate burden has breached a certain threshold).

A number of causal mutations have been associated with each of the LSDs. In certain disorders, such as Tay–Sachs disease, Gaucher disease, and Niemann–Pick A and B, which are prevalent among individuals of Ashkenazi Jewish ancestry, there are common disease alleles. This fact permits carrier screening prior to marriage introductions among the Orthodox community, and the consideration of prenatal diagnosis in carrier couples at risk. For most of the other LSDs, certain mutations may be common in particular population groups (e.g., Caucasians), although the frequency is not high enough to justify general screening. In most cases, individual families tend to have unique mutations ('private alleles') and mutation analysis is available on a research basis only. Studies have shown genotype–phenotype correlations often to be imperfect.

Table 3 Disorders with CNS involvement but no significant somatic signs

- GM2 gangliosidosis
- α-*N*-Acetylgalactosaminidase (Schindler disease)
- Krabbe disease (globoid cell leukodystrophy)
- Metachromatic leukodystrophy
- Sialidosis type 1
- Mucolipidosis IV
- Neuronal ceroid lipofuscinosis

Microscopic examination of tissue from certain patients suspected to have an LSD may reveal residual bodies within the lysosome – for example, particulate glycogen in glycogenosis type II (Pompe disease) and Danon disease, and lamellar profiles in the sphingolipidoses (i.e., membranous cytoplasmic bodies in Tay–Sachs disease, zebra bodies in the mucopolysaccharidoses, and prismatic inclusions in MLD). Analysis of peripheral smear and skin biopsy may also provide a clue to the diagnosis and help to focus testing and avoid random or sequential screening for a battery of lysosomal enzyme activities. Skin biopsy examination for the presence of characteristic storage bodies is specific in the diagnosis of two disorders, neuronal ceroid lipofuscinosis and mucolipidosis IV. Identification of the underlying defects in mucolipidosis IV (ML IV) and certain forms of neuronal ceroid lipofuscinosis (NCL; see later) now enables mutation analysis as a means of diagnosis for these autosomal recessive disorders in clinically suspected cases. These advances obviate the need for invasive diagnostic procedures and for the required expertise, which is often not readily available, for accurate interpretation of biopsy findings.

When a skin biopsy is performed for ultrastructural studies, it is usually preferable to obtain a second sample for culture; the cultured sample can then be used to analyze specific enzyme activity and also can serve as a source of DNA for subsequent mutation analysis. Moreover, in patients suspected to have Niemann–Pick type C (NPC), analysis of cholesterol esterification and staining for filipin may be performed on skin fibroblasts. This method is also the basis of prenatal diagnosis for NPC, using either cultured villi (CVS; chorionic villus sample) or amniocytes, when the causal mutations are unknown.

It is likely that a host of other factors, including mechanical and vascular changes and immune-mediated events, contributes to the development of various disease-related complications. For instance, a marked increase and abnormal distribution of endothelin-1 have been noted in the neurons and glial cells of a patient with galactosialidosis. In addition, evidence of loss of CD31 immunoreactivity and

the breakdown of vascular cell adhesion molecules in vacuolated endothelial cells has also been reported. These findings are felt to promote development of brain infarctions and the other pathological changes seen in patients with galactosialidosis. In Fabry disease, patients show increased serum levels of various endothelial prothrombotic factors and leukocyte adhesion-molecule expression, changes that are felt to influence the likelihood of stroke. In Krabbe disease (KD, or globoid cell leukodystrophy), the death of oligodendrocytes and loss of myelin have been attributed to psychosine (galactosylsphingosine) accumulation. Recent studies involving the twitcher mouse (a model for KD) brain revealed progressive loss of peroxisomal proteins/functions and induction of expression of inflammatory cytokine tumor necrosis factor-α (TNF-α), which may represent one of the pathways leading to cell death.

Increased knowledge about LSDs and the availability of treatment, including bone marrow transplantation (BMT), enzyme replacement therapy, and substrate reduction therapy, in some forms has stimulated interest in population-based screening. In the absence of specific and effective therapy for most other clinical types, an advantage to early identification of cases includes the prevention of recurrence in families at risk. Furthermore, early diagnosis will allow clinicians to take advantage of the opportunity presented by the naturally suppressed immune system of the neonate, potentially improving outcome following BMT/hematopoietic stem cell transplant (HSCT). Screening strategies that are under development or validation have used blood spots on filter paper (Guthrie cards) as the means of sampling, because of ease in shipping and handling and the potential for large-scale automation. Methods of detection have included a combination of immune-quantification assay or enzyme microanalytic methods, to measure by-products of lysosomal metabolism (lysosomal-associated membrane protein 1 and saposin C) and/or enzyme protein concentration or levels of activity. These approaches may address the limitations of a DNA-based strategy, which can be labor intensive because of the large number of causal mutations associated with most LSDs and low mutant-allele frequencies (i.e., absence of a common mutation).

Several animals (including dogs and cats) have been identified as having a LSD. Additionally, homologous recombination and embryonic stem cell technology have enabled development of authentic animal (usually mouse) models for several entities, including all the sphingolipidoses, two mucopolysaccharidoses, and aspartylglucosaminuria.

Recent Advances

This section highlights recent findings in a few selected disorders, including the neuronal ceroid lipofuscinosis, pycnodysostosis, ML IV, NPC, and Danon diseases. The NCLs are a group of neurodegenerative disorders (outlined in Table 4) characterized by the accumulation of fluorescent storage material in neurons and other cell types. The unifying clinical features include visual impairment, progressive myoclonic epilepsy,

Disease	*Gene map*	*Defect*	*Ultrastructure*
Infantile NCL (Haltia–Santavuori disease), allelic with juvenile-onset NCL with granular osmiophilic deposits (GRODs)	1p32, *CLN1*	Lysosomal palmitoyl-protein thioesterase (PPT)	GRODs, saposins A and D
Classic late-infantile NCL (Jansky–Bielschowsky disease)	11p15, *CLN2*	Pepstatin-insensitive lysosomal tripeptidyl peptidase	Curvilinear (CV) bodies; fingerprint (FP) bodies, subunit C of ATP synthase
Juvenile-onset NCL (JNCL; Batten disease)	16p12, *CLN3*	Gene encoding a 438-amino-acid (AA) membrane protein with unknown function	FP bodies, subunit C of ATP synthase
Adult NCL	Unassigned, *CLN4*	438-AA membrane protein, unknown function	Mixed, subunit C of ATP synthase
Finnish variant late-infantile NCL	13q22, *CLN5*	407-AA membrane protein, unknown function	CV and FP bodies, saposins A and D
Variant late-infantile NCL	15q21-q23, *CLN6*	311-AA membrane protein, unknown function	CV and FP bodies, subunit C of ATP synthase
Turkish variant late-infantile NCL (LINCL)	8p23, *CLN7*	Unknown	FP bodies or mixed
Northern epilepsy	8p23, *CLN8*	Unknown	Curvilinear or GROD-like bodies, subunit C of ATP synthase
Variant JNCL (vJNCL)	Unknown, *CLN9*	Unknown	CV and FP bodies, GROD, subunit C of ATP synthase

and cognitive decline. There are several NCL subtypes, delineated on the basis of age of onset, clinical course, and ultrastructural biopsy findings (e.g., granular osmiophilic bodies; curvilinear or fingerprint pattern). The underlying molecular genetic defects for certain subtypes are known (Table 4). Biochemical testing and DNA analysis have recently become available for some forms. The specific roles of the various gene products and the mechanisms involved in neuronal cell degeneration remain to be established. The *CLN3* gene product (the protein CLN3P, or battenin) is a transmembrane protein found in endosomal or lysosomal membranes and may function as a regulator of intravesicular pH. An abnormality of lysosomal pH could lead to faulty protein degradation and explain the presence of storage material found in defective cells. More recently, the neuronal loss in Batten disease has been shown to be due to a combination of apoptosis and autophagy, suggesting that CLN3P, the defective protein, may have an antineuronal death function.

In addition to the NCLs, pycnodysostosis has recently been added to the list of LSDs. Pycnodysostosis is an autosomal recessive skeletal dysplasia characterized by osteosclerosis, bone fragility, and short stature. The gene defect has been mapped to chromosome 1q21. Its protein product, cathepsin K, is a lysosomal cysteine protease that is highly expressed in osteoclasts and is involved in bone remodeling.

Mucolipidosis IV is a progressive disorder associated with corneal clouding, severely delayed developmental milestones, and mental retardation. Neuronal loss and astrocytosis can be found in the cerebral cortex, basal ganglia, deep cerebellar nuclei, and brain stem nuclei. The defective gene (*MCOL-1*) has been mapped to chromosome 19p13.2-p13.3. The gene product (mucolipin-1), a nonspecific cation channel, is speculated to play a role in the late-endocytic pathway and final stages of parietal cell activation. Unlike the other types of mucolipidosis, patients with ML IV do not show skeletal changes or organomegaly. Diagnosis is based on demonstration of inclusion bodies in the lysosomes of different cells types (e.g., skin or conjunctiva). Ultrastructural studies reveal heterogeneous lysosomal storage of laminated membranous material and granular, amorphous vacuoles. Prenatal diagnosis is possible through specific mutation analysis, or linkage studies in cases where the causal mutation is unknown and with electron microscopic examination of amniocytes in search of the inclusion bodies.

Niemann–Pick type C is a neurovisceral disorder characterized by a wide spectrum of manifestations, ranging from fatal neonatal liver disease to isolated splenomegaly in late childhood. Neurological findings include ataxia, vertical supranuclear ophthalmoplegia, dystonia, and dementia with progressive deterioration. Neurofibrillary tangles have been found in the brain of patients with a slowly progressive course. Biochemically, there is evidence of lysosomal sequestration of endocytosed low-density lipoprotein (LDL)-derived cholesterol, premature and abnormal enrichment of cholesterol in *trans*-Golgi cisternae, and accompanying anomalies in intracellular sterol trafficking. Genetic heterogeneity, established by cell hybridization and linkage studies, has indicated the presence of two complementation groups that are indistinguishable from each other from a clinical, cellular, or biochemical perspective. Molecular studies have found that NPC can arise from a defect of a major locus, *NPC1* (~95% of cases) mapped to chromosome 18q11, or a minor locus (the *NPC2*, or *HE1*, gene) on chromosome 14q24.3. The *NPC1* gene encodes a multidomain membrane protein that may play a role in retrograde transport of several types of lysosomal cargo and/or may function as a transmembrane molecular pump. The *NPC2* (*HE1*) gene encodes a soluble lysosomal protein with cholesterol-binding properties. The accumulation of various glycosphingolipids, including GM2 ganglioside, in NPC is believed to contribute to the neurodegenerative changes encountered in this condition.

Studies have shown that Niemann–Pick type D (NPD), which is relatively common in southwestern Nova Scotia due to a founder effect (i.e., a high incidence within a population derived from a common ancestor), also arises from mutation of *NPC1*. Thus, Niemann–Pick types C and D are allelic disorders – that is, they are disorders which result from different mutations in the same gene. A point mutation within the *NPC1* gene (G3097→T; Gly992→Trp) has been demonstrated in NPD patients.

Danon disease (lysosomal glycogen storage disease with normal acid maltase) is a rare disorder characterized by mental retardation, myopathy, and cardiomyopathy. It is inherited in an X-linked inheritance fashion. As in Pompe disease (an acid maltase, i.e., β-glucosidase, deficiency), muscle cells exhibit intracytoplasmic vacuoles containing glycogen and autophagocytic material. Defects in the gene encoding lysosomal-associated membrane protein 2 (LAMP-2) have been identified as the cause. It is suspected that storage in Danon disease occurs secondary to a failure of fusion of autophagic vacuoles with endosomes/lysosomes or the maturation of autophagolysosomes into digestive organelles.

Additional very rare LSDs have been described. Glutamyl ribose-5-phosphate storage disease is a newly delineated lysosomal storage disorder associated with progressive neurological deterioration (developmental delay, seizures) and renal failure. In this disease the

deficiency of adenosine diphosphate (ADP)-ribosyl protein lyase results in a defect of posttranslational modification (ADP-ribosylation) of proteins. Patients demonstrate neuronal storage of periodic acid–Schiff (PAS)-positive material. Recently, a deficiency of serum hyaluronidase (designated as mucopolysaccharidosis IX) was reported associated with a mild clinical phenotype characterized by periarticular soft tissue masses, mild short stature, and absence of neurological or visceral involvement. The patient showed histological and ultrastructural evidence of a lysosomal storage disease. A mutation in hyaluronidase 1 (chromosome 3p21.3) was identified. In addition, recent examination of the biochemical and molecular data of patients with α-*N*-acetylgalactosaminidase (α-NAGA) deficiency, which is thought to lead to a form of neuroaxonal dystrophy (Schindler disease), strongly suggests that factors other than α-NAGA may be relevant in determining disease expression.

Management

The mainstay of treatment for most of the LSDs has been primarily palliative or supportive care. Early complementation studies have shown that when two cells lines from patients with different LSDs, such as Hurler (MPS I) and Hunter (MPS II) syndromes, are co-cultured, there is often cross-correction of the metabolic defect. This observation provided the rationale for consideration of cellular (bone marrow) transplantation, enzyme therapy, and gene therapy.

Bone marrow therapy and hematopoietic stem cell transplantation have been attempted for a variety of LSDs, with varying success. The differences in response appear to be dependent on the age of onset and rate of disease progression. Treatment is directed at prevention or amelioration of the inexorable neurological deterioration that is the major pathophysiological event. Recent reports on BMT include description of long-term engraftment in a single patient with Wolman disease; this led to normalization of peripheral leukocyte lysosomal acid lipase enzyme activity, associated with gains in developmental milestones, normal liver function, and normal levels of cholesterol and triglyceride. In a patient (a 9.6-month-old female) with Farber disease, BMT was reported to result in resolution of several features, including subcutaneous lipogranulomata, pain on joint motion, and hoarseness, 2 months posttransplant. Despite modest gains in cognitive and language development, hypotonia and delayed motor skills persisted and there was progressive decline with loss of engraftment, and death at 28 months after BMT (age 37.5 months). In four patients with late-onset Krabbe disease (globoid cell leukodystrophy), the central nervous system deterioration was reversed. Brain magnetic resonance imaging (MRI) showed a decrease in signal intensity in the three patients with late-onset disease who were assessed both before and after transplantation, and abnormalities in cerebrospinal fluid total protein levels were corrected in three of these patients. Long-term data on a greater number of patients for whom BMT has been attempted are required before consideration of its more generalized application.

The high morbidity and mortality associated with BMT has prompted consideration of other therapeutic approaches. Enzyme therapy for Gaucher disease was introduced in 1991, initially using the purified human placental-derived glucocerebrosidase (acid β-glucosidase). Subsequently, the placental product (Ceredase) was replaced with a recombinant enzyme (Cerezyme), isolated from Chinese hamster ovary (CHO) cells transduced with the human gene sequence and subsequently modified to expose the α-mannosyl residues of the protein product for enhanced uptake by the macrophage. The use of these enzyme formulations in symptomatic patients has been shown to be safe and effective in reversing the clinical manifestations of Gaucher disease. Other disorders in which enzyme therapy is available include Fabry disease, Pompe disease, and certain subtypes of MPS (I, II, and VI). These diseases are associated with well-characterized phenotypes and defined single-enzyme deficiencies. In contrast to the recombinant enzyme administered to patients with Gaucher disease, the enzyme formulations for the latter LSDs rely primarily on targeted delivery of the relevant enzyme through the M-6-P receptors. For Fabry disease, two enzyme formulations are currently available in Europe, distinguished based on the cellular source of the recombinant enzyme. The recombinant α-galactosidase A is generated using either human (Replagal) or CHO (Fabrazyme) cells; the latter formulation is currently the only form available in the United States.

Substrate synthesis inhibition (also referred to as substrate reduction therapy), using miglustat (an imino sugar), has recently been approved for the treatment of Gaucher disease. The same molecule is being explored as a therapeutic option for other types of sphingolipidosis (GM2 gangliosidosis, including Sandhoff disease and Fabry disease) and for Niemann–Pick type C. This approach relies on maintaining substrate flux by limiting the amount of precursor substrate synthesized and ultimately presented to an impaired enzyme that has low but some degree of residual activity. An interesting study recently reported on the potential for the use of phosphocysteamine in patients with neuronal ceroid lipofuscinosis. Phosphocysteamine has been administered to patients with nephropathic

cystinosis as a means of suppressing lysosomal cystine storage. Phosphocysteamine also shows the ability to disrupt thioester linkages in palmitoylated protein and, thus, may mediate the depletion of lysosomal ceroids in the NCLs. Gene therapy is also being considered, although most trials have been restricted to animal models of disease. A limited trial performed on humans with Gaucher disease has not been shown to lead to sustained benefit because enzyme expression was not persistent in the virally transduced cells. More recent investigational strategies include chaperone-mediated enzyme enhancement and stop-codon readthrough.

Lysosome and Endosome Organization and Transport in Neurons

Introduction

The cellular compartments interposed between the trans-Golgi and plasma membrane are essential for neuron development and function. Neuronal endosomal and lysosomal pathways are similar to other cell types in the response to extracellular signals, dissociation of signal from receptor, receptor down-regulation, and killing of foreign invaders. Neurons also use endosomal pathways to recycle synaptic vesicles and reload them with neurotransmitter. A key question is how compartments of the endosome–lysosome pathway are related spatially in the neuronal cytoplasm, and how the often great distances between them are traversed in light of temporal parameters of cellular processes such as cell death, differentiation, and intercellular communication. The actin and microtubule cytoskeletal elements and their associated motor proteins effect the movement of endosomal vesicles in neurons. Membrane budding and fusion events are tightly regulated in response to changing conditions within and outside the neuron, and vesicle budding and fusion events are coupled to the recruitment of specific motor proteins through the activity of the Rab superfamily of small guanosine triphosphatase (GTPase) proteins. Disruption of endosomal transport pathways through impairment of motor protein function can cause neurodegenerative disease, whereas illnesses related to disruption of cholesterol homeostasis and glycolipid metabolism are caused by loss of function or transport of specific lysosomal enzymes. Here we review the importance of endosomal and lysosomal transport pathways in neurons, the role and regulation of motor proteins involved in those pathways, and the consequences of disrupting their normal function.

Endosome to Lysosome, with Stops along the Way

Endosome and lysosome compartments are characterized by their morphological and functional properties. Endosomes are typically involved with the sorting and delivery of lipid vesicles and their contents to and from the plasma membrane. 'Early' endosomes are positioned close to sites of active endocytosis, where they can act as a recycling compartment for vesicles budding from the plasma membrane. In this way, early endosomes provide a sorting environment for lipid, protein, and extracellular molecules contained within endocytic vesicles. Early endosomes are sometimes formed by the fusion of several endocytic vesicles, but they often exist as stable structures near the presynaptic and postsynaptic membranes. Sorting signals on transmembrane and soluble proteins provide instructional cues regarding whether a protein will return to the plasma membrane or be packaged into membrane-bound organelles destined for the 'late' endosome. For example, transmembrane receptors essential for neurotransmission may be returned to the plasma membrane, but components of active signaling pathways may be transported to the cell body, where those cues are amplified and implemented by downstream signaling events. In some neurons, a distinct recycling endosome is positioned between the early endosome and plasma membrane in the recycling pathway.

Membrane-bound organelles destined for the late endosome bud from the early endosome and are transported in a retrograde fashion toward the cell interior. In some neurons, a perinuclear endocytic recycling compartment serves as an intermediate stopping point between early and late endosomes. The transport 'carriers' between early and late endosomes can be individual vesicles, elongated tubules, or multivesicular bodies (MVBs) formed by fusion and subsequent modification of early endosome vesicles. There is some evidence that specialized signaling endosomes, having characteristics of early endosomes, transport growth factor signals along the axon, providing rapid signal propagation and spatial-temporal regulation of signaling cues.

The late endosome is a key sorting point for membrane vesicles and their contents. Proteins destined for the lysosome arrive at the late endosome from the trans-Golgi and early endosome compartments; vesicles bud from the late endosome to travel to the trans-Golgi or lysosome. Signal motifs and post-translational modifications such as glycosylation determine whether a protein in the late endosome will be incorporated into vesicles destined for the trans-Golgi or lysosome. For example, transmembrane receptors transported to the late endosome are usually transported to lysosomes, but phagocytosed virus particles and active signal transduction pathway components are transported to the trans-Golgi. In addition, cytosolic cysteine residues of many membrane-associated proteins can be targeted with ubiquitin to signal their transport to multivesicular bodies from the endosomal pathway and subsequent degradation within lysosomes.

Lysosomes are acidic organelles that facilitate the digestion of proteins, organelles, and extracellular debris through the action of acid hydrolases. In neurons, lysosomes have an important role in receptor downregulation of membrane receptors to attenuate response to extracellular ligands. Lysosomes are also essential for degrading G-protein aggregates associated with neuropathies such as Huntington's disease (HD) and are important for regulating cholesterol homeostasis. Receptor proteins on the plasma membrane are delivered directly to lysosomes through the formation of MVBs that fuse with the lysosome. Cytoplasmic structures such as organelles, ribosomes, and protein aggregates are delivered to lysosomes through the formation of autophagic vacuoles by membrane cisterna that surround the cytoplasmic component to be degraded and then fuse with the lysosome. Lysosomes are also formed by the maturation and acidification of late endosomes, thereby degrading endocytosed material not targeted to the trans-Golgi for recycling.

Positioning of Endosomes and Lysosomes in Neurons

A stereotypical neuron has morphology analogous to that of a polarized epithelial cell. The axon is the apical surface; organelles are actively targeted to the axon using cargo-specific information and cytoskeletal modifications; organelles and proteins lacking an axon targeting signal are excluded from axons at the axon hillock and thus reside in the cell body. Early and recycling endosomes are located near the presynaptic and postsynaptic membranes and in the cell body, but lysosomes are typically juxtanuclear, near the microtubule organizing center (MTOC). Late endosomes are usually found in the cell body near the Golgi complex. To ensure normal neuron function, organelles of the endosome pathway must be located at their appropriate locations within the cell, and protein–protein and membrane–membrane interactions must occur specifically and efficiently. Small GTPases act as master regulators of organelle positioning and membrane dynamics, whereas motor proteins and the microtubule and actin cytoskeleton facilitate interorganelle transport and maintenance of organelle distribution.

A Large Family of Small GTPases Controls Transport and Fusion Events

Fusion of donor and target membranes in the endosome pathway must be controlled precisely to maintain the distinctiveness of each compartment and deliver macromolecules to the appropriate destination. Membrane interactions among cell compartments are controlled by small GTPases that cycle between guanosine diphosphate (GDP)-bound cytosolic and GTP-bound membrane-associated states. The Rab superfamily of small GTPases regulates membrane budding, transport, and fusion events within the endosome pathway. There are many different Rab family members, each of which interacts with a different membrane type to facilitate homotypic or heterotypic membrane fusion and provide directionality to membrane transport. Rab proteins do not perform membrane budding, transport, and fusion; rather, GTP-bound Rabs recruit specific proteins to donor and target membranes to facilitate these events. For example, early endosome membranes bind Rab5-GTP through the activity of Rab5-binding protein Rabex5 and Rabaptin5. Next, Rab5 recruits phosphatidylinositol-3-OH kinase (PI(3)K) effectors that add phosphate groups to phosphatidylinositol to generate phosphatidylinositol-3-phosphate (PtdIns(3)P). Proteins containing the Fab1p, YOTB, Vac1p, and EEA1 (FYVE) finger structural motif bind to PtdIns(3)P and are recruited to microdomains of PtdIns(3)P on early endosomes. FYVE finger proteins act as Rab5 effectors to facilitate vesicle budding, transport, and fusion events away from early endosomes, congression of vesicles during early endosome formation, and tethering of early endosome membranes in close apposition to donor compartments such as the presynaptic membrane. These findings and others support a model in which different Rabs are recruited to specific membrane compartments and the binding partners and effectors of these Rabs impart each membrane compartment with its specific functional properties. Therefore, while the detailed mechanisms controlling effector protein recruitment and function differ for individual Rabs, the general theme of Rabs as the master controllers of endosome pathway transport is shared within the endomembrane system.

Microtubule Motors Involved in Endosome and Lysosome Transport

Microtubule motor proteins convert the energy of ATP hydrolysis into processive movement along microtubules. There are two major classes of microtubule motor proteins, kinesins and dyneins. Kinesins typically walk toward the plus end of microtubules, whereas dyneins walk toward the minus end. Microtubules are usually oriented so that the plus end is located at the cell periphery and the minus end is closer to the cell body. In neurons, microtubule plus ends point toward the presynaptic membrane, but dendritic microtubules are of mixed polarity. The orientation of microtubules is important for developing hypotheses for which types of motor

protein can drive organelle translocation and positioning in the endosome–lysosome system. For example, plus end-directed motors such as kinesin-1 could be involved in delivering receptors from recycling endosomes to the plasma membrane, whereas dynein could be responsible for delivering endosome-derived tubules and multivesicular bodies from distal locations to late endosomes in the cell body. Several microtubule motors have been shown to mediate membrane transport in the endosome–lysosome pathway. Although some studies have been conducted in nonneuronal systems, such as cultured mammalian cells, the motors described below are expressed in the nervous system; a reasonable prediction is that these proteins display similar transport properties in neurons.

KIF13A

The kinesin-3 family member KIF13A transports vesicles from the trans-Golgi to endosomes, lysosomes, and plasma membrane through direct binding to β1-adaptin component of the adaptor protein 1 (AP-1) adaptor complex. KIF13A messenger RNA (mRNA) is expressed ubiquitously in the developing and adult mouse and is found in membrane and cytosolic fractions from mouse brain lysates, and immunostaining shows that KIF13A is associated with the trans-Golgi and AP-1-containing cytoplasmic vesicles. AP-1 associates with membranes through its interaction with the transmembrane mannose-6-phosphate receptor (M6PR) in the trans-Golgi, providing a cue to build a clathrin-coated vesicle at the site of AP-1 binding and tether a motor to the nascent vesicle. The M6PR directs proteins from the trans-Golgi to late endosomes and lysosomes through cytoplasmic binding of AP-1 and lumenal binding of glycoproteins modified with M6P. The phenotype of KIF13A knockouts is not known; overexpression of KIF13A in cultured cells causes redistribution of AP-1 and M6PR from the Golgi to the tips of neuritelike processes, but the overall distribution of endosomes and Golgi membranes is not affected. M6PR at the plasma membrane binds to soluble ligands such as insulin-like growth factor II, mediating their endocytosis and degradation within the lysosome. This suggests a model in which KIF13A might have an indirect role in nervous system development by delivering M6PR to the plasma membrane. M6PR could then attenuate the extracellular concentration of specific growth factors through their endocytosis and lysosomal degradation.

KIF16B

The kinesin-3 family member KIF16B has a Phox homology (PX) lipid-binding domain that facilitates interaction with membranes containing PtdIns(3)P-lipids. Rab5 recruits KIF16B to early endosomes through Rab5 effector hVPS34/p150, which catalyzes formation of the phospholipid PtdIns(3)P on early endosome membranes. In cultured cells, KIF16B is localized to early endosomes in a PtdIns(3)P- and Rab5-dependent manner. Overexpression of KIF16B causes early endosomes to redistribute to the cell periphery, and loss of KIF16B function causes perinuclear endosome clustering. Knockout experiments in cultured cells implicate KIF16B in early endosome recycling events, such as recycling of transferrin and epidermal growth factor receptor (EGFR) to the plasma membrane. Reduction of KIF16B function causes delayed recycling of transferrin receptor back to the plasma membrane and prevents the entry of endocytosed EGFR into the lysosomal degradation pathway. This leads to an accumulation of EGFR in early endosomes of cells that lack KIF16B. Because epidermal growth factor and its receptors have important roles in the development and differentiation of pre- and postmitotic neurons, KIF16B, like KIF13A, could have an important but indirect role in neural cell signaling pathways during and after embryonic development.

Kinesin-2

Kinesin-2 is important for the transport and distribution of membrane-bound organelles in neuronal and nonneuronal cells. Loss of kinesin-2 function causes defects in axonal transport in *Drosophila* sensory neurons, failure to transport pigment granules in vertebrate photoreceptor and pigmented epithelial cells, and loss of cilia required for sense organ and kidney function. Recent experiments in cultured cells have demonstrated that loss of kinesin-2 function causes late endosomes and lysosomes to become concentrated in the cell interior near the MTOC. This effect is caused by a reduction in outward plus end movement of late endosomes and lysosomes away from the MTOC. While the transport of endocytosed probes from early to late endosomes is not affected in cells lacking kinesin-2, it is plausible that recycling of endocytosed receptors back to the plasma membrane could require kinesin-2 function. Kinesin-2 interacts directly and indirectly with membrane cargoes through protein–protein interactions between the kinesin-2 tail domain and proteins on the cargo surface. Regulation of membrane–kinesin-2 interactions can occur directly, as endosomal Rab4 binds kinesin-2 in coimmunoprecipitation experiments, or indirectly, as kinesin-2 binds cytoplasmic dynein, which can also bind membrane cargoes (described below). Kinesin-2 is expressed ubiquitously but accumulates at highest levels in the nervous system; future work will explore further the potential role of kinesin-2 in lysosome and late endosome transport *in vivo*.

Kinesin-1

Kinesin-1 is the major anterograde motor for transport along microtubules. Loss of kinesin-1 function results in lethality and defects in intracellular transport and nervous system development. Kinesin-1 is essential for the transport of mitochondria, endoplasmic reticulum- and Golgi-derived vesicles, messenger RNAs, and tubulin and intermediate filament subunits, but kinesin-1 family members such as mouse KIF5 are also directly involved in endosome and lysosome transport in neurons. Mutations that block KIF5 motor activity block centrifugal transport of lysosomes. Earlier studies also show that kinesin-1 is involved in the movement of endosome-derived membranes and dispersion of vesicles from the endosome recycling compartment. Another important function of kinesin-1 is the transport of minus end-directed microtubule motors such as dynein and KIFC2 to the cell periphery, where they can bind to cargoes for centripetal transport toward the cell interior. Like kinesin-2, specific protein–protein interactions mediate cargo–kinesin-1 interactions; for example, the adapter protein glutamate receptor interacting protein 1 links kinesin-1 to dendritic-recycling endosomes containing the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor. Although plus end motors such as kinesin-2, KIF16B, and KIF13A are required for specific endosomal transport events, it is likely that there is some functional redundancy among these motors and kinesin-1.

KIFC2

The minus end-directed kinesin-14 family member KIFC2 carries multivesicular bodies to dendrites and is essential for the fission of vesicles destined for late endosomes from early endosomes. KIFC2 is expressed in the developing and adult mouse brain and is found associated with membrane-bound organelles such as endosomes and MVBs in dendrites, axons, and cell body. In mammalian cells, KIFC2 and kinesin-1 are associated with early endosomes, but dynein, KIFC2, and kinesin-2 are found on late endosomes. Rab4 regulates KIFC2 activity, but in an unexpected way. Rab4-GDP enhances KIFC2 activity, in contrast to kinesin-2, whose activity is enhanced by Rab4-GTP. This observation suggests that the nucleotide-bound state of Rab4 may regulate whether early endosomes move toward the plasma membrane (Rab4-GTP, kinesin-2 active) or toward the late endosome (Rab4-GDP, KIFC2 active). There are some questions about the *in vivo* importance of KIFC2-dependent transport, as mice lacking KIFC2 are normal; perhaps this reflects functional redundancy with other minus end microtubule motors such as dynein. Therefore, while KIFC2 clearly functions in the retrograde transport of early endosomes, further work is required to better understand the relevance of KIFC2-mediated transport *in vivo*.

Cytoplasmic Dynein

The minus end-directed microtubule motor cytoplasmic dynein transports organelles toward the cell interior. It is composed of many subunits, some of which hydrolyze ATP to generate force and others, such as dynactin, regulate dynein-based transport and link motor activity to cargo transport. Dynein is important for transporting retrograde signaling endosomes inward from the synapse and delivering autophagosome contents to lysosomes, and it has an essential role in the formation of aggresomes, which are clusters of cytoplasmic protein aggregates transported toward the MTOC. Aggresomes are thought to have a neuroprotective function by concentrating protein aggregates in one location, thereby helping to facilitate their removal by autophagy.

A current model for dynein-dependent membrane transport is that dynein and its associated proteins are transported by kinesins to the plus end of microtubules at the cell periphery, where dynactin and membrane cargoes bind to the microtubule tip in a CLIP170-dependent manner. Next, dynactin recruits dynein, and the motor cargo complex proceeds along microtubules toward the cell interior. An alternative scenario is that stable microtubules located near cortical actin filaments can have cargoes delivered to their plus ends by actin–myosin-dependent pathways. Subunits of the dynein–dynactin complex interact with membranes through protein–protein and protein–lipid interactions. For example, dynein light chain and dynactin are Rab4 and Rab5 effectors on early endosomes, and the Rab7 effector protein called Rab-interacting lysosomal protein recruits dynein to late endosomes.

Role of Actin and Myosin in Endosome–Lysosome Transport

The actin cytoskeleton has an important role in membrane transport within the endosome pathway. Like microtubules, actin filaments have an intrinsic polarity. The plus (barbed) end of actin filaments is typically oriented toward the plasma membrane, so myosin motors that move toward the barbed end have been proposed to be involved in moving organelles toward the plasma membrane, whereas minus (pointed) end-directed myosins may be involved in centripetal transport events. While actin filaments can serve as a substrate for myosin-based transport events, actin filament polymerization near membranes can provide

mechanical forces sufficient for vesicle movement. The Rho family of small GTPases, such as RhoA, Rac1, and Cdc42, can bind membranes and recruit proteins that nucleate actin filament growth. Rho GTPases can also affect actin dynamics by stimulating actin filament severing and depolymerization. This facilitates remodeling of the actin cytoskeleton near the cell surface, which is often required for endocytosis, exocytosis, and phagocytosis to occur. In the endosome–lysosome pathway, Cdc42-like protein TCL is required for delivery of clathrin-coated vesicles to early endosomes, and RhoB and RhoD affect endosome dynamics through recruitment of actin filaments to early endosomes. Therefore, it appears that actin dynamics have an essential role in intracellular membrane dynamics, as has been observed for cell motility phenomena.

Myosin-V

The plus end-directed myosin-V translocates vesicles processively along actin filaments, thus enabling this motor to transport cargoes over relatively long distances, but it also plays an important role in tethering organelles near the plasma membrane. Myosin-V has been implicated in the transport of specialized lysosomal organelles called melanophores in pigmented epithelial cells, in addition to phagosomes and vesicles associated with early endosomes. Regulated attachment of myosin-Va to melanophores is mediated by melanophilin, which links myosin-Va to Rab27 on the melanosome surface. Loss of myosin-Va, Rab27, or melanophilin function in mice results in skin pigmentation defects because of dynein-dependent transport of melanophores away from the plasma membrane. Myosin-Vb binds to Rab11 family of interacting protein 2 (Rab11-FIP2), an effector of Rab11 on recycling endosomes, suggesting that FIP2 recruits myosin-Vb to recycling endosomes, perhaps for delivery of vesicles along actin filaments to the plasma membrane. Interactions between myosin-V, dynein, and kinesin have been observed, suggesting that these motors may link actin- and microtubule-dependent transport.

Myosin-VI

The nonprocessive minus end-directed motor myosin-VI has an important role in diverse membrane transport events. It is found associated with clathrin-coated endocytic vesicles, Golgi membranes, and secretory vesicles. Because myosin-VI is a minus end motor, a model for its function is the delivery of endocytic vesicles to early endosomes, as well as the maintenance of Golgi morphology. Loss of myosin-VI function in *Snell's waltzer* mice results in deafness, defects in endocytosis, and a small Golgi phenotype. Myosin-VI binds to trans-Golgi membranes through its interaction with optineurin, which is an effector of Rab8. Similar interactions are observed between myosin-VI and Rab11-FIP2, an effector of Rab11 on recycling endosomes, much like the interaction observed between myosin-Vb and Rab11-FIP2. During endocytosis, myosin-VI interacts with Dab2, which binds to the low-density lipoprotein (LDL) receptor and clathrin adapter protein AP-2. Therefore, it appears that Dab2 links centripetal actin-dependent transport by myosin-VI with formation of endocytic vesicles containing the LDL receptor.

Myosin-VII

Myosin-VII is a plus end-directed actin motor required for melanosome and lysosome transport. Loss of myosin-VIIa function is responsible for the *shaker-1* mouse phenotype and causes human Usher syndrome type 1B (USH1B). The symptoms of USH1B include deafness, blindness, and vestibular dysfunction. The blindness observed in USH1B patients is caused by a failure of melanosome transport in retinal pigmented epithelial cells, as well as defective phagocytosis of photoreceptor disks, a process essential for the replacement of aging rhodopsin-containing membranes. Myosin-VIIa binds to membranes using a mechanism similar to myosin-Va, using the Rab27 effector melanophilin to bind membranes in a Rab27-dependent manner.

Myosin-X

The plus end-directed myosin-X is essential for phagocytosis in mammalian cells. Like KIF16B, myosin-X binds to phospholipids modified by PI(3)K. Myosin-X is important for filipodia extension in motile cells; by analogy, perhaps it provides motile forces for pseudopod extension at the plus end of actin filaments. This observation leads to the appealing model that small GTPases recruit PI(3)K to sites where phagocytosis will occur, and then the generation of PtdIns (3)P recruits myosin-X, resulting in the formation of a phagocytotic cup around the particle to be engulfed. At this time, the identity of the proteins required for recruitment of myosin-X to membranes is unknown.

Involvement of Endosome–Lysosome Transport in Neurological Disease

Defects in the endosomal pathway have been implicated in the pathogenesis of various neuropathies. Disruption of nerve growth factor (NGF) signaling, which leads to a decreased rate of neurite outgrowth, has been implicated in a number of neurodegenerative diseases, including Down syndrome, Alzheimer's disease (AD) and HD. Binding of NGF to the TrkA receptor at the synapse triggers the NGF signaling pathway,

which induces receptor dimerization, phosphorylation, and the formation of early endosomes transported by dynein to late endosomes. There, TrkA dissociates under increasingly acidic conditions and is usually recycled back to the plasma membrane, whereas NGF translocates to the nucleus to regulate transcription of select genes. NGF signaling is disrupted in the mouse model for Down syndrome, which displays similar pathology to AD, and these defects are similar to those observed in NGF or TrkA knockout mutants.

TrkA expression is downregulated and neurite outgrowth is impaired in cells in which huntingtin-associated protein-1 (HAP1) is mutated. HAP1 was originally identified in a yeast two-hybrid screen for proteins that bind huntingtin, which contains polyglutamine expansion mutations that form aggregates in HD. HAP1 also binds the kinesin light chain and the p150Glued subunit of dynactin, indicating that it may be involved in motor protein-mediated trafficking. Neurons in which HAP1 is expressed display less-serious degenerative phenotypes, and it is interesting that HAP1 also binds vesicles containing amyloid precursor protein, providing a possible connection to the defects in NGF signaling displayed in AD.

A second huntingtin-associated protein, HAP40, mediates the recruitment of huntingtin to early endosomes in a Rab5-dependent manner and may help early endosomes move from actin-dependent transport near the plasma membrane to microtubules. Upregulation of HAP40 is observed in fibroblasts in HD patients, resulting in reduced movement of early endosomes along microtubules and preferential localization of HAP40 to cortical actin filaments.

The clearance of aggregate-prone proteins, including huntingtin, appears to be mediated by dynein, which facilitates autophagosome–lysosome fusion. Autophagy is important in the clearance of the small, oligomeric precursors into larger protein aggregates that appear to be particularly harmful in neurodegenerative disease. Dynein, as previously mentioned, also mediates the formation of larger protein aggregates, known as aggresomes, which it transports toward the MTOC. In contrast to smaller aggregate precursors, aggresomes appear to play a protective role in neurodegenerative disease.

Disruption of the function or regulation of individual Rabs may contribute to some neurological diseases. Charcot–Marie–Tooth syndrome (CMTS) and Niemann–Pick disease involve inhibition of the bidirectional transport and elevated cholesterol levels of late endosomes. Symptoms of these diseases include impaired motor skills, loss of nerve sensitivity, and paralysis. Cholesterol upregulates the Rab7 cycle, in which Rab7 induces the recruitment of dynein–dynactin to late endosomes. Forms of CMTS are caused by mutations in either Rab7 or the plus end-directed KIF1B motor protein that impairs anterograde transport of cholesterol-containing endosomes, leading to defects in cholesterol metabolism. Mutations in ALS2 can cause amyotrophic lateral sclerosis (ALS), and ALS2 binds Rab5 *in vitro* and functions as an Rab5 guanine exchange factor. In addition, ALS2 associates with endocytic membranes, further supporting a role for ALS2 in endocytic vesicle formation and trafficking and suggesting that ALS symptoms could partially result from a disruption of Rab5-dependent endosome transport.

In addition to its involvement in disease, dynein-mediated retrograde endosomal signaling is important in the response to nerve injury. Dynein binds proteins such as importins that link it to a variety of signals involved in nerve injury response pathways. Importins bind proteins with nuclear localization signals, including transcription factors and members of the microtubule-associated protein (MAP) kinase family, transporting them to the cell body and toward the nucleus through their association with dynein. In addition, scaffold proteins involved in the endosomal pathway, such as vimentin and JIP3, are also implicated in the connection between importins and signaling molecules. Vimentin binds both the MAP kinase Erk and importin-α, and JIP3 and its activated binding partner, Jnk, interact with both dynein and kinesin-1 and are associated with vesicles in axons following injury. The transport of this injury-signaling complex results in various cellular responses, including the downregulation of neurotrophic signaling.

Machine Haptics

Introduction

Modern haptics can be defined as the science, technology, and applications associated with information acquisition and object manipulation through touch. Within this broad multidisciplinary field, human haptics is concerned with manual exploration and manipulation by humans, whereas machine haptics is concerned with touch-based interactions mediated by electromechanical and computational devices. Haptic interfaces enable users to engage manually with things and people that are either virtual or distant. This may seem like science fiction, but it is in many ways not dissimilar from visual interfaces, which are now so commonplace as to seem completely natural. In visual interfaces, an image of a real or imagined object or medium is rendered graphically and the digital representation is available to be manipulated by a computer, sent from computer to computer, or displayed on screens; with haptic interfaces, a digital representation of the feel – the three-dimensional contour, hardness, and smoothness – of an object is conveyed to the user, which can be manipulated, transported, and available to different kinds of displays that are described later. Haptic interfaces seem less natural to us than visual interfaces partially because they are not yet prevalent and partially because haptic interfaces offer real differences from our accustomed ways of interacting with computers, some of which follow from the unique properties of the sense of touch.

Touch is the most immediate of the primary senses (touch, sight, and audition) with which we apprehend the world. Unlike the things we see and the things we hear, which, even when not apprehended through machines, are always at some remove from us, the things we feel are things that are in contact with us, things that are touching us as we touch them. Once immediate senses, such as touch and taste, are added to the engagement with computers, the experience becomes manifestly more immediate, more participatory, more part of a real world, and more immersive. Moreover, touch is the most consciously active, and most symmetric, of our senses. The things we feel are, often, things that we are actively exploring through our hands and are always things that can be affected by that exploration. Therefore, machine haptics, to a much larger extent than visual or aural interaction with computers, has this dual nature, consisting of the following:

- *Haptic displays*. Devices that provide simulations of the feel of objects during sensory-dominant manual exploration and motor-dominant manipulation. The use of these devices is parallel to that of a computer screen or an audio speaker.
- *Haptic sensors*. Devices that respond to information gained from the motions and/or forces of users' interactions. These are used to gather information about a user's manipulations similar to the computer mouse and in some ways are parallel to scanners and cameras that gather visual information about objects, or microphones that gather sound. However, haptic sensors are used to infer user's intention in interacting with objects and models of objects and interactions are built to take advantage of this information.

A full machine haptic system would incorporate both of these aspects and their interaction. For example, imagine a physical interface that worked as a kind of virtual plastic modeling material, such as plasticene or clay whose material behavior can be controlled through a computer program. Suppose its shape, texture, and hardness could be continually updated using a computer model based on the forces applied by the user's hands. That recomputed model would then affect what the user feels through the haptic display, thus enabling different object feels through the same physical interface.This scenario is beyond the scope of current technology but will eventually be realizable. It is important to note how this kind of system differs from vision. A full visual system may have a camera to take visual input and a screen to give graphical output, but the very act of the user looking at the screen does not provide much information to the system. The haptic interface is more similar to a head-mounted visual display in which the position and orientation of the user's head drives the graphical image.

Machine haptics can involve both the stimulation and the simulation of the human haptic system, as represented by two broad categories of systems in which haptic machines are used: virtual environments (VEs), in which the human interacts with a computer-based synthetic environment, and teleoperation (TO), in which the human can operate on the real environment at a distance through interface devices.

In the case of VE systems, the computer represents a VE and there are essentially two actors in the system: the human and the computer. Figure 1 shows the

relationship between the machine and the human in a haptics-enabled VE. The central box contains the tip of a haptic interface device which the user grasps. The left-hand loop of the picture shows the human interaction with the device. The human senses, through his/her contact with the device, forces to which he/she responds by providing motor signals that move his/her hand, which in turn affects the device. As shown in the right-hand loop, the computer attached to the device senses the movement of the device and responds by sending commands that create the forces the device applies on the human. Both the human and the computer systems have sensors (receptors and encoders), processors (brain and computer), and actuators (muscles and motors). That is, the machine haptic system mirrors and extends the human haptic system.

In the case of TO systems, the haptic interface is connected to a computer as previously discussed, but that computer, in turn, is connected to another computer, either directly or over a network such as the Internet, and haptic signals are sent back and forth between the two. This allows a user of the first computer to interact with a real environment through an interface device such as a robot that is connected to the second computer. This kind of TO system is summarized in Figure 2.

Figure 1 Human–machine haptic interaction in virtual environments.

More complex haptic interactions are possible with a system that combines VEs with TO to enable two-way interactions across a network. One case of this was in 2002 when people at the MIT Touch Lab shook hands, transatlantically, with people at University College, London. In the future, haptic interactions at a distance will be prevalent, powerful, and important. These systems bring with them several new technical challenges (e.g., dealing with the latency of the transmitted signals) as well as new kinds of applications. However, for the sake of ease of explication, this article is confined to the more simply explained VE paradigm until the applications section, in which emerging practical uses of VE and TO systems are discussed together. The section above brings out at least two reasons why a neuroscientist might be interested in machine haptics. First, machine haptics provides a particular way of doing neuroscience: having unprecedented control over touch stimuli displayed through haptic interfaces allows experimentation with the human haptic sensory system, the human motor system, and interactions between the two, as well as with other sensory systems such as vision and hearing. Second, machine haptics provides an application area for neuroscience: bringing neuroscientific knowledge of the human haptic system to engineering design will help create improved haptic interfaces in the future. The development of engaging, compelling haptic interfaces will require an understanding of the roles played by the mechanical, sensory, motor, and cognitive subsystems of the human haptic system. Therefore, machine haptics, both as a research topic and as a branch of engineering, in its search to provide natural touch interfaces for computers, requires an understanding of human haptics and an understanding of the psychology of human–machine and human–human interactions in VE and TO systems, as well as the technological questions of hardware and software.

Figure 2 Human–machine haptic interaction in teleoperated environments.

However, because human haptics is treated in another article in this encyclopedia, we concentrate here on the technological aspects, providing discussions of how far the technology (both hardware and software) has already come in providing effective interfaces, what will make more engaging interfaces in the future, and current and potential application areas for these technologies.

What Needs to Be Simulated?

Although haptics includes feeling by other parts of the body as well, including tongues and backs, the vast majority of haptic machines, to date, concerns interfacing with hands. The goal of this work is to create systems that will respond to a user's interactions in ways that are similar to, and ultimately indistinguishable from, real objects when they are explored by a user's hands, either directly or through the use of a tool. The properties of an object that need to be modeled and simulated, therefore, are exactly those properties that people explore with their hands. These include shape, size, and possibly weight, but also surface properties of the material, such as roughness and compliance, as well as thermal properties.

Moreover, the interface, if it is to get input from the user's interactions, must also model the user. That is, there must be pressure exerted by the user on the object and even the user's movements when no contact is made. Imagine the situation of picking up an object and moving it. To be able to sense this, the system must be able to track (1) free motion, in which no physical contact is made with objects in the environment; (2) contact involving unbalanced resultant forces, such as pressing an object with a finger pad; and (3) contact involving self-equilibrating forces, such as squeezing an object in a pinch grasp. The design of a haptic interface depends fundamentally on which of these two last elements you are most interested in simulating.

Haptic Interfaces: How Can Touch Be Simulated?

To give a sense of what machine haptics is about, we describe the basic operations of two kinds of haptic displays, and one idea for a haptic input device, before generalizing to map out a taxonomy of machine haptics.

Tool-Based, Force Feedback Haptic Displays

This kind of display aims to simulate the experience of touching an object with a penlike tool, or stylus. The user holds the stylus and moves it, while the movement is impeded in a way that simulates probing the displayed object with a penlike object in the real world. Figure 3 show one such device, SensAble Technologies' Phantom.

Figure 3 The Phantom haptic interface.

The stylus is attached to the tip of what is essentially a small robot arm through three rotary joints. The robot arm has three additional rotary joints, each controlled by an independent motor. The device exerts forces on the hand through the stylus by sending appropriate currents to the motors, controlling how easily each of the joints can rotate. In this way, force on the user can be approxiate currents to in any direction. The computer that is connected to the force-feedback interface takes readings, roughly once every millisecond, from all the six joints. Using this information, the computer can work out the position and orientation of the stylus to determine where the stylus maps onto the virtual world and its proximity to the virtual object being touched.

When the virtual position of the stylus collides with one of the objects in the virtual world, one or more of the motors stiffen a joint or several joints to exert a force on the user's hands that simulates the force that the modeled object would have exerted had the user collided with it in the real world. By moving the stylus around the space and probing until a force is felt, a user is essentially exploring the space, getting a sense of the contour, hardness, and texture of the objects. The user is prevented from penetrating the virtual object in a way that mimics the solidity of the physical object that is represented, unless penetration is desired, as in the case of virtual injections or surgery.

Tactile Display Arrays

Whereas the device described previously simulates the effect of exploring a space or an object with a tool, tactile arrays re-create the sense of exploring with fingers. This clearly calls for much finer distinctions and more delicate ways of imparting information. There are various technologies for trying to achieve this, including shape-changing displays, which convey the local shape of contact by controlling the deformation or forces distributed on the skin; vibrotactile displays,

which deliver mechanical energy through an array of vibrating pins placed against the skin; and electrotactile displays, which stimulate the skin through surface electrodes. Figure 4 shows one tactile display device developed at the MIT Touch Lab.

The display shown in Figure 4 has 30 pins, separated by about 2 mm. Each pin is capable of providing flexible mechanical stimulation in a wide range (static to ~325 Hz) with a normal displacement (~700 μm), large enough to feel even at low frequencies. This kind of device requires a finer modeling than tool-based systems. Here, small mechanical signals are imparted to the fingertips in an attempt to stimulate the same neural signals from the fingers to the brain as would be sent if the finger had been in contact with an object with particular material properties. This device has been shown to successfully display a wide variety of textures that are perceivable by human subject, although the current technology is limited. This technology is not yet mature and it does not permit spatial resolution that is as fine as that of the human fingertip, where mechanoreceptors are densely packed. When a user is attending closely to the display, he or she can still feel the individual pins, but this is a technical limitation that is expected to be overcome in the near future.

Haptic Sensing: Tactile Sensor Array

The two already-described devices are both displays providing outputs to the user so that he or she can feel an object. There are also haptic interactions in the other direction in which the computer gets information from the user's touch. A computer mouse is a haptic sensing device. The user touches the mouse, pressing buttons and/or moving the mouse's position, and the computer responds to those actions. Compared to the hand, the mouse is a crude device which only responds in a binary way to button pressing. There are much more sophisticated ways of reading the touch of a hand. One such is an array of pressure sensors from pressure profile systems, as shown in Figure 5.

The array contains a soft middle layer, surrounded by a layer of electrodes on either side. Two more soft layers enclose the electrodes to form the outer skin at the top and bottom. Pressure exerted on any part of the array alters the capacitance in the local area by decreasing the distance between the two electrode layers. In this way, a profile of how much a user is pressing each part of the material can be computed. If, for example, a material containing this kind of array was used to cover a joystick, then the system could gather accurate information about what parts of the joystick were being squeezed, and with what force, at any time, allowing for a quite intricate form of computer control. Tactiles sensor arrays are also used in robotics, when a robot is fitted with an array as a way of gathering information about the world it is exploring.

The two display and one haptic input technologies we have described are just three of many. In the next section, we put these in context by creating a general taxonomy.

Figure 4 Tactile display device.

Classification of Haptic Technologies

We have already discussed the fact that haptic interfaces come in several varieties. In this section, we enumerate some of the properties that differentiate haptic interfaces from one another and give an account of what kind of devices satisfy some of the combinations of attributes.

Figure 5 Array of pressure sensors.

Displays or Sensors

As already discussed, some devices are primarily displays, giving haptic information to the user, whereas others are sensing devices that take readings from the user's haptic interactions and interpret them as input data for the computer. In mechanical engineering terms, a system that puts out motions and forces is called 'active' and a system that only measures motions and forces is said to be 'passive.' In these terms, pure input devices are passive and haptic displays are necessarily active. Previously, we described the hypothetical medium of virtual clay, which we might think of as an active device.

Tool-Based or Direct Touch

Some haptic interface systems work by direct contact and others by simulating the use of tools. The directly felt interfaces could be meant for hands or fingers, but they also may be wearable devices that give signals directly to (and/or receive signals directly from) other parts of the body. A perfectly realistic interface would allow both tool-based and direct simulation.

Ground-Based or Body-Based Interface Device

Haptic interfaces may be stand-alone devices resting on a surface external to the user or they may be worn by the user. Since the forces applied by the user on the device in manipulating it need to be balanced by equal and opposite ground forces, the path of how these forces are eventually transmitted to the ground – whether directly through the device or through the user's body – strongly influences the user's haptic experience.

As each of these attributes takes on one of two values, their set leads to a taxonomy of eight classes, all of which are theoretically possible. Each of the previously discussed attributes is described with the more easily achieved value first, so the easiest kind of interface to develop is one that is passive (i.e., an input device), tool-based, and ground-based. A computer mouse is such a device: it is an input device, it responds to your touch, responding as a tool would, and it is based on the desktop. So is a keyboard and the simplest joysticks. However, the case of joysticks can be more complicated because even the earliest of these, developed to control aircraft and connected by mechanical wires to the flight surfaces of the aircraft, unwittingly presented force information about loads on the flight surfaces to the pilot, so they were a sort of active interface device. Some joysticks currently available for games purposely give force-feedback information to the user. The PHANTOM, for example, is a ground-based active device capable of simulating tool-based touch interactions.

In terms of body-based devices, a wearable one with sensors that track your body's interactions with real or imagined surfaces but do not send you signals is a passive, body-based interface. For example, there are wearable haptic gloves, such as the CyberGlove from Immersion Corporation, which have joint angle sensors that can track hand posture. A glove like this, when coupled with some kind of spatial tracking of the whole hand, provides an interface that keeps track of the user's hand position in free space as well as his/her finger positions during interaction with virtual objects. Some of the earliest body-based systems developed for teleoperation, however, were already active. These were exoskeletal devices that fit over and move with the limbs or fingers of the user. An example is the CyberGrasp from Immersion Corporation, which uses a CyberGlove to track hand and finger posture and the exoskeletal structure to transmit forces to the fingertips (Figure 6).

Because body-based devices can move as much as arms and hands do, they can typically monitor and stimulate over a much wider range of unrestricted user motion than can be provided by ground-based devices. However, they are awkward to wear, and providing high-quality force feedback with such devices that is commensurate with human resolution is proved to be difficult and places great demands on actuator size minimization and control bandwidth.

On the other hand, with a tactile display embedded in an item of clothing or glove, people can interact with computers by receiving information through feeling. This can provide a much more compelling sensation of being immersed in a virtual environment than sound and vision alone. With this kind of wearable display, for example, you could virtually bump into objects and people, or feel the wind brush past you. While some limited demonstrations have been achieved, this type of technology is not yet ready for such highly realistic and immersive sensation, but its

Figure 6 The CyberGrasp.

potential is vast. Human tactile perception is robust and our skin provides approximately 20 square feet of touch receptors. There are already prototype systems based on a variety of tactile stimulation and sensing technologies and these can be very valuable. Even without the difficult application of simulating bodily engagement with a whole world, wearable tactile displays provide a channel for information gathering that is complementary to audio and visual signals and can be unintrusive and natural. They are discrete and seamlessly integrate with most human activity. Tactile displays will neither conflict with nor replace audio and visual displays but, rather, support information on these other displays and fill in the gaps where necessary.

In fact, the perfect haptic interface would be both input and output, modeling the user's actions as it provides information to him/her, and also simulate both touching with hands directly and interacting with tools. Such an interface would seamlessly measure the position and posture of the user's hand and send forces to the hand. However, the large number of degrees of freedom of the hand, the extreme sensitivities of cutaneous receptors, together with the presence of mass, friction, and limitations of sensors and actuators in the interface, make such an ideal impossible to achieve with current technology. The technology will eventually mature so that such a system is possible.

Haptic interfaces will always only offer approximations of real interactions, just as do any of the current visual and auditory interfaces. However, that does not mean that haptic interfaces will always feel unconvincing. Much thought has gone into the way in which a sequence of discrete images can be made to appear visually continuous, relying on the persistence of vision (which can be thought of as a limitation on the acuity of human vision). We expect that there are similar approximations that will take advantage of the limits of human haptic acuity to generate synthetic haptic experiences that are indistinguishable from real lived experience. To develop these approximations will require quantitative human studies. Basic understanding of the biomechanical, sensorimotor, and cognitive abilities of the human haptic system is critical for proper design specification of the hardware and software of haptic interfaces.

In the next section, we discuss applications of the present and future technologies.

Applications

There are two main modalities of applications of haptic interfaces: one concerns interfaces to VEs that only exist with a computer, and the other concerns TO, taking haptic and other information from and/or making its own distant presence felt on a nearby or far-away real environment. Many of the application areas have instances of both as we shall see. A few of the many potential applications are described in the following.

Medicine

One of the very active areas for haptic applications is in the development of virtual reality-based systems for training medical personnel. Here, the computer acts as a virtual human body, both graphically and haptically. For example, the trainee surgeon sees a screen containing a picture that might resemble a televised picture of a human body being operated upon while the surgeon moves his/her scalpel and feels, using a force-feedback output device, a simulation of probing and cutting the body. This is not necessarily an inferior replacement for the cadavers, which are currently relatively rare in medical schools, but it could in principle provide a more accurate feel than either a deceased human or a different live animal. A TO version of this application could not only train surgeons at a distance but also improve the interface for real surgery performed from a distance. Such a system could filter out the natural hand tremors of a surgeon and the system could be designed such that the macroscopic motions of the surgeon are translated into microscopic motions of the robot performing surgery on a patient. Similar medical applications include micro and macro robots for minimally invasive surgery and remote diagnosis of diseases.

Communication across the Internet

The idea of seeing people over the Internet, through the use of webcams as sensory devices and computer screens as display devices, is now commonplace. Much the same thing could be done with the kind of input and display devices we have described above, as was done during the transatlantic touch demonstration described previously. This could be the harbinger of a future version of the Internet, in which remote physical contact plays a large part.

Psychological Studies of Perception

Having a virtual world in which the haptic aspects are under the control of the experimenter could be as beneficial to studies of haptic perception, and perception in general, as virtual worlds have been in studies of visual perception. The TO version of this could enable studies to be done collaboratively by researchers in different laboratories, potentially in very different parts of the world.

Entertainment

Haptic interfaces can make video games and simulators more engaging by adding another dimension to their interaction. There are already force-feedback joysticks in use in various games, allowing players to feel as if they are really shooting guns or flying planes. These will be replaced by much more accurate, more sensitive, and more engaging force and tactile feedback interfaces.

Education

Haptic interfaces can help us feel otherwise intangible worlds, such as nano-, macro-, or astronomical-scale worlds. For example, a project in the United States is exploring how the addition of haptic feedback to computer-generated 3D virtual models of an animal cell influences students' understandings of cell concepts. The Haptic Cell Exploration instructional program contains a virtual model that depicts the 3D nature and spatial arrangement of an animal cell, including its typical parts (organelles), and allows students to feel the various parts of the cell.

Training

Tactile sensory and display arrays could be used to train people in a very wide variety of tasks, such as how to hold tools and to operate equipment correctly. The arrays could send the information to a computer that would be able to inform the user how well he or she is doing.

Art and Design

Haptic interfaces could be integrated into CAD systems so that designers could manipulate their designs. Similarly, sculptures could be created by capturing the results of virtual manipulations and sending the results to three-dimensional printers. In a TO mode, this could lead to cooperative virtual sculpting across the Internet.

Access to Art and Artifacts

Several experimental museum and gallery exhibitions in which visitors used technology to feel simulations of a museum's collections have occurred already. In the long term, it may be possible to access the feel of a museum's collection over the Internet as easily as we can now access visual images. Moreover, there can be virtual art exhibits, concert rooms, and museums in which the user can log in remotely to, for example, play the musical instruments as part of the concert.

Aids to Overcome Blindness and Other Disabilities

Tactile vibrating devices have long been used to convey speech information to people who are deaf. New haptic displays could be used to provide information from the Internet in ways that are accessible to people for whom the Internet or museum collections are inaccessible, for example. They have even been used as training systems in the rehabilitation of individuals with motor impairment.

Macroglial Lineages

A M Butt, University of Portsmouth, Portsmouth, UK

© 2009 Published by Elsevier Ltd.

Introduction

Macroglia together with neurons make up the two classes of neural cells in the central nervous system (CNS); both macroglia and neurons have a common neuroectodermal embryonic origin. The three major subtypes of macroglia are astrocytes, oligodendrocytes, and the ependymal cells. The fourth major glial cell type in the CNS is the microglia, which are nonneuronal cells that have a mesodermal origin; microglia originate from macrophages that invade the brain during early development. There are also many glia in the peripheral nervous system (PNS), mainly Schwann cells, together with satellite cells of sensory and sympathetic ganglia and glial cells of the enteric nervous system of the gastrointestinal tract. CNS and PNS neural cells have clearly distinct lineages from an early stage of embryonic development.

Astroglia and oligodendroglia are the most numerous and functionally important macroglial cell types; ependymal cells are simple cuboidal cells that line the ventricles in the brain and the central canal in the spinal cord. Astrocytes are morphologically and functionally diverse and have a widespread distribution throughout the brain and spinal cord; astrocytes have the archetypal feature of expressing glial fibrillary acidic protein (GFAP). The two major classes of astrocytes are protoplasmic astrocytes and fibrous astrocytes, which are found in the gray and white matter, respectively. In addition, there are specialized astroglial cells throughout the CNS; for example, radial glia are bipolar astroglial cells that predominate in the developing brain, and Müller glia and Bergmann glia are specialized astroglia restricted to the retina and cerebellum, respectively. Unlike astroglia, oligodendroglia are highly specialized cells and consequently have a more restricted distribution; oligodendrocytes form the myelin sheaths that insulate axons in the CNS and are most numerous in white matter. Until recently, the accepted model was that macroglia and neurons were derived from separate glial and neural progenitors. However, glial and neuronal lineages are much more closely related than was previously thought. Astrocytes and oligodendrocytes develop from multipotent neural stem cells that also generate neurons. Indeed, astroglial stem cells and oligodendrocyte progenitor cells (OPCs) persist in the mature brain and are potential sources of new neurons in the adult.

Neuroepithelium

Neurons and macroglia derive from the neuroepithelium, which at the earliest stages of development forms the neural plate. As the neural plate thickens, the neural groove forms and the neural plate closes dorsally to form the neural tube, the lumen of which becomes the ventricular system. The cells lining the ventricles of the neural tube form a primary proliferative zone termed the ventricular zone (VZ), and a secondary proliferative zone called the subventricular zone (SVZ) emerges later from the VZ. The VZ ultimately disappears, but the SFV persists into adulthood within the forebrain. As the neural tube expands, the rostral area delineates into the forebrain, midbrain, and hindbrain, and the caudal neural tube forms the spinal cord. During this regionalization, neural crest cells differentiate from the neural tube and migrate to specific regions to form the neurons and glia of the PNS. Thus, CNS and PNS neural cells have clearly distinct lineages from an early stage.

Radial Glia Are Neural Stem Cells

The neuroepithelial cells of the VZ can be considered multipotent neural stem cells in the sense that their progeny gives rise to all of the neurons and macroglia in the CNS. The first cells that emerge from the neuroepithelium are the radial glia. These are distinguished from neuroepithelial cells by the expression of a number of antigens, including the astroglial markers GFAP, vimentin, and the calcium-binding protein S-100β, as well as the glutamate transporter GLAST, nestin, and tenascin-C. The somatas of radial glial cells are located in the VZ and their processes extend to the opposite wall of the neural tube or the pial surface. Radial glia are the main neural stem cells during development and are responsible for most of the subsequent neurogenesis, giving rise first to neurons and later to astrocytes and some oligodendrocytes by a process of 'transdifferentiation.' The majority of oligodendrocytes, however, originate at an early stage of development from glial precursors that are generated in specific sites in the brain and spinal cord. Astrocytes are generated later in development, both from radial glia and from glial precursors that also give rise to oligodendrocytes; the proportion of the final population of astrocytes derived from radial glia and glial precursors depends on the region of the CNS. Radial glia not only produce neurons and glia but also form a scaffold along which newborn progenitors migrate from the SVZ. Moreover, the radial glial cells and astrocytes that differentiate from them retain the function of stem cells in the adult brain.

Glial Restricted Precursors

Multipotent neural stem cells (neuroepithelium) do not differentiate into astrocytes and oligodendrocytes directly but, rather, through intermediate lineage-restricted stages. The first of these to develop are the glial-restricted precursors, which are distinguished from neuroepithelial cells by expression of A2B5 and nestin and are localized to the ventral neural tube. Several stages in the development of astrocytes and oligodendrocytes have been distinguished, with the main ones being oligodendrocyte and type-2 astrocyte precursors (O2A cells), oligodendrocyte precursors, astrocyte precursors, and NG2-expressing glia. The first stage in the differentiation of oligodendrocytes and probably astrocytes is the bipotential O2A glial precursor, which *in vitro* can generate either type of glial cell; O2A cells are distinguished by expression of platelet-derived growth factor-α receptors (PDGF-αRs) and NG2, in addition to A2B5. It is uncertain to what extent O2A cells are bipotential *in vivo*, where they may serve predominantly as OPCs which generate only oligodendrocytes. OPCs express the early oligodendrocyte lineage markers PDGF-αR and NG2 and later the homeobox transcription factor Nkx2.2 and the oligodendrocyte lineage gene Olig2 (basic helix–loop–helix factor). Astrocyte precursors have been isolated from numerous regions of the embryonic CNS; they express A2B5 but not GFAP until a relatively late stage of differentiation, and they are therefore difficult to distinguish from glial precursors and O2A cells. Expression of the extracellular matrix transmembrane protein CD44 may serve as an astrocyte precursor marker. Early glial precursors are small cells, with one or more processes, and are highly mobile, migrating from multiple sites to colonize the entire CNS white and gray matter. They do not express early glial antigens such as PDGF-αR and NG2 until they exit the SVZ, and as they migrate, they begin to acquire markers of OPCs and astrocytes. The relative contributions of O2A cells, OPCs, and astrocyte precursors to gliogenesis *in vivo* are not clear; they display many similarities and may represent different stages in glial precursor differentiation or distinct lineages that arise separately from neural precursors. Indeed, at least *in vitro*, glial precursors are not truly lineage restricted in that they can generate neurons, astrocytes, and oligodendrocytes under appropriate culture conditions. In addition, after generating oligodendrocytes during development, a significant population of NG2 glia persists throughout the white and gray matter of the adult brain; the functions of adult NG2 glia are unresolved, but they serve in part as a pool of adult OPCs and they may even be multipotent adult neural stem cells. There are also GFAP-positive astrocyte-like neural stem cells in specific regions of the adult CNS, and these are multipotent and self-renewing.

Regional Variations

In the forebrain, glial precursors in the SVZ migrate along radial glia to their final sites in the white matter and cortex to generate oligodendrocytes and some astrocytes, in addition to adult NG2 glia. Astrocytes are derived from migratory glial precursors and from radial glia. In early forebrain development, oligodendrocyte precursors are generated in localized sites ventrally and migrate dorsally. Later, glial precursors that originate from a large dorsolateral SVZ near the lateral ventricle give rise to oligodendrocytes and some astrocytes. Oligodendrocytes and the diverse astrocyte cell types in the cerebellum are derived predominantly from migratory glial precursors from an area dorsal to the fourth ventricle; Bergmann glia arise from embryonic radial glia and share a common lineage with Purkinje neurons. In the embryonic retina, Muller glia arise from a common precursor with neurons, and astrocytes develop at a later stage from glial precursors that migrate into the retina via the optic nerve; oligodendrocytes are absent from the retina of most species. Most astrocytes in the optic nerve are derived from intrinsic radial-like astroglia, whereas oligodendrocyte precursors migrate into the nerve during the perinatal period. In the spinal cord, oligodendrocytes originate from neural stem cells in the ventral neuroepithelium, which first generate neurons and then oligodendrocyte precursors. Later, oligodendrocyte precursors also originate from dorsal areas. Spinal cord astrocytes appear to be derived from separate astrocyte precursors after neurons and oligodendrocytes; as in other areas of the CNS, astrocytes most likely also arise from radial glia.

Gliogenesis in the Adult Central Nervous System

Gliogenesis occurs at a slow rate throughout the adult CNS. New glial cells are born locally, predominantly from parenchymal multipotent glial precursor cells and also, in the case of astrocytes, from division of mature cells. The type of cell produced is determined by locality of the precursors; they mostly produce oligodendrocytes in white matter, whereas astrocytes and oligodendrocytes are produced in the same quantities elsewhere. These glial precursors do not express GFAP, but they do express nestin and NG2. It is not clear that all NG2-expressing glia in the adult CNS are glial precursors. NG2 glia are slowly proliferating

cells that can generate oligodendrocytes *in vivo* and can also generate astrocytes and neurons *in vitro*. Nonetheless, the substantial majority of NG2 glia in the mature CNS appear to be nonmitotic, but like astrocytes, they may retain the function of stem cells in the brain throughout maturation and adulthood. In addition, self-renewing and multipotent neural stem cells are widespread in the ventricle walls of the adult CNS. These neural stem cells have morphological, physiological, and biochemical/immunological characteristics of astrocytes; those located in the hippocampus and olfactory subendyma generate neurons throughout life. The relative contributions of parenchymal NG2 glia and 'stem' astrocytes to gliogenesis in the adult remain to be resolved.

Magnetic Resonance Spectroscopy

J R Alger, University of California at Los Angeles, Los Angeles, CA, USA

Introduction

Magnetic resonance spectroscopy (MRS) is an analytical tool that detects radio frequency electromagnetic signals that are produced by the atomic nuclei within molecules. It can be used to obtain *in situ* concentration measures for certain chemicals in complex samples, such as the living brain. In certain specific circumstances, MRS also provides means of performing kinetic analyses of dynamic neurochemical processes.

MRS is essentially identical with nuclear magnetic resonance (NMR) spectroscopy, which has been a part of chemistry and physics for the past half century. MRS is the specific term that is used when an NMR spectroscopy procedure is applied in a biological or medical context. Terminology that eliminates 'nuclear' was adopted for medical and biological NMR procedures to avoid the implication that nuclear radioactivity is somehow involved in the procedure.

MRS overlaps to a very great extent with magnetic resonance imaging (MRI). MRS studies usually involve the detection of NMR signals produced by chemical compounds other than water, with the goal generally being to evaluate *in situ* biochemistry, whereas MRI usually detects NMR signals produced by the tissue water, with the goal being to make images that depict the macroscopic anatomy of soft tissues such as the brain.

MRS as a Neuroscience Tool

The development of MRS as a neuroscience tool grew from several key advances in science and technology that have occurred over the past few centuries. These include Fourier's eighteenth-century techniques for working with complicated periodic mathematical functions, nineteenth-century descriptions of electricity and magnetism by Faraday, Ampere, and Maxwell, the early twentieth-century discovery of quantum mechanics by Planck, Heisenberg, and Born, the description of the basic magnetic properties of atomic nuclei by Stern, Rabi, Bloch, and Purcell in the 1930s and 1940s, and the elucidation of intermediary metabolism beginning with the work of Krebs and Lippman in the 1940s. Moreover, MRS would not be possible without twentieth-century technological advances in radio communication, digital computing, and superconducting magnets. In 1991, Richard Ernst was awarded the Nobel Prize in Chemistry for work done in the 1960s and 1970s that directly led to the development of MRS techniques that are used today for neuroscience research and for routine evaluation of patients. In 2003, Sir Peter Mansfield and Paul Lauterbur were jointly awarded the Nobel Prize in Physiology or Medicine for discoveries related to the imaging procedures that are now used in MRI and MRS.

This convergence of science and technology advances has made it possible to perform MRS studies in the brains of animals and humans since the early 1980s. Other parts of the body can also be studied by MRS, but the brain has been the most well-explored organ system because it has fortuitous chemical, physical, and structural properties that make it readily amenable to MRS study. During the 1980s and 1990s many studies established MRS as a valid neuroscience tool. This validation work is still proceeding in concert with further technological development of MRS. It is now possible to routinely perform MRS examinations of clinical brain disorders in human patients. Although the preponderance of recent MRS developmental emphasis has been on clinical applications, MRS also has value for addressing fundamental neuroscience questions. MRS studies of animals, such as genetically altered rodents, are feasible as are studies of cultured cells, histological tissue samples, and chemical extracts of neurologically significant tissues. The section titled 'Further reading' at the end of this article provides an introduction to full scope of neuroscientific MRS applications, including clinical and basic science applications.

Physical Principles of MRS

MRS utilizes the fact that certain atomic nuclei behave as if they were spinning bar magnets. The nuclear magnetic fields interact with a magnetic field that is produced by a strong magnet in which is placed the sample that is being examined. Through this magnetic interaction, energy is exchanged between the nuclear magnetic fields and the externally applied field. Energy exchange of this sort is known in physics and engineering as 'resonance.' In physics and chemistry, 'spectroscopy' is used to describe the study of the specific frequency (or wavelength) at which resonance occurs. In the typical MRS study, the magnetic resonance has a time dependence that is analogous with the electromagnetic oscillation of the radio waves that are used in radio and television

Figure 1 Signal frequency measurements in magnetic resonance spectroscopy (MRST). MRS signals from different atomic nuclei (e.g., ^{13}C, ^{31}P, ^{19}F, and ^{1}H) are distinguished by their unique frequencies at a particular field strength. The characteristic frequencies for some isotopes commonly used in brain MRS are shown. The spectrum in the upper right-hand corner shows localized ^{1}H-MRS data from a normal human brain. It illustrates that particular ^{1}H nuclei located on different molecules, or in different parts of the same molecule, are shifted in frequency by a small amount relative to the characteristic frequency for ^{1}H. The shifts are conveniently measured in parts per million (ppm) relative to the characteristic frequency for the nucleus.

communication. Accordingly, MRS is sometimes referred to as a type of radio frequency spectroscopy.

The typical MRS hardware designed for the study of humans uses superconducting magnet technology to immerse the sample, organism, or organ being studied in a static magnetic field of 1.5 T (about 30 000 times stronger than the Earth's magnetic field). MRS examinations of animals and *in vitro* MRS studies are usually done using magnetic fields that are two to ten times stronger. MRS signal strength generally improves as the static magnetic field strength is increased, and it is desirable to use the strongest magnetic field available. However, there are practical limitations. Magnets having a field strength greater than 3.0 T that are sufficiently large to accommodate the human body are very expensive and are presently used only in research studies.

A second externally applied magnetic field, the strength of which has a temporal periodicity, is also necessary for MRS. It is through this time-varying magnetic field that the specific resonance interaction can be detected (i.e., the spectroscopy). Because the applied time-varying magnetic field must have temporal characteristics similar to those found in the radio waves used in radio and television, the term 'radio frequency (rf) field' is often used to denote this second obligatory magnetic field. The device that produces the rf field is the rf coil, which must be placed around or very near to the sample or body part being examined.

The basic procedure for acquiring MRS data is to place the item of interest in the strong static magnetic field and also within an rf coil. The rf coil is then turned on (i.e., pulsed) very briefly under computer control to create an rf field that interacts with a broad range of different types of atomic nuclei within the sample. Once the rf pulse is turned off, the magnetic interaction between the nuclear magnetism and the static magnetic field produces distinct electromagnetic signals in the rf coil at distinct frequencies. These signals are subjected to analog and digital processing to result in a magnetic resonance spectrum. A spectrum is a two-dimensional plot of frequency on the horizontal axis and intensity of resonance interaction on the vertical axis (**Figures 1** and **2**). Many variants of this basic procedure are available to meet specific goals. The rf pulse is usually turned on more than once during the procedure, and the term 'pulse sequence' is used to convey the idea that the data are generated by a complicated series of pulses designed to meet specific experimental needs.

MRS signals are generally quite weak compared with other types of spectroscopy used in biology and medicine. It usually is necessary to repeat the signal detection multiple times and to average the results to acquire a sufficiently strong MRS signal to identify the MRS signals above the noise that is inherently detected as part of the signal detection procedure. Signal averaging is productive because the desired

Figure 2 Normal brain magnetic resonance spectroscopy (MRS), showing ^{1}H-MRS with fitting and quantitation. Localized single-volume ^{1}H-MRS of normal human brain is depicted by the black tracing. Note the presence of noise in the black tracing, illustrating an inherent limitation in the detection of certain weaker signals. Some of the key signals are labeled in blue. The baseline arises primarily from low molecular weight macromolecules present in the tissue. The red line shows the best fit to a spectrum model containing contributions from the molecules that are likely to be present in brain tissue. From the fitting process the relative amplitudes (signal area) of each of the contributors can be determined. When these areas are related to the water signal area (not shown), the tissue concentration can be determined because the water concentration is known. The resultant concentration determinations for different neurochemicals are provided in tabular format in the upper right. Fitting and quantitation were performed using a commercially available software package (LCModel, available online at http://S-provencher.com/pages/lcmodel.shtml).

signal is identical on each repeat, whereas the noise is random and differs between repeats.

In Vitro and *In Vivo* MRS

In vitro MRS studies frequently use some form of sample preparation. Typically an acid extraction procedure is used to separate the water-soluble low molecular weight molecules from a tissue sample. The tissue extract is then subjected to the same NMR spectroscopy procedures that would be used in an analytical chemistry NMR laboratory. Extraction has the advantage of providing a magnetically homogeneous and dynamically stable sample that can be examined using a very high magnetic field strength, leading to very high-quality spectra. Extract spectra of the type shown in Figure 3 provide an MRS fingerprint of all chemicals that are present with a far greater sensitivity and specificity than can be obtained with *in vivo* MRS observations.

For *in vivo* MRS there is the need to examine only a small well-defined portion of the brain. Unless special localization measures are taken, one tends to obtain signals from the entire brain and overlying tissue, rather than just part of it. The inherent sensitivity of the MRS technique places a lower theoretical limit on the volume of tissue that can provide adequate MRS signal strength within a limited time. In human brain studies, this practical lower limit is approximately 1 cm^3. A typical human brain MRS region of interest is shown in Figure 4. For animal studies, volumes in the range of 10–50 mm^3 can be examined with the appropriate equipment. Two general MRS localization procedures are available. These are known as localized single-volume MRS (SV-MRS) and magnetic resonance spectroscopic imaging (MRSI). In SV-MRS, one uses a set of magnetic resonance images to define the location of tissue to be examined, and only the MRS signals from this location are acquired (Figure 4). In MRSI, one uses MRI to define a larger

Figure 3 Brain magnetic resonance spectroscopy (MRS), showing brain extract ^{1}H-MRS. ^{1}H-MRS of an acid extract of rat brain tissue is provided in two frames, showing the spectrum's 0.5–3.0 ppm portion (a) and the 2.8–4.5 ppm portion (b). As can be appreciated by comparing this spectrum with those shown in **Figures 1** and **2**, extract spectra provide greater detail than do *in vivo* spectra. Many more signals can be uniquely identified with better sensitivity. The tissue molecules that generated many of the signals are identified by abbreviations in the figure. A discussion of the individual signals and the molecules responsible for them is beyond the scope of this article. For these details the reader should consult the original source. Reproduced from Govindaraju V, Young K, and Maudsley AA (2000) Proton NMR chemical shifts and coupling constants for brain metabolites. *NMR in Biomedicine* 13: 129–153.

Figure 4 Localized magnetic resonance spectroscopy (MRS) volume selection. In localized MRS studies of brain, a magnetic resonance image (MRI) study is first performed. One then uses the anatomy visualization provided by MRI to define which single volume of brain tissue to examine with MRS. The white squares in the figure illustrate the size of the typical volume used in single-volume MRS. The figure also illustrates that the MRS volume has thickness. It can intersect with more than one of the MRI slices. The figure shows all of the MRI slices that overlap with the chosen MRS volume. Examples of spectra that result from such localization procedures appear in **Figures 1** and **2.**

region of interest (Figure 5). MRSI produces an array of spectra from all the volume elements within the region of interest. Using these data, it is possible to create images that depict how individual signals vary through the array or to evaluate the spectra produced by specific locations.

The time required for data acquisition is an important factor for *in vivo* MRS studies. The individual must remain essentially motionless over the 10 or more minutes required to perform the MRS data acquisition. Although this is tolerable for many humans, some ill patients and younger children find this difficult. For these individuals, sedation or anesthesia is required. For animal studies, sedation, anesthesia, or paralysis is almost always required to prevent movement during the MRS data acquisition.

Figure 5 Magnetic resonance spectroscopic imaging (MRSI) procedure. An MRI study is performed to determine the slice of interest (shown as a white square overlaid onto the grayscale MRI), after which MRS procedures are used to obtain a spectrum from each of the volume elements shown in the green grid (array of spectra shown to the right).

Detectable Neurochemicals

Only certain atomic nuclei (isotopes) behave as spinning bar magnets and are capable of producing MRS signals. The nuclei relevant to medical or biological MRS studies are ^{1}H, ^{31}P, ^{13}C, ^{7}Li, and ^{19}F. MRS signals produced by these unique isotopes are easily distinguished by their very different characteristic frequencies (Figure 1). For instance, at a static magnetic field strength of 3.0 T, all ^{1}H nuclei produce signals in the immediate vicinity of 127 million cycles per second, whereas all ^{31}P nuclei produce signals in the immediate vicinity of 52 million cycles per second. These between-nuclei differences are so great, that different rf coils are usually needed for different nuclei. The relevant nuclei have different attributes and practical limitations with respect to MRS signal production. An equal number of each type of nucleus produces differing inherent signal strengths. Furthermore, all MRS nuclei do not have the same abundance in nature. ^{13}C, for instance has a natural abundance of only 1%. Of the aforementioned nuclei, ^{1}H produces the strongest MRS signal because it has a natural abundance of almost 100% and it has the highest inherent sensitivity of all the magnetic nuclei. For this reason it is the most frequently exploited nucleus in routine clinical MRS implementations. Moreover, ^{1}H-MRS is somewhat easier to perform than are other types of MRS, because it uses the same equipment as used in conventional MRI.

The ability to detect unique signals from different chemicals with MRS results from the fact that the frequency of the magnetic interaction is directly proportional to the static magnetic field strength at the nucleus. The electron clouds which surround the atomic nuclei within molecules circulate in ways that tends to alter the actual magnetic field at the atomic nucleus, and this causes small alterations in the MRS signal frequency. In this manner, the electrons that make up the unique chemical structure surrounding each atomic nucleus cause different nuclei within the same molecule, and the nuclei within different molecules, to produce unique and often distinguishable MRS frequencies. The difference in frequency resulting from chemical structure is rather small (Figure 1). Important MRS signals may be separated from each other in frequency by only a few cycles per second, with each of their signals having a frequency of millions of cycles per second. For this reason it is common practice to specify the frequency of a particular signal by stating how much its frequency differs from some that are produced by an accepted standard nucleus. This practice leads to the specification of signal frequencies in parts per million (ppm).

There are two major factors that practically limit the number of neurochemicals that can be detected with MRS. First, the signal-producing molecules must be relatively free to move from place to place and tumble around within the various aqueous solutions that make up biological tissue. Macromolecules having molecular masses greater than about 20 000 daltons fail to move with sufficient freedom, and signals arising from the atomic nuclei within such structures cannot be practically detected. Second, overcoming the inherent noise in the signal-detection process is challenging. There must be sufficient atomic nuclei of a specific type to generate a recognizable signal above the noise level. The necessary amount of material varies somewhat depending on the type of MRS study and the nucleus. A good rule of thumb for the ^{1}H-MRS is that there must be at least about 10^{18} molecules of interest (1 μmol) in the volume of interest for signal recognition. Frequently the sample or tissue volume that is examined is adjusted to achieve this requirement. This leads to volume elements of the sizes illustrated in Figures 4 and 5.

Only the most heavily concentrated neurochemicals can be detected *in situ* with MRS because of its sensitivity requirements. In ^{1}H-MRS and ^{13}C-MRS, signals are readily detected from a variety of intermediary metabolites, amino acids, and some neurotransmitters (Figures 2 and 3). Certain interesting neurotransmitters (e.g., dopamine, serotonin) cannot be detected because their levels are too low. Hence ^{1}H-MRS and ^{13}C-MRS can be used to evaluate metabolism and its derangements in brain tissue. Because neurons and glia have differing metabolite profiles, alterations in the signal patterns detected with MRS in disease conditions are frequently interpreted in terms of altered densities of neurons and glia in the tissue. ^{31}P-MRS (Figure 6) is used to detect signals from metabolites involved in energy metabolism, including adenosine triphosphate, phosphocreatine, and inorganic phosphate. Magnesium ion concentration and pH can be determined from measures of frequency differences between certain metabolite signals. Also detectible with ^{31}P-MRS are certain metabolites associated with phospholipid and membrane metabolism. Studies with ^{19}F-MRS have demonstrated that the brain levels of certain fluorinated drugs can be measured. Similarly ^{7}Li-MRS can be used to detect and measure the lithium levels in the brains of patients being treated for depressive conditions.

Figure 6 Brain magnetic resonance spectroscopy (MRS), showing ^{31}P-MRS of human brain. This spectrum was obtained from a 20 mm-thick axial brain volume that mostly encompassed the frontal lobes. The key signals are shown. Adenosine triphosphate (ATP) is the predominant contributor to the nucleotide triphosphate (NTP) signals. The phosphodiesters and phosphomonoesters are produced by metabolites involved in membrane metabolism. These signals are frequently of interest in conditions in which there is an acceleration of membrane synthesis (i.e., cancer) or a degeneration of membranes (i.e., neurodegenerative conditions). The intracellular concentrations of hydrogen ion (pH) and magnesium ion (pMg^{2+}) can be inferred from measurements of certain signal frequency differences.

Quantification of Neurochemical Levels

Magnetic resonance instruments can provide a highly accurate measure of signal frequency but are not designed to produce such exact measures of signal amplitude (the area under the signal) that are calibrated against a defined universal standard. Hence MRS permits ready conclusions about whether a particular neurochemical signal is present above the noise level at a specific frequency, but it is somewhat more difficult to determine exactly what is the tissue concentration of the signal-producing neurochemical. Measures of signal intensity must be quoted with reference to some calibration signal that is also present in the spectrum being analyzed or can be acquired from some other MRS or MRI measurement of the same tissue region in the same individual. For this reason, MRS results are often reported as the ratio of two signals (e.g., the ratio of the amplitudes of the *N*-acetylaspartate and creatine signals). Studies performed during the past few years have demonstrated that the tissue water can provide a stable reproducible calibration signal. Because the concentration of water is known and reasonably uniform within soft tissue, it is possible to estimate the absolute concentrations of other signal-producing neurochemicals through measurement of their signal amplitudes relative to that of water. The absolute concentrations derived in this way have varying precision (Figure 2). Amplitude measures of the smaller signals are influenced to a greater proportional extent by noise compared with measures of the larger signals. Therefore, the concentration estimates for the weaker signals are correspondingly less precise. Furthermore, it is frequently the case that one MRS signal overlaps with another

MRS signal, and errors in concentration estimation can arise from the inability to correctly attribute signal amplitude to different signal-generating molecules (Figure 2).

Metabolic Flux Measurements

MRS is primarily a method for detecting and measuring the concentrations of particular signal-generating neurochemicals. It does not inherently measure metabolic flux except in special study designs. In this regard, MRS is quite distinct from other metabolic imaging techniques, such as positron emission tomography, that use radiotracers to measure metabolic flux.

There are several MRS study designs that can provide metabolic flux measures. One may introduce a physiological perturbation and then repetitively collect MRS data over time. Such data provide measures of neurochemical concentration versus time, from which metabolic flux measures can be derived. ^{31}P-MRS studies of the influence of ischemia on brain energy metabolites have been performed in this fashion. Another method involves labeling certain metabolic pools with stable isotopes that can be detected with MRS. ^{13}C is an example of one such isotope. It has a low natural abundance and produces almost no background MRS signal. It is possible to purchase certain precursor metabolites (e.g., glucose) enriched with ^{13}C at specific carbon positions. Such labeled molecules can be introduced into the bloodstream and their metabolism followed through time course measures of MRS signals produced by the labeled precursor and its metabolites. In the case of some relatively fast metabolic reactions, it is also possible to use MRS to follow the flux of magnetic labels (which are noninvasively introduced by the scanner hardware) between products and reactants. Such methods have been most frequently used to measure creatine kinase flux with ^{31}P-MRS.

Summary

MRS provides a means of measuring the concentrations of the more concentrated neurochemicals in the brain or in tissue extracts using magnetic resonance signals produced by atomic nuclei. Brain MRS measurements can be made with regional specificity and without exposure to ionizing radiation. The technique requires only exposure to magnetic fields. MRS is now becoming routinely used in clinical settings to evaluate a number of brain diseases. It can also be useful in basic neuroscientific investigations.

Magnetic Sense in Animal Navigation

T Ritz, University of California at Irvine, Irvine, CA, USA

© 2009 Published by Elsevier Ltd.

Introduction

The geomagnetic field provides an omnipresent clue that can be used, in principle, to obtain information about direction and position, in particular geographic latitudes. Although migratory birds present perhaps a particularly spectacular example, magnetic sensory capabilities are widespread and have been demonstrated in animals as different as bacteria, honey bees, newts, mollusks, salmon, sea turtles, migratory and nonmigratory birds (pigeons and chicks), and mole rats, to name a few. It is likely that magnetic sensing presents an evolutionary advantage to many territorial animals, for example, for finding the closest hiding place or food storage location from the current position of an animal. Migratory animals may have developed this useful ability further to aid them in their long-distance orientation tasks.

Unlike other sensory modalities, such as vision, hearing, touch, and olfaction, very little is known about the receptors, signal transduction, and neural processes underlying magnetic sensing. Most of the available information about magnetic sensing today is based on sometimes variable and contradictory behavioral observations and only very few electrophysiological and anatomical studies. The reasons for the comparative lack of knowledge about magnetoreceptors may be rooted in the unusual features of magnetic fields as stimuli. Magnetic fields pass relatively freely through tissue, making it less obvious where to pinpoint loci for potential magnetosensory structures. Unlike other stimuli, the geomagnetic field is not an on/off stimulus but is always present in similar intensity, suggesting that standard test approaches such as measuring dose–response curves or action spectra in behavioral tests may be less meaningful than for other sensory modalities. On the other hand, the geomagnetic field is sufficiently weak, which limits the possible physical mechanisms of magnetic field detection to less than a handful of plausible hypotheses. Theoretical considerations thus allow the design of diagnostic experiments to identify the underlying mechanism for a particular response. Two hypotheses in particular – magnetoreception based on magnetite (a biogenic magnetic material) and magnetoreception based on magnetically sensitive photoreceptor-based reactions – have received much attention.

In this article, we first briefly review the various types of well-documented magnetic responses and then present both the magnetite and photoreceptor hypotheses of magnetic sensing. In recent years, much progress has been made toward accumulating evidence for both hypotheses, raising the prospect of solving the long-standing mystery of magnetic sensing in the not-too-distant future.

Examples of Magnetic Sensing in Animal Navigation

Magnetic Compasses

The most convincing type of experiment that has been used to study magnetic sensing measures magnetic compass responses. In magnetic compass experiments, an animal is placed in an arena where it is motivated to move in a particular direction. For example, a migratory bird in the Northern Hemisphere is motivated to move north in the spring and will do so even in a small funnel cage. As the direction of the magnetic field in the arena is changed in repeated tests, we find that the headings of the animals change accordingly. Such magnetic compass abilities have been detected and reproduced for many species of migratory birds as well as for many other animals, including chicks, sea turtles, honey bees, mole rats, and newts. In migratory birds, the magnetic compass responses have been characterized in the most detail. Migratory birds are sensitive to the dip or inclination angle; reversing the vertical component of the magnetic field results in a reversal of directions, whereas a change in the polarity of the magnetic field has no effect on their orientation. Ambient light conditions affect the magnetic responses significantly. Under full-spectrum (white) light, birds respond by moving in the appropriate migratory direction. However, under monochromatic light, birds may either orient in the appropriate migratory direction, be disoriented, or move along a direction or axis that is unrelated to the migratory direction (called fixed-direction or fixed-axis responses). It appears that, under monochromatic light conditions, normal migratory behavior is observed mostly under short-wavelength blue and green light of low intensity, corresponding to light approximately 45 min after sunset. Disoriented responses are more frequent under long-wavelength yellow and red light of any intensity, whereas fixed-direction or fixed-axis responses appear mostly for higher-intensity short-wavelength light. No clear picture has emerged yet as to which photoreceptors might be involved in these responses.

Signposts or Markers

Birds as well as sea turtles follow often complex migratory routes; for example, sea turtles follow large currents such as the North Atlantic gyre. At certain points along those routes, crucial orientation decisions need to be made. For example, sea turtles need to decide to stay in the Atlantic gyre. When exposed in a lab setting to magnetic field conditions that they encountered at these crucial points, sea turtles responded by swimming in a direction that would keep them within the gyre. Likewise, some birds in Europe plot a migratory route that leads them through Spain, thereby crossing the Mediterranean Sea at its narrowest point on their way to Central Africa. Exposure of these birds to the magnetic field conditions in Spain plays a role in triggering the necessary route change from southwest to southeast. Specific magnetic field conditions also trigger the fattening of birds prior to crossing large deserts. In this way, magnetic fields can act as markers or signposts. A particularly intriguing aspect of these signpost responses is that they are observed even in freshly hatched sea turtles, suggesting that they are either genetically coded or determined in the embryonic stages.

Conditioning

For a long time, conditioning animals to magnetic stimuli was unsuccessful, but in recent years the number of studies reporting successful conditioning has grown significantly. Operant conditioning to magnetic stimuli has been reported for honey bees, different species of fish including the genetic model zebra fish, and, very recently, pigeons. The last study is particularly noteworthy because more than a dozen previous attempts failed to achieve magnetic conditioning in pigeons. In the study, pigeons learned to discriminate between the presence and absence of a magnetic anomaly created in the center of a tunnel-shaped arena. The discrimination performance is relatively low, suggesting that discrimination of the magnetic stimulus is a difficult task. Conditioning experiments may open the way to better identifying what information animals derive from the geomagnetic field by identifying the thresholds of intensity and/or spatial inhomogeneities required for successful conditioning. Conditioning to magnetic directions has very recently been reported for chicks.

Magnetite-Based Magnetoreception

Magnetite (γ-Fe_3O_4) is a widespread iron oxide that can be produced in biological cells. Its magnetic properties depend on the size and geometry of the magnetite crystals. In very small crystals, thermal fluctuations prevent them from carrying a stable magnetization. However, an external magnetic field induces magnetization in a collection of such particles, which is lost once the field is switched off. Such a collective behavior is called superparamagnetism (with the prefix super referring to the fact that such a collective has a surprisingly high susceptibility, that is, even a field of low intensity can induce a large magnetization). Larger crystals become ferromagnetic, that is, they possess a permanent magnetic dipole moment at room temperature. Crystals of this size are often labeled single-domain crystals to distinguish them from even larger crystals with multiple magnetic domains, each with a permanent magnetic dipole.

For ferromagnetic materials and certain geometries of superparamagnetic material, the geomagnetic field exerts a torque on the magnetite, thereby providing a force that rotates it into the direction of the magnetic field. Such a torque mechanism is, of course, the basis of the mariner's compass needle and is theoretically well understood. A torque produces mechanical deformation, which in combination with a mechanoreceptor could create a receptor potential and, hence, trigger a nerve signal. Moreover, there is biological precedence – a torque mechanism is realized in magnetic bacteria that contain chains of magnetite and can be considered microscopic compass needles. Due to the torque of the magnetic field, the bacteria become aligned with the geomagnetic field lines and use this to swim in upward or downward directions. It is less clear whether the detection of the magnetic field by bacteria amounts to true sensing or whether it is merely a passive effect because the torque of the magnetic field will rotate living and dead bacteria alike.

Evidence for Magnetite-Based Magnetoreception

Simple detection of magnetite in organisms can be taken only as a first step toward identifying possible magnetoreceptive structures because magnetite can also be produced as a by-product of iron metabolism and it is used for physiological functions independent of magnetic field detection (e.g., for the stabilization of bone tissue because it is hard and within vestibular systems because of its high density). Characterization of the structure and physical properties of the detected magnetic material is needed as a further step to determining that this material is indeed involved in magnetic field detection.

Ferromagnetic crystals of magnetite have been found in animal tissue and closely resemble bacterial magnetite crystals. For example, magnetite crystals have been extracted from ethmoid tissue of the sockeye salmon,

with a small range of grain sizes, as is typical of biologically controlled mineralization processes. Due to the extraction procedure, however, there was no information left about the *in situ* disposition of crystals and their histological context. Strong evidence for a magnetite-based magnetoreceptor cell has been found in another fish, the trout. Through tracing from magnetically sensitive neurons, candidate magnetoreceptor cells were identified in the olfactory lamellae. Within these cells, iron-rich crystals were identified, and it was later shown that these crystals have a permanent magnetic moment. The exact physical arrangements of the crystals and their connections to the nerve cells still remain to be determined.

In birds, ultrastructural analysis reveals an intriguing magnetite-containing structure in the beak with rather different properties from the structures observed in fish. The bird structure contains nanometer-size magnetic particles that fill corpuscles of approximately 2 μm in diameter, as well as bands of approximately 15–25 magnetic platelets, each approximately $1 \times 1 \times 0.1$ μm in size. Furthermore, vesicles of unknown material of approximately 5 μm in diameter can be seen that are encased by magnetite platelets. From the size of the platelets and particles, we expect that all magnetic material is superparamagnetic. Overall, six such structures are located in the upper beak of birds, three on each side of the beak. The magnetite-containing structures are located in the vicinity of nerve endings that are likely to be sensitive to mechanical, but not surface, stimulation and could be well suited for the detection of mechanical strains. It remains to be seen how strong a magnetic field needs to be to produce mechanical deformations that trigger nerve signals. One interesting aspect of the arrangement of the bands of platelets is that their axes appear to be oriented in different, almost perpendicular directions in the three structures in each side of the beak. Thus, each of the three structures could, in principle, measure a different component of the geomagnetic field vector, allowing a one-shot measurement of the magnetic field intensity comparable to a three-axis magnetometer.

Beyond the suggestive arrangement of magnetite structures, evidence for magnetite-based magnetoreception derives from behavioral experiments in which animals were exposed to strong (>0.5 T) but short (several milliseconds) magnetic pulses prior to magnetic orientation testing. Such strong magnetic pulses should remagnetize ferromagnetic magnetic material and we therefore expect disoriented responses if magnetoreceptors are based on such material. In adult migratory birds and homing pigeons, the application of pulse magnetization resulted in a significant deflection of oriented responses and sometimes in bimodal (as opposed to unimodal) responses. The effects of pulse magnetization usually vanished after several days, and all birds returned to normal migratory orientation after 1 week. The disruptive effect of pulse magnetization in adult birds suggests that magnetite is involved in magnetic field detection, although we cannot conclusively exclude nonspecific effects on other substrates because of the strength of the pulse. On the other hand, the lack of effects on magnetic orientation in juvenile birds suggests that all magnetoreception in birds is not based on magnetite. The difference between adult and juvenile birds is commonly rationalized by assuming that adult or experienced birds (i.e., birds that have completed migratory or homing routes) have developed a magnetic map with the magnetite-based sensor providing map information through intensity measurements. On the other hand, juvenile birds are assumed to only use the magnetic compass, presumably not based on magnetite. Pulse magnetization would then disrupt only the map sensor but not the compass sensor. For adult birds, the effects of pulse magnetization vanished when the ophthalmic nerve was anesthetized, suggesting that the structure affected by the pulse is located in the beak or nose, which is consistent with the structural observations. Juvenile birds continued to show normal magnetic orientation even when the ophthalmic nerve was anesthetized. Pigeons lost the ability to discriminate a strong magnetic anomaly in conditioning experiments when the ophthalmic nerve was cut, suggesting that the magnetite-based beak structure is also involved in detecting such anomalies.

Chemical- (or Photoreceptor-) Based Sensing

Magnetic fields can affect the electronic states of atoms and molecules, in particular their spin states. The magnetic fields required to overcome thermal fluctuations are usually much stronger than the geomagnetic field. However, in chemical reactions that involve an intermediate step with unpaired electron spins (called radical-pair intermediates) much weaker magnetic fields can change spin states and thus change the yields and rates of spin-dependent products. The size of magnetic field effects depends on the internal magnetic fields within the molecules (called hyperfine interactions) and on the lifetime of the radical-pair intermediates with lifetimes of at least several hundred nanoseconds required for the effects of Earth-strength magnetic fields to develop. The size of magnetic field effects can be calculated if the molecular determinants are known and the effects of Earth-strength magnetic fields on radical-pair reactions have indeed been measured *in vitro*.

Because hyperfine interactions of many nuclei are anisotropic, the effects of an external magnetic field on a single radical-pair reaction depend on the strength as well as on the direction of the external magnetic field with respect to the molecular frame of reference.

The formation of radical pairs is quite common in biological systems, in particular for reactions involving photopigments. Photopigments can respond to light in fundamentally different ways. Photopigments such as retinal in the opsin family of photoreceptors undergo a conformational change upon light absorption, triggering the reaction cascade underlying normal visual photoreception. Other photopigments, such as chlorophylls and flavins, use light energy to transfer electrons to nearby molecules, thereby generating radical pairs. The angular dependence of magnetic field effects on radical-pair reaction yields can, in principle, form the basis for a physiological magnetic compass, provided that:

1. Photopigments that can form long-lived radical pairs exist in birds.
2. A sufficient number of photopigments are fixed in the same orientation to provide directional information.
3. A link of photopigments to a signal transduction system (e.g., the visual system) exists.

Unlike other sensory receptor mechanisms, in which a stimulus creates a signal, in the radical-pair mechanism, a magnetic stimulus modulates an already existing signal by changing the balance between two intermediate reaction products. Magnetic fields can, in this way, be detected by their indirect influence on another signal transduction pathway. Considering photopigments as magnetic field effect mediators, it appears most plausible that magnetic fields affect photoreception. The absorption of light by a photopigment with appropriate photochemistry triggers a radical-pair reaction, thereby modulating the spin states of the photopigment. If, for example, only the singlet state (but not the triplet state) of the photopigment can initiate subsequent signal transduction steps, the change of singlet yields by the magnetic field results in proportional changes in the photoreceptor signal intensity. Assuming a fixed orientation of the radical-forming photopigments inside the retinal cells of the eye, the magnetic field modulates radical-pair reactions differently in different parts of the retina, leading to the perception of the magnetic field as visual modulation patterns.

Evidence for Chemical- (or Photoreceptor-) Based Sensing

Initial support for the radical-pair hypothesis was derived from studies demonstrating that the compass of birds is affected by the availability of light with specific wavelengths. Furthermore, birds with their pineal gland removed can still orient magnetically, suggesting that the eyes are the most likely site of processing light information in relation to the magnetic compass. Recently, it was shown that magnetic compass responses of European robins appear to be strongly lateralized and possibly located in the right eye because covering up the right eye of migratory birds seemed to destroy their magnetic compass-orientation capabilities. However, none of these studies rules out the possibility that a change in light conditions affects behavioral responses due to a change in motivation or other reasons unrelated to the magnetic-sensing mechanism. Thus, the effects of ambient light alone cannot be taken as evidence for the existence of a radical-pair mechanism.

In principle, spectroscopy with oscillating magnetic fields can reveal the chemical nature of the molecules involved in a radical-pair reaction. Such electron spin resonance spectroscopy is only possible *in vitro* because fluorescence of the product yields is too small to be detectable *in vivo*. However, a form of *in vivo* magnetic resonance spectroscopy can be attempted by detecting the effect of high-frequency oscillating magnetic fields on the behavior of the animal. Oscillating fields in the 1–100 MHz range are expected to interfere with detection of the geomagnetic field in a radical-pair mechanism, and sufficiently strong oscillating fields should therefore result in disorientation in a behavioral test. The application of oscillating magnetic fields, indeed, resulted in bird responses consistent with expectations from the radical-pair mechanism. Fields of 1.3 and 7 MHz at a strength of 470 nT resulted in disorientation in magnetic compass responses unless they were presented parallel to the static (i.e., geomagnetic field), in which case no effect of the oscillating fields was discernible, as expected for a resonance effect. Other orientation responses of birds and responses of mole rats, with a compass presumably based on magnetite, were unaffected by the oscillating fields. These tests together provide strong indirect evidence that the magnetic compass of bird involves a radical-pair mechanism, but provide no information about the chemical nature of the radical pair.

Cryptochromes have been suggested as possible magnetoreceptor candidates because they have the ability to form long-lived radical pairs and because they are found in the eye of birds. In plants, cryptochromes mediate several blue-light-dependent responses, for example, growth inhibition and flowering time. Recently, it was shown that cryptochrome-dependent responses are enhanced through a change in the intensity of the local magnetic field from 33–44 to 500 μT. Control

responses mediated by other photororeceptors or in mutants lacking cryptochromes showed no magnetic field effects.

These findings demonstrate a link between light sensing through cryptochromes and magnetic field effects, and they pave the way toward the identification of the magnetic signal transduction mechanism through molecular biological and genetic studies in the *Arabidopsis* model system.

Other Mechanisms

In principle, magnetic fields could be detected through induction by sufficiently sensitive electric sensors, such as the Lorenzini ampullae in fish. However, because air is a much less conductive medium than water, the consensus view is that the electric sensory structures in land-based animals or birds have to be even larger. That is, they would be of such size that they could hardly be overlooked by standard anatomical characterizations. The lack of a candidate anatomical structure suggests that induction-based magnetoreception may be an issue of interest only for animals in aqueous environments. There exist a plethora of suggested possible alternative mechanisms for detecting the geomagnetic field in biological systems. However, though many of these suggestions are plausible for the detection of magnetic fields ten or hundred times stronger than the geomagnetic field, none of these suggestions has provided a convincing physical mechanism by which magnetic fields of geomagnetic field strength (30–70 μT) can be detected against the background of thermal and molecular shot noise. To date, magnetite-based and radical-pair reaction-based magnetoreception are the only two mechanisms for which *in vitro* experimental evidence demonstrates the effects of Earth-strength magnetic fields. Although some behavioral data suggest that much smaller intensity changes (down to less than 20 nT) may be detected in animals, no plausible physical mechanism exists yet that can explain how biological sensors can detect such tiny changes.

Neurophysiological Approaches

Early electrophysiological recordings suggested several centers in birds where magnetoreception might be processed. The firing rates of neurons in the nucleus of the basal optic root (nBOR), a center that combines visual with vestibular information, changed in response to a magnetic field stimulus with slowly changing direction. A comparable stimulus also resulted in changes of neuron responses in the optic tectum, with either response disappearing when the optic nerves were cut. Increased neural responses were furthermore recorded in trigeminal ganglion cells when the vertical magnetic field intensity was increased by 5 mT or more beyond the local magnetic field intensity, resulting in a change both of total intensity and inclination of the magnetic field. Responses of neurons in the trigeminal nerve were also observed in trout, in which single neurons were identified in the superficial ophthalmic branch (ros V) of the trigeminal nerve that responded to changes in the intensity but not the direction of an imposed magnetic field. The discrimination of a magnetic anomaly by pigeons in conditioning experiments was disrupted when the ophthalmic branch of the trigeminal nerve was cut. The responses in the nBOR and optic tectum are consistent with a magnetic sensor in the eye, whereas the responses in the ophthalmic branch of the trigeminal nerve are consistent with a magnetic sensor in the beak or nose. However, many of the electrophysiological studies date back to more than 20 years ago, and later attempts to reproduce the results of the bird studies have sometimes met with difficulties.

In recent years, several neurophysiological studies have focused on behavioral molecular mapping techniques. Immediate early genes such as ZENK and c-fos are expressed only in cells showing neuronal activity and can therefore be used to identify brain areas active during a particular behavioral or sensory task. In mole rats (which are subterranean mammals), neuronal activity levels in neurons in the suprachiasmatic nucleus (SCN) differed between control animals and those placed in an unfamiliar environment with a changed magnetic field. In birds, a brain area named cluster N was identified in the forebrain; it is active at night during magnetic orientation and loses activity when the eyes are covered. However, no changes of neuronal activity could be observed for different magnetic field conditions. This could mean that, instead of cluster N, other brain areas are involved in magnetic processing that do not express the genetic markers such as is the case for the nBOR and the thalamus of birds. Alternatively, mapping with genetic markers that integrate over neuronal activity may not be sufficiently sensitive to detect changes in activity patterns due to magnetic fields in birds. Imaging techniques with better time resolution, such as Ca imaging may be able to resolve the magnetically sensitive centers in the brain.

Outlook

Much of the debate in the past on the mechanistic aspects of magnetic sensing centered on the question of whether a magnetite or a radical-pair-based mechanism is the exclusive basis of magnetic sensing. This somewhat myopic view is now gradually changing to a recognition that both mechanisms may operate,

possibly even in the same animal. In hindsight, such multiplicity does not appear surprising because sensory systems often show the specialization of receptors for different tasks.

In fish, there is strong evidence for a ferromagnetic magnetite-based structure providing magnetic information and no hint of additional magnetic sensory structures. Neurons in the trigeminal ganglion are prime candidates for electrophysiological studies revealing the sensitivity of the structure to intensity and directional stimuli.

In birds, an interesting magnetite-containing structure has been identified in the beak of birds. Magnetic information is probably transmitted from this structure through the ophthalmic branch of the trigeminal nerve in adult (but not juvenile) birds, but the biological function of this information is not yet entirely clear. Behavioral evidence points to the existence of a second magnetic sensory structure responsible for normal magnetic compass orientation that operates on a radical-pair mechanism; it is probably linked to photoreception, possibly in the retina. The location and structure of this sensor and the pathway of neural information remain unknown. Visual centers and ganglion cells appear the best candidates for electrophysiological studies. The confluence of results of modeling with increased predictive power, novel behavioral studies with more diagnostic conditions, and neurobiological mapping studies suggests that the field is nearing the unequivocal identification of the magnetoreceptors.

Introduction

The same fluctuating electrical sources in the brain that produce the scalp potentials of the electroencephalogram (EEG) also produce a magnetic field over the head. A measurement of this field is called a magnetoencephalogram (MEG). Because the MEG and EEG are produced by the same sources, MEG recordings can resemble those of EEG. For example, a single MEG trace (a recording of the fluctuating magnetic field vs. time at one location on the head) can resemble an EEG trace recorded at a related location. However, some MEG recordings look different from equivalent EEG recordings. Thus, an MEG spatial map over the head is quite different from the equivalent EEG map, where each map shows the magnetic field or scalp potential over a large region of the head, at one particular instant in time (sometimes called a snapshot). They are different because the MEG spatially samples the electrical sources differently. This allows the MEG map to provide some different information about the sources in the brain than does the EEG map. In that sense, the MEG is complementary to the EEG, and both are necessary to obtain the maximum amount of information about these electrical sources.

Among the noninvasive techniques for functional imaging of the human brain, the MEG and EEG are unique in that they are directly and instantaneously tied to neuronal currents, the brain's information-processing mechanism. In particular, the MEG and EEG signals are mostly produced by the postsynaptic currents in the pyramidal cells of layers III and V of the cortex. In contrast, functional magnetic resonance imaging (fMRI), positron emission tomography, and single-photon emission tomography have an indirect and delayed relationship to synaptic events through hemodynamics or metabolism. However, the spatial localization of MEG and EEG sources is uncertain, in contrast to definitive localization of the three tomographic methodologies. Other forms of brain imaging, such as MRI and computer assisted tomography, only look at anatomic structures, not functions. Use of the MEG is sometimes called magnetic source imaging.

The brain's fluctuating magnetic field is very weak, commensurate with the weak potentials measured by the EEG. MEG signal levels are typically below 10^{-12} T (tesla), or 10^{-8} G (gauss) in older units; this is much weaker than the urban fluctuating magnetic background of approximately 10^{-7} T or 10^{-3} G and weaker than the earth's steady field of approximately 0.5×10^{-4} T or 0.5 G. Therefore, the two main requirements for measuring the MEG are a magnetic detector of high sensitivity and the suppression of the fluctuating magnetic background (the steady background usually presents no problem).

The sensitive detector used is the SQUID (Superconducting Quantum Interference Device), which operates at 4 K and is therefore contained in a liquid helium dewar. Modern MEG dewars are helmet shaped and enclose most of the head. The dewar typically contains several hundred SQUIDs, where each SQUID is fed by a magnetic sensing coil, and most of these coils are arrayed on a spherical section over the head at grid points 2 or 3 cm apart. This spherical section is at an average distance of approximately 2 cm from the adult scalp, where some of the separation is due to the vacuum space in the dewar. The many sensing coils allow simultaneous magnetic field measurements at the many coil locations over the head, resulting in a continuous series of 'snapshot' maps over the head. The most fundamental choice of sensing coil is a simple wire loop, which measures the component of the magnetic field vector normal to the loop, B_z. One loop connected to its SQUID is called a magnetometer, and if all sensors in a dewar were chosen to be magnetometers, then each snapshot is a map of the magnetic component B_z over the head.

The fluctuating background is suppressed mostly in two ways. First, the measurements are made in a magnetically shielded room, which can exclude almost all of the fluctuating external fields. An early example is shown in Figure 1. Second, the gradient of B_z can be measured instead of B_z itself, where the gradient is the difference in B_z at two locations over the head. These can be neighboring locations along the spherical surface, parallel to the skull, or they can be radially separated locations, perpendicular to the skull. The measurement in each case is said to be due, respectively, to a planar or a radial gradiometer. The planar gradiometer coil consists of two side-by-side loops magnetometer connected in opposition, whereas the radial gradiometer coil consists of two coaxial loops connected in opposition, separated radially. The background is suppressed because the gradient of the background is much reduced compared with that of the brain. In other words, a background source which is distant gives almost equal signals to the two gradiometer coils and hence is largely canceled,

Figure 1 The magnetically shielded room at the Massachusetts Institute of Technology, where the first MEG measurements with the SQUID were made by one of the authors (Cohen) in 1972. This illustrates heavy, effective magnetic shielding. The walls contain five layers of shielding: three are of the expensive high-mu shielding material called moly permalloy, and two are of pure aluminum, for eddy current shielding. The room is roughly spherical because of the efficiency of this shape. This is an example of an effective room that removes almost all urban background, but it is expensive to build. Newer rooms are larger, to accommodate the large helmet dewars, but are box shaped and usually have fewer layers of moly permalloy and hence are basically less expensive. Also illustrated here is the basic setup for measuring the MEG. The subject is shown positioned for recording his MEG and wears clothes that contain no magnetic materials (no zippers or shoes), which could cause relatively large magnetic disturbances. The large white cylinder near the subject's head is the liquid helium dewar, and this early dewar contains only a single SQUID detector in the tail. At that time, before whole-head dewars were developed, maps were made by tedious sequential measurements over the head.

whereas the field from the nearby brain is different in each and hence is not canceled. A good, multilayer room can eliminate the background almost completely but adds expense, whereas the gradiometer method, although less expensive, cannot eliminate background as well. Each MEG system is a compromise among these various factors and can contain magnetometers, gradiometers, or a combination of these, housed in a particular choice of shielded room. The background can also be reduced in a third way – via software processing of the MEG signals, where the software is able to recognize signals from an outside source and reduce or eliminate them. The cost of an entire MEG system, including shielded room, SQUID system, hardware, and software, is approximately $3 million. For example, see Figure 2.

Using the MEG

MEG measurements are made in the following way. First, all magnetic material on the subject's body is removed or demagnetized, and the subject changes into magnetic-free clothes. Fiducial locations on the head are accurately noted; in one system, three small coils are attached, which will be continuously sensed by the MEG for accurate head location. If the EEG is to be recorded simultaneously with the MEG for complementary information, EEG electrodes are now applied to the scalp. Next, the subject, seated or in the supine position, is placed with his or her head in the helmet dewar, as shown in Figure 2. Next, the raw recordings are made, which consist of MEG traces on all channels, due either to evoked neural activity or to spontaneous activity, depending on the purpose of the session.

Then, in most cases, steps are taken to extract the signal from the noise, where the noise is often unwanted MEG signal from areas of the head not being measured. Traditionally, this entails averaging the signal with respect to a repeated event (e.g., sensory stimulus onset) to produce an 'event-related field' completely analogous to the 'event-related potential' derived by averaging EEG. Increasingly, such 'time-domain' processing is supplemented by 'frequency domain' analyses in which the power in different frequency bands is estimated at different latencies after the stimulus and then averaged across trials. Such processing permits activity that is not strictly phase-locked to the stimulus to be studied. Finally, a sequence of spatial maps (snapshots) are extracted from the trace maps, each for a different instant in time, and used to estimate the neural sources in the brain that are generating the signals. This estimate is termed the 'inverse solution' and is usually the purpose of the measurements.

Unfortunately, inverse solution MEG (and EEG) maps have no unique solution and are handled as follows. All inverse solutions require, in addition to the MEG field map, two elements. First, they require a biophysical model for calculating how activity in any particular brain region would appear at the sensors. Such 'forward calculations' vary in regard to how accurately they model the shape of the head and the conductance in its various compartments. All inverse solutions also require *a priori* assumptions, allowing them to choose between the infinite

Figure 2 An example of a state-of-the-art MEG system. Although not apparent, this system is housed in a large shielded room. The entire structure at the subject's head is called a gantry, and it is set to perform an MEG scan of a subject in the supine position. The gantry can also be swung upward when needed to accommodate a subject in the sitting position. As in **Figure 1**, the subject wears no magnetic material. The subject's head is shown positioned in a helmet-shaped liquid helium dewar, as part of the gantry. This dewar contains 306 sensors surrounding the head, illustrated in the inset at left, oriented as if the patient was in the sitting position (head vertical). The sensors consist of 306 'pickup coils' centered at 102 locations over the head, with three different coils at each location. One coil is a simple outside square and hence a magnetometer; the other two are rectangular planar gradiometers, oriented at right angles to each other. Three SQUIDS are part of each square. Thus, the entire system consists of 102 magnetometers and 204 planar gradiometers for a total of 306 MEG channels. This MEG system, called Vector View 306, is made by Elekta AB (Finland). Other manufacturers supply similar systems, each with its own distinctive features.

number of current sources that can produce any given MEG (or EEG) map. The simplest inverse solutions assume that the field is generated by a single focal source, called a current dipole, that is defined by its position, orientation, and strength. Such assumptions are strictly accurate for only the first few milliseconds after the initial arrival of activity in sensory cortex – for example, prior to 20 ms in somatosensory cortex. However, in many cases the MEG field can be well approximated by an equivalent current dipole even when it is known to be generated in multiple locations of varying extent. Other *a priori* assumptions may concern how many brain areas are contributing to the solution, their focality, and/or their correlation with one another.

There exists extensive literature on MEG inverse methods. Some methods estimate the activity at all brain locations, whereas others restrict possible sources to dipoles that are in the cortex and perpendicular to its local surface, as determined from the MRI in the same subject. This assumption is reasonable because the MEG is mainly generated by currents within the apical dendrites of pyramidal neurons, which are oriented perpendicularly. These currents may be from ligand-gated channels at excitatory or inhibitory synapses or from voltage-gated active conductances. Action-potentials do not contribute significantly to the MEG due to the random (canceling) spatial arrangement of their generating currents and their lack of synchrony relative to their short duration; further, their 'ends' cancel internally. Note that although MEG and EEG are generated by current sources, most sources do not contribute to either one because of cancellation at many spatial levels within the same dendrite, cell, or cortical column

or between cortical areas. Thus, even if the inverse estimate were accurate, it would show only the uncanceled sources.

Inverse methods often use additional assumptions to localize activity, such as the assumption that the brain minimizes the total power across its surface or total current. Such assumptions have little, if any, biological justification. Consequently, it is important to seek validation of proposed solutions using more certain methods. The most direct validation can be obtained from intracranial EEG recordings during the same tasks as those recorded with MEG. Although certain localization can be obtained with intracranial EEG, such recordings are only obtained in the context of severe epilepsy, and only in clinically indicated locations, so issues of pathology and sampling limit their availability and interpretation. In healthy subjects, the reasonableness of MEG inverse estimates can be judged against fMRI results in the same task. However, there are many reasons why MEG and fMRI signals may be generated in different locations, so the lack of correspondence is not definitive. Conversely, the locations of fMRI activations may be used to bias MEG inverse estimates, provided that the method allows for mismatches between the underlying generators.

Differences between MEG and EEG

There are three differences between MEG and EEG instantaneous spatial maps that allow the MEG to give different information from the EEG. These differences are calculated when the head is idealized as a system of concentric spherical shells representing the scalp and skull, etc. Also, the current source generating the MEG and EEG is idealized to be a dipole, the simplest source possible (a more complex neural source can always be synthesized as a sum of dipoles). In the following, we discuss the calculated MEG and EEG maps and compare them with regard to their ability to determine the location and angle of the dipole which generated them – that is, to localize the originating dipole.

The first difference is due only to the orientation of the dipole. For a dipole oriented radially to the spherical surface (skull), it can be shown, surprisingly, that the external magnetic field is everywhere zero; hence, there is no MEG signal. This is due to the symmetry cancellations in perfectly spherical conductors. Therefore, there is only an MEG signal for a dipole oriented tangentially, where there is no perfect symmetry cancellation. Because the MEG/EEG sources are mostly pyramidal cells in the cortex, and these have a net direction perpendicular to the cortical surface, it follows that sources radial to the skull are mostly located on the gyri and tangential sources mostly in the sulci, as shown in Figure 3. Thus, the MEG is largely due to the sources in the sulci; the EEG is due to both. Therefore, one consequence of this difference is that the MEG should see those tangential sources that on the EEG may be dominated or masked by strong radial sources. Indeed, radial sources tend to dominate the EEG because on the gyri they are closer to the electrodes on the scalp. The fact that radial sources produce zero external field has an important consequence for sources deep in the head. Because a dipole at the center of a sphere is always a radial source and hence produces zero external field, it follows that the MEG due to deep sources is suppressed compared to the EEG; the deeper the source, the more the suppression. Because of this radial–dipole difference, the MEG map is due to a subgroup of the sources seen on the EEG. That is, the MEG sees less than does the EEG.

Figure 3 Two electrical sources in the cortex; one is oriented tangentially to the spherical skull and the other radially. Each is represented as a current dipole (arrows). Because sources in the cortex are oriented perpendicularly to the cortical surface, tangential sources are located in the sulci and radial sources are in the gyri. Although the EEG sees both sources, it is dominated by the radial sources in the gyri. If the radial dipole were shifted, for example, to the right, slightly into the bend, it would then have a small tangential component and hence would now be visible on the MEG. Thus, the gyral area of invisibility is less than is apparent. Also, in cases in which the lower ends of sulci bend around, there are radial–tangential complications.

The other two differences in MEG and EEG maps involve actual map patterns due to a tangential dipole. These are illustrated in Figure 4. First, the MEG pattern is seen to be oriented perpendicularly to the EEG pattern due to a basic orthogonality between magnetic and electrical fields. Consequently, MEG localizes a source better in the y direction, whereas the EEG localizes better in the x direction. Second, the MEG pattern is somewhat tighter, largely due to the smearing by the high-resistivity skull of the surface potentials measured by the EEG. In contrast, for perfectly spherical surfaces, the MEG is unaffected by the resistivities of the different layers. The consequence of this size difference is that the MEG localizes a tangential dipole somewhat better in its best direction (y), in comparison to the EEG in its best direction (x), if all other factors are equal, such as

Figure 4 Difference between the MEG and EEG maps, computed by using an ideal spherical model of the head containing a tangential dipole source (arrow) at a depth of 2.7 cm. The model cutaway shows four spherical boundaries representing scalp, skull, cerebrospinal fluid, and brain. The continuous spreading currents generated by the dipole are seen as thin lines. The maps are shown on a spherical 'cap,' which has *x* and *y* coordinates with ticks at each centimeter, with contour lines every 20%. The MEG map is of the component of magnetic field vector normal to the surface (B_z), whereas the EEG map is of the surface potential *V*. The MEG map is different from the EEG map in that it is oriented by 90° and is tighter by approximately 30%. It can therefore localize somewhat better in its 'best' direction (*y*) compared with the best direction (*x*) in the EEG, according to this ideal model.

modeling errors – for example, errors in knowing the conductivities of all the layers. However, such modeling errors are considered worse for the EEG, which thus favors the MEG.

Thus, all in all, MEG advantage in localizing a dipole is in the range of about 30% better (dipole shown here) to perhaps a factor of 2 better, depending for example, on resistivity errors in the EEG modeling. Also, in the actual nonspherical head, the difference between radical and tangential dipoles becomes diffused. Although there have been recurrent claims that the MEG can localize a dipole source far better than can the EEG – for example, to within 2 mm (because of reduced sensitivity to conductivity errors) – there is no experimental evidence for this claim in the human head. The one reported experiment under these conditions, using implanted current sources in the brain, has shown only a minor advantage, yielding 8 mm accuracy for the MEG versus 10 mm for the EEG. Also, several advanced computer modeling studies have shown no significant MEG localization advantage. Finally, because MEG calculated sources are laid onto MRIs of the subjects, there is a co-registration error from MRI to MEG of approximately 3 mm. In brief, the 2 mm claim is unproven and unreasonable. However, the MEG has contributed to EEG source localization in an unexpected way. Because the MEG was developed in physics labs, advanced techniques were used for inverse solutions on the maps to find the sources. EEG data had usually been interpreted

by visual inspection, occasionally with large errors. However, EEG manufacturers began duplicating the MEG inverse solutions, and now include such software in EEG systems, so that EEG localization is now more accurate.

Based on the three differences discussed above, it can simply be stated as "the MEG usually sees less than the EEG sees, but sees it somewhat more clearly".

There are other MEG–EEG differences that are of a more practical nature. One difference, favorable to the EEG, is the MEG nuisance of embedded magnetic material in the subject, such as magnetic dental work, which creates large interfering magnetic signals. This material can often be demagnetized with a handheld magnetic eraser. However, there are differences that are favorable to the MEG. One is that the MEG does not require electrodes to be pasted on the head, as does the EEG. Perhaps a more important difference concerns DC; galvanic skin (scalp) potentials severely hamper EEG DC measurements, but the MEG does not see these obstacles. In this regard, the MEG has a distinct advantage that has yet to be fully exploited.

Current Status and Future Prospects

There are approximately 120 whole-head MEG systems in use or on order throughout the world, some with more than 300 SQUIDs per helmet. Many of these systems are located in Germany, Japan, the United States, Finland, and Canada. Thus, an increasing number of MEG maps are being recorded, often in combination with EEG maps, due both to spontaneous signals and to event-related signals. The overall purpose is to determine if the selectivity of the MEG can clarify the sources of the signals. The efforts are divided into two broad areas: research on the workings of the normal brain and the search for clinical applications of the MEG.

In research on the normal brain, MEGs are being studied for responses evoked by stimulation of each of the five senses. To date, MEG has produced evidence supporting locations of sources in the primary sensory cortices. One early example is the well-studied 20 ms somatosensory signal from the human brain in response to peripheral nerve (wrist) stimulation. From the EEG alone, the source of this signal had been ambiguous, with a choice between two radial or one tangential sources. However, the combination of MEG and EEG maps showed the source to be mostly a tangential dipole. In another example involving somatosensory cortex, MEG and EEG were combined to study the finger representation in the cortex. It was found that MEG and EEG combined gave more localization accuracy than each separately. Some of the studies used MEG without EEG; one such study reported increased strength of cortical sources of left fingers of string players. Without EEG maps, however, there can be doubt that the useful information obtained was indeed due to MEG selectivity.

Overall, MEG has demonstrated internal organization in some of the primary areas of the human brain – organization that was previously seen only in the animal brain. MEG has also shown the separation of activity between primary and secondary areas, for example, in the somatosensory cortex and in the auditory cortex. Interactions between successive cortical areas are increasingly being inferred from the phase-locking, coherence, or Granger causality, calculated on individual trials between waveforms recorded at different locations.

MEGs are being studied with regard to the later components as well. After processing in these initial sensory areas of the brain, there are further processors that decode certain classes of stimuli, such as faces. MEG has been able to localize the face area to the same location identified with fMRI and intracranial EEG and has been used to characterize its cognitive responses to a range of face-like stimuli (**Figure 5**). The situation becomes more complicated when moving further downstream to neural activity underlying higher cognitive functions, such as understanding sentences. The fact that neural activity can spread to distant cortical areas in approximately 20 ms suggests that multiple widespread cortical areas may be involved in the response to words, which peaks at approximately 400 ms. Modeling in such situations with a distributed source instead of a dipole (**Figure 6**) localizes MEG activity to the same locations that have been found with hemodynamic measures and with direct intracranial EEG recordings in epileptic patients. Data suggest that in situations such as these, efforts to localize distributed generators appear to have been more successful with MEG than with EEG. If true, this may be due to the fact that, as previously mentioned, the MEG sees fewer sources with a somewhat tighter field than EEG and thus is better able to disentangle multiple distributed sources. However, it is also possible that with better forward models and inverse methods, EEG will be equally successful in localizing complex distributed generators. In any case, modeling studies and some experiments clearly suggest that the best localization will only be obtained by combining MEG and EEG.

Concerning clinical application of MEG, efforts are being made to evaluate MEG usefulness in various areas, including presurgical functional mapping, head injury, and epileptic spike localization. The purpose of presurgical mapping is to locate the regions of the sensorimotor strip using evoked response in order to

Figure 5 Use of MEG in face recognition research. (a) MEG contour map (50 fT step/line) drawn on the head of the subject and sampled at 165 ms after a photo has been viewed. The head is viewed from the right rear; the dark spot marks the right ear. The pattern is seen to be roughly dipolar; hence, a single dipole was assumed for the source. An inverse solution located the dipole(green arrow), where the depth is not seen here. (b) The same dipole source superimposed on the subject's MRI, seen from the front. Here, the dipole is shown as a white dot, for accurate location, in the right fusiform gyrus. The attached rod gives the dipole direction and amplitude. (c) The dipole amplitudes after viewing any of five face photographs and controls, averaged over ten subjects. The normal human face evokes the largest response. The MEG can thus be used to estimate the location, timing, and strength of a neural process associated with face encoding (Halgren et al.).

Figure 6 Use of the MEG with multimodal integration in reading research. Subjects read words and made a semantic judgment (pressing a key if the word referred to an object or animal more than 1 foot in length). MEG maps were produced by subtracting the signals evoked by novel words from those evoked by words that had been read previously in the same task. (a) MEG contour map, viewed from the subject's left, at 540 ms after stimulus onset. Again, the pattern is roughly dipolar, and the green arrow shows the computed source dipole. It appears 'off-center' in this case because of the angle of view. (b) A determination of the sources, from the same contour map, using a nondipolar advanced inverse method allowing a continuous distribution, but sources are now constrained to be on the cortical surface (Dale et al.). The 'inflated' left cortical surface is shown in the same view as in (a). (c) The same data as b, except the source has been further biased by the fMRI location of activation in the same subject and task. Note the increased spatial detail revealed by the integration of the fMRI information in the same task. The MEG data thus reflect the repetition priming effect on semantic processing.

minimize neurological deficit due to surgery. MEG localizes well in this task, as does fMRI. In some cases, the hemodynamic response near a tumor or arteriovenous malformation may be abnormal, and MEG may thus be preferable. In head injury, MEG appears to show focal slow-wave abnormalities more reliably than does EEG; hence, it shows more promise of providing localizing information. In the measurement of epileptic spikes, MEG, when used with EEG, is able to clarify or localize some epileptic foci better than can EEG alone. MEG has also shown spikes that appear to be masked on EEG by other spontaneous brain activity, seen less on MEG. Definitive localization of seizure foci, adequate to guide their surgical removal, often requires the placement of intracerebral electrodes. The hope is that the noninvasive combination of MEG and EEG may allow such electrodes to be more successfully targeted or, in some cases, to be avoided altogether. MEG also appears useful when a skull defect from a prior operation severely distorts the propagation of EEG to the scalp. In this regard, MEG of neonates, which have begun to be measured with smaller helmets, has an advantage in source localization because the fontanelles in the infant skull cause larger errors in EEG. Also, MEG research studies on neuropsychiatric disorders such as schizophrenia, autism, and pain often show promise because of MEG's greater specificity compared with EEG. These studies can provide insight into the neural bases of severe dysfunction in the absence of any structural abnormality.

Expansion of clinical MEG use from regional referral centers to community hospitals will require further evaluation.

Concerning future possibilities, work measuring low-field MRIs using SQUID detectors shows promise for simultaneous measurement of MEG and MRI, eliminating the coregistration error (~3 mm). The future possibilities of MEG depend on how well its advantages will balance against its practical problems and high cost. The practical problems include not only the reduction of magnetic background but also the effort in maintaining a cryogenic system that needs refilling with liquid helium once or twice per week. A cost reduction would make MEG more attractive for clinical diagnosis. In any case, MEG will be used well into the future, both because the large MEG systems now in use or coming online will generate many years of investigations and because there is a general, long-term need for noninvasive measurements of the brain.

Magnocellular Neurosecretory System: Organization, Plasticity, Model Peptidergic Neurons

G I Hatton, University of California, Riverside, CA, USA

Introduction and Historical Perspective on Neurosecretion

Studies of the magnocellular hypothalamo-neurohypophysial system (mHNS) began before anyone was aware that there was such a system. Cells of the pituitary gland were firmly believed to be the sources of all factors controlling the functions now known to be carried out by peptides that originate in the brain. One of these functions, the 'oxytocic principle,' as he called it, was discovered quite serendipitously in 1909 by Henry Dale, widely known as the propounder of Dale's principle of neurotransmitter release. Dale found that smooth muscle contractions resulted when posterior pituitary extracts were placed on strips of virgin guinea pig uterus. Similar pituitary extracts were shown by others to cause antidiuresis and pressor effects. Not until du Vigneaud and colleagues in the 1950s sequenced the peptides oxytocin (OT) and vasopressin (VP) was it determined that two separate peptides were responsible for the different actions of neurohypophysial extracts. This ambiguity had endured because, at the high concentrations that were typically used, each of these peptides has some action at the other peptide's receptors.

At about this same time, an important histological advance, the eponymous Gomori stain (chrome alum hematoxylin) was being used to investigate brain areas that are rich in disulfide bond-containing compounds, such as those in the neurohypophysis. This work was done by the team of Wolfgang Bargmann and Ernst and Berta Scharrer. To the disbelief of the entire field of endocrinology, they showed that the active substances in the posterior pituitary actually originated in the hypothalamus, in cells that were best described as neurons. Difficult to accept in those early days was the idea that substances were made in neurons up in the brain and transported down the axons to remote release sites in the neurohypophysis. Furthermore, these neurons had axons that terminated, not in the usual synapses, but nonsynaptically near blood vessels, and these neural terminals in the posterior pituitary were the sites of peptide hormone storage. Thus was born the concept of neurosecretion. Ultimate acceptance of this concept would come only after much debate and the completion of many functional studies. Even then, it was hard for some to believe that the electrical activity of neurons had anything to do with hormonal responses to physiological challenges. As late as the early1970s, those neuroendocrinologists having an electrophysiological bent always felt compelled to point out to their still skeptical colleagues evidence that confirmed the close positive relationship between neuronal electrical activity and peptide release. This, of course, is widely accepted today.

These neurosecretory cells and their main release products, OT and VP, attracted the attention of a relatively small but active cadre of scientists around the world, whose collective work over the years became a large database that supported increasingly sophisticated analyses of this system. Ultimately, this accumulated database facilitated meaningful answers to questions about the mHNS that were not so easily extractable from others, and the mHNS became a model system for the study of neurosecretion and of the brain's peptidergic neurons.

Ubiquitous in the brains of mammalian species, the mHNS and its functions in peripheral tissues have been most thoroughly characterized in the rat. Much of what has been discovered and described in the rat, however, has been generalizable to the other species that have been investigated. Anatomically, this includes the types of neurons and glial cells in the mHNS, as well as their relationships to one another, and the relationships of the various cellular compartments comprising the mHNS to the brain vasculature. Capillary density is generally found to be high in peptidergic systems, owing largely to their elevated metabolic rates. Capillary density in the brain reaches its zenith in the mHNS.

Basic Organization of the mHNS

Shown in Figure 1 is a three-dimensional representation of a rat brain cut away at the level of the anterior hypothalamus to reveal two prominent mHNS nuclei: the paraventricular nuclei (PVN), positioned on either side of the dorsal third ventricle, and the supraoptic nuclei (SON), lateral to the optic tracts. In the inset at lower left, a Nissl-stained section reveals the dense packing of the magnocellular cell bodies in these two nuclei. Projection neurons of the SON are all magnocellular and are either OTergic or VPergic. The PVN consists of groups of both magnocellular (laterally) and parvocellular (medially) neurons (see inset in Figure 1). OT and VP neurons of the former groups project axons laterally and ventrally to join those of the dorsomedially projecting SON neurons.

Figure 1 Basic organization of the hypothalamo-neurohypophysial system. Three-dimensional representation of rat brain at the level of paraventricular (PVN) and supraoptic nuclei (SON) in the anterior hypothalamus. Major axonal projections of the magnocellular neurons via the pituitary stalk to the neurohypophysis are shown. PVN parvocellular axonal projections to the median eminence are also diagrammed. Inset: Nissl-stained section taken at the same level as shown in the diagram. Magnification 60×. 3V, third ventricle; OT, optic tract.

Together, all these axons then project posteromedially and ventrally in the internal zone of the median eminence to travel in the pituitary stalk. Principal axonal outputs of the magnocellular neurons in these two nuclei are shown in the diagram projecting via the pituitary stalk to terminate in the neurohypophysis. Also shown are projections from the parvocellular neurons of the PVN (not part of the mHNS) to the external zone of the median eminence, where, along with projections of peptidergic neurons from other hypothalamic cell groups, they influence the anterior pituitary.

The focus in this article is on the neurons, glia, and other important structural elements of the SON and neurohypophysis since most of the more enlightening recent developments relative to the topic being covered have involved these portions of the mHNS. It is important to note that the presence of readily identifiable peptides, either OT or VP, makes it possible to study the dendrites and somata in the hypothalamus of unequivocally the same neurons, the axons and terminals of which can be investigated in the neural stalk and neurohypophysis. This advantage is found in few other places in the mammalian central nervous system.

Organization of the SON

Among hypothalamic nuclei, the SON is one of the most highly organized, another factor contributing to its model status. As alluded to earlier, SON neurons are magnocellular and normally synthesize either OT or VP. There are, however, some special circumstances under which a subset of SON neurons synthesizes both peptides. Figure 2(a) is a diagrammatic representation of some of the prominent features of SON organization. The right SON is shown in Figure 2(a); thus the nucleus lies to the right of the optic tract. The nucleus has been partitioned into three zones. Dorsalmost is the somatic zone (SZ). Magnocellular neurons here are shown to be tightly packed, generally bipolar cells with primary dendrites tending to project dorsolaterally or ventromedially. Axons arise from the dorsal primary dendrites and exit the nucleus dorsally or dorsolaterally, as shown in the immunocytochemical stain for both OT and VP in Figure 2(b). Returning to Figure 2(a), ventral to the SZ, the dendritic zone (DZ) consists primarily of the ventrally projecting dendrites that have turned to run parallel to the brain surface and are, therefore, shown here in cross section. Not shown in the simplified diagram, but quite salient in the immunostained image of Figure 2(b), is a spur of SON dendrites that projects ventrolaterally along the pial surface of the periamygdaloid cortex. These dendrites receive direct synaptic input from the mitral cells of the main and accessory olfactory bulbs. Subjacent to the DZ lies a line of astrocyte cell bodies, shown in the diagram as filled ovoids. If projected in three dimensions, this line of astrocytes becomes a sheet that underlies the entire nucleus. Astrocytic processes from these glia fill the spaces between the dendrites, between the somata, and between the neural compartment and the basal

Figure 2 Basic organization of the supraoptic nuclei (SON). (a) Semidiagrammatic representation of the right SON with the myelinated fibers of the optic tract (OT) shown on the left. Large somata lie dorsally, their dendrites truncated, in the somatic zone (SZ). Primary dorsal dendrites are shown giving rise the axonal processes (*). Ventrally projecting dendrites turn to course anteroposteriorly in the dendritic zone (DZ), parallel to the pial surface (open arrowheads). Subjacent to these dendrites lie the cell bodies (filled ovoids) of the astrocytes that constitute the ventral glial lamina (vgl). Processes of these astrocytes fill the clear space between the black ovoids and the basal lamina (small arrows). (b) SON cells stained immunocytochemically for oxytocin and vasopressin. Individual axons leaving the SON are indicated by arrowheads. A special group of SON dendrites projects along the periamygdaloid cortex. These dendrites receive olfactory inputs. Magnification 120×. bv, blood vessel.

lamina lining the pial surface of the brain. Important details are shown in Figure 3. Although there are conventional, star-shaped astrocytes in the more dorsal regions of the SON (not shown in the diagram), it is these ventrally positioned astrocytes in the ventral glial lamina (vgl) whose processes are most involved in the plasticity and remodeling of the nucleus in response to physiological stimulation (discussed in the section titled 'Morphological plasticity: Function-related remodeling in the mHNS').

Figures 3(a) and 3(b) presents two different perspectives on the ventral portion of the SON. On the left, an electron micrograph shows the astrocytic membrane filling the space of the vgl and surrounding a group of ventral dendrites (seen in cross section). Note that the folds of astrocytic membrane are oriented in a predominantly vertical (dorsoventral) direction. Dual fluorescence immunostaining for OT (VP neurons appear as black holes) and for the astrocyte marker glial fibrillary acidic protein (GFAP) are shown in the confocal micrograph on the right. Since staining of the intermediate filament, GFAP, reveals only about 15% of the astrocyte volume, the space-filling capacity of these astrocytes is not well represented in Figure 3(b) (cf. Figure 3(a)). Well shown in Figure 3(b), however, are the astrocytic processes projecting dorsally to separate adjacent OT dendrites and somata. Individual processes from these ventrally positioned astrocytes usually project all the way to the dorsal aspects of the nucleus, that is, they span the entire dorsoventral extent of the SON neuronal compartment.

Organization of the Neurohypophysis

Dominating the neurohypophysial landscape are the pituicytes, specialized astrocytes that constitute the only resident cell population there. Although they can be identified by their expression of GFAP, pituicytes are also morphologically distinctive in having large lipid inclusions (see Figure 4). As is true of astrocytes in the brain, the pituicytes tend to occupy the basal lamina that separates neural from non-neural tissue, such as the neural from the vascular compartment. Unlike the SON, in the posterior pituitary, the vascular compartment contains fenestrated capillaries. Both the pituicytes and the neuronal elements found there are, therefore, located outside the blood–brain barrier. Neurohypophysis-bound axons of mHNS neurons arborize on entering the organ. Individual terminal branches and axonal endings can be found either within a pituicyte (Figures 4 and 5), among pituicytes, or adjacent to the basal lamina along the perivascular space. It was most likely these neurosecretory granule-containing axons, completely engulfed by pituicytes, that misled earlier investigators into the belief that the pituicytes were the secretory cells of the neurohypophysis. Various types of neurosecretory terminal endings, showing their relationships with the other structures, are depicted in Figures 4 and 5.

Morphological Plasticity: Function-Related Remodeling in the mHNS

Early work had established that the dehydration attendant on water deprivation or saline drinking for several days resulted in substantial increases in the somatic volumes of SON neurons. Not unexpectedly, rehydration after a period of dehydration reversed the changes wrought by the dehydrating

Figure 3 Astrocyte occupation of the ventral supraoptic nuclei (SON). (a) Electron micrograph of the ventral glial lamina (vgl) showing astrocytic membrane filling the space between the ventralmost distal dendrites (d), appearing in cross section, and the pial surface (PS) of the brain. As, astrocyte nucleus. (b) Confocal image of the SON, including the ventral somatic zone (SZ), the dendritic zone (DZ), and the vgl areas diagrammed in (a). Immunostained are optic tract (OT) neurons (N) in red and glial fibrillary acidic protein in green. Astrocytic processes (As) projecting toward the dorsal SON separate adjacent OT neuronal dendrites and somata. Scale bar = 2 μm (a), 20 μm (b).

Figure 4 Under basal conditions, a neurohypophysial astrocyte, pituicyte (P), lies adjacent to the perivascular space (PVS) near a fenestrated capillary (fc) and occupies a large percentage of the local basal lamina (arrowheads). Several neurosecretory axons (ax) lie surrounded by pituicyte cytoplasm. Small amounts of extracellular space (ECS) are visible. L, lipid bodies; Mac, perivascular macrophage; Nu, pituicyte nucleus.

stimuli. Such morphological alterations paralleled the changes in electrical activity that were observed under similar dehydration and/or rehydration conditions. It had long been known that such activating stimuli caused depletion of neurosecretory material from the posterior pituitary and that rehydration resulted in the replenishment of the peptide stores there. Thus, stimuli that activated the mHNS reliably produced modifications in both SON and neurohypophysial morphology, and these changes were readily detectable when comparisons were made between activated and basal conditions. Electron microscopic studies of the

Figure 5 Scanning electron micrographs of neurohypophysis. (a) Pituicyte (P) shown at low magnification, torn open to reveal neurosecretory axons (ax) inside or penetrating its cytoplasm. (b) Higher magnification of the axons shown in (a). The membrane has been partially torn off in the preparation, revealing the densely packed neurosecretory granules.

mHNS comparing basal and dehydrated conditions revealed that, in addition to somatic size increases, rather profound morphological changes took place in cell–cell juxtapositions (involving both neurons and astrocytes) of the SON.

Basal Conditions

Animals in a temperature- and humidity- controlled environment, with free access to food and water and not in any special reproductive state (e.g., pregnant or lactating), are generally considered to be in a basal state with regard to the functions of the mHNS. Under basal conditions, neuronal excitability and firing rates are low.

Morphology: SON Despite being densely packed, the neurons of the SON under basal conditions are usually separated from their closest neighbors by astrocytic processes, as seen at low magnification in Figure 3(b). A deeper appreciation for the glial–neuronal juxtapositions is gained at the ultrastructural level. Figure 6 shows the typical relationships observed between SON astrocytes and their associated neuronal somata (Figure 6(a)) and dendrites (Figure 6(b)) under basal conditions. One or more fine astrocytic processes insinuate themselves between adjacent neuronal somata, also enclosing the terminal boutons making axosomatic synapses (not shown). It is known that these astrocytic processes, as elsewhere in the brain, are vested with the responsibility of (1) taking up extracellular potassium concentration (K_o^+), which rises when the neurons increase their firing of action potentials; (2) taking up synaptically released transmitters, such as glutamate or γ-aminobutyric acid (GABA); and (3) control of the extracellular space

Figure 6 Typical supraoptic nuclei (SON) ultrastructure under basal conditions. (a) Two neurosecretory somata (S1 and S2) are separated by a fine astrocytic process (*) and extracellular space (lower left). (b) Dendrites (*) tend to be wrapped by astrocytic processes and are generally not in close apposition with neighboring dendrites.

volume. Overwhelmingly, the type of synapse seen under basal conditions is the conventional 'single' synapse, in which one terminal bouton forms a synapse with only one postsynaptic element, in this case a

Figure 7 Supraoptic nuclei (SON) astrocyte surrounding a dendrite (D) and part of an axon (ax) whose synaptic bouton (b) is making contact with the dendrite. Glial filaments (gf) can be seen in this astrocyte, which is immunostained for taurine (basal conditions). Scale bar = 290 nm.

Figure 8 Neurosecretory axon terminal containing dense core vesicles (*) and microvesicles (mv) making a synaptoid contact with a pituicyte (P). Note that the microvesicles form an active zone similar to a synapse and that the dense core vesicles are away from this zone. There is no membrane specialization of the pituicyte side of this contact zone. Mit: mitochondrion; Nu: nucleus.

soma. This has been determined quantitatively by serial section analysis at the ultrastructural level.

SON dendrites, too, tend to be separated from their immediate neighbors by astrocytic processes (Figure 6(b)). Axo-dendritic synapses also tend to be enclosed by astrocytes (see Figure 7), and these synapses are predominantly of the single type. Although these interposed astrocytic processes limit dendritic contact under based conditions, a low, but detectable, level of dendro-dendritic gap junctional communication appears to exist at this time. SON gap junctions have been inferred largely from dye and/or tracer coupling experiments. In such studies the fluorescent dye Lucifer yellow or the tracer neurobiotin or both together have been injected into single SON neurons in slices. Transfer of the injectant to other cells is taken as evidence of gap junctions. The coupling observed is between the dendrites in relative close proximity to one another and is homotypic with regard to cell type; that is, there is no cross-coupling between OT and VP neurons. Finally, as illustrated in Figure 3(a), there is an overall vertical orientation of the astrocytic processes filling the vgl under basal conditions.

Chemistry: SON Although OT and VP neurons are indistinguishable solely on the basis of morphology, they have been shown to differ in their expression of proteins other than OT and VP. Two of these are the calcium-binding proteins calbindin-D_{28k} and calretinin, expression of which appears to be related to the patterns of firing displayed by the two types of neurons and to the changes that occur when the mHNS is activated. Under basal conditions, OT neurons more or less uniformly express relatively large amounts of calbindin-D_{28k} and lesser amounts of calretinin. Calbindin-D_{28k} is expressed in either relatively small amounts or is unexpressed in individual VP neurons, and calretinin is virtually absent. SON astrocytes synthesize and release the GABA-like amino acid taurine (Figure 7) under basal conditions, that is, low extracellular fluid osmotic pressure, contributing to tonic inhibition of VP neurons at the hypothalamic level, via glycine receptors.

Basal Conditions: Neurohypophysis

Morphology Pituicytes, the resident astrocytes of the posterior pituitary, occupy approximately 30% of the total neurohypophysial volume and an even higher percentage (~70%) of the perivascular basal lamina under basal physiological conditions. To a large extent, the neurosecretory axons and axonal endings are surrounded or completely engulfed by pituicytes at this time (see Figures 4 and 5). Moreover, each axon or axonal ending tends to be completely filled with dense core vesicles. Specialized contacts exist between some of the neurosecretory axons and pituicytes. These 'synaptoid' contacts resemble synapses; however, unlike synapses, they have only presynaptoid specializations, with no postsynaptoid densities and no obvious extracellular matrix material in the synaptoid cleft (Figure 8). Therefore, they are called synaptoid contacts and are relatively small in number under basal conditions. Synaptoid contacts are thought to be conduits for glial–neuronal signaling.

Chemistry As would be expected, the distribution of calbindin-D_{28k} and calretinin in the neurohypophysial processes is similar to what exists in the

SON neurons where the major protein synthesis takes place, with the OT axons expressing both proteins and the VP neurons expressing little, if any, of the former and none of the latter. Like the SON astrocytes, the pituicytes are rich in and release taurine under basal conditions. Thus, taurine, via glycine receptors, appears to exert a controlling influence at both the somatodendritic and axon terminal portions of the mHNS.

Plastic Changes with Activation: The Stimuli

Dehydration stimuli are not uniquely capable of activating the mHNS, such as by elevating neuronal firing rates and excitability or increasing synthesis and release of OT and VP. Dehydration is a popular experimental tool because it is convenient to use, its onset can be relatively accurately estimated, and it is powerful in that it produces effects that are both reliable and robust. Furthermore, acute versus chronic effects of dehydration can be readily assessed. Hemorrhage and other stressors, such as physical restraint, also activate the system. These stimuli, however, are not entirely physiological, a criticism that has also been leveled at some methods of producing dehydration. Events that occur during the natural course of pregnancy, parturition, and lactation and suckling of the young also activate the mHNS and are considered unqualifiedly physiological. One or another of these conditions, in particular lactation and suckling, has often been used in studies of morphological plasticity and remodeling of the mHNS. The effects produced by this stimulus complex are every bit as robust as those of dehydration, if not more so. Robust effects are especially observable in the OT cell portion of the mHNS. Furthermore, weaning of the young, not unlike rehydration after dehydration, has been effective in reversing the changes wrought by pregnancy, parturition, and lactation. Except for hemorrhage, which has not been tested, activation of the mHNS by any of these methods produces quite similar morphological changes.

Plastic Changes with Activation: SON

Morphology As measured from the animal's last voluntary drink, as little as 12 h (with a trend already established by 4 h) of water deprivation physiologically activates SON neurons, producing observable changes in endoplasmic reticulum and other subcellular organelles. Presumably, this detection of increased extracellular fluid concentration and/or decreased volume by mHNS cells (neurons and glia), and by other osmosensitive neurons that are synaptically connected to SON cells, also leads to the enhanced neuronal firing that results in OT and VP release. If intake of exogenous water does not correct the extracellular fluid imbalance, the SON undergoes a series of functional changes and rather remarkable morphological remodeling. First, even slight increases in extracellular fluid osmotic pressure curtail release of taurine in most cells tested. Thus, that source of tonic inhibition by the local astrocytes is eliminated. Increased action potential production due to this disinhibition and to increased synaptic drive from amino acid and catecholaminergic inputs apparently acts on both the SON neurons and their associated astrocytes via combinations of α-amino-3-hyroxy-5-methyl-4-isoxazole-propionic acid, *N*-methyl-D-aspartate, GABA, and α- and/or β-adrenergic receptors. Collectively, the results of the extracellular microenvironmental changes and receptor activation produce retraction of the fine glial processes separating adjacent SON dendrites and somata from their respective neighbors. Astrocyte membrane filling the vgl also undergoes reorganization from its usual predominantly vertical orientation to a more horizontal one. One effect of this reorganization is to reduce vgl thickness, thereby reducing the distance between the cerebrospinal fluid and the SON neuronal compartments.

In the SZ, astrocytic process retraction results in increased soma-somatic appositions (**Figure 9(a)**); that is, somatic membrane that was formerly apposed (across a $\sim$10 nm extracellular space) to the membrane of an astrocytic process now faces another neuronal membrane. Axo-somatic synapses that were formerly covered by astrocytes that would take up excess transmitter and K_o^+ are now also apposed to neuronal membrane. The functional implications of these changes are exactly what would be expected from the increases observed in neuronal excitation under these conditions. Less of the K_o^+ generated by the now more frequently occurring action potentials is taken up due to the relative paucity of astrocytic processes separating somata, leading to increased depolarization. Amino acid transmitters can now more readily spill over and remain longer in the vicinity after glial retraction. Consequences too complex to discuss in depth here accrue from reduced transmitter uptake due to retracted glial processes. These include enhanced potential activation of GABA receptors (usually more frequent on the soma); of glutamate receptors, both ionotropic and metabotropic; and reduced breakdown of adenosine triphosphate (ATP) to adenosine, since ecto-5′-nucleotidase, an important enzyme in ATP metabolism, is of astrocytic origin. This latter reduction in glial participation means that the generally excitatory effects of ATP on SON neurons last longer because the adenosine-induced inhibitory effects, via adenosine A_1 receptors, are delayed.

Figure 9 Ultrastructural features of the supraoptic nuclei (SON) under activated conditions. (a) Two somata (S1 and S2) in close apposition (i.e., without an intervening astrocytic process). This apposition (between vertical lines) is more than 10 µm in length. Nu: nucleus. (b) Axosomatic multiple synapse made by axon terminal 1 (at1) with the two somata (arrows). A conventional single synapse is made by at2 with S2 (arrow). A fine glial process separates at2 from S1 (white arrowheads). (c) Dendro-dendritic close appositions (bundling) and multiple synapses. Three dendritic bundles (i.e., two or more dendrites without intervening glial processes) are identified with the same numbers (1, 2, or 3). Two multiple synapses (*) are evident at bundles 2 and 3.

One of the more remarkable occurrences in response to physiological activation of the mHNS is the appearance of new synapses. Unlike the conventional ones seen under basal conditions, in the new synapses one synaptic bouton contacts two or more (up to seven have been documented) postsynaptic neurons (Figure 9(b)). These so-called multiple or shared synapses are thought to be formed from the conventional single synapses shortly after astrocytic process withdrawal exposes the synaptic terminal membrane, which had previously been covered by glia, to another neuronal membrane. Several pieces of evidence support this hypothesis. First, the appearance of multiple synapses is too rapid (minutes to a few hours) to be due to axonal sprouting. Second, no growth cones have ever been observed during this time. Third, and perhaps most convincing, is the observation that the increase in multiple synapses is accompanied by a decrease in the percentage of single synapses. Since glutamatergic and GABAergic multiple synapses both increase with prolonged activation of the system, current thinking is that one effect of increased multiple synapses is to enhance the coordination of incoming signals to influence excitability and, under certain circumstances, even synchrony. It well may be that this increase in the number of synapses also compensates for the loss of overall synaptic efficacy that would occur as the SON somata enlarge under chronic stimulation.

Remodeling similar to that described for the SZ occurs in the DZ. Astrocytic process retraction here allows dendro-dendritic close appositions, so several neighboring dendrites are more likely to be apposed to each other than to glial processes (Figure 9(c)). This has been termed 'dendritic bundling.' DZ multiple synapses also increase in frequency as the single synapses are exposed to other neuronal membrane. Often these new synapses appear to make contact with two or more dendritic bundles. Demonstrations that SON neurons can release peptides, and perhaps glutamate, from their dendrites as well as from their axon terminals add considerable complexity to the potential effects of astrocytic process withdrawal. Functional implications of this are still under investigation, but the effects on neuronal activity of dendritic VP versus OT release differ in important ways from one another. Glial process withdrawal with activation of the system is coincident with an increased frequency of neuronal dye coupling, unique to the dendritic portion of these cells. It is likely that the multiple synapses in the DZ coordinate mostly excitatory input. Increased junctional communication would tend to aid in this coordination by bringing the membrane potentials of local groups of neurons into register. Thus, the SON could be said to be 'rewired' by physiological stimulation of any significant duration.

Chemistry The plastic changes that accompany dehydration are cotemporal with downregulation of tenascin-C, an extracellular matrix molecule expressed by astrocytes and identified in the stabilization of synapses. Activation by dehydration causes an upregulation of calretinin protein expression in the OT

neurons, with no change in expression of calbindin-D_{28k} in either OT or VP neurons. It may be of some functional importance that dehydration-activated OT neurons fire many more action potentials per unit time than do VP cells, which fire phasic bursts interrupted by significant silent periods. Since the calretinin tends to be membrane-bound, whereas calbindin-D_{28k} is cytosolic, upregulation of calretinin may aid the OT cell in dealing with increased calcium loads via voltage-gated calcium channels during times of heightened electrical activity and secretion. Molecular studies have determined that many genes, in addition to those for OT and VP, are upregulated during dehydration, but that a nearly equal number are downregulated. The formidable task of sorting these out is ongoing.

Plastic Changes with Activation: Neurohypophysis

Morphology Alterations occur in the neurohypophysis that parallel those in the SON. Under the influence of catecholaminergic input from both brain and blood, acting on β-adrenergic receptors, pituicytes become process-bearing and release the axons that they engulf under basal conditions (Figure 10). Pituicytes also withdraw from their prominent occupation of the basal lamina separating the neural compartment from the perivascular space surrounding the fenestrated capillaries. This allows direct basal laminar contact by more neurosecretory terminals. For example, in the hour or so that it takes to deliver a litter of pups, the percentage of the basal lamina occupied by neural versus astrocyte membrane can rise from 30% to 70%. Another consequence of the pituicyte shape changes is an expansion of the extracellular space within the neurohypophysis (cf. Figure 10). Dehydration stimuli also have the capacity to increase the number of neurohypophysial synaptoid contacts. Except for the latter change, which is still not clearly understood, these modifications all work to facilitate the entry of secreted peptide into the blood.

Figure 10 Under activated conditions (immediately following parturition), pituicytes (P) are process bearing (Ast P) and engulf no neurosecretory axons (ax). Pituicytes occupy relatively much less than previously of the basal lamina (arrowheads) along the perivascular space (PVS). This is now occupied by neuronal membrane, such as that of the axon terminals (at) that have released their contents and appear devoid of dense core vesicles. The extracellular space (ECS) is also expanded by activation. L, lipid bodies; Nu, pituicyte nucleus.

Chemistry As with the morphology, the activation-associated changes in chemistry parallel those in the SON. Calretinin is selectively upregulated in OT axon terminals, where significant peptide release occurs. Meanwhile, tenascin-C in the extracellular space is downregulated.

Perhaps it bears reiterating here that all these plastic changes that occur in response to activation of the mHNS are reversible. That is, with rehydration or weaning of the pups, or with relief from a prior restraint stress, the mHNS returns to the morphology and the chemistry of the status quo ante. It is also worth mentioning that reversal of the changes occurs over a longer time than the induced remodeling.

Model Peptidergic Neurons: Older versus Current Ideas

Rather than endocrine cells that have taken on a few neuronal characteristics, peptidergic neurons are primarily neurons, albeit ones that have, in the words of Berta Scharrer, "developed secretory activity to the point where it takes precedence over all the other functions of the cell." Secretory activity taking precedence, it has since been learned, does not mean that these cells do not behave like neurons. Instead they have added a dimension to their complexity. Those seeking to emphasize one or another aspect of their genomic, biosynthetic, or neurochemical nature have often missed or ignored the complexity of peptidergic neurons. Perhaps a more complete description of the model neurons from the mHNS will help correct some long-surviving misconceptions (see Figure 11).

Outdated Neurosecretory Models

Peptidergic neurons are often diagrammed, even in recent publications, as a smooth bag of synthetic machinery with a stubby terminal end-foot landing directly on a blood vessel. Such portrayals could easily mislead one into concluding that peptidergic neurons are entirely different from neurons in general. All peptides secreted from those conceptualized neurons are pictured as being liberated from the terminal

Figure 11 Updated model of a peptidergic neuron based on accumulated knowledge of the hypothalamo-neurohypophysial system. Peptidergic neurons have dendrites that play important functional roles. Peptides can be selectively released from sites other than the axon terminals, such as dendrites and somata. In addition to dense core vesicles (dark blue), the dendrites contain and may release neurotransmitters such as glutamate from microvesicles (clear circles). Both are shown here. NH, neurohypophysis. Arrows at bottom right indicate medial (M) and ventral (V). The inset depicts a neurosecretory axon terminal that also contains dense core vesicles and microvesicles in the arrangement found in actual terminals, that is, with the microvesicles forming an active zone and with the dense core vesicles peripherally located. This terminal is juxtaposed to, not a blood vessel, but the basal lamina (BL, in green) separating the neural compartment from the pia mater (Pia), which is itself separated from the fenestrated capillary (fc) by perivascular space and another BL. See text for comparison with earlier models.

end-foot, as though into a synaptic cleft. These depictions have also implied that all the observed intracellular vesicles in these neurons are somehow related to the neurosecretory process (e.g., either secretory vesicles or recycled membrane), an unwarranted inference. Conceptualizing the neuron's cell body as a smooth bag should be taken, not so much as an indicator of ignorance that these neurons possess dendrites, but instead as indicating the belief that the dendrites are an unimportant feature of neurosecretory cells, a belief in need of correction.

An Updated Conceptualization

Figure 11 is a semidiagrammatic presentation of a model neuron from the SON, complete with dendrites that contain dense core vesicles. This feature is crucial since we know that there is dendritic release of peptide during certain types of activation. Microvesicles are also depicted in the dendrites, as recent evidence shows that SON neurons express vesicular glutamate transporters in dendrites and terminals. It is of some importance that the axon arises from a primary

dendrite, since this is consistent with the cell's ability to selectively release peptides from either the dendrites or the axon or both. In the inset, the terminal is shown to contain both dense core vesicles and clear microvesicles. These are arranged as they are in most neurons that release both peptides and classical transmitters, with the microvesicles clustered at an 'active zone' and the neurosecretory vesicles peripheral to that zone (cf. Figure 8). The terminal membrane abuts the basal lamina separating the neural compartment from the pia mater, which in turn is separated from the fenestrated capillary by perivascular space and another basal lamina.

Concluding Remarks

Our understanding of the peptidergic neuron and its relationship to the structures with which it interacts, both neural and nonneural, has changed in rather important ways in recent years. Investigators better understand the complexities of this neuron type and have a fuller appreciation for its neuronal characteristics, in addition to its secretory role. As well researched as is the remarkable morphological plasticity of the mHNS, mechanisms underlying this rewiring of a brain area in response to physiological stimulation are still hot topics of study. Many other brain areas appear to share at least some of these plastic capabilities, making future work in this field more exciting.

Discovery of Neuropeptides

As early as the 1890s, it was noted that extracts of tissues and organs contained biologically active substances which could be purified in later years. Isolation has been guided by bioassays from the beginning up to today; first *in vivo* effects or organ preparations were used, but now sophisticated high-throughput cell systems with engineered receptors and proteomics lead to the discovery of novel neuropeptides.

In the 1950s, it became technically possible to determine the amino acid sequence of peptides, leading to the elucidation of the chemical structure and chemical synthesis of neuropeptides, such as oxytocin (OXT) and vasopressin (AVP) by Du Vignaud. Such peptides were mostly studied as hormones, but in the 1960s it was recognized that hormones could affect brain functions as monitored by behavioral assay. The structural requirements for central activity were often distinct from the endocrine effects, pointing to a multiplicity of receptors. De Wied called these as neuroactive fragments or neuropeptides and developed the neuropeptide concept. The neuropeptide field fully bloomed after the discovery of the enkephalins by Terenius and Kosterlitz in 1975.

Toward a Definition of Neuropeptides

With the growing number of peptides and small proteins affecting neural cells in some way or the other, a definition pinpointing the essence of a neuropeptide has lagged behind. The hallmarks of neuropeptides are (1) gene expression and biosynthesis by neural cells, (2) regulated release, and (3) the ability to modulate or mediate neural functioning. Each of these elements alone may not be exclusive to what we generally call neuropeptides.

Synthesis by Neural Cell

Neuropeptide gene expression and biosynthesis are associated *a priori* with neurons. However, glial cells, in particular microglia, synthesize and secrete numerous soluble factors, such as chemokines, cytokines, neurotrophic factors, hormones, and complement proteins, which have biological activities in the nervous system. This raises the issue of whether these can be considered neuropeptides.

Regulated Release

Controlled secretion is a basis for the regulation of chemical communication. Neurons expressing classical neuropeptides use the regulated secretory pathway, allowing the storage of synthesized peptides in large dense-cored vesicles and controlled release after a stimulus. The neuropeptide precursor contains the structural prerequisites to be sorted into the regulated secretory pathway and to be processed into active peptides. A signal sequence is key to entry into the regulated secretory pathway. Thus, neuropeptide precursors contain distinct structural characteristics. However, other proteins not classically considered neuropeptides can also be funneled through the regulated secretory pathway due to a signal sequence and can undergo processing. Still other proteineous factors are secreted through the constitute pathway, but achieve a regulated mode by strictly controlled gene transcription.

Architecture of Neuropeptide Precursors

Neuropeptide precursors, or preproneuropeptides, are the initial gene products and are structured to undergo appropriate biosynthesis in the regulated secretory pathway of a neuron. Both proteolytic and derivatizing posttranslational modifications are involved in biosynthesis. The salient structural characteristics of these modifications, and hence of neuropeptide precursors, are:

1. *The signal peptide*. This 20–25-amino-acid long N-terminal portion is required for the entry of the newly synthesized gene product into the lumen of the endoplasmatic reticulum (ER). It is cleaved off during passage of the ER membrane, leaving the proneuropeptide in the ER-Golgi for further sorting into the regulated secretory pathway.
2. *The basic motifs*. Pairs of the basic amino acids lysine (Lys, K) and arginine (Arg, R), or more rarely a single Arg, in the appropriate structural environment of the precursor serve as recognition sites and substrates of prohormone convertases (PCs). These PCs belong to a small family of subtilisin proteases with cell-specific expression. Cleavage leads to the generation of specific peptides and to cell-specific differences in PCs to different sets of peptides from the same precursor.
3. *C-terminal amidation*. PC-generated peptides can be subject to further modification by peptidylaminotransferase (PAM). This enzyme uses a C-terminal glycine (Gly, G) as the amide donor for the preceding amino acid. This results in a peptide with a C-terminal amide. This amide

occurs in many neuropeptides and is often essential for biological activity. This structural characteristic was elegantly exploited by Mutt to isolated novel neuropeptides and peptide hormones on the bases of a chemical assay for C-terminal amides, such as neuropeptide Y, peptide YY, and peptide HI (all named after the C-terminal-amidated amino acid).

Modulation of Neural Functions

Neuropeptides have neural bioactivities that are observable at almost all levels of neural functioning. Effects of neuropeptides have been established at the genetic, biochemical, cellular, organism, and behavioral levels. In this respect, the biological activities of many neuropeptides have been indicated to be pleiotropic. Such effects are not always distinguishable from that of cytokines, or growth factors. Typical for the cellular action of neuropeptides are the relatively slow response and action compared to excitatory amino acids and catecholamines. The relatively slow response of neuropeptide secretion is due to storage in dense-cored vesicles that are not docked at the cellular release site (e.g., the synaps or synaptic button), requiring recruitment first. This happens at elevated Ca^{2+} levels, which require enhanced or repeated stimulation unlike the fast transmitters, which are ready for release.

The relatively slow action is further due to the type of receptor that almost all neuropeptides act on – G-protein-coupled receptors (GPCRs). These receptors trigger an intracellular cascade of molecular events that results in cellular responses. The time span over which such a response is in effect (seconds or longer) is considerably longer than that of neurotransmitters that modulate ion fluxes directly through action on ion channels (milliseconds).

Definition of Neuropeptides

Based on these considerations, here is a conservative definition of a neuropeptide: a small proteineous substance produced by the processing of a precursor, released in a regulated fashion by neurons and acting on neural substrates (e.g., neurons), glial cells, or neuronal target cells (e.g., a gland or muscle). Approximately 90 genes encoding for such neuropeptides have been recognized (Table 1). A more liberal definition includes all neural secretory peptides and proteins of the brain, defined as proteineous substance produced and released by neural cells and acting on any neural substrate or target. This includes peptides that are known best as peptide hormones of the endocrine system, chemokines of the immune system, and growth factors if synthesized by neurons. This definition still excludes hormones of nonneuronal peripheral origin which signal to the brain as being neuropeptides.

Table 1 lists the peptides that have been recognized as neuropeptides according to the conservative definition. To appreciate peptide hormones, chemokines, and growth factors as candidate neuropeptides, these classes of proteineous signaling molecules are briefly addressed next.

Candidate Neuropeptides

Peptide Hormones

De Wied discovered neuropeptides by studying the behavioral effects of the peptide hormones adrenocorticotropin (ACTH) and AVP. A hormone is a substance that is secreted by one organ and acts on another after transport by the bloodstream. In this way, cells at different locations in the organism communicate in an endocrine fashion. Many peptide hormones are also synthesized by neurons and indisputably belong to the classical neuropeptides according the conservative definition, like those derived from proopiomelanocortin (POMC). Sometimes the forms in which related peptides act are different between the nervous system and the endocrine system. For example, ACTH and β-lipotropin are the prime peptide hormones derived from POMC in the periphery, whereas α-melanocyte-stimulating hormone (α-MSH) and β-endorphin are the major POMC neuropeptides in the brain. This is due to differences in processing between adrenocorticotrophes of the anterior pituitary gland, secreting ACTH for peripheral action, and the hypothalamic POMC neurons, secreting α-MSH and β-endorphin from neuronal processes. The different sets of biologically active peptides are accommodated by differences between the peripheral and central receptors. In addition, differential expression of two paralogous genes and differential splicing of one gene transcript can result in a nervous system-specific population of neuropeptides distinct from the related peripheral peptide hormones. Examples are found in the calcitonin/calcitonin gene-related peptide (CGRP) family of genes and peptides.

Some classical peptide hormones, such as prolactin, appear to be expressed in a restricted manner in the nervous system, together with its receptor. Other peptide hormones have not been found to be expressed in the brain or have not been addressed for this issue extensively, for instance growth hormone. The latter cannot be considered neuropeptides and have not been included in Table 1. However, with ongoing examination of brain-expressed genes, we may find that several of these may be synthesized in the nervous

Table 1 Portal to neuropeptide gene families hyperlinked to bioinformatics data sources

Gene (abbreviation)[a]	*Human chromosomal localization*[a]	*Precursor*[b]	*Active peptide(s)*[c]
Opioid gene family			
Proenkephalin gene (PENK)	chr8 (q12.1)	Preproenkephalin	Leu-enkephalin, Met-enkephalin, amidorphin, adrenorphin, peptide B, peptide E, peptide F, BAM22P
Proopiomelanocortin gene (POMC)	chr2 (q12.2)	POMC	α-Melanocyte-stimulating hormone (α-MSH), γ-melanocyte-stimulating hormone (γ-MSH), β-melanocyte-stimulating hormone (β-MSH), adrenocorticotropic hormone (ACTH), β-endorphin, α-endorphin, γ-endorphin, β-lipoprotein (β-LPH), γ-lipoprotein (γ-LPH), corticotropin-like intermediate peptide (CLIP)
Prodynorphin gene (PDYN)	chr20 (p13)	Preprodynorphin	Dynorphin A, dynorphin B, α-neo-endorphin, β-neo-endorphin, dynorphin-32, leu-morphin
Orphanin gene, pre-pronociceptin gene (PNOC)	chr8 (p21.1)	Prepronociceptin, preproorphanin	Nociceptin (orphanin FQ), neuropeptide 1, neuropeptide 2
Vasopressin/oxytocin gene family			
Vasopressin gene (AVP)	chr20 (p13)	Preprovasopressin-neurophysin Ii	Vasopressin (VP), neurophysin II (NP II), C-terminal glycopeptide CPP
Oxytocin gene (OXT)	chr20 (p13)	Preprooxytocin-neurophysin I	Oxytocin (OT), neurophysin I (NP 1)

Adipose neuroepeptides			
Leptin/ob gene (LEP)	chr7 (q32.1)	Preproleptin	Leptin (obesin)
Adiponectin gene (ADIPOQ)	chr3 (q27.3)	Adiponectin precursor	Adiponectin (Acpr30)

Visfatin gene (PBEF1)	chr7 (q22.2)		Visfatin precursor	Visfatin-1 (pre-B cell colony enhancing factor-1 (PBEF1), nicotinamide phosphoribosyltrans-ferase)
Resistin gene (RETN)	chr19 (p13.2)		Resistin precursor	Resistin (Cysteine-rich secreted protein FIZZ3, Adipose tissue-specific secretory factor, Cysteine-rich secreted protein A12-alpha-like 2)
			Resistin-delta2 precursor	Resistin-delta2
Resistin-like gene (RETLB)	chr3 (q13.13)		Resistin-like molecule Beta precursor (RELMbeta)	Resistin-like molecule (cysteine-rich secreted protein FIZZ2, colon- and small intestine-specific cysteine-rich protein, cysteine-rich secreted protein A12-alpha-like 1, colon carcinoma-related gene protein)
Nucleobindin-2/NEFA gene (NUCB2)	chr11 (p15.1)		Nucleobindin-2	Nesfatin-1

[a]Genes are abbreviated according to the official human gene nomenclature and linked to the corresponding locus in the human genome (March 2006 assembly) through the USCS Genome Browser. The ideograms show the human chromosomal localization. The USCS Genome Browser provides bioinformatics data on transcripts, expression, homologies to other species and gene variations. The Allen Brain Atlas provides data on *in situ* hybridization in the mouse brain for each gene.
[b]Precursors are given as prepro-peptide and are linked to homologous proteins of human and other species through the National Institutes of Health NCBI . Primary structures of precursors are found here by GI numbers. Different splice variants of the same gene are given separately.
[c]Neuropeptides are presented as the processed, biologically active products of the neuropeptide precursors (prepro-peptide) and the encoding gene. The presented neuropeptides fall under the conservative definition, and brain expression has been reported. The exception is the family of adipose neuropeptides, which have been implicated as hormones produced by adipose tissues signaling to the brain. However, increasing evidence indicates that they can also be produced by neurons within the nervous system. Neuropeptide genes are classified into families that share structural similarities or functional similarities (opioid peptides). Biological activities and cognate receptors have not been described for all mentioned neuropeptides.
This table was condensed from the online neuropeptide database http://www.neuropeptides.nl

system and should therefore be added to the class of neuropeptides.

Chemokines

Chemokines (from chemotactic cytokines) are originally known as secreted factors that mediate leukocyte trafficking. They form a family of approximately 50 proteins of 8–14 kDa and share structural similarities that classify them in the C, CC, CXC, and CXXXC subfamilies. This classification refers to the structural configuration of two conserved Cys residues. The nomenclature of individual chemokines is, for example, XCL1, CCL1, CXCL1, and CX3CL1, respectively. An extensive database is available online.

There is growing evidence for the neuronal expression of chemokines, chemokine receptor expression by neurons, and electrophysiological effects of chemokines on neurons. Neural functions of chemokines have been implicated in neuronal migration, neuroinflammation, and neuronal excitability. Chemokines, at least a number of them, may thus be considered as potential neuropeptides.

Neural Growth Factors

Growth factors are proteineous signaling molecules that are produced and secreted from cells. They provide extracellular support to the proliferation, differentiation, and maintenance of other or the same cells in a paracrine or autocrine fashion, respectively. Among the growth factors, many are expressed in the brain, where they act during embryonic development and during plastic neuronal changes and maintenance states of the adult nervous system. Some may act like transmitters, for example brain-derived neurotropic factor (BDNF); these growth factors fulfill the criteria of neuropeptides and should be considered as such. Growth factors come in many families, often with a large and diverse family tree. Examples are the neurotropins, fibroblast growth factors (FGFs), Wnts, bone morphogenic factors (BMPs), epidermal growth factor (EGF), and transforming growth factor (TGF-)α and -o, including inhibin/activins, granulins, and others. For many or most individual members, the expression in the nervous system and their participation in neural communication is not known. It is beyond the scope of this article to list all the growth factors which could potentially considered neuropeptides.

Bioinformatics of Neuropeptides

Bioinformatics provides tools for the analysis of large amounts of data which can be used in originals ways to answer biological questions. Public databases have become an important starting point for bioinformatics; for example, data on genome, gene, and transcript for all neuropeptides can be found in the Human Genome Browser. A comparison of the chromosomal localization of the neuropeptide genes (**Figure 1**) shows, first, that neuropeptide genes are localized all over the human genome and, second, that genes of neuropeptides that belong to the same families are not generally clustered in the same locus. This indicates that neuropeptides with related structural or functional features are not the result of recent gene duplication, but have an ancient evolutionary origin. Only a few hot spots can be distinguished:

- *Chromosome 1(p36)*. The CST, UTS2, NPPA, and NPPB genes.
- *Chromosome 11(p15)*. The CALCA, CALCB, ADM, NUCB2, SCT, IGF2, and INS genes.
- *Chromosome 17(q21)*. The GAS, HCRT, PPY, PYY, GIP, and HXPH3 genes.

In these three loci, closely related genes consecutive to one another exist: NPPA-NPPB on chromosome 1 (p36.22), CALCA-CALCB on chromosome 11(p15.2), INS-IGF2 on chromosome 11(p15.5), and PPY-PYY on chromosome 17(q21.31). The AVP–OXT locus on chromosome 20(p13) is another locus with two related genes. These are probably rare examples of evolutionary gene duplications. The later genes share a high degree of homology, are positioned in the opposite orientation with a very short intergenic region, are expressed by related magnocellular neurons in the hypothalamo-neurophypophysial system, and code for highly homologous precursors, but still the active peptides AVP and OXT have distinct physiological functions. The pro-melanin-concentrating hormone (PMCH) and insulin-like growth factor (IGF-)1 genes are neighbors on chromosome 12(q23.2). Notably, the INS-IGF2 gene is a read-through gene which overlaps with the insulin (INS) gene at the 5′ region and with the IGF2 gene at the 3′ region. The INS-IGF2 locus is on chromosome 11(p15.5).

Comparing structures of neuropeptide precursors between species (**Table 1**) shows that neuropeptide precursors are not very strongly conserved proteins, in contrast to, for example, transcription factors. However, the highest conservation is always found for the peptide domains that carry biological activities. With the notion that these are flanked by paired-basic PC cleavage sites and sometimes have a C-terminal Gly for amidation, bioinformatics searches can be designed for these features to discover new biologically active peptides in existing precursors or even to perhaps find novel neuropeptide precursors and genes. In this respect, knowledge about the expression in neural systems is essential. The online Allen Brain Atlas provides valuable data about *in situ* hybridization for virtually

Figure 1 Ideogram of the chromosomal localization of neuropeptide genes in the human genome. Gene loci are indicated by red dots. Blue dots localize gene duplications within the same locus. Note the presence of hot spots, such as those on chromosomes 1, 11, 12, 17, and X, and the more empty chromosomes 4, 5, 9, 13, and 21.

all annotated genes in the mouse genome. These data can be accessed for all neuropeptides mentioned in Table 1.

Conclusion

Almost 90 genes exist in the mammalian genome that encode neuropeptide precursors. Clustering on structural features and on rather arbitrary functional aspects results in approximately 10 subfamilies and many no-family peptides that do not have a close structural similarity to neuropeptides. The definition of these 90 genes is largely based on a classical view on neuropeptides. A broader view may include genes that encode other signaling proteins and peptides. These and the analysis of the large number of hypothetical proteins in the genome identified by bioinformatics may lead to an expansion of the neuropeptide family, making the neuropeptides by far the largest class of signaling molecules in the brain.

Mammalian Sleep and Circadian Rhythms: Flies

J M Donlea and P J Shaw, Washington University in St. Louis, St. Louis, MO, USA

Does the Fruit Fly Sleep?

Although the fruit fly has been effective in elucidating fundamental biological principles that are relevant for human health and disease, the observation that it lacks the neural architecture to generate mammalian-like sleep electroencephalogram (EEG) patterns has raised concerns. These concerns are based on two issues: (1) Can an organism with little structural similarity to mammals inform us about the mammalian condition? And (2) are the electrophysiological signals characteristic of mammalian sleep required to carry out sleep function? A growing amount of data indicates that, even in the absence of structural similarities, the fly can identify common elements relevant for mammalian physiology. For example, while the auditory organ, visual apparatus, olfactory systems, and core circadian pacemaker of the fly share no overt structural similarities with those of mammals, they all share common molecular frameworks. Moreover, electrophysiological activity of the cerebral cortex may not be required to carry out critical sleep functions. That is, recent data by Cirelli and colleagues suggest that the cellular processes associated with sleep occur in brain regions, such as the cerebellum, in which the signature sleep EEG patterns are either attenuated or absent. This finding suggests that cortical EEG patterns may only be important to carry out some, but not all, of sleep's functions. Together these data indicate that, in the absence of mammalian-like cortical structures and EEG patterns, *Drosophila* can be utilized to identify fundamental sleep processes.

Historically, sleep has been defined by both electrophysiological and behavioral criteria. In mammals and birds, sleep has been subdivided into two separate states, nonrapid eye movement (NREM) and rapid eye movement (REM) sleep. These states can be distinguished from each other and from waking based upon the distinct patterns of electrical potentials measured in the cortex (EEG), the muscle (electromyogram; EMG), the eye (electrooculogram; EOG), and, in some species, the deep brain structures (e.g., pontogeniculooccipital waves). No single electrophysiological signal has yet proved sufficient to unambiguously describe sleep. Similarly, behavioral definitions of sleep also require the simultaneous evaluation of several criteria. These criteria include (1) prolonged periods of quiescence, (2) reduced responsiveness to external stimuli, (3) rapid reversibility, which distinguishes sleep from hibernation or coma, and (4) homeostatic regulation – the increased need for sleep that follows sleep deprivation.

Careful observations of fly behavior using a variety of monitoring techniques have demonstrated that *Drosophila* flies exhibit consolidated periods of both activity and quiescence. During periods of quiescence lasting 5 min or longer, flies are unresponsive to mild external stimuli but can be quickly aroused with stronger stimulation. Furthermore, when flies are kept awake they respond by exhibiting large compensatory increases in the amount of quiescence the next day. These periods of quiescence are associated with increased arousal thresholds and cannot be explained by confounding variables, such as the intensity of the stimulation used to keep them awake, increased locomotor activity, or food deprivation. Indeed, homeostatic regulation has now been observed in flies that have been kept awake using at least five distinct deprivation methods. Thus, all of the behavioral requirements of sleep, originally defined for mammals, are observed in the fly.

Do quiescent periods in the fly share other important similarities with mammalian sleep? As in mammals, pharmacological agents such as caffeine, amphetamine, and cocaine increase waking in flies. In addition, pharmacological agents that promote sleep in mammals, such as antihistamines, also increase sleep and reduce the latency to sleep onset in flies. More importantly, several molecular markers that are modulated by sleep and waking in mammals are similarly modulated in *Drosophila*. Thus, with the exception of showing sleep spindles, K-complexes, and slow synchronized cortical activity in the frequency range 1–4 Hz, sleep in the fruit fly is remarkably similar to that found in mammals and birds. Indeed, behavioral, ontogenetic, pharmacological, molecular, and genetic studies indicate that quiescence in *Drosophila* shares many of the critical features of mammalian sleep.

What Can Circadian Mutants Tell Us about Sleep?

In mammals, sleep is regulated by the interaction between two processes. The first is a homeostatic process which increases during waking and dissipates during sleep. The second is a circadian process which alternatively promotes both sleep and wakefulness at specific circadian times. Thus, a wake-promoting signal, generated by the circadian clock, increases throughout the biological day to counter increasing

sleep drive and maintain appropriate levels of alertness. During the latter part of the biological night, a sleep-promoting signal, also generated by the circadian clock, increases to preserve sleep as homeostatic signals are dissipated. These signals create wake-maintenance and sleep-maintenance zones, respectively. Just as it is difficult to stay awake and vigilant during the sleep-maintenance zone, sleep is distorted when it occurs during the wake-maintenance zone. Nonetheless, elucidating the anatomy, physiology, and neural circuitry necessary for the clock to modulate sleep and waking in mammals poses a significant challenge. Fortunately, *Drosophila* chronobiologists have generated a number of genetic tools to investigate the cellular physiology of both pacemaker cells and their outputs.

The Timing of Sleep Is Influenced by the Circadian Clock in *Drosophila*

Both flies and humans spend the majority of their biological day engaged in waking activities and consolidate the majority of their sleep during the biological night (Figure 1). Interestingly, flies, like humans, display biphasic sleep patterns with a circadian-modulated elevation in sleeptime during the mid-afternoon (a 'siesta'). Moreover, flies exhibit evidence for a wake-maintenance zone at the end of the biological day as measured by increased wake time and an increase in the intensity of activity (Figures 1(a) and 1(b)). Thus, the clock influences the amount and timing of both sleep and waking during the biological day. Does the clock influence the amount and timing of sleep at night? As sleep drive increases, flies would sleep in longer bouts. Thus, the longest sleep bouts should occur at the point of the circadian day, when sleep drive is highest and circadian wake-promoting signals are low. Indeed, the longest sleep bouts tend to occur at the beginning of the biological night (Figure 1(c)). This pattern is reminiscent of that seen when evaluating electrophysiological makers of sleep intensity in mammals. Thus, as in mammals, sleep and waking are strongly modulated by the clock during both the biological day and night.

Homeostatic Sleep Drive Is Gated by the Circadian Clock in *Drosophila*

When wild-type *Canton-S* (*Cs*) flies are kept awake at night, they exhibit a compensatory increase in sleep the next day. In the morning following sleep deprivation, sleep is dramatically increased over baseline but declines during the wake-maintenance zone (Figure 2). Sleep remains at pretreatment levels during the subsequent biological night, presumably due to ceiling effects, and then increases again above baseline the second day during the noontime siesta. Sleep once again declines during the wake-maintenance zone in the late day and increases above baseline once again the following afternoon. Thus, the clock gates the timing of homeostatic discharge. This interpretation is further supported by the observation that sleep homeostasis is attenuated or blocked when flies are released into recovery during the wake-maintenance zone. As seen in Figure 2, the sleep rebound did not occur during the last 3 h or the wake-maintenance zone and was delayed ~15 h until the next morning. Together these data indicate that the clock can either facilitate or interfere with sleep at various times of the circadian day, even when sleep drive is very high.

Sleep Homeostasis Is Altered in Canonical Loss-of-Function Clock Mutants

Sleep homeostasis has been evaluated in the canonical loss-of-function clock mutants *period* (per^{01}), *timeless* (tim^{01}), *Clock* (Clk^{jrk}), and *cycle* (cyc^{01}) to investigate the interaction between homeostatic and circadian processes. When per^{01}, tim^{01}, and Clk^{jrk} flies are kept awake for 12 h, they are able to reclaim 100% of the sleep that was lost within the first 12 h of recovery (Figure 3). In comparison, wild-type flies with an intact circadian clock recover between 40% and 50% of their lost sleep within the same time frame (Figure 2(a)). These experiments succeeded in replicating the classic studies in rodents showing that sleep homeostasis was preserved in animals in which the SCN had been ablated. However, the failure to observe homeostasis in tim^{01} mutants following shorter sleep deprivation protocols suggested that the components of the clock may play additional roles beyond simply keeping time. Indeed, cyc^{01} mutants demonstrate one of the most dramatic responses to sleep deprivation yet described. Even minor disruptions in sleep in cyc^{01} mutant flies, lasting as little as 2–3 h, produce a vigorous compensatory sleep rebound that is 6 times larger than that of wild-type flies and is not complete until the cyc^{01} fly has slept an additional 3 min over baseline for each minute of sleep lost. Increased sleep homeostasis was observed even when the cyc^{01} mutation had been placed into three additional genetic backgrounds and tested with the appropriate deficiency, indicating that the observation was unlikely a result of background effects. Perhaps the most interesting finding was that the cyc^{01} flies began to die when they were kept awake for 10 h. It should be noted that death following 12 h of sleep deprivation is an extremely uncommon occurrence. For example, it requires approximately 70 h for *Cs*, per^{01}, and Clk^{jrk} mutants to succumb from sleep loss. Interestingly, the other clock mutant with altered homeostasis, tim^{01},

Figure 1 Circadian distribution of sleep and waking. (a) Minutes of sleep (mean ± SEM) for each hour of the 24 h day in female *Canton-S* flies maintained on a 12:12 light:dark schedule. (b) Locomotor activity as measured by infrared beam crossing in TriKinetics activity monitors. (c) Percentage of flies that exhibit their longest sleep bout of the day as a function of circadian time. Values are calculated separately for day and night to allow visualization of daytime sleep. Brackets and values indicate the sum of sleeptime activity during 4-h blocks in the morning, afternoon, and evening. Open horizontal bar indicates lights on; closed horizontal bar indicates lights off.

succumbed in 30 h, half as much time required for wild-type flies. Sleep deprivation-induced lethality was observed in cyc^{01} using three independent deprivation methods, while no lethality was observed when cyc^{01} flies were administered the same total number of stimuli but without producing 12 h of continuous wakefulness. Importantly, cyc^{01} mutants were more resistant than were other clock mutants to various stressors. These data indicate that the mortality associated with sleep deprivation was not due to hypersensitivity to nonspecific environmental stimuli.

Following sleep deprivation, cyc^{01} flies exhibited a small but consistent reduction in the expression of several stress response genes, including *hsp70*, *Hsp83*, *droj1*, and *hsc70-3*. In contrast, these genes remained near baseline or were elevated in the other clock mutants and wild-type flies, a result also observed in rats and mice. When chaperone proteins are activated in cyc^{01} flies by briefly exposing them to heat prior to sleep deprivation, the lethal effects of sleep loss are ameliorated. In addition, flies carrying a mutation for the *heat shock protein Hsp83* ($Hsp^{8308445}$) showed exaggerated homeostatic response and died after sleep deprivation. Taken together, these data indicate that the induction of certain chaperone proteins protects against the lethal effects of sleep loss and provides a first hint about the functional targets of sleep and its molecular mechanisms.

Figure 2 Sleep homeostasis is gated by the clock. (a) Following 12 h of sleep deprivation, homoeostasis occurs predominantly during the noontime siesta (black arrows). (b) Following 24 h of sleep deprivation ending during the wake-maintenance zone (black arrow), homeostasis is delayed by ~15 h (gray arrow). Minutes of sleep per hour in female flies maintained on a 12:12 light:dark schedule ($n = 32$). Sleep deprivation is indicated by hashed horizontal bars.

Figure 3 Sleep is disrupted in older flies. (a) Minutes of sleep per hour in young (circles), middle-aged (diamonds), and older (triangles) flies maintained on a 12:12 light:dark schedule. Bar indicates lights on and lights off. (b) Average sleep bout duration declines with age (black) while the number of nighttime awakenings increases (white).

Aging

Aging is associated with modification in both sleep and circadian systems. In humans, sleep duration declines with age and is associated with increased nighttime awakenings and reduced slow-wave sleep. Aging is also associated with modification in circadian timing as measured by reduced period and amplitude of temperature, sleep, and hormonal rhythms. These altered rhythms are associated with observable changes in the functioning of the suprachiasmatic nucleus, which is the master circadian pacemaker in mammals. One example is an age-dependent reduction in the expression of core clock genes, including *Clock* and the mammalian homolog, *cycle* (*Bmal1*). Frequently, the circadian sleep cycle is phase advanced such that older adults both go to sleep earlier and wake up

earlier than do younger individuals. Not surprisingly, the prevalence of sleep disorders such as sleep apnea, periodic limb movement disorder, restless legs syndrome, and insomnia increase with age and pose an increased risk for health problems and reduced quality of life.

Because sleep deficits both precede and follow age-related changes in physical and mental illnesses, a causal role of sleep on aging remains unproved. While it is clear that disease can interfere with sleep, data now indicate that sleep quality can, in turn, influence the progression of disease. It should be noted that no intervention study in humans has evaluated the long-term effects of sleep deficits in older adults. As a consequence, there is no consensus regarding which, if any, age-related sleep changes are normative. One barrier to understanding how sleep and aging interact is the high cost of long-term sleep recordings in humans and rodents. An additional barrier for establishing a causative role of sleep on aging is the absence of an experimental protocol that can induce sleep deficits recapitulating those found in older human adults. Virtually, all sleep disruption experiments in humans and animals are very short in duration, lasting between hours and a few days. The amount of sleep lost expressed as a percentage of lifetime sleep is quite small (~0.037%). Even lethal doses of chronic long-term sleep deprivation in rats can be viewed as an acute challenge in that only 2% of lifetime sleep is lost during a discrete portion of the animal's life. In contrast, the common sleep deficits reported by humans tend to last for several years or more. For example, it has been estimated that an individual will suffer from sleep apnea between 4 and 14 years before being diagnosed. Even after diagnosis, full-time compliance with recommended treatment options is rare. The median duration of severe insomnia is 4 years, and 44% of these individuals continue to report symptoms 10 years later. Excessive daytime sleepiness can be quite protracted in older adults, and in Parkinson's disease patients persists for 4 years or more. Not only do current sleep disruption protocols fall short of approximating the sleep loss found in clinical sleep disorders, they may not even reflect the amount of sleep lost in healthy adults due to chronic voluntary or involuntary (e.g., shift work) sleep restriction. To summarize, sleep deprivations in human and animal studies occur once during a discrete portion of the individual's life, are short in duration, and do not approximate challenges that are commonly observed in populations that experience sleep deficits. Consequently, the long-term effects of chronic sleep disruption on health and aging are largely unknown.

Given its short life span, ~60 days, *Drosophila* is an ideal model system to study the relationship between sleep and aging. As with humans, sleeptime starts to decline in middle-aged *Drosophila* and continues to fall in older flies (**Figure 3(a)**). In addition to changes in sleeptime, older *Drosophila* display other alterations in sleep architecture that resemble those found in older human adults. Thus, sleep becomes fragmented, longer sleep episodes become rare, and the animals display an increase in nighttime awakenings (**Figure 3(b)**). Sehgal and colleagues have shown that sleep fragmentation is associated with a reduction in the strength of sleep–wake cycles as measured by fast Fourier transform. As flies become very old, daytime sleep increases, presumably in an effort to compensate for poor sleep at night, such that total sleep duration is not reduced further. Aging in the fly can be easily manipulated by simply rearing the animals at different ambient temperatures. Flies reared at warm temperatures (29 °C) have a reduced life span compared to flies reared at cooler temperatures (18 °C). Interestingly, when flies were housed at cooler temperatures, sleep impairments were slowed substantially over time compared with their accelerated-aging siblings. Thus, Sehgal and colleagues demonstrated that sleep fragmentation is associated with physiological, not chronological, age. Such a conclusion would not be possible using mammalian protocols and emphasize the utility of the fly to address problems that have been intractable using traditional approaches. It should be noted that intensive research efforts have begun to separately elucidate biological principles of aging and sleep. By combining these tools, it should be possible to determine the precise relationship between sleep and aging.

Plasticity

Both sleep and circadian rhythms play an important role in synaptic plasticity. Rhythms influence plasticity by modulating both transcription and neuronal firing rates during specific times of the biological day. Similarly, sleep is associated with specific changes in transcription and neuronal firing rates that are conducive for the modulation of synaptic strength. Indeed, studies in humans, rodents, and birds report that waking neuronal activity in specific circuits is replayed during sleep, and this replay is associated with improved performance. For example, when new memories are cued with an odor during waking and that odor is presented during sleep to facilitate reactivation of the circuit, individuals exhibit improved retention of memories. Although the earliest investigations in humans yielded conflicting

results, recent human studies have clearly established a connection between memory consolidation and sleep. These studies are complemented by a large number of studies in smaller animals; these studies have begun to tell a clear story – that sleep following a novel experience aids in the consolidation of newly formed memories into longer-lasting behavioral changes and that this function of sleep is phylogenetically conserved.

Given the success of using *Drosophila* as a model organism to identify candidate genes that are involved in complex behaviors such as circadian rhythms and learning and memory, it seems likely that the fly could be a valuable tool to elucidate the genetic and neural mechanisms of sleep-dependent plasticity. Indeed, Ganguly–Fitzgerald's recent data have provided a basis for the examination of sleep-dependent behavioral plasticity in the fly. Using a behavioral paradigm in which age-matched sisters were held either in social isolation (housed individually in small food tubes) or in social enrichment (housed in groups in larger food vials), it was found that after several days of enrichment, wild-type flies exhibit a significant increase in daytime sleeptime and intensity that lasts for several days. Through this social enrichment paradigm, genetic pathways that mediate experience-dependent changes in sleep were explored; flies that were mutant for several classical learning and memory genes showed defects in experience-dependent sleep following social enrichment. Many of these mutants, including rutabaga and dunce, are involved in the protein kinase A/cyclic adenosine monophosphate (PKA/cAMP) signaling cascade. This pathway has previously been implicated by Hendricks and colleagues in the modulation of sleeptime in the fly; several mutations that resulted in a downregulation of cAMP signaling induced a decrease in total sleeptime while, conversely, mutations that increased cAMP signaling elevated total sleeptime. This work also found that expression of an activating isoform of the transcription factor cAMP response element-binding protein (CREB) increases sleeptime in flies, while expression of a repressor isoform of CREB decreases total sleeptime. Interestingly, it has also been shown that CREB

Figure 4 Sleep is necessary for memory consolidation. (a) Following a spaced training protocol consisting of three 1 h training periods with males that express aphrodisiac pheromones, a conditioned-stimulus male will display significantly reduced courtship toward a virgin female for up to 5 days. (b) Minutes of sleep per hour exhibited by either recently trained males (diamonds) or their naive brothers (squares). (c) Trained male flies demonstrate a significant reduction in Courtship Index toward virgin females for several days following training if allowed to rest *ad libitum* following training. Sleep deprivation immediately following courtship training prevents this long-lasting reduction in courtship.

activity plays an important role in the consolidation of short-term memory into longer-lasting changes in behavior; the same CREB activator that increases sleep also enhances memory consolidation while expression of the CREB repressor blocks memory consolidation.

While the neural circuits that mediate and are altered by sleep-dependent plasticity are unknown, independent studies at Northwestern University and the University of Pennsylvania have implicated the mushroom bodies (MBs) in sleep regulation. Insect MBs are higher-order sensory processing centers that have been shown to regulate olfactory learning and memory. This work demonstrated that disruption of cAMP/PKA signaling in subsets of neurons contained in the MBs was sufficient to profoundly alter sleeptime. Although these studies did not directly examine the effect of modulation of MB activity on sleep-dependent plasticity, the finding that MB neurons can play a role in sleep regulation suggests that the MB could be an important component of a circuit that relies on sleep to modulate the strength of synaptic connections.

While the molecular and anatomical components of experience-dependent changes in sleep have not been fully uncovered, it is clear that experience-dependent sleep plays a necessary role in the consolidation of transient, short-term memory into longer-lasting behavioral changes. This relationship has been studied more specifically in the fly using an associative memory paradigm called courtship conditioning (**Figure 4(a)**). In this paradigm, a male attempts to court, but is rejected by, recently mated females or males expressing aphrodisiac pheromones. As a result of this training, male flies will exhibit a dramatic long-lasting reduction in courtship toward normally attractive virgin females relative to their untrained naive brothers. During memory consolidation immediately after training, flies exhibit increased sleep (**Figure 4(b)**). Moreover, their sleep appears to be deeper during consolidation as evidenced by an increase in sleep bout duration. Importantly, depriving newly trained flies of sleep disrupts memory consolidation (**Figure 4(c)**). Thus, the increase in sleep following training appears to play an important role in the process of consolidation. These data are consistent with results obtained in humans, rodents, and birds, providing additional phylogenetic evidence that sleep plays an important role in memory consolidation. Together, all of these data suggest that this role may well be universally conserved. Future studies of sleep-dependent plasticity must take advantage of these complementary model systems to be most productive; ultimately, the fly may have much to tell us about how sleep alters the synapse.

MAP Kinase Signaling in Learning and Memory

S Blum and P K Dash, University of Texas Medical School at Houston, Houston, TX, USA

© 2009 Published by Elsevier Ltd.

Introduction

Structural and/or functional changes at synapses (synaptic plasticity) allow the nervous system to remain modifiable throughout life. These modifications in the nervous system are thought to allow learning and memory for events experienced by the organism and for adaptive responses in behavior. Two principal molecular mechanisms of synaptic plasticity are modification (e.g., phosphorylation) of existing proteins, and stimulation of gene expression and protein synthesis. While short-term memory (memories lasting for minutes to hours) involves phosphorylation of existing proteins, long-term memory (memories lasting days to weeks, and sometimes a lifetime) requires gene expression and protein synthesis. Gene expression and protein synthesis are initiated by phosphorylation of transcription factors and components of protein synthesis machinery.

The mitogen-activated protein kinases (MAPKs) are a group of related kinases which modulate the activity of intracellular proteins via phosphorylation, and can lead to changes in gene expression and protein synthesis. Three different families of MAPKs have been well characterized: the extracellular signal-regulated kinase (ERK), protein 38 (p38) MAPK, and c-jun N-terminal kinase (JNK) MAPK. These kinases are activated by growth factors, neurotransmitters, stress, and cell death signals. The basic MAPK cascade activation module applies to all three families, and consists of three kinases that are phosphorylated in a sequential manner: MAP kinase kinase kinases (MAPKKKs) are serine/threonine kinases that, when activated, phosphorylate and activate MAP kinase kinase (MAPKK). MAPKKs are dual-specificity kinases that phosphorylate both threonine and tyrosine residues within a Thr-X-Tyr (T-X-Y) motif in MAPKs that leads to MAPK activation (Figure 1). The X corresponds to the amino acid Glu in ERK, a Pro in JNK MAPK and a Gly in p38 MAPK.

Two mechanisms have been proposed to explain how specificity is achieved from an upstream MAPKKK to a specific MAPK: (1) scaffolding proteins that assemble different components of a specific MAPK cascade and (2) direct physical contact between the components of a cascade. MAPKs are serine/threonine kinases that, when activated, phosphorylate a large number of substrate proteins in the cell, including ion channels and transcription factors. The best-characterized MAPK pathway is the ERK pathway. Initially, ERK was found to be principally involved in cell responses to growth factors and other mitogens, controlling cell proliferation and differentiation. It was subsequently observed that ERK is highly expressed in mature neurons, which do not divide and are terminally differentiated. This, along with observations that ERK can be activated by glutamate and other neurotransmitters, pointed to a role for this cascade in synaptic plasticity, and learning and memory. Although roles in synaptic plasticity for the other two major MAPK cascades, JNK MAPK and p38 MAPK, are beginning to emerge, this article specifically focuses on the basic features of the ERK cascade and its role in synaptic plasticity, and learning and memory.

The Cascade

The prototypic members of the MAPK family, ERK1 (p44 MAPK) and ERK2 (p42 MAPK), are activated in response to growth factors and other neurotransmitters (Figure 1). The 'classical' mechanism for growth factor-mediated ERK activation is via receptor tyrosine kinases (RTKs) that become autophosphorylated on specific tyrosine residues following growth factor binding. When phosphorylated, these tyrosine residues create docking sites for the binding of adapter proteins such as growth factor receptor-binding protein 2 (Grb2), or intermediate factors such as Shc, FRS2, IRS-1, and IRS-2. Binding of Grb2 results in the accumulation of Grb2–son of sevenless (SOS) complexes near the cell membrane where SOS (a guanine exchange factor or GEF) activates Ras, a G-protein. Ras is activated when bound to the nucleotide GTP, an interaction facilitated by SOS. Conversely, Ras is inactivated when the GTP is hydrolyzed, a process augmented by GAPs (GTPase activating proteins). In addition to this 'classical' activation cascade, Ras can be activated following membrane depolarization or glutamatergic signaling via increased intracellular calcium. The mechanism by which elevated calcium triggers Ras activation differs slightly among cell types and various neurotransmitter stimuli, but invariably depends on GEFs and GAPs.

Immediate downstream signal transducers of Ras are the Raf family of proteins (Raf1, A-Raf, and B-Raf), which are the MAPKKKs of the ERK cascade. The major, and possibly only function of Ras in the activation of Raf, is the relocation of Raf to the cell membrane, where it can be activated by an unknown

Figure 1 Activation of (a) MAPK cascade and (b) ERK cascade.

mechanism. Once activated, Raf then initiates the sequential phosphorylation and activation of MAPKKs or MEKs and ERK. Activated ERK phosphorylates a large range of substrates, including transcription factors, cytoskeletal proteins, regulatory enzymes, and other kinases.

In addition to ERK1 and 2, ERK3–8 have been identified. Of these, ERK5 (also called big ERK or BMK5) has received the most attention because of the discovery that commonly used MEK1/2 inhibitors PD98059 and U0126 also block the ERK5 pathway. Although the involvement of ERK5 in neuronal survival has been established, its role in learning and memory has not been examined.

Signal transduction for the MAPK family of proteins involves growth factor and/or neurotransmitter receptor-mediated activation of small G-proteins (e.g., Ras for the ERK pathway). In the absence of ligand or calcium rise, G-proteins are bound to GDP and are inactive. The activity of the G-protein is enhanced by ligand binding and the exchange of GDP for GTP, a process facilitated by GEFs. GTP-bound G-protein activates the MAPKKK (Raf for the ERK cascade), which, in turn, initiates the sequential phosphorylation of MAPKK and MAPK. Dual phosphorylation of MAPK on T-X-Y residues results in MAPK (or ERK) activation. MAPK can directly modulate cellular functions by phosphorylating cellular proteins, and indirectly through the activation of other kinases such as $p90^{rsk}$.

The ERK Cascade in Synaptic Plasticity

ERK is expressed at high levels in brain areas implicated in learning and memory. Pharmacological inhibitors of the ERK cascade (PD98059, SL327, UO126) became available in the mid-1990s and have intensified the investigation of the role of ERK in synaptic plasticity. These studies have utilized a variety of approaches, including cell culture, electrophysiology, and *in vitro* correlates of learning and memory, to evaluate the necessity of the ERK cascade in enhancing synaptic communication. For example, many features of learning and memory in *Aplysia californica* (a marine mollusk) can be reproduced in an *in vitro* co-culture system consisting of a sensory neuron and a motor neuron. In this preparation, a single application of the transmitter serotonin (a transmitter released during sensitization training) enhances synaptic communication between the sensory and the motor neuron that lasts for minutes, a correlate of short-term memory. Multiple applications of serotonin enhance synaptic transmission that can last for days, a correlate of long-term memory called long-term facilitation (LTF). Blockade of the ERK cascade, either by a blocking antibody against ERK (blocking or neutralizing antibodies bind to the protein of interest and inhibit its function) or by pharmacological inhibition of the upstream kinase MEK, impairs this LTF of synaptic transmission. Interestingly, MEK inhibition has no effect on short-term synaptic facilitation. Similarly, studies of ERK phosphorylation in *Hermissenda* have shown that both one-trial and multiple-trial conditioning paradigms (both paradigms induce long-lasting plasticity) are associated with increased activation of the ERK cascade.

Delineation of the role of the ERK cascade in synaptic plasticity has been furthered by electrophysiological studies. ERK signaling has been best studied in the classical LTP between CA3 and CA1 synapses of the hippocampus that requires *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors. Tetanizing stimulation that induces LTP in hippocampal CA3–CA1 synapses is associated with increased ERK phosphorylation, leading to its activation. This activation was found to occur in area CA1 and was dependent on both protein kinase C activity and stimulation of NMDA receptors. A requirement for ERK has also been demonstrated in cortical LTP. For example, ERK is required for a shift in ocular dominance following monocular deprivation. This process, thought to depend on cortical LTP, is prevented by MEK inhibitors. Similar to that seen for LTP, a requirement for ERK activity has also been observed in long-term depression (LTD), the weakening of neuronal synaptic strength. For example, cerebellar LTD (a proposed mechanism for motor learning and memory) is associated with activation of ERK in Purkinje cells and can be blocked by application of an MEK inhibitor or by intracellular infusion of an MAPK blocking antibody. ERK activity has also been shown to affect hippocampal CA1 theta frequency firing. This pattern of neuronal firing is typical when rats are learning about their environment, and appears to be

dependent on an ERK-mediated suppression of potassium channel function and an increase in membrane excitability. For example, inhibition of ERK activity in the CA1 subfield blocks complex spike bursting and the LTP that would normally be induced. One potassium channel, in particular, the voltage-dependent K^+ channel K_v 4.2, is an excellent ERK substrate and may mediate the influence of ERK on CA1 theta frequency firing.

Learning and Memory

The studies described above and others show that ERK activity is required for long-lasting synaptic plasticity. Consistent with these findings, ERK has been demonstrated to be critical for long-term memory in intact animals. The behavioral tasks in which the role of ERK has been best characterized are fear conditioning and spatial learning using rodents. Fear conditioning, a type of Pavlovian conditioning, is typically performed by training the subject to associate an otherwise nonthreatening cue such as a tone (called the conditioned stimulus or CS) with an aversive stimulus such as a mild footshock (the unconditioned stimulus or US). Upon subsequent presentation of the tone, trained animals display a characteristic period of immobility called the freezing response that can be monitored and used as a measure of fear memory. This cue-elicited fear response has been shown to depend on the function of the amygdala. In addition to this simple association, animals also learn to fear the specific environment (the context) in which the conditioning took place. Contextual fear, which is tested by placing the conditioned animal back into the training environment and monitoring freezing behavior, is dependent on both the hippocampus and the amygdala. Using phosphorylated ERK as an indicator of increased ERK activity, it has been reported that fear conditioning is associated with increased ERK activity in the hippocampus and the lateral amygdala of conditioned rats. Both systemic and targeted application of MEK inhibitors into animals prior to conditioning significantly impairs long-term fear memory. Consistent with this, transgenic mice carrying a dominant-negative MEK have decreased hippocampal ERK activity and reduced context-specific fear memory.

Spatial learning and memory, a hippocampus-dependent behavior necessary for spatial navigation, is commonly tested using the Morris water maze task. In this task, rats learn to use extra-maze cues to find the location of an escape platform hidden below the surface of the water. Training in the Morris water maze results in a significant increase in the number of hippocampal neurons, specifically those in area CA1, that contain activated ERK. *In vivo* inhibition of the ERK cascade within the hippocampus blocks the training-related activation of ERK and impairs long-term, but not short-term, memory for the location of the hidden platform. Importantly, this memory impairment only occurs when the inhibitor is administered at the time of ERK activation. Delaying the infusion beyond the time of ERK activation results in normal long-term spatial memory. In addition to fear conditioning and spatial learning, ERK activity has been shown to be necessary for long-term memory in other tasks such as taste-aversion conditioning, memory extinction, and recognition memory, demonstrating a conserved role for this kinase in numerous brain structures and associated behaviors.

Disruption of ERK-mediated plasticity in different parts of the brain may therefore provide insights into the contribution of a structure to a particular component of memory. For instance, lesion studies have shown that the prefrontal cortex is required for trace conditioning (a type of fear conditioning in which the CS and US are separated by a time gap), but not delay conditioning (a type of fear conditioning in which the CS and US co-terminate). However, it was not clear if the role of the prefrontal cortex in trace conditioning was due to memory storage or merely information processing. Using targeted infusions of MEK inhibitors, it has been shown that ERK-mediated plasticity in the prefrontal cortex is required for the storage of information related to the temporal relationship between two separated events. In contrast, ERK activation is not observed in the prefrontal cortex, but rather in the amygdala, following delay conditioning. These studies therefore confirmed the earlier findings regarding the involvement of the prefrontal cortex in trace conditioning, and extended this role to included one for memory storage rather than just information processing. In addition to differentiating the role of a structure in different behaviors, blockade of ERK-mediated plasticity can be used to identify the roles of specific structures within a behavior. For example, direct examination of the consequences of ERK inhibition in two structures required for performance in the water maze task, the hippocampus and the entorhinal cortex, has allowed for further delineation of the roles of these two structures in spatial memory. These studies revealed that ERK-mediated plasticity in the entorhinal cortex may be involved in storage of information related to the strategy needed for solving this spatial task, whereas the hippocampus appears to store information related to the actual location of the hidden platform. In concert, the memories stored in the entorhinal cortex and the hippocampus may allow for an animal to navigate from a distance to a known spatial

location. In contrast to the complimentary roles of these structures in spatial memory, inhibition of ERK-mediated plasticity in the hippocampus blunts, while its inhibition in the entorhinal cortex enhances, long-term contextual memory. These and other studies have demonstrated that targeted disruption of ERK signaling can be used as a method of specifically impairing long-lasting plasticity in order to assess the type of information stored within the structure of interest.

Downstream Effects of ERK Activation

The mechanism by which ERK-mediated signaling contributes to long-term synaptic plasticity and memory is likely to involve multiple cellular and molecular processes. As will be discussed below, these processes include enhanced synaptic transmission, changes in gene expression, protein synthesis, and morphological changes (Figure 2).

A number of mechanisms by which ERK alters neuronal properties have been identified, and include (1) synaptic insertion of AMPA receptors that can enhance synaptic communication, (2) phosphorylation of cytoskeletal proteins that can alter neuronal morphology, and (3) modulation of translational and transcriptional machineries that can cause long-lasting alterations in neuronal plasticity.

Synaptic Transmission

Several studies have indicated that an increase in number of postsynaptic AMPA subtype glutamate receptors is an important mechanism for LTP. This is thought to occur by insertion of AMPA receptors into the postsynaptic sites following LTP-inducing stimulation. LTP, as well as the synaptic insertion of AMPA receptors, requires the activity of calcium/calmodulin-dependent protein kinase II (CaMKII). Expression of an active form of Ras, which activates ERK, increases synaptic AMPA receptors and this effect is blocked by the MEK inhibitor PD98059. Furthermore, CaMKII-driven synaptic insertion of AMPA receptors also requires ERK activity (Figure 3). These studies suggest that ERK participates in synaptic plasticity by regulating insertion of AMPA receptors into postsynaptic sites, thereby increasing synaptic strength.

Gene Expression

One of the key requirements of long-term memory formation is altered expression of specific genes as a result of learning. Once activated, ERK can directly (via translocation to the nucleus as a dimer) and indirectly (via activation and subsequent translocation of downstream kinases) phosphorylate several transcription factors that alter the expression of target genes (Figure 2). These include the transcription factor CREB (cAMP response element binding protein), the ternary complex factor (TCF) family members Elk-1 and SAP-1, and the AP-1 (activator protein-1) family members c-Jun, c-Fos, and ATF-2. In support of a role for ERK in regulating memory-related gene expression, its translocation to the nucleus of hippocampal neurons has been observed following training of rodents in the Morris water maze task. Furthermore, the phosphorylation of

Figure 2 ERK-mediated synaptic plasticity may involve several downstream processes.

Figure 3 Synaptic plasticity requires ERK-mediated neuronal changes.

Elk-1 associated with *in vivo* LTP induction in the dentate gyrus can be blocked by a MEK inhibitor.

The phosphorylation of CREB on Ser133 increases the expression of genes containing the calcium/cAMP-response element (CRE) in their promoter regions. In response to neuronal activity, a rapid initial phosphorylation of Ser133 is carried out by CaMKIV, followed by a sustained phosphorylation mediated by ERK. Ser133 phosphorylation by ERK appears to be indirect and involves ribosomal protein S6 kinase 2 (RSK2, also called p90RSK or MAPKAP kinase-1) and/or mitogen and stress-activated kinase (MSK). CREB-mediated gene expression has been shown to be a necessary step for formation of long-term synaptic plasticity and memory in a variety of species. For example, blockade of CREB activity impairs long-term facilitation between *Aplysia* sensory–motor synapse, causes long-term memory dysfunction in the fruit fly *Drosophila melanogaster*, and impairs long-term spatial memory in mice and rats.

The expression of genes containing the serum response element (SRE) is enhanced by binding of the serum response factor (SRF)-Elk-1 complex. Elk-1 (and related TCF family members SAP-1 and SAP-2) are phosphorylated in response to ERK activation which facilitates DNA binding and complex formation with SRF. Genes whose protein products have been implicated in plasticity and memory such as zif268 and egr-1 are known to contain SRE sequences in their promoter regions, suggesting a role for SRF-Elk-1 in memory formation. Consistent with this suggestion, blockade of SRF-Elk-1 binding by direct hippocampal infusion of synthetic SRE sequence-containing decoy oligonucleotides impairs long-term spatial memory formation. Furthermore, Elk-1 phosphorylation is enhanced in the insular cortex following taste-aversion conditioning, the memory of which can be blocked by targeted infusion of a reversible MEK inhibitor.

In addition to phosphorylating specific transcription factors, ERK also phosphorylates other proteins that participate in transcription. For example, ERK-mediated histone H3 phosphorylation has been observed in the hippocampus of rats trained in a contextual fear-conditioning task, and histone acetyltransferase activity may be regulated, in part, through ERK-mediated signaling. As histone acetylation is a prerequisite for gene expression, these epigenetic mechanisms of ERK action may also play a role in regulating gene expression and long-lasting synaptic plasticity.

Protein Synthesis

The synthesis of proteins (or translation) from mRNA in general, and from mRNA localized at synapses that are activated during learning in particular, is thought to be critical for maintaining memory. Recent studies are beginning to show that ERK can regulate the translation of both somatically and dendritically localized mRNAs. The translation of mRNA requires not only ribosomes, but several additional proteins as well that participate in the initiation of translation. Of these proteins, translation initiation protein eIF4E (eukaryotic initiation factor 4), 4EBP-1 (eukaryotic initiation factor 4E-binding protein 1), and the ribosomal protein S6 have been demonstrated to be regulated by ERK-mediated phosphorylation. For example, mice expressing a forebrain-specific, dominant negative isoform of MEK (resulting in inhibited ERK activity) have impaired translation-dependent LTP that is associated with reduced phosphorylation of eIF4E, 4EBP-1, and S6. Similarly, NMDA-mediated activation of Mnk1 (the kinase

responsible for eIF4E phosphorylation) has been shown to depend on ERK activity. As ERK-dependent Mnk1 activation occurs in both the cell soma and the dendrites of NMDA stimulated neurons, this may represent a mechanism by which local and global mRNA translation are regulated for the development of long-lasting plasticity.

Morphological Changes

Morphological changes such as new synapse formation, enlarged spines, and postsynaptic density are routinely associated with long-term synaptic plasticity and memory. For example, stimulation to induce LTP and depolarization of neurons in culture have been associated with increase in the number of filopodia, a precursor of synapse formation, and the size of dendritic spines (Figure 3). Similarly, exposure of hippocampal CA1 slice cultures to brain-derived neurotrophic factor (BDNF), a potent mediator of synaptic plasticity, increases spine density in apical dendrites. Although the mechanism by which ERK participates in these processes has not been fully delineated, each of these morphological changes has been shown to be blocked by ERK inhibition. As MAPK was initially identified based on its ability to phosphorylate microtubule-associated protein (MAP), the phosphorylation of cytoskeletal proteins participating in spine morphology and synapse formation is likely to be involved. Alternatively (or in addition), enhanced translation of dendritically localized mRNA in response to ERK activity may underlie these morphological changes.

In response to training-related release of growth factors or neurotransmitters, activated ERK initiates cellular changes that alters synaptic plasticity. These include enlargement of dendritic spines, insertion of postsynaptic AMPA receptors, and the growth of new filopodium, an initial process for the formation of new synapses. Each of these processes has been shown to be blocked in response to treatments which inhibit the ERK cascade.

Ras-ERK Pathway in Human Memory

Mutation in genes encoding for proteins in the Ras-ERK cascade has been linked to cognitive and memory impairments in humans. The neurofibromatosis-1 gene (NF-1) encodes for a Ras-GAP. Mutations in the NF-1 gene prolong Ras activation leading to excessive stimulation of ERK and its downstream substrate proteins and are associated with learning and memory deficits in humans. Coffin–Lowery syndrome (CLS) is associated with dysfunctional motor learning and low IQ scores. This syndrome is caused by mutations in the RSK2 gene, a downstream effector of ERK. Tuberous sclerosis (TS) syndrome results from mutations in tuberin or hamartin (components of the tuberous sclerosis complex (TSC) that regulates protein translation) and is associated with reduced B-Raf and ERK activity. TS results in severe mental retardation, autism, seizures, and tumors of the brain, heart, and kidneys. Finally, Rubenstein–Taybi syndrome is caused by mutations in the gene encoding the CREB-binding protein (CBP – a histone acetylase) and is associated with mental retardation and poor learning and memory. These studies suggest that an optimal level of ERK activation may be required for normal memory formation with excessive or insufficient activation of the ERK cascade giving rise to cognitive dysfunction.

Further studies are needed to fully delineate the mechanisms by which ERK and its downstream effectors influence neuronal morphology and plasticity. Although several mechanisms have been suggested, the manner in which one or more of these processes is specifically initiated is a subject of continued investigation. Further examination of the interaction between the ERK cascade and other intracellular signaling pathways will shed light on the manner in which individual stimuli, or multiple stimuli in concert, give rise to plasticity-related cellular changes.

Map Plasticity and Recovery from Stroke

R J Nudo and S Barbay, University of Kansas Medical Center, Kansas City, KS, USA

Introduction

One of the more remarkable discoveries of the late twentieth century regarding neural organization was that the brain, and in particular the cerebral cortex, is alterable throughout life. Maps of sensory and motor topography in the cortex are mutable, and functional boundaries can be altered in detail by use-dependent mechanisms. While such functional and structural plasticity had long been known during critical developmental stages, adult plasticity has heuristic appeal as it provides a framework to explain how the brain might accommodate the learning of new skills and behavioral strategies or adapt existing abilities to environmental challenges. In addition, neuroplasticity has come to be appreciated as one of the principal mechanisms for recovery of behavioral function after injury to the nervous system. While this area of research is still evolving, it appears that recovery after cortical (and perhaps subcortical) injury in adult mammals coincides with extensive functional and structural reorganization of the cerebral cortex. This article provides an overview of the role of cortical plasticity in recovery of function after a common clinical condition, ischemic stroke.

Stroke is the result of a cerebrovascular event that interrupts blood flow in the brain, depriving cells of oxygen and glucose. Necrosis can occur within minutes and, if not treated within the first few hours after onset, will likely result in some loss of function. Acute stroke therapy is still limited (e.g., thrombolysis, clot removal), and thus most stroke survivors experience some permanent loss of motor function. The motor areas of the cerebral cortex are typically affected by stroke as a result of reduced blood flow in the middle and anterior cerebral arteries that branch from the common carotid arteries supplying the brain with oxygenated blood. An occlusion in the middle cerebral artery, the most common location for clots to occur, can result in functional deficits in the upper extremities, such as the arm, hand, and face contralateral to the damaged cerebral hemisphere. Functional impairments in the lower extremities are also common after stroke.

Though residual impairments are often permanent, drastically affecting a stroke survivor's quality of life and ability to maintain independence, substantial recovery often occurs, especially in the first few weeks to months after the event. Such recovery is often said to be 'spontaneous' as it does not seem to depend on any particular intervention, such as physical or occupational therapy. Three basic theories regarding the underlying mechanisms contributing to spontaneous recovery are resolution of diaschisis, compensatory behavior, and adaptive plasticity (Figure 1). Diaschisis refers to the disruption in blood flow and metabolism in otherwise intact regions of the brain that are anatomically connected with the injured zone. Since these areas survive the acute event, metabolism and blood flow eventually are normalized, and thus at least some recovery is thought to result from the resolution of this process. Compensatory behaviors are common after stroke in humans and in animal models. As the affected limb is used less, individuals become functional by using the better limb or by employing alternative kinematic strategies (e.g., use of proximal musculature to propel a weak distal limb forward). Finally, adaptive plasticity is now thought to occur in both the peri-infarct and more remote tissue and is the focus of the remainder of this article. It has long been assumed that other, undamaged portions of the cerebral cortex must have the ability to 'take over' the function of the damaged region. A better understanding of how this process occurs, therefore, might open a path to development of novel interventions that optimize this process.

New technologies now allow us to track functional changes in the cerebral cortex after stroke. Cortical plasticity is therefore becoming a major focus for diagnostic assessment of stroke patients through various noninvasive techniques such as functional magnetic resonance imaging (fMRI) and transcranial magnetic stimulation (TMS). Interpretation of information derived from these techniques is greatly influenced by basic animal research that allows for more-precise measures of cortical function than is currently possible with humans. The consequence from bridging basic and clinical research is a better understanding of how cortical motor areas interact within various neural networks to produce adaptive motor control under normal and perturbed conditions.

Animal research has been vital in addressing basic mechanistic questions regarding normal cortical function as well as how the cortex responds to injury. The goal of current research is to understand how neural plasticity can be directed through behavioral and pharmacological therapies to optimize recovery of function and foster relearning of motor skills.

Figure 1 Acute and chronic processes contributing to initial functional deficits and subsequent spontaneous recovery after stroke. Neuronal cell loss occurs rapidly in the ischemic core. Further neuronal cell loss occurs over the course of hours to days in the peri-infarct region (penumbra). Neuronal populations remote from, but connected to, the injured core undergo a reduction in blood flow and metabolism. Spontaneous recovery (i.e., recovery in the absence of specific interventions) is thought to occur via resolution of diaschisis, employment of compensatory kinematic strategies (use of opposite limb or more-proximal muscles of the affected limb), and adaptive plasticity. Adaptive plasticity, or neuroplasticity, is a phenomenon based on several synaptic and cellular mechanisms, such as axonal and dendritic sprouting, synaptogenesis, long-term potentiation, long-term depression, and unmasking.

Organization of Primate Motor Cortex

Motor Cortex Defined

Classically, cortical motor function has been ascribed to that part of the cerebral cortex that is most excitable via electrical stimulation. That is, the primary motor cortex (M1) located in the precentral gyrus was originally defined on the basis of the ability to evoke contractions in skeletal muscles by applying electrical current either on the surface of the brain or deep within the cortical grey matter. The currents required for evoking such contractions are lowest in M1, and using electrical stimulation techniques, a complete representation of body parts can be demonstrated. Later, premotor or secondary motor areas were discovered in more anterior parts of the frontal cortex. These areas are also somatotopically arranged, but somewhat higher currents are required to elicit movements or muscle contractions.

Based on these physiological criteria, frontal cortex was classically seen as motor in function, while parietal cortex was seen as sensory in function. However, there is increasing evidence for a dynamic interaction between motor and sensory areas for learning new motor skills, performing goal-directed behaviors, or adapting old behavioral repertoires to new conditions. At least two cortical pathways have been identified for sensorimotor integration in the cortex. First, sensory information (primarily somatosensory, but also visual) originating in the parietal cortex innervates several motor areas in the frontal cortex. Sensory information also reaches the frontal cortex from the cerebellum and basal ganglia. These connections are important for fundamental behaviors such as sensorimotor integration for reaching and grasping.

Multiple Motor Areas Contributing to Motor Control in Primates

In the frontal cortex, several separate but interrelated motor areas have been identified in primates. The separation between M1 and primary somatosensory cortex (S1) marks the posterior limits of the frontal cortical area. In most primates, this area is buried in the depths of the central sulcus, that is, within the precentral gyrus. More anterior are several nonprimary motor cortices. The medial premotor cortex is referred to as the supplementary motor area (SMA), and the lateral premotor cortex is divided into the dorsal premotor area (PMd) and the ventral premotor area (PMv). In many primate species, these areas have been further subdivided into caudal and rostral components. Other motor areas in the frontal cortex include the cingulate motor areas within the medial wall of the cortex. A common characteristic of these motor areas is that each has neurons that project directly to the spinal cord (corticospinal neurons), influencing motor neuron output and hence muscle activity. Corticospinal neurons in many primate species have monosynaptic connections with motor neurons in the ventral horn of the spinal cord (corticomotor neuronal cells). Corticomotor neuronal cells contribute to hand dexterity, allowing for individual movement of the digits. This organization provides parallel influence on populations of motor neurons in the spinal cord from different motor areas. Therefore, there is not a strict serial control of movements, with M1 being the final common pathway for activation of motor neurons. All the motor areas contribute to voluntary control of movement within an integrated network from cortex to spinal cord.

There are several functional differences among these motor areas. First, M1 contains a complete somatotopic movement representation of major body parts organized from lower extremity on the medial cortical surface to upper extremity on the lateral surface of the cortex. A complete somatotopic map is not true of all motor areas. For example, PMv contains an upper extremity and face representation but no lower extremity representation. Most of the corticospinal projections originate in the frontal

cortex (~70%), and about 30–35% of these originate in M1. The rest of the corticospinal projections are distributed among the other nonprimary motor areas, as well as parietal areas. The vast majority of corticomotor neuronal cells originate in M1. These anatomical features in M1 indicate that this area has the most direct control of kinetic and kinematic aspects of movement control. Nonprimary motor areas are involved more in context-dependent organization of movements (both internal context related to self-initiated movements and environmental context related to spatial information and stimulus associations). In general, PMv mediates visual–motor and somatosensory–motor integration for motor control of the upper extremity. PMd mediates visuomotor association tasks, and SMA mediates motor sequences and bimanual motor control. Cingulate motor functions are similar to SMA and depend on self-initiated movements (i.e., they rely on motor cues).

The functional differences between M1 and nonprimary motor areas are not absolute. Functional properties of individual neurons overlap across M1 and nonprimary motor areas. It is this functional overlap between motor areas, in addition to shared intercortical connections and parallel corticospinal connections, that may allow for adaptive reorganization of motor control in the injured brain.

Divergence of Motor Cortex Outputs as a Basis for Dynamic Organization

There is also functional overlap within each motor area. Single projection neurons can influence multiple muscles. Also, clusters of cortical neurons that typically converge on the same motor neuron pool may overlap within the cortex with a cluster of neurons converging on a different motor neuron pool. Thus, stimulation within overlapping clusters of neurons produces movements of multiple joints (Figure 2). In addition to this divergent/convergent output pathway to the spinal cord, local circuits may contribute to plasticity in the cortical output neurons selected for a particular motor act. Plasticity of local, or intrinsic, circuitry is thought to be mediated by the well-known synaptic plasticity mechanisms, long-term potentiation and long-term depression.

Figure 2 Overlapping of distal and proximal forelimb muscle representations in primary motor cortex of macaque monkeys. Inset depicts a lateral view of the macaque monkey cortex. The enlarged area depicts the results of a motor mapping procedure in which microelectrodes probed the depths of the precentral gyrus to determine what muscles were facilitated by electrical stimulation at each of dozens of sites. Electromyographic (EMG) activity was recorded simultaneously from 24 muscles in the proximal and distal forelimb. Typically, each corticomotor neuronal cell can influence up to four or five different motor neuron pools. The blue area denotes sites where stimulation evoked EMG activity in distal muscles only, and the red area denotes sites where stimulation evoked EMG activity in proximal muscles only. In the intervening zone (purple), stimulation evoked EMG activity in both distal and proximal muscles. Together, this data suggests that the organization of primary motor cortex is highly overlapping with respect to corticospinal outputs to motor neuron pools. Such divergence in basic descending anatomy may underlie the capacity for functional plasticity in this system during learning and after injury. Solid line indicates the convexity of the precentral gyrus, and the dotted line indicates the trough of the central sulcus. Physiological and Anatomical Reorganization in Motor Cortex

Microelectrode Stimulation Methods for Monitoring Motor Map Topography

The advent of electrophysiological techniques in the mid-nineteenth century provided a method to map movement representations within an intact cerebral cortex via surface stimulation. The resolution of these maps is coarse due to spread of current over-extensive areas of cortex. New electrophysiological techniques developed in the 1960s and 1970s required less current and thus provided higher-resolution motor maps. This popular approach is typically called intracortical microstimulation (ICMS) when it is applied to the cerebral cortex. Small-diameter stimulating microelectrodes are introduced into the deep layers of cortex, in the vicinity of the corticospinal neuron cell bodies. Employed in either awake or anesthetized animals, low-current pulse trains stimulate relatively small clusters of neurons, resulting in contraction of skeletal musculature (Figure 2). In addition to

stimulation-based techniques, the functional organization of motor cortex can be explored by recording a neuron's activity while an awake animal engages in a behavioral task. The relationship between neuronal firing patterns and kinetic and kinematic aspects of movement, as well as the distribution of electromyographic activity, has provided important insights into motor cortex function. These methods have contributed complementary information about functional organization of the motor cortex and are capable of detecting functional changes in the cortex as behavioral demands are varied.

Role of Postinfarct Behavioral Experience on Motor Map Plasticity after Stroke

A series of ICMS experiments beginning in the 1990s have characterized several fundamental aspects of cortical plasticity phenomena associated with recovery of function. These experiments have mainly used a nonhuman primate ischemic infarct model, but rat models have also been employed. Squirrel monkeys (genus *Saimiri*) were used because their lissencephalic cortex provides an optimal substrate for deriving highly detailed functional maps. In these studies, reach and grasp behavior was assessed for its clinical relevance. Squirrel monkeys were trained to retrieve small food pellets from various sizes of food wells drilled into a Plexiglas board (modified Klüver board). ICMS maps of the forelimb were derived to determine the spatial organization of motor cortex before and after either motor skill training or subtotal ischemic damage in the cortical motor regions. Then the effects of postinfarct training to relearn the reach and retrieval task (rehabilitative intervention) were examined.

The first studies explored cortical plasticity within M1 of normal (uninjured) monkeys and provided a basic description of fundamental properties of cortical plasticity relative to the distal and proximal forelimb representation in M1. Functional reorganization of motor maps was found to be dependent on prior behavioral experience. Cortical maps remain stable from one mapping session to the next unless the monkeys are required to learn a new motor skill. Reach and retrieval training on the Klüver board results in an increase in the representation of the digits in M1 and a relative decrease in the representation of the wrist and forearm. If the task is changed to require the monkeys to turn a handle to receive a food pellet, shifting the behavioral demand from digit action to wrist action, wrist representations expand at the expense of digit representations. Further, multijoint movement representations appear after training, reflecting joint combinations and sequences used in the actual task. Multijoint representations thus are driven by temporally correlated activation of two or more movements during training and may reflect the development of muscle and joint synergies in motor cortex. Rat studies have shown that training on similar tasks increases the number of synapses per neuron in motor cortex. These behaviorally driven changes in motor maps appear to be skill or learning dependent, as training animals on a task requiring no additional learning or skill acquisition (e.g., monkeys retrieving pellets from a large well) results in no changes in either motor maps (shown in monkeys and rats) or synaptic density (rats).

Following a subtotal ischemic infarct within M1, monkeys recover the previously learned reach and retrieval skills without any specific behavioral intervention (spontaneous recovery). However, this recovery is associated with a shift in functional borders between distal and proximal forelimb representations, resulting in a further loss of digit, wrist, and forearm representations as proximal (elbow and shoulder) representations expand. It is possible that this seemingly maladaptive expansion is due to compensatory use of more-proximal muscles to accomplish the task. For example, in human stroke survivors, the trunk is used in a compensatory manner in retrieving objects. As the distal limb has less range of motion, the proximal muscles aid in propelling the limb forward. Thus, while individuals can become functional after cortical injuries, the tasks are accomplished by very different kinematic patterns accompanied by altered cortical motor organization.

Rehabilitative training beginning within the first week after the ischemic infarct alters the pattern of cortical reorganization, resulting in maintenance of distal forelimb representations spared by the initial infarct and in some cases in an expansion of distal forelimb representations into the proximal forelimb area (Figure 3). Delaying rehabilitative training by 1 month constrains functional reorganization such that no appreciable recovery of spared distal forelimb representation is maintained, similar to what is seen after spontaneous recovery. However, there is an increase in the representation of atypical multijoint movements in the spared distal forelimb area. Most of these multijoint movements involve distal and proximal movements (such as simultaneous wrist and shoulder movements). Results from these initial studies demonstrate the advantages of rehabilitative training for postinfarct recovery of function on a cortical level, distinguishing it from recovery that may occur without directed intervention. These results also suggest that such poststroke rehabilitative training should be introduced early after the ischemic event to maximize the effect on cortical reorganization.

Figure 3 Effects of behavioral experience on spared distal forelimb representations after a subtotal ischemic lesion in primary motor cortex (M1). Nonhuman primate studies have demonstrated that after a small ischemic lesion in M1 affecting less than 50% of the M1 distal forelimb (hand) representation, the remaining hand representation is altered. However, if monkeys recover spontaneously, that is, without any rehabilitative training, the remaining spared distal forelimb representation in M1 shrinks further. However, if monkeys undergo repetitive training with the impaired forelimb on reach and retrieval tasks requiring increasing levels of manual skill, the spared distal forelimb representation is maintained. This result emphasizes the importance of rehabilitative training in recovery after stroke. Later studies demonstrated that the benefit of training on postinfarct maps in M1 occurs only when the training is introduced early after injury.

Physiological and Anatomical Plasticity in Remote Motor Areas after Stroke

Nonprimary motor areas have properties of cortical plasticity similar to those observed in M1. For example, in PMv, the general topography of the proximal and distal forelimb is similar: There is a fractionated map of digit, wrist, and forearm representations surrounded by proximal limb representations. After M1 infarction, PMv forelimb representations are altered, even though the forelimb escapes the direct impact of the ischemic event. More specifically, there is a positive linear relationship between expansion of the distal forelimb area in PMv and the size of M1 infarction. In all cases in which at least 50% of M1 distal forelimb area was damaged, digit, wrist, and forearm representations expanded. This may be an example of vicarious substitution in that it is possible that to some extent PMv assumed M1's role in skilled hand behaviors. It is possible that functional plasticity associated with recovery of motor function is distributed across all motor-related areas in the cortex.

Recently, anatomical evidence consistent with the vicarious substitution hypothesis regarding PMv has been shown in squirrel monkeys. In primates, M1 receives cutaneous and proprioceptive somatosensory information related to the distal forelimb from portions of S1. Normally, there are virtually no connections between S1 and PMv. However, several months after a large M1 infarct, novel projections are found between PMv and S1 areas 1 and 2. This suggests that somatosensory information from the forelimb may be reestablished within the motor network through PMv. This study represents the first evidence of a major alteration of intracortical wiring patterns between different cortical fields in any adult mammal. Earlier studies in rats demonstrated anatomical changes within the peri-infarct region after motor cortex injury, such as increase in neuropil, synaptogenesis, and local axonal sprouting over about 1–2 mm. Such anatomical reorganization may be much more extensive than previously thought.

Other evidence from rats demonstrates that unilateral cortical damage has substantial impact on the anatomy of remote areas, especially in the contralateral (uninjured) motor cortex. A time-dependent increase in dendritic branching occurs in the contralateral cortex, followed by pruning and synaptogenesis. At least some of this anatomical change may be related to increased use of the less-impaired forelimb for manipulation, locomotion, and postural support. In addition, the uninjured motor cortex sprouts novel connections with subcortical structures. Normally, the motor cortex on one side sends axons to the striatum of the same side only. However, after unilateral injury, the intact motor cortex sends projections across the midline to terminate in the contralateral striatum.

Plasticity in Cerebral Cortex Associated with Stroke in Humans

Differences between Animal Models and Clinical Stroke

Animal models provide important information regarding mechanisms underlying postinjury recovery. Their value lies in the ability to control various parameters of the stroke event, such as lesion size and location, temperature, and behavioral conditions. One can monitor the organization of brain activity before and after the ischemic insult, allowing specific hypotheses to be tested empirically. However, these distinct advantages must be considered along with some notable caveats regarding the translation of information from animal models to the understanding of human stroke. Most often, animal studies of stroke are conducted in young, healthy specimens as they are most feasible for *in vivo* analysis of physiology, behavior, and so forth. However, human stroke frequently occurs in frail, older individuals with a host of comorbid conditions, such as high blood pressure, diabetes, and so forth. In fact, stroke prevalence doubles by decade

after about age 50. Following stroke, a significant proportion of individuals experience clinical depression, which may also alter the course of recovery. Thus, while animal studies are invaluable to our understanding, they paint an incomplete picture of clinical stroke and its aftermath.

Nevertheless, certain fundamental traits are common between experiment stroke in animals and clinical stroke in humans. For example, humans undergo substantial recovery after stroke, regardless of the presence or absence of rehabilitative interventions. This phenomenon is known as spontaneous recovery and is most rapid during the first month poststroke. However, it is likely to continue for several months. Specific types of poststroke treatment can enhance recovery. One popular approach, known as constraint- induced movement therapy, constrains the good hand in a sling or mitten and encourages frequent use of the more impaired hand.

Methods for Mapping Brain Reorganization in Humans

Two approaches are commonly used for mapping brain plasticity after stroke in humans. The first, fMRI, depends on magnetic susceptibility of certain substances in brain tissue, such as hemoglobin in blood. Patients are placed in a high magnetic field, and images of relative magnetic susceptibility can be derived from thin, sequential 'slices' through the brain. Deoxygenation of hemoglobin, which occurs when neurons are physiologically active, produces a signal change in the magnetic field. Thus, the fMRI images represent a correlate of neural activity in the brain. A second noninvasive method, TMS, relies on the ability of rapidly changing magnetic fields to induce a weak electrical current in brain tissue. By the use of a magnetic field focused on a relatively small part of the brain by means of a handheld wand, a map of motor outputs from the cerebral cortex can be derived, much like those described via invasive experiments in animals. However, the spatial resolution of TMS is at best an order of magnitude more crude than the invasive procedures used in animals. Both of these techniques are relatively safe, even in clinical populations, and thus have been used in numerous human stroke studies to determine patterns of reorganization.

Cortical Reorganization in Humans after Stroke

On the basis of TMS and fMRI mapping studies after stroke, some conclusions may be drawn. First, as in animal studies, human brains undergo substantial plasticity after stroke. As recovery proceeds, enhanced activity is often seen in the spared tissue adjacent to the stroke injury. Second, additional activity is seen in remote cortical areas on the injured side of the brain, as well as on the uninjured side. The major question that still remains is whether such changes in activation patterns are adaptive, maladaptive, or epiphenomenal.

There has been considerable interest in determining whether contralesional activation after stroke might be adaptive. It is well known from developmental studies in animals that unilateral damage to the cortex results in atypical ipsilateral corticospinal projections in the adult. Presumably, early in development, exuberant projections exist such that corticospinal innervation of the cord is bilateral. During development, the ipsilateral connection is largely pruned back. The unilateral injury at a critical developmental stage may prevent the pruning. Whether unilateral damage results in significant sprouting of descending pathways in adults is still subject to some debate. However, it is important that as stroke recovery proceeds, the contralesional activity seen in fMRI appears to wane as more ipsilesional activity waxes. Further, when stroke patients are trained to use their impaired hand, improved performance is correlated with enhanced ipsilesional activity. Therefore, information to date would suggest that poststroke contralesional activity is not critical for recovery and may possibly be maladaptive. However, this issue is still somewhat unsettled, especially with regard to very large infarcts, in which ipsilesional motor areas are largely eliminated.

New Therapies for Poststroke Plasticity and Recovery

As theories regarding neuroplasticity after stroke have matured, several innovative therapeutic approaches have been developed that purportedly modulate these processes. Central to most of these therapies is the potent influence that behavioral experience has on physiological and anatomical organization in the injured brain. The effectiveness of constraint-induced movement therapy has been demonstrated in a recent phase-III clinical trial. Several adjuvant therapies that are used in conjunction with behavioral training are now being explored. There is a large literature in animal research demonstrating the interactive effect of d-amphetamine and behavioral experience after brain injury. The combined treatment appears to be more effective than either treatment alone. Clinical trials are now investigating its use in human stroke. Further, a new approach combining epidural electrical stimulation and behavioral training has shown promise in both animal models of stroke and early clinical trials in humans. While the mechanisms underlying

these adjuvant therapies are not well known, it is likely that they act by establishing a more receptive environment for behavioral interventions to have their maximal effect on neuroplasticity mechanisms.

Marsupial Neocortex

S J Karlen and L Krubitzer, University of California at Davis, Davis, CA, USA

© 2009 Published by Elsevier Ltd.

Introduction

Although most of us are familiar with only a few species of marsupials, such as kangaroos, koalas, and opossums, there are actually hundreds of marsupial species. Like placental mammals, they are an extremely diverse group that has a number of behavioral specializations related to individual lifestyles. For example, there are marsupials that are terrestrial, arboreal, burrowing, and aquatic. Marsupials can be highly social, such as the striped possum, or solitary, such as the koala; they can be carnivorous, herbivorous, or omnivorous. This diversification is tied to the evolution of unique peripheral morphologies and highly specialized behaviors, both of which are related to alterations in overall brain size, neocortical organization, and connectivity.

In this article, we begin by examining the general lifestyle and morphological characteristics of all marsupials. We then describe the organization of somatosensory, visual, auditory, and motor cortex in marsupials. Finally, we discuss how alterations in the basic plan of organization are associated with specialized behaviors and individual lifestyles.

General Features of Marsupials

Marsupials represent one of three subclasses of mammals that include Prototherians (monotremes), Metatherians (marsupials), and Eutherians (placentals). Monotremes diverged early in evolution, and evidence from gene sequencing studies indicates that marsupials arose concurrently with placental mammals, approximately 180 Ma (Figure 1). The first marsupials are thought to have arisen in North or South America and subsequently migrated to Australia and Southeast Asia, possibly through Antarctica; however, an alternative theory suggests that marsupials may have arisen in Laurasia, somewhere in present-day Asia, and migrated to North America.

Extant marsupials have been subdivided into seven different orders, and more than 270 species have been identified (Figure 1). The exact phylogenetic relationship between marsupial orders is unresolved because different types of data result in conflicting phylogenetic relationships. In general, Didelphimorphia are considered to be the oldest order. This group is relatively homogeneous, and all species within this order have relatively small brains with few cortical fields. The orders Paucituberculata and Microbiotheria are also found in the Americas, but very little is known about the organization of their neocortex. The remaining four orders are found in Australia, Tasmania, New Guinea, and neighboring islands, and they include most of the well-known marsupials.

Regardless of phylogeny, there are a number of features that all marsupials share. The most noted is the marsupium, or pouch, from which they derive their name. The marsupium varies between species from a closed pouch to a small, primal pouch or no pouch at all. Marsupials have a short gestation, between 8 and 42 days, and are born in an immature state. When born, they must make their way to the marsupium and attach to the mother's nipple in order to survive (Figure 2). Once in the pouch, the young animals reside there for the remainder of gestation.

Marsupial brains vary dramatically in size, shape, smoothness of the neocortical surface, and encephalization (the expected size of the brain relative to body size). For example, some marsupials have small, smooth brains with a small proportion of the brain devoted to the neocortex, whereas others have relatively larger, fissured brains with a larger proportion of the brain devoted to the neocortex (Figure 3). In terms of brain organization, perhaps the most notable feature of the forebrain is that marsupials (and monotremes) lack a corpus callosum. Instead, most interhemispheric communication occurs through the anterior commissure, which has been shown to be functionally equivalent to the corpus callosum in placental mammals.

Finally, all but three species of marsupials are nocturnal or crepuscular. This aspect of lifestyle is particularly interesting since all monotremes are nocturnal, suggesting that the common mammalian ancestor was nocturnal.

Somatosensory Cortex

The organization of somatosensory cortex has been studied in several species, all of which have a primary somatosensory area (S1) and a second somatosensory area (S2) located caudolateral to S1. The functional organization of S1 has been described using electrophysiological mapping techniques. In all species examined, S1 contains a complete and inverted representation of the contralateral body surface with the tail represented most medially, followed by the representation of the hindlimb, trunk, forelimb, forepaw, face, and oral structures in a medial to lateral progression. Most neurons in S1 respond to cutaneous

Figure 1 A phylogenetic tree illustrating the relationship between marsupials and other mammals. The seven extant marsupial orders are shown in blue, names of the families within each order are given in red, and examples of well-known species are in green. The timescale is in millions of years ago and is based on DNA sequence data from a 2004 study by Murphy et al. Asterisks indicate branch points that are ambiguous.

Figure 2 Marsupials are born at a very immature state, and they must make their way to the marsupium, or pouch, and attach to the mother's nipple in order to survive. (a) A litter of short-tailed opossums, a pouchless marsupial, on the day of birth. The immaturity of the young is evident in the embryonic developmental state of most of their body features and sensory organs (b). They are hairless, their eyes and ears are poorly developed, the hindlimbs and tail are stumps, and bone development is extremely immature. Only their olfactory system, their forelimbs, and, to a lesser extent, portions of the somatosensory system are developed at birth.

stimulation, and receptive fields for neurons are generally small, particularly on specialized morphological structures such as the vibrissae or forepaws.

In many instances, the specialized morphological structures are associated with unique behaviors. For example, the structure of the forepaw can vary dramatically between species from the spade-shaped forepaw of the marsupial mole, used for digging, to the specially elongated fourth digit of the striped possum used to extract insects while foraging. The cortical representation of these specialized body parts in marsupials is generally enlarged in S1. This is called cortical magnification and is found in placental and monotreme mammals as well.

Figure 3 Lateral views of nine representative marsupial brains. Marsupial brains vary dramatically in their overall size; compare the brain of the Western gray kangaroo with that of the slender-tailed dunnart. The relative size of distinct brain areas also differs between species, such as the size of the olfactory bulb and pyriform cortex (gray), the size of the neocortex (light orange), and the size of the cerebellum (dark gray). Finally, the smoothness of the neocortical surface varies between species, such as the lissencephalic neocortex of the Virginia opossum versus the highly fissured neocortex of the Tasmanian wombat. Lines denote phylogenetic relationships between species; rostral is left and medial is up.

Caudolateral to S1 lies a second, smaller representation of the contralateral body surface called S2. This area has been electrophysiologically identified in all marsupials examined. As in placental mammals, S2 in marsupials contains a complete, noninverted representation of the contralateral body surface with the representation of the face and oral structures located adjacent to similar representations in S1. The forelimb and hindlimb representations are located progressively caudal, and the trunk and proximal body parts are represented medially. The receptive fields for neurons in S2 are larger than those for neurons in S1 and are often responsive to bilateral somatosensory stimulation and/or auditory stimulation. In many species, the S2 region actually contains two separate fields, a rostral field called the parietal ventral area (PV) and a caudal field termed S2. Both fields are somatotopically organized, and neurons in each field have large receptive fields.

Two other fields have been identified in the parietal cortex of several marsupial species; one field is rostral to S1, called the somatosensory rostral field (SR), and the other is caudal to S1, called the somatosensory caudal field (SC). Neurons in both of these fields respond to stimulation of deep receptors or high-threshold cutaneous receptors. Because of similarities in location, stimulus preference, and patterns of connectivity, we have proposed that these areas correspond to fields that have been identified in other mammals, specifically that SR is homologous to area 3a of primates and flying foxes and that SC is homologous to the posterior parietal area (PP) in squirrels and posterior parietal cortex in rats. However, this hypothesis has not been tested.

Studies of corticocortical and thalamocortical connections of somatosensory cortex in marsupials are relatively restricted to the connections of S1. Corticocortical connections have been examined in the brush-tailed possum, Virginia opossum, white-eared opossum, short-tailed opossum, striped possum, and Northern quoll. In all animals, S1 has dense corticocortical connections with S2, PV, SR, SC, cortex immediately lateral to S1, and, in the brush-tailed possum only, motor cortex. S1 has sparse connections with cortex of the medial wall. Interhemispheric connections are restricted to S1, PV, and cortex lateral

to S1. Thalamocortical connections have been examined in the Virginia opossum, the brush-tailed possum, the Northern quoll, and the Tammar wallaby. In the Virginia opossum, thalamic connections with S1 arise predominantly from the ventroposterior nucleus (VP). Moderate projections are also from the ventrolateral nucleus (VL), the central intralaminar nucleus (CIN), the central lateral nucleus (CL), and the ventromedial nucleus (VM). Similar patterns of thalamocortical connectivity have been observed after injections into parietofrontal cortex (which contains S1) in the brush-tailed possum and the Northern quoll.

Taken together, the electrophysiological recording data and architectonic analysis indicate that two unimodal somatosensory fields are present in the neocortex of marsupials, S1 and S2. In some species, PV is clearly present as well. An additional field, SR, is associated with the somatosensory system but is also likely associated with motor processing. Likewise, the field caudal to S1, SC, is associated with somatosensory processing but may be homologous to one or more fields in the posterior parietal cortex of primates that are involved in sensorimotor integration.

Visual Cortex

The organization of the primary visual area (V1) has been examined using electrophysiological recording techniques in several different marsupials, including the Virginia opossum, the white-eared opossum, the big-eared opossum, the brush-tailed possum, the Tammar wallaby, the Northern quoll, and the short-tailed opossum. As in other mammals, V1 is located at the caudal pole of the occipital lobe and contains a complete visuotopically organized representation of the contralateral visual field. The representation of the upper visual field is located caudolaterally in cortex, the lower visual field representation is located rostromedially, the horizontal meridian bisects the upper and lower visual field representations, and the vertical meridian forms the rostrolateral boundary of this field. Several studies have demonstrated that cortex immediately rostral to V1 contains neurons responsive to visual stimulation, and this area, called the second visual area (V2), has been mapped in detail in the Northern quoll. As in placental mammals, V2 contains a complete representation of the visual hemifield, with the vertical meridian represented at the caudomedial border of the field, adjacent to the vertical meridian border of V1. The horizontal meridian bisects the field and forms the rostrolateral boundary of the field. The lower visual quadrant is represented rostromedially and the upper visual quadrant is represented caudolaterally.

In studies in which electrophysiological recordings were combined with architectonic analysis, V1 has been shown to be architectonically distinct from V2, and its appearance is similar to that described for V1 in placental mammals. In Northern quolls, V2 stains lightly for both myelin and cytochrome oxidase (CO), and in favorable preparations V2 is actually composed of heterogeneous light and dark patches in CO-stained tissue.

The cortical connections of V1 are similar in all species examined. For example, in the Virginia opossum, brush-tailed possum, mouse opossum, Tammar wallaby, big-eared opossum, and short-tailed opossum, V1 is densely connected with V2 (peristriate cortex), cortex just lateral to V2 in multimodal cortex (parietal cortex and PP), the caudotemporal area (CT), posterolateral peristriate cortex, and perirhinal cortex. Furthermore, the connections of V1 are not restricted to the representation of the vertical meridian, as is the case for a number of placental mammals. Instead, connections of V1 are found throughout V2 and CT of the ipsilateral hemisphere, although the connections with V2 are patchy and appear to be related to heterogeneities identified using CO stains. Studies of the overall pattern of commissural connections also demonstrate a patchy distribution with V1 and V2 of the opposite hemisphere, indicating that V2 may be modularly organized as it is in primates and other mammals.

Thalamocortical connections of V1 in marsupials are similar to those described in a number of placental mammals. In the brush-tailed possum, the Virginia opossum, the big-eared opossum, the Tammar wallaby, and the short-tailed opossum, the primary source of input to V1 is from the dorsal division of the lateral geniculate nucleus (LGd), with moderate inputs arising from the lateral posterior nucleus (LP). In the brush-tailed possum, the primary source of input to V2 is from LP, with sparse input from LGd. In the Virginia opossum, the lateral intermediate nucleus also projects sparsely to V2.

Taken together, the data indicate that visual cortex in marsupials contains at least two cortical areas, V1 and V2. Each field is topographically organized similar to that in placental mammals. Furthermore, features of neural response properties, histochemical appearance, cortical and subcortical connections, and even the presence of a modular organization are common for visual cortex across all mammals.

Auditory Cortex

Little is known about the number of auditory areas or the detailed organization of auditory cortex across marsupials. Most of what we do know comes from

work on two species, the Northern quoll (previously called the native cat) and the brush-tailed possum. In the Northern quoll, detailed maps of the primary auditory area (A1) have been generated, and these maps are tonotopically organized, as in placental mammals. Specifically, isofrequency bands run mediolateral in auditory cortex, with high frequencies represented rostrally and low frequencies represented caudally. In these animals, there is a disproportionate representation of high frequencies, and neurons in this high-frequency representation have very low thresholds. Studies of adult and juvenile Northern quoll vocalizations indicate that most adult vocalizations occur at the lower end of the hearing range, between 0.4 and 2 kHz, but that juveniles have calls within the peak frequencies of adult hearing, between 6 and 12 kHz. Furthermore, vocalizations and other sounds made by predators and prey of this species have a peak energy between 2 and 5 kHz and greater than 10 kHz, suggesting that the cortical magnification of high frequencies in the Northern quoll is important for predator and prey localization. Another auditory field just rostral to A1 was identified in the Northern quoll, but the data on this field were relatively sparse.

In the brush-tailed possum, the orientation of A1 is different than in other mammals in that high frequencies are represented dorsally and low frequencies are represented ventrally. However, as in the Northern quoll, the lowest thresholds for neurons in A1 in the brush-tailed possum fall between 12 and 21 kHz, similar to the range of frequencies used in vocalizations of the Virginia opossum.

Thalamocortical and corticocortical connections of auditory cortex have been examined in the Virginia opossum, the brush-tailed possum, and the Northern quoll. In all of these marsupials, the primary input to A1 is from the medial geniculate nucleus (MGN). Sparse projections also arise from the suprageniculate nucleus. Since injections into different best frequency representations in the cortex produced discrete bands of label in MGN, the results indicate that projections from MGN to A1 are organized tonotopically.

Although ipsilateral cortical connections of A1 have not been described for any marsupial, dense projections from homotopic locations in A1 in the hemisphere contralateral to that injected have been described for both the brush-tailed possum and the Northern quoll. Furthermore, in the Northern quoll, A1 has been reported to connect ipsilaterally with the putamen and bilaterally with the lateral amygdala. Direct connections between the amygdala and A1 have not been reported for any placental mammal and may be a specialization of the Northern quoll or may represent a primitive pathway of mammals that was subsequently lost in placental mammals with the addition of more auditory cortical fields. Support for the latter supposition comes from studies in marmoset monkeys which indicate that higher order auditory areas, such as the rostromedial field, have ipsilateral connections with the lateral amygdala.

Motor Cortex

The state of motor cortex in marsupials is contentious. The earliest experiments used gross electrical stimulation with unipolar and bipolar electrodes and demonstrated that motor cortex is located at the rostral pole of the neocortex, usually around the orbital sulcus. These experiments found that movements of individual body areas, such as the face, vibrissa, and forepaws, are represented progressively across the cortical surface; however, only half of the studies were able to find a clear representation of body areas posterior to the forepaws (i.e., the hindpaws and tail). Thus, for many years there was a debate as to whether marsupials had a motor representation of the lower body.

As techniques improved, several studies tried to address this issue. In 1939, Golby demonstrated the existence of a complete motor representation of the body at the rostral pole of the neocortex in the brush-tailed possum. Architectonic examination of cortex in this stimulated area confirmed that it corresponded to primary motor area (M1), as described in monotremes and placental mammals. Concurrently, Abbie demonstrated that body movements could be evoked at the far rostral pole of cortex in six different species of marsupials – the long-nosed bandicoot, the Tasmanian devil, the Eastern quoll, the brush-tailed possum, the red-necked wallaby, and the agile wallaby. His results demonstrated that motor cortex was topographically organized in all six species, although in the long-nosed bandicoot, the Tasmanian devil, and the Eastern quoll, the neocortex did not include a motor representation of the lower body. He concluded that there was probably no cortical motor representation of the lower body in the orders Peramelemorphia and Dasyuromorphia, but that there was a complete representation in the order Diprotodontia. Furthermore, he observed that the excitable cortex in all six species was coextensive with a larger layer IV, indicative of sensory cortex, which suggested that motor and somatosensory cortex overlapped.

In the early 1960s, Lende used more refined methods of cortical stimulation to explore sensory and motor cortex in the Virginia opossum and the wallaby. His results confirmed the presence of hindlimb and tail motor representation on the medial wall of the neocortex in both species (orders Didelphimorphia and Diprotodontia, respectively). Unlike earlier

marsupial studies, Lende demonstrated that these animals had a complete overlap of S1 and M1, which he called a sensory–motor amalgam. At the time, the results from his study were surprising but seemed to be in agreement with earlier data. These findings spurred a number of important ideas regarding cortical field evolution in mammals. Most notably, Lende proposed that marsupials represent a primitive state of cortical organization in which S1 and M1 are completely overlapping and that the evolution of this region is marked by a progressive separation of these fields in placental mammals, ultimately into two complete and separate sensory (S1) and motor (M1) representations (**Figure 4(a)**).

Early observations by Lende have been supported by several subsequent cortical stimulation studies in marsupials, including the brush-tailed possum, the white-eared opossum, and the short-tailed opossum. However, in the short-tailed opossum only movements of the jaw and vibrissae could be evoked in this sensory–motor amalgam. The finding that no other body part movements (particularly forepaw movements) could be evoked anywhere in the motor cortex of the short-tailed opossum is surprising in light of previous studies that demonstrated that dense corticospinal projections originate in S1.

Lende's hypothesis of a complete sensory–motor amalgam is not supported by all marsupial motor studies. In particular, in some marsupials there is a region of cortex located anterior to the proposed sensory–motor amalgam that does not respond to somatosensory stimulation and does not have connections with VP. Since these marsupials are in the order Diprotodontia, Haight and Neylon proposed that this order does not have a complete overlap of sensory and motor areas. Instead, they divided mammalian sensory motor organization into three types: (1) in placental mammals, S1 and M1 are completely separate and the body representations are mirror images of one another; (2) in marsupials and placental edentates, there is a complete overlap of S1 and M1, both with the same orientation; and (3) in monotremes, there is dual motor representation with one being coextensive with S1 and possessing the same orientation and the other occupying an anterior, mirrored position (**Figure 4(b)**). The partially separated S1/M1 in Diprotodontia and the fully separated S1 and M1 in placental mammals may represent evolutionary convergence.

Like cortical stimulation studies, neuroanatomical studies indicate that S1 and M1 in marsupials are partially overlapping, but the data are equivocal with respect to the completely overlapping sensory–motor amalgam. For example, in the Virginia opossum, projections from VL (associated with the motor system), VP (associated with the somatosensory system), and CIN (associated with convergent somatic and cerebellar input) all converge on S1. Furthermore, the projections of VL are restricted to S1, supporting the idea of a completely overlapping sensory–motor amalgam. On the other hand, in the brush-tailed possum, thalamocortical projections appear to fall into three distinct zones. Cortex at the far rostral pole receives inputs from the mediodorsal

Figure 4 A diagram of the two prominent hypotheses on the evolution of sensory–motor cortex in mammals. (a) In 1969, Lende proposed that marsupials represent a primitive state of cortical organization in which S1 and M1 are completely overlapping and that the evolution of this region is marked by a progressive separation of these fields in placental mammals, ultimately into two complete and separate sensory (S1) and motor (M1) representations. (b) In 1979, Haight and Neylon proposed that there are three types of sensory motor organization. In monotremes (and potentially the common ancestor), there is dual motor representation with one being coextensive with S1 and possessing the same orientation and the other occupying an anterior, mirrored position. In placental mammals, S1 and M1 are completely separate and the body representations are mirror images of one another. In marsupials and placental edentates, there is a complete overlap of S1 and M1, both with the same orientation.

nucleus, generally associated with frontal cortex in placental mammals. Agranular cortex just caudal to this frontal region and rostral to S1, in the location of M1 in placentals mammals, receives input predominantly from VL and less dense inputs from VP. Projections to S1, as described previously, are predominantly from VP and the posterior nucleus and sparsely from VL. Furthermore, comparative studies in which retrograde tracers were injected into the spinal cord of a number of different mammals indicate that the major source of spinal input from the cortex is similar in all mammals investigated, including several marsupial species. Specifically, there are two or three corticospinal projection zones (termed A, B, and C) that all mammals have, at least in part. One of these projection zones (A) appears to correspond to somatosensory and motor cortex. Although no direct correlations were made, projection zone A in the Virginia opossum and the short-tailed opossum appears to be restricted to somatosensory cortex, whereas this same projection zone in rodents and primates has a rostral extension into the location of motor cortex.

When considered together, results from cortical stimulation and neuroanatomical studies in marsupials are somewhat conflicting. Early cortical stimulation studies in marsupials indicate that motor cortex is at most partially overlapping with somatosensory cortex, whereas later studies indicate that motor cortex is completely overlapping with somatosensory cortex, but only in certain species. These differences could be due to techniques used, anesthetic effects, and species differences. For instance, studies in which the data appear to support a complete overlap were performed in two relatively primitive species, the Virginia opossum and the short-tailed opossum, both from the order Didelphimorphia. Furthermore, the restriction of thalamic projections from motor nuclei of the thalamus to S1 was observed only in the Virginia opossum. Thus, it may be that the order Didelphimorphia represents a more primitive state, and that modern Australian radiations have evolved motor cortex organization that more closely resembles that of most placental mammals.

The Evolution of Cortical Fields in Marsupials and Other Mammals

Comparative studies of sensory and motor neocortex in a number of marsupials indicate that despite differences in lifestyle, size, and phylogeny, all marsupials share a common plan of cortical organization (Figure 5). For somatosensory cortex, S1 and S2 are present in all marsupials investigated, as well as in placental and monotreme mammals. This suggests that these fields arose very early in mammalian evolution and were retained in all lineages. Three other somatosensory fields (PV, SR3a, and SC/PP) have been identified in several marsupials, although in some species these fields are more primitive and poorly developed, such as in the Virginia opossum and the short-tailed opossum (Figures 5(a) and 5(b)). As in marsupials, area 3a in placental mammals is well developed in some species, such as primates, and poorly developed in other species, such as mice. Similarly, PP is present in placental mammals but has been greatly expanded in primates into a large area with numerous cortical fields. The presence of these fields in both marsupials and placentals, but not in monotremes (the presence of a separate S2 and PV in monotremes is unresolved), indicates that these fields arose after the monotreme radiation.

For visual cortex, V1 and V2 have been identified in all marsupial and placental mammals studied, indicating that both fields were present in the common ancestor. However, V2 is less well developed in some species than in others. V1 has been identified in monotremes, but V2 does not appear to be present in this group. This suggests that V2 arose after the monotreme radiation.

Although less work has been done on the organization of auditory cortex, A1 has been identified (electrophysiologically and/or architectonically) in all marsupials investigated, as well as in placental and monotreme mammals. The ubiquity of this field in all subclasses indicates that it was present in the earliest common ancestor.

Finally, the status of motor cortex in marsupials is contentious. However, when all data are examined it appears that two types of organization exist. The first type is represented in primitive marsupials, such as the order Didelphimorphia. In these animals, there appears to be a complete sensory–motor overlap in that S1 is coextensive with M1. In more advanced marsupials, such as the order Diprotodontia, S1 and M1 only partially overlap. The state of organization in the common ancestor of all mammals is difficult to deduce from existing data. However, when comparing data across species, we believe that the common ancestor had a complete sensory–motor overlap. In the three species of extant monotremes, which are highly derived, these fields became distinct. In early marsupials, this overlap was inherited from the common ancestor, and in some advanced marsupial lineages these fields have become more distinguished and now only partially overlap. We propose that in early placental mammals a sensory–motor overlap existed, and it still exists for some primitive groups such as insectivores. In other groups, such as rodents, these areas are partially separated, and in some groups, such as primates, these areas have completely separated.

Although similarities exist in the organization of the cortex across all mammalian species, there are several

Figure 5 A summary of sensory neocortical organization in five marsupial species. Somatosensory areas S1 (red) and S2 (orange) have been identified in all marsupials (a–e) and all mammals. In some species, S2 has been subdivided into S2 and PV (yellow; (b, c, e). Two additional fields, 3a (gray) and PP (black), have also been identified (a–e), although in some species, such as the short-tailed opossum (a) and the Virginia opossum (b), these fields are more primitive (primitive 3a (gray striped) and primitive PP (black striped)). Visual areas V1 (dark blue) and V2 (light blue) have been identified in all marsupials (a–e); however V2 has only been fully described in the Northern quoll (d). Similarly, the primary auditory area A1 (green) has been identified in all marsupials (a–e) and all mammals; however, it has only been described in detail in the Northern quoll and brush-tailed possum (d, e). Rostral is to the left; medial is up. differences in cortical field organization that relate to species-specific lifestyle. The first is a difference in the amount of cortex devoted to a particular sensory system. For example, in the Northern quoll (Figure 5(d)), visual cortex and auditory cortex are relatively large compared to the size of somatosensory cortex. This may be related to the Northern quoll's carnivorous lifestyle; it is an agile hunter and likely coordinates both auditory and visual information to capture prey. Conversely, the brush-tailed possum, which is a phalanger with a well-developed hand, typically eats leaves and flowers and has a larger somatosensory cortex than either visual or auditory cortex (Figure 5(e)). The second difference between species is the cortical magnification of behaviorally relevant sensory surfaces. For example, in the striped possum the representations of the fourth digit and the tongue are relatively large compared to other body part representations within S1 and compared to similar representations in S1 of other species. In the striped possum, the fourth digit and the tongue are both used in their specialized feeding behavior. In the Tammar wallaby, one of only three diurnal marsupials, an enlarged representation of central vision is present within V1, as compared to the organization of V1 in nocturnal marsupials. Finally, high-frequency representations are relatively large in the Northern quoll, and these frequencies match the vocalization frequencies of predators and prey of this species.

The types of adaptations that have been made to cortical fields in marsupials are remarkably similar to those described in placental mammals. This is not

surprising given that marsupials, like placental mammals, have undergone significant radiations during evolution and have diversified greatly, particularly in Australia. This diversification consists of a wide array of morphological, behavioral, and cortical specializations. Many of the morphological and behavioral specializations are associated with patterns of activity (diurnal vs. nocturnal), habitat selection (arboreal, terrestrial, aquatic, or subterranean), and diet (carnivorous, herbivorous, omnivorous, or frugivorous). The similarities in cortical field organization indicate that there are large constraints imposed on evolving systems and that similar solutions to environmental challenges have independently emerged.

Mass Spectroscopy of Proteins

Introduction

Mass spectrometry (MS) is an analytical technique for the determination of the composition of chemical substances by measuring accurate molecular masses. In MS analysis, the molecules of interest are vaporized and ionized, and the mass-to-charge (m/z) ratios of molecular ions are determined. When these gas-phase ions are broken down into characteristic fragments, the measurement of the masses of the fragments provides information on the original ion's molecular structure. Although MS has been used to characterize small molecules for almost a century, the ability to vaporize and ionize larger biopolymers such as proteins was limited, preventing the application of MS to many protein characterization tasks. However, breakthrough developments in soft ionization methods, acknowledged by the Nobel Prize to K Tanaka and JB Fenn in 2002, advanced the application of MS to protein analysis. By combining liquid-phase separations to fractionate complex samples with modern MS measurement techniques, a wide range of peptide and protein characterization efforts are now possible. In recent decades, MS has developed into a highly sensitive, accurate, and powerful tool for rapid qualitative and semi-quantitative characterization of peptides and proteins present in samples ranging from individual cells, tissue sections, and biological fluids to entire organisms. This article provides a brief overview of the capabilities of MS for protein measurements, with an emphasis on neuroscience-related samples. Throughout the article, illustrative references provide additional information.

Principles of Mass Spectrometric Analysis and Instrumentation

MS analysis consists of two essential steps: (1) a process to vaporize and ionize analytes of interest from a sample, followed by (2) a means to measure the masses of the resulting ions. The most effective ionization of proteins is achieved by soft ionization methods such as electrospray ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI) (Figure 1). The ionization of biological samples by both ESI and MALDI imparts low internal energies on to ionized molecules, limiting their fragmentation/breakdown so that larger molecules can be studied. Briefly, in MALDI a liquid or solid biological sample is co-crystallized with a large excess of ultraviolet (UV)-absorbing matrix; illumination of the matrix-sample crystals by a UV laser results in a microexplosion that produces primarily singly charged gaseous analyte ions. In ESI, electric potential is applied to a capillary filled with a liquid sample. This generates an electrospray consisting of small liquid droplets containing the sample, which are desolvated and form multiply charged gas-phase ions. Unlike a MALDI mass spectrum, an ESI mass spectrum of an individual peptide or protein contains a number of signals corresponding to different charge states of each analyte.

The two approaches are complementary and can be used for the same samples. However, differing capabilities and figures of merit often suggest one approach may be more suited to a particular sample type than another. As an example, samples containing high levels of salts, or those that require direct measurement of compounds from a tissue, may be better suited to MALDI approaches, whereas liquid-phase purifications of biological samples may be more easily interfaced to an ESI MS system. Both ionization approaches are often combined with triple quadrupole, ion trap, Fourier transform (FT) ion cyclotron resonance (ICR) or time-of-flight (TOF) mass analyzers (see Box 1), each of which has particular advantages for protein identification. The wide range of current mass spectrometric instrumentation provides a choice of tools for a variety of applications in life sciences.

Protein Identification and Structure Determination

Identifying the protein components of specific brain regions and individual nerve cells provides a basis for understanding numerous neurobiological phenomena. MS methodologies have the capability of identifying proteins by directly deducing their primary structure. The most common approach, known as peptide mass fingerprinting or a bottom-up measurement, involves digestion of a purified protein of interest or a simple protein mixture into smaller peptides using enzymes such as trypsin. The masses of the resulting peptide ions are measured, compared to predicted masses of proteolytic peptides from a database (which often are unique for a given protein), and mapped to protein sequence stretches that match experimentally observed peptide masses (Figure 2). Peptide mass fingerprinting alleviates the need for characterizing high-molecular-weight proteins and makes protein analysis amenable

Figure 1 Two ionization techniques commonly used in biological mass spectroscopy: (a) electrospray ionization (ESI); (b) matrix-assisted laser desorption/ionization (MALDI). As shown in (a), ESI is an ionization technique that uses high voltage at a capillary tip to disperse and spray solvated analytes from the capillary. The spray produces multiply charged ions that are transferred directly into a mass analyzer. As shown in (b), MALDI is a technique that uses a laser to irradiate analytes co-crystallized with a matrix that absorbs the laser energy and forms singly charged gaseous analyte ions.

Box 1 The mass analyzers used for MS-based characterization

The mass analyzer is the part of the measurement process that subjects the ions to a series of electric or magnetic fields in order to allow determination of the *m/z* of the ions. As different mass analyzers offer different figures of merit (measurement speed, mass resolution, mass range, dynamic range), a brief understanding of these differences can help the user select the appropriate instruments for a specific measurement task. The following briefly describes and illustrates four common mass analyzers:

(a) In quadrupole mass analyzers, the ions generated from either of the ionization techniques (ESI or MALDI) pass through a set of four rods that have DC and alternating RF potentials applied to them that focus the ions and allow selected ions to reach the detector. In a triple quadrupole instrument, the ions pass through successive sets of quadrupoles, with each set used for ion selection, ion focusing, and fragmentation, respectively, before they reach the detector.
(b) Quadrupole ion trap instruments use hyperbolic-shaped electrodes to confine ions to stable trajectories inside a specific region, the ion trap, with the potentials applied to these electrodes set depending on the *m/z* range of the ions to be measured. The confined ions can then be either ejected into the detector or dissociated by collisions prior to remeasurement or ejection.
(c) In TOF analyzers, the ions are formed in the ionization source and accelerated by an applied potential so that all ions have the same kinetic energy before being introduced to the field-free region of the mass analyzer. Thus, ions travel at different velocities related to the kinetic energy of the ion. The flight time that each ion spends traveling in the field-free region is converted to an *m/z* value. Conceptually, the TOF instrument is a simple mass analyzer that has the ability to measure ions over a wide mass range.
(d) The operational principle of FT-ICR is to subject ions to a uniform, high magnetic field while in the ICR cell; this field causes the ions to orbit in circular orbits (e.g., cyclotron motion). Because a large number of orbits can be measured, the frequency of ion motion can be measured accurately and precisely. These frequencies are converted to *m/z* values using the Fourier transform algorithm. FT-ICR offers unparalleled mass accuracy and resolution.

Figure 2 Peptide mass fingerprint of myoglobin by matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectroscopy. Mass spectrum shows multiple peaks that represent peptides resulting from proteolytic digestion of purified horse myoglobin standard. Peptide peaks are labeled by position of the peptide amino acids in the protein sequence. Identities of measured peptides are often assigned using bioinformatics approaches such as MASCOT. This program compares the detected masses in the spectra to predicted masses of proteolytic peptides from the protein database and determines which proteins best match statistically with the experimental data. Sequence stretches underlined in blue denote the peptide identified in the spectrum, and red denotes the sites of trypsin cleavage. In this example, the resulting tryptic peptides cover 94% of the protein sequence. *m/z*, mass-to-charge ratio.

to several types of mass spectrometers. However, if a crude extract containing numerous proteins is digested, it places severe demands on the separation and analysis system; a sample that initially contained hundreds of protein compounds contains tens of thousands of proteolytic peptides after digestion.

Existing knowledge on gene expression in the biological tissue or organism under analysis allows identification of proteins by peptide fingerprinting when combined with database searches. Numerous search algorithms are available that rank the recovered protein sequences according to their probability of producing a peptide map that matches the experimentally observed peptides. As the number of organisms with known genomes increases, peptide fingerprinting is proving to be an excellent verification tool in protein expression studies.

Instrumentation platforms that couple two or more mass analyzers in succession, known as tandem mass spectrometry (MS/MS), enable identification of a protein by fragmenting the analyte to allow the determination of its partial or complete amino acid sequence. For example, when analyzing a protein digest by MS/MS, one of the proteolytic peptides can be chosen after the first MS measurement and its molecular ions selectively fragmented by a variety of physical approaches for molecular dissociation. Ideally, fragmentation produces a ladder series of fragment ions (truncated forms of the initial peptide ions) that are analyzed by a second mass analyzer. Mass differences between fragment ions provide information on the arrangement of the amino acids within the fragmented peptide. The deduced peptide sequence, in turn, can be statistically matched to a specific part of a protein

in the database. The ability to sequence peptides by fragmentation minimizes the number of proteolytic peptides needed for confident protein assignment, which extends the use of the mass fingerprinting approach to identification of proteins in more complex mixtures, as well as to proteins that produce fewer proteolytic peptides. Sequencing of peptides from unknown proteins (*de novo* sequencing) may lead to the characterization of new gene products and annotation of new genes.

With the advent of high-resolution mass spectrometers, a second, newer approach to protein identification has been developed, referred to as top-down MS. Unlike peptide mass fingerprinting, top-down analysis begins with direct MS detection and sequencing of an intact protein and lays a foundation for full structural protein characterization. The sequencing of intact proteins is achieved by producing various truncated forms of an entire protein ion by fragmentation inside the mass spectrometer (Figure 3). Thus far, FT-ICR MS appears well suited for top-down protein analysis because it has the required high resolving power of mass measurement and sensitivity. In addition, highly efficient fragmentation techniques that yield complementary information on whole protein fragment ions have been developed specifically for FT-ICR MS. For protein assignment, the data obtained by top-down MS/MS can be processed by search engines in a manner similar to that of the bottom-up approach already described. Although highly accurate and effective in protein identification, the top-down approach is challenging when routinely

Figure 3 Schematic of the top-down approach for protein sequencing and identification. First, the mass of the whole protein ion is determined. Protein ions are then fragmented within the mass spectrometer and the accurate mass of each of the resulting fragments is measured. Patterns of mass shifts between fragment ions are indicative of the sequence in which amino acids are arranged in the original molecular ion. Analysis of fragment ion patterns allows reconstruction of the protein sequence from both or either terminus. Known variations of mass shifts in fragment ion patterns elucidate the presence of posttranslational modifications. Identification of the deduced protein sequences requires database searches. *m/z*, mass-to-charge ratio.

handling proteins >50 kDa, crude samples with >200 proteins, or complex posttranslational modifications such as glycosylation.

Characterization of Protein Posttranslational Modifications and Differential Gene Expression

According to a finding of the Human Genome Project, expressed protein forms outnumber the protein-coding genes by an order of magnitude (~20 000–25 000 genes vs. ~400 000 proteins). Protein diversity that begins with a single nucleotide polymorphism, cell- or tissue-specific alternative splicing, or editing of mRNAs encoded by one gene can be increased further by the addition or removal of various chemical groups to or from the primary protein structure after translation. These chemical changes, known as posttranslational modifications (PTMs), result in alterations of inherent molecular properties such as charge or conformation. These changes often confer unique bioactivity to the modified protein. MS is ideal for the discovery and characterization of PTMs on proteins because most PTMs result in characteristic mass changes to the original molecular ion. For example, phosphorylation of a protein molecule at serine, threonine, tyrosine, or aspartate results in a mass shift of 80 Da due to the addition of a phosphate group. In many cases, comparing calculated and measured molecular masses of intact ions can be sufficient to determine whether a protein or peptide molecule carries a PTM. With the help of the fragmentation techniques already described, the location of an anticipated PTM can be mapped to a particular amino acid residue within the protein by analyzing mass shifts among the fragment ions generated in an MS/MS spectrum.

MS is also effective for the study of protein isoforms resulting from differentially expressed genes. Minor changes in a protein's primary structure associated with alternative splicing or editing of the protein-encoding mRNA lead to changes in the molecular masses of the original protein ion. Top-down protein identification by FT MS is especially effective in this case because various direct fragmentation techniques yield complementary fragment ions that often provide 100% protein sequence coverage and localize sites of basic PTMs.

Quantitative Analysis of Protein Expression

MS approaches to quantify protein levels from two or more complex mixtures use the ability of MS to differentiate isotopically distinct but chemically identical analytes. The technique is based on labeling each sample using isotopic labels, thus conferring a mass change that is detected using MS (Figure 4).

Various labeling approaches have been developed for quantitative analysis of protein expression in biological samples, with isotopic labels, incorporated via metabolic, enzymatic, or chemical reaction, being the most widely used. In metabolic labeling, isotopes such as N^{15} or C^{13} are incorporated into cultured cells via a culture medium that is enriched with amino acids containing stable isotopes in light and heavy forms. The intensity ratio of the peptide peaks labeled with light and heavy isotopes in a mass spectrum reflects the relative abundance of the two peptide species in the sample (Figure 4(c)). Alternatively, isotopes can be introduced at particular places on protein molecules via specific chemical or enzymatic reactions with isotopically encoded reagents. The two MS-based quantitative reagents that have rapidly gained popularity are isotope-coded affinity tags and isobaric tags for relative and absolute quantification.

Strategies for MS determination of the absolute amounts of selected proteins in a sample rely on the addition of known amounts of isotopically labeled recombinant or synthetic internal standards of native proteins found in the sample. When added to a protein tryptic digest, such standards undergo trypsin treatment along with the endogenous proteins. The resulting tryptic peptides are then detected in a mass spectrometer as pairs of labeled and unlabeled identical peptides, differing by the mass of the known isotopic tag. The relative abundance of the endogenous proteins in the original sample is deduced from the ratio between the peak intensities of each peptide pair.

Applications of Mass Spectrometry in Functional Proteomics

Dynamic molecular networks, which often include supramolecular assemblies of noncovalent protein–protein, protein–DNA, and protein–ligand complexes, regulate central neurophysiological processes such as signal transduction and plasticity. Although the structural analysis of macromolecular formations presents a significant analytical challenge, MS becomes increasingly useful in mapping protein interactions. One MS-based approach for studying protein complexes uses the ability of ESI to preserve noncovalent interactions during analysis. In contrast to biophysical techniques such as X-ray crystallography and nuclear magnetic resonance spectroscopy (NMR), MS has the ability to detect different species simultaneously, often at lower concentrations. Using MS, it is possible to measure the mass of the entire complex, as well as the individual subunits produced by molecular collisions inside a tandem mass spectrometer. MS measurements

Figure 4 Protein quantitation using stable isotope labeling and liquid chromatography (LC) mass spectroscopy: (a) labeling and mixing samples A and B; (b) reverse phase liquid chromatography separation (RP-LC); (c) mass spectrometry. In (a), proteins from two different samples (A and B) are isolated and digested using a proteolytic enzyme. Resulting proteolytic peptides are labeled using either heavy (sample A) or light (sample B) isotopic modifiers and combined. In (b), this mixture is fractionated by LC. Identical peptides originating from samples A and B, now carrying heavy or light isotope labels, respectively, coelute in the chromatogram. Coeluting, identically labeled peptides differ by Δm, which equals the mass difference between heavy and light isotope labels. Therefore, identical peptides from different samples can be resolved and analyzed using a mass spectrometer (c). The differences in peak intensities of the labeled peptides reflect the differences in the peptide amounts in the original samples. The lower trace in (c) shows an example of a high-resolution zoom-in view of a typical quantitative mass spectrum. *m/z*, mass-to-charge ratio.

help deduce the stoichiometry of the components making up the complex and may reveal the presence of various metals in metalloproteins. The energy (voltage) required for dissociation of each particular complex serves as a relative measure of complex stability and interaction strength. Because MS can be applied to mapping protein interactions on a global scale, it may also be considered an improved alternative to yeast two-hybrid screening, co-immunoprecipitation, and affinity chromatography – methods used extensively in neuroscience.

Mass Spectrometry for Biomarker Discovery

The ability to measure simultaneously numerous protein components in a sample, and to differentiate between proteins and peptides with PTMs, makes MS well suited for large-scale comparisons of protein expression profiles in search of protein biomarkers that establish links to normal or pathogenic health conditions, disease progression, or therapeutic responses. The power of MS in biomarker discovery is that, in contrast to biomarker screening methods based on the use of selective probes, MS can be used without prior information on the form of the resulting biomarker. Moreover, instead of tracing changes in just a few particular proteins targeted by probes, MS screening can detect unexpected sets of diverse molecular changes that encompass a range of functional pathways in affected individuals. MS screening can be performed on a limited amount of tissue extract or body fluid and, in some cases, without extensive sample purification. Furthermore, MS profiling can be helpful in diagnosing conditions that include genetic abnormalities such as progressive mutations, as well as identifying PTMs. Current discovery efforts are focused on cancer, heart disease, Alzheimer's disease, and rheumatoid arthritis markers.

Mass Spectrometric Measurements in the Brain

This article describes the capability of MS to detect, structurally characterize, identify, compare, and

quantify compounds in biological samples at different organismal levels, facilitating investigations in many subfields of neuroscience. For instance, analysis of proteins at the system level is challenging because of the inherent complexity of the brain. Fractionation techniques such as two-dimensional gel electrophoresis, liquid chromatography, and affinity purifications are commonly used in conjunction with MS to reduce the chemical complexity of such samples and to enhance investigation at the protein level. Profiling of protein expression directly in brain tissues or brain extracts contributes to comparative proteomic analyses in normal as well as pathological conditions, including neurodegeneration, neurotrauma, psychiatric diseases, drug addiction, and nervous system tumors.

An alternative approach is to decrease anatomical complexity and perform the analysis at the level of the individual neuron or even subcellular compartments. Currently, single-cell MS is effectively being used to map the cellular localization of novel peptide transmitters and analyze neuropeptide release at identified release areas. Combined with electrophysiology and molecular biology, single-cell MS has become an indispensable tool for delineating neuronal circuits that regulate simple behaviors in model invertebrates.

A newer application of MS in neuroscience is imaging mass spectrometry. Unlike other imaging techniques, such as immunohistochemistry and autoradiography, MS imaging simultaneously detects numerous compounds without the use of specific molecular probes and labels. Imaging MS becomes increasingly practical for mapping the spatial distribution of peptides and proteins and their structural variances directly in brain tissue and even individual neurons.

Currently, MS is a mainstream neuroproteomic technology well suited for studying protein function. Progress in sampling and separation methodologies, engineering, microfabrication, and bioinformatics continues to advance MS-based approaches for the investigation of protein structure and function in the central nervous system.

Introduction

Mechanoreceptors are primary sensory structures that provide information about mechanical features of the internal and external environments. They always contain at least one sensory neuron that responds to mechanical stimuli with a change in membrane potential. This graded receptor potential usually initiates or modulates action potentials that propagate along an axon to the central nervous system. Some mechanoreceptors, such as vertebrate auditory organs, separate the two functions between two different cells, with the first cell releasing a chemical transmitter to excite action potentials in a second cell. Also, some invertebrate sensory neurons are close enough to the central nervous system to transmit the graded receptor potential directly. Mechanoreceptors detect a wide range of mechanical stimuli from both the external environment (e.g., touch, vibration, and hearing) and the internal environment (e.g., muscle length and hollow organ distension).

Mechanoreception can be conceptually divided into three stages: coupling, transduction, and encoding. The mechanical stimulus is usually coupled by a physical structure to produce stress at the sensitive membrane of the sensory neuron. These physical structures are often complex, and their morphologies have been used to identify and classify different types of mechanoreceptors. Examples include the hair follicles that cover much of the mammalian body and the chordotonal organs of arthropods that provide hearing and vibration sensitivity. Transduction is the process by which mechanical stress in the cell membrane produces the receptor current, leading to the receptor potential. This essential and defining property of all mechanosensory neurons is due to the presence of mechanically activated ion channels in the cell membrane. However, mechanically activated ion channels also occur in cells that are not mechanosensory neurons. The receptor potential is usually encoded into action potentials by a process generally similar to action potential encoding in other neurons. Variations in the sensitivity and dynamic properties of encoding often contribute to the functional properties of the mechanoreceptor, such as the high-frequency response of some vibration detectors.

Mechanical Coupling to the Sensitive Membrane

Structures of both invertebrate and vertebrate mechanoreceptors vary from simple unbranched dendrite endings to complex and elaborate forms made from additional cells and extracellular materials. Many soft-bodied animals have relatively simple sensory endings just below the outer layers of the integument. For example, the roundworm, *Caenorhabditis elegans*, has single nerve cell endings that approach the skin, where they are surrounded by hypodermal cells and a dense sheath of extracellular matrix. However, mechanoreceptors of more elaborate animals, including vertebrates and arthropods, range from relatively simple to very complex forms.

Arthropods have highly specialized cuticular structures that allow external mechanical stimuli to reach the sensory endings through the hard exoskeleton. However, the wide range of external shapes and sizes of these structures can be classified into four basic types: hair, campaniform, chordotonal, and slit sensilla (Figure 1). Hair sensilla respond to disturbances of air or fluid outside the animal, campaniform sensilla detect stress in the cuticle, and chordotonal sensilla respond to a variety of stimuli that originate inside or outside the body, including vibration and sound. Slit sensilla have only been found in arachnids and serve functions similar to those of the campaniform sensilla of insects.

Arthropods also contain another type of mechanoreceptor, the multipolar receptors. These are found throughout the body, from just below the integument to deep tissues such as muscle, gut, and reproductive organs. They have highly branched nerve endings that are usually sheathed by glial cells and connective tissue, except for the extreme tips of the dendrites, where naked nerve endings are assumed to transduce mechanical displacements of the innervated tissues.

Vertebrate mechanoreceptors possess an even wider range of morphological forms, which has made classification difficult. Mammalian mechanoreceptors vary from unbranched nerve endings, apparently lacking any specialization, to complex structures such as the Pacinian corpuscles with their numerous lamellar wrappings (Figure 2). The increasing morphological complexity is correlated with several other factors, including the embryonic origin of the tissues surrounding the sensory ending, the range of animals in which the receptors are found, and the sensitivity to rapidly changing, rather than sustained, mechanical stimuli. Simpler endings are generally associated with

Figure 1 Examples of typical arthropod cuticular mechanoreceptors. In each case bipolar neurons (blue) send distal sensory dendrites to interact with cuticular structures. The tips of the dendrites are surrounded by a lymph space that is sealed from the interstitial space by tight junctions between epithelial cells (yellow). The lymph space contains a high concentration of the ion that carries the sensory current and is often at a positive potential relative to interstitial fluid. Hair structures have a wide range of shapes and sizes, from long, thin wind-detecting hairs to short bristles and pegs. Multiple neurons may be present below the hairs. Chordotonal sensilla are further below the cuticular surface and have a set of scolopale rods, like the staves of a barrel, surrounding the sensory dendrites. Many auditory organs are based on chordotonal receptors. Campaniform sensilla have a characteristic bell-shaped cap that squeezes the dendrite tip when the cuticle is stressed. Slit sensilla of spiders serve a function similar to that of campaniform sensilla, but have long slits that usually compress multiple pairs of dendrites.

Figure 2 Some vertebrate skin mechanoreceptors. From top to bottom: Sensory neurons (blue) surrounded by increasingly complex morphological structures, from bare nerve endings to the elaborate lamellar wrappings of the Pacinian corpuscles. There is a corresponding transition from receptors with little adaptation, such as the Ruffini endings that detect steady indentation of the skin, to rapidly adapting receptors, such as Pacinian and Meissner endings that detect vibration. The function of the additional Merkel cell (yellow) is still controversial and may include mechanotransduction. Bare nerve endings and some Ruffini-type endings may be innervated by unmyelinated axons, but the more complex receptors have myelinated axons.

tissues of mesodermal origin (connective tissues and muscle) and include the Ruffini endings of joints and skin, Golgi tendon organs, and muscle spindles. These receptors are found throughout the vertebrates and they usually respond to steady deformation, such as the constant firing of joint and muscle receptors that gives kinesthesia, or awareness of body posture. At the other end of the scale are structurally complex receptors associated with tissues of endodermal or ectodermal origin such as the Meissner and Pacinian corpuscles of the skin. These preferentially respond to rapidly changing stimuli such as vibration, or movement of the skin across a rough surface. They are unknown in fish, uncommon in amphibians or reptiles, and increasingly common in birds and mammals, suggesting a relatively recent evolution of complex morphological endings in the vertebrates, possibly associated with the shift from aquatic to terrestrial environments.

Relatively little is known about the detailed functional properties of external structures surrounding mechanically sensitive nerve endings in vertebrates or invertebrates, because, in most cases, the exact location of transduction, the mechanical properties of the external components, and the component mechanical connections are unknown. The Pacinian corpuscle is a very rapidly adapting receptor, responding best to high-frequency vibration. A significant part of this adaptation is due to the numerous lamellar wrappings, because the receptor potential adapts much less when most of them are removed. Slow indentations allow the lamellae to move relative to each other but more rapid stimuli are transmitted by the viscosity of the fluids between them. However, other mechanisms are capable of producing rapid adaptation in mechanoreceptors, so it is not clear if this is the major function of the lamellae or how significant are the detailed differences between the various vertebrate receptor structures.

The functions of external coupling structures are better understood in some arthropod mechanoreceptors. Hair sensilla form levers that allow movements of external air or water to compress sensory dendrite endings, while the bell-shaped caps of campaniform sensilla convert stress in the cuticle to compression at the tips of sensory dendrites. Slit organs of spiders perform similar stress-detecting functions, although the coupling mechanisms are not so clear. Chordotonal sensilla of insects and crustaceans contain particularly elaborate structures, the functions of which are still uncertain. While all arthropod cuticular sensilla have dendrites derived from modified ciliary structures, there is evidence that the cilia of chordotonal sensilla may retain the capacity to move actively, leading to the idea of feedback loops between mechanotransduction and ciliary movement. Positive feedback could enhance sensitivity to small stimuli, or negative feedback could serve as a gain control for large stimuli. Possibly, both mechanisms operate. Interestingly, chordotonal sensilla function as auditory receptors in many insects, and similar positive or negative feedback loops have been proposed between the outer and inner hair cells of vertebrate auditory systems.

Although the general functions of many arthropod coupling structures are understood, their dynamic properties remain largely unknown; partly because the mechanical properties of the individual components are difficult to measure or estimate. The dynamic properties of spider slit organs have been studied intensively, and there is some evidence for frequency tuning by slit length, but the overall dynamic responses seem dominated by ionic events during action potential encoding. In general, the reasons for the evolution of such varying and complex coupling structures are enigmatic, particularly since arthropod multipolar receptors seem to provide many similar functions without any comparable coupling structures.

Transduction of Mechanical Stimuli

Mechanotransduction produces a receptor current through the membrane of the sensory ending. This current charges the membrane capacitance to give a membrane potential, which is depolarizing in all cases where it has been measured. It is now widely agreed that transduction is mediated by mechanically activated ion channels that open in response to mechanical deformation of the membrane. Possible alternative mechanisms include mechanically sensitive membrane receptors that activate ion channels by a second messenger cascade or, for ciliary receptors, a reversed ciliary beat in which the forced sliding of dynein arms leads to a chemical signal. However, there is no direct evidence for any kind of chemical intermediates, and the speed of mechanotransduction can approach submillisecond timescales, arguing strongly for a direct mechanism.

Although mechanically activated ion channels have been characterized in a wide range of preparations, from bacteria to human cells, direct observations of single channels that are clearly producing transduction in a mechanosensory neuron have proved elusive. Similarly, no genes or protein molecules have been identified that definitely provide sensory mechanotransduction. Differences in the ionic basis of transduction in different mechanoreceptors suggest that a range of different proteins may be involved. The receptor currents of Pacinian corpuscles and muscle spindles are carried primarily by sodium ions, although the channels are permeable to a range of cations. A similar situation prevails in crayfish stretch receptors, which are multipolar receptors. Spider slit sensilla also use sodium as the current carrier, but in this case the channels are highly selective for sodium, and lithium ions pass only with greatly reduced permeability. In contrast to these systems, both vertebrates and invertebrates have mechanoreceptors in which potassium is the main charge carrier, although some of these are relatively unselective for cations, including calcium. They include the hair cells of the vertebrate hearing and vestibular organs, as well as all of the insect cuticular sensilla that have been examined.

Another feature found in many vertebrate and invertebrate mechanoreceptors is the existence of a specialized lymph space surrounding the region of the sensory neuron where transduction is believed to occur (**Figure 1**). Lymph spaces are usually lined by epithelial cells, which produce a relatively high concentration of the ion that carries the receptor current, and often an electrical potential that tends to drive those ions into the sensory ending. These arrangements seem clearly designed to increase the electrochemical force driving the receptor current, and therefore amplify the effect of opening the mechanically activated ion channels.

Two major groups of ion channel molecules have been associated with mechanotransduction. Members of the transient receptor potential (TRP) family of channels have been implicated in a range of sensory functions of both vertebrates and invertebrates, including phototransduction, thermal transduction, mechanotransduction, pain, and osmosensation. TRP channels have been strongly linked to hearing and touch in *Drosophila*, and to touch in *C. elegans*. Homologous molecules have been found in vertebrates, but primarily are associated with osmolarity detection in a wide range of neural and nonneural tissues. Other TRP channels have been found in vertebrate pain receptors, as well as mouse, bullfrog, and

zebra fish inner ear hair receptors, appearing at the same embryonic stage as does sound sensitivity in mice. However, none of the evidence yet gives clear proof that these channels are the primary source of the receptor current.

The other channel family associated with mechanotransduction is the degenerin/acid-sensitive ion channel/epithelial sodium channel (DEG/ASIC/ENaC) family, best known for the amiloride-blockable epithelial sodium channels that conduct sodium flux through a wide range of epithelia. In *C. elegans*, two of four proteins found only in mechanoreceptor cells are DEG molecules that have been proposed to form the core of the mechanotransduction channels, and the receptor current was carried by sodium ions. A DEG gene family was also associated with mechanosensitivity in *Drosophila* larvae. In rodents, several members of the DEG family have been found in dorsal root ganglia and in fine nerve endings surrounding tactile hairs. Knockout animals for one channel, BNC1, showed reductions, but not elimination, of mechanosensation, and none of these molecules has yet been identified in well-known skin mechanoreceptors, such as Pacinian corpuscles or Ruffini endings.

Although the molecular evidence favors TRP channels in *Drosophila* mechanotransduction, indirect evidence in another arthropod preparation, spider slit sensilla, is more supportive of ASICs. Receptor current in these neurons is highly selective for sodium, blocked by amiloride, and strongly increased by low pH, which are all characteristic properties of acid-sensitive channels. Other members of this channel family have exhibited mechanosensitivity in expression systems.

A few single-channel measurements have been made from mechanoreceptor cells, with conductance estimates of about 40–100 pS. Single-channel openings of about 100 pS conductance are seen in whole-cell recordings from cochlear hair cells during mechanical stimulation. Noise analysis, which examines the statistical properties of the receptor current, has also been used in several preparations, including hair cells and spider slit sensilla, giving generally lower (5–50 pS) estimates of single-channel conductance.

Two other commonly proposed features of sensory mechanically activated channels are heteromeric construction and connections to extracellular and intracellular structural proteins. Evidence from several preparations indicates that multiple proteins are required to form functioning eukaryotic mechanically activated channels, and this may explain the difficulty of demonstrating mechanosensitivity from proteins expressed in oocytes or other systems. Mechanical connections to cytoskeletal and extracellular matrix structures have been proposed by several lines of evidence, including the amino acid sequences of proposed channel molecules. It has also been argued that lipid membrane alone could not provide enough force to open a protein channel. Microtubules are often prominent in mechanoreceptor endings, and in some cases have been suggested to form a cytoskeletal anchor, but several studies in arthropods and in *C. elegans* have shown that mechanotransduction persists after pharmacological destruction of microtubules.

Encoding Mechanosensory Information

With the exception of a few unusual cases, the depolarizing receptor potential leads to action potentials that conduct the encoded mechanical signal to the central nervous system. The usual mechanism for this encoding is the familiar combination of regenerative voltage-activated sodium channels and delayed rectifier voltage-activated potassium channels. However, a range of variations on this theme has been found. Important issues in encoding are where in the sensory cell the action potentials begin, what other ion currents are activated during the encoding, and how these various ion currents contribute to the overall sensitivity and dynamics of mechanoreception.

Initial measurements in Pacinian corpuscles suggested that the receptor potential is conducted passively from the distal nerve ending to the first node of Ranvier of the myelinated axon, which is still within the lamellar capsule. However, more recent work indicates that voltage-activated sodium channels are found in the most distal parts of the neuron, where transduction occurs, suggesting that action potentials may be initiated immediately following transduction by the same area of membrane. In muscle spindles there is also evidence for spiking activity in the most distal regions of the sensory endings, where transduction takes place.

A similar shift of opinion has occurred for the bipolar neurons of arthropod cuticular mechanoreceptors. Here, it was initially assumed that the receptor potential propagates passively through the sensory dendrite and soma to produce action potentials in the first part of the axon. However, voltage-activated sodium channels have been detected throughout these neurons, and both intracellular and extracellular recordings of several mechanosensory neurons have clearly shown that action potentials start in the most distal dendrites. Encoding of action potentials as close as possible to the transduction site must result in rapid transmission of information to the central nervous system, with obvious evolutionary advantages.

There is not much direct evidence of other voltage-activated currents in vertebrate somatic mechanosensory neurons, but voltage-activated calcium currents are well characterized in vertebrate hair cells. Calcium

plays important roles in hair cell adaptation, both by acting on motor proteins within the cells and by opening calcium-activated potassium channels. In some vertebrate hair cells the feedback loop – formed by membrane potential, calcium current, calcium-activated potassium current, and membrane potential – has been implicated in tuning the optimal frequency sensitivity of mechanotransduction. Calcium currents, calcium-activated potassium currents, and several different types of voltage-activated potassium currents have also been characterized in arthropod cuticular receptors and multipolar receptors. Different combinations of such additional currents seem to be characteristic of each particular type of mechanosensory neuron, and result in different patterns of action potential firing.

Mechanosensory neurons display a wide range of action potential encoding, from the relatively steady firing of muscle spindles and Ruffini endings to the brief, transient responses of Pacinian corpuscles as a mechanical stimulus is applied and withdrawn. A similar range is found in invertebrate receptors, even sometimes within one structure, such as the position and acceleration detectors of leg joint chordotonal organs, the two types of spider slit sensilla neurons, and crustacean stretch receptors. Although mechanical components and receptor current have often been implicated in the overall dynamics, as described earlier, voltage-activated currents also play major roles. In Pacinian corpuscles the action potential encoding is transient, even when most of the mechanical adaptation has been removed. In cockroach tactile spine neurons both voltage-activated and calcium-activated potassium currents seem to control the rapid reduction of firing following a step movement, while the rapid adaptation of spider slit sensilla neurons could be completely explained by the inactivation properties of the voltage-activated sodium channels. It seems that a wide variety of components have been used in different mechanoreceptors to control the relationship between mechanical stimulus and the resulting action potential train.

Following encoding, action potentials from mechanosensory neurons propagate into the central nervous system along nerve axons. In vertebrates, the cell bodies of these neurons are located in the dorsal root ganglia of the spinal cord, and the axons enter via the dorsal roots. Mechanosensory axons are generally in the Aα and Aβ groups of myelinated fibers with conduction velocities in the range of 40–120 m s^{-1}. Bare nerve endings are innervated by myelinated Aδ or unmyelinated C fibers, with conduction velocities in the range of 0.5–30 m s^{-1}. The major transmitter at the first central synapse in vertebrates is probably the excitatory amino acid glutamate. Arthropod cuticular mechanosensory neurons have their cell bodies in the periphery and send axons into the central nervous system via nerve roots of the segmental ganglia, which are sometimes fused into larger structures. Conduction velocities are typically 1–5 m s^{-1}. The dominant transmitter for arthropod mechanoreceptors is acetylcholine.

Efferent and Humoral Modulation of Mechanosensory Neurons

Evidence indicates that the sensory neurons of all vertebrate and invertebrate mechanoreceptors receive inhibitory efferent innervation of their centrally located axon terminals. Well-known examples are the efferent innervation of vertebrate muscle spindle and tendon organ terminals. Peripheral mechanoreceptors and pain receptors receive similar synaptic inputs onto their central projections. This type of presynaptic innervation of mechanosensory neurons is remarkably similar in all vertebrate and invertebrate species studied so far. The most common transmitter released from the efferent neurons is γ-aminobutyric acid (GABA), and its effects have been well characterized in insects, crustaceans, and vertebrates.

In addition to this inhibitory control of axon terminals, there is accumulating evidence that modulation of many mechanosensory neurons occurs at their distal sensory endings and cell bodies. The γ-innervation of muscle spindles and the inhibitory neurons of crustacean stretch receptors (Figure 3) provide vertebrate and invertebrate examples. Somatic innervation is indicated by transmitter receptors found in vertebrate dorsal root ganglion neurons. In the vertebrate periphery, unmyelinated nerve fibers have been seen associated with slowly adapting cutaneous mechanoreceptors, as well as inside the capsules of Pacinian corpuscles. Some of these endings are probably efferent and have been suggested to modulate sensory reception. There is also evidence that Merkel cells may function as secretory cells, rather than as mechanoreceptors, and modulate their associated nerve endings. However, the function of Merkel cells remains controversial. Modulation of vertebrate cutaneous mechanoreceptors and pain receptors by circulating factors also occurs. Sympathetic efferents have modulatory effects on muscle spindles, Pacinian corpuscles, several types of low-threshold skin mechanoreceptors, and pain receptors, and these neurons express adrenergic receptors. Rohon–Beard neurons, which are developmentally early amphibian and fish touch receptors, have serotonergic efferent innervation, and serotonin is suggested to alter their mechanical sensitivity by inhibiting both low- and high-voltage activated calcium currents.

Figure 3 Invertebrate mechanoreceptors with well-characterized efferent modulation. Crustacean stretch receptors (left) are multipolar mechanoreceptors that, in this example, detect muscle stretch. Their sensory neurons (blue) are modulated by several efferent neurons that synapse onto their cell bodies and dendrites, as well as the muscle cells, releasing γ-aminobutyric acid and glutamate. Spider slit sensilla (right) contain pairs of mechanosensory neurons, the axons, cell bodies, and dendrites of which receive extensive innervation from at least four different efferent neurons. γ-Aminobutyric acid, glutamate, octopamine, and acetylcholine synaptic transmissions have been characterized.

Insect mechanosensory neurons are often modulated by biogenic amines, especially octopamine, and the locust dorsal unpaired median neurons, which secrete octopamine, have terminals in the periphery closely associated with sensory dendrites. Previous findings of octopamine effects in situations in which axon terminals were removed during recordings also suggested that octopamine receptors are located in the neurons' peripheral parts. Although octopamine modulation of insect mechanoreceptors is probably the most thoroughly studied neuromodulatory system, there are no clear conclusions about the mechanisms involved. Octopamine may increase or decrease spiking frequency, even in the same neuron.

Efferent innervation of the peripheral regions of mechanosensory neurons has been clearly demonstrated by morphological and immunocytochemical findings in arachnids and crustaceans (Figure 3). Both groups of sensory neurons have dense efferent innervation, forming several types of synapses on all parts of the sensory neurons, including their somata and dendrites. GABAergic inhibition of crustacean stretch receptor neurons is mediated by ionotropic anion receptors. Slit sensilla and other cuticular mechanoreceptors of spiders have at least four different types of synaptic structures on the efferent terminals, based on the shapes and sizes of synaptic vesicles and immunogold labeling. Several chemical transmission systems have been identified, including GABAergic inhibition via both ionotropic and metabotropic receptors, glutamatergic inhibition, octopaminergic excitation, and cholinergic inhibition. The effects of these different types of synaptic modulation on mechanoreception are not well understood, but could include control of the overall sensitivity and dynamic responses of the neurons or more selective tuning to specific signals. It seems likely that both vertebrate and invertebrate central nervous systems are able to rapidly adjust the behavior of many types of mechanosensory neurons, but the functional significance of this widespread control is not yet established.

Conclusions

While the basic steps of mechanoreception are well established, each of the three major stages (coupling, transduction, and encoding) continues to present major challenges that require further research. The functional significance of the wide range of coupling structures and the mechanical properties of their individual components remain largely unknown. We have yet to clearly identify any of the proteins involved in mechanotransduction, the channel-opening mechanisms, or their connections to other structures. Encoding is well understood in some preparations, but its wide variability and locations within complex neuronal geometries make it difficult to generalize. Finally, the efferent and humoral modulation of mechanosensory neurons in the periphery, although not completely novel, has recently proved surprisingly widespread and complex, with little information yet about its central organization or functional roles.

Introduction

Viscerosensory neurons are specialized to detect changes within the lumen or wall of visceral organs, and through the generation of trains of action potentials convey the coded information that keeps the central nervous system (CNS) abreast of events in internal organs, such as the bladder, bowel, or cardiovascular system. Most of this information goes unperceived but is used instead to trigger reflexes and behaviors that coordinate visceral function and maintain homeostasis. However, some sensory afferents also mediate sensations such as bladder fullness and urge to defecate. Some also mediate pain, which tends to be vague and poorly localized, often being referred to somatic sites (dermatomes) because of the way visceral and somatic sensory inputs converge in the spinal cord. This article discusses the transduction mechanisms responsible for signaling reflex and sensory function, with an emphasis on the gastrointestinal (GI) tract; because of its dual sensory innervation, the GI tract has functional subpopulations of visceral afferents that are specialized to signal low-intensity (physiological) and high-intensity (nociceptive) information.

Sensory Innervation to the GI Tract

Sensory neurons innervating the GI tract terminate within the gut wall in various layers, including muscle, mucosal epithelia, and enteric ganglia. Other endings terminate in the serosa and mesenteric attachments and form a dense network around mesenteric blood vessels and their tributaries in the gut wall. These various ending maintain a steady flow of afferent traffic to the CNS, relaying information on activity both within and outside the gut wall. This sensory information is conveyed to the CNS by separate vagal and spinal pathways to the brain stem and spinal cord, from where information is processed and projected to higher brain areas. Spinal afferents can also be subdivided into those running via the splanchnic nerves and those in the pelvic nerves.

Vagal and pelvic afferents generally process physiological information (e.g., the nature and composition of the luminal contents, the presence and amplitude of ongoing motor activity of the gut). In contrast, splanchnic afferents also process pathophysiological information, including potentially noxious mechanical or chemical stimuli arising through tissue injury, ischemia, and inflammation. However, there is a degree of overlap in the sensitivity of these two pathways, and there is also some interplay between them.

Sensory Endings

A majority of GI afferents terminate within the gut wall as bare nerve endings. Thus the differential sensitivity of afferents arises from their location in the gut wall, their relationship with other structures, and the receptors and ion channels that they express.

Mucosal Afferents

Afferent endings in the mucosa are in close association with the lamina propria adjunct to the mucosal epithelium, but are never exposed directly to the contents of the lumen. Mucosal afferents are chemosensitive, responding to the chemical nature of luminal contents. They do not respond to distension, but are exquisitely sensitive to local mechanical stimulation that deforms the mucosal epithelium.

Muscle Afferents

Vagal afferent endings within the muscle layers and associated myenteric plexus have been classified into two types: intramuscular arrays (IMAs) and intraganglionic laminar endings (IGLEs). IMAs are distributed within the muscle sheets and appear to make direct contact either with the muscle fibers or with intramuscular interstitial cells of Cajal (ICCs), which may play a role in mechanotransduction, responding to stretch or contraction of the muscle bundles. In contrast, IGLEs consist of flattened endings that branch extensively inside the connective tissue sheath surrounding myenteric ganglia. Their role had been obscure until recent studies showed that they, but not their parent axons, were sensitive to mechanical stimulation. Since IGLEs are located between the circular and longitudinal muscle layers, they are exposed to shearing forces generated during muscle stretch or contraction and have been suggested to convey mechanosensory information relevant to distension and contraction of the bowel wall. Vagal IGLEs are mainly found in the esophagus and stomach. A similar type of ending has been identified in the rectum. The latter types of endings are not derived from vagal afferents, but are likely to arise from afferents running in pelvic nerves.

Serosal and Mesenteric Afferents

Spinal afferent terminals are distributed throughout the gut wall but are also located in the serosa and mesenteric attachments, often associated with mesenteric blood vessels. Their location and response characteristics suggest that spinal afferents respond to distortion of the viscera during distension and contraction. However, spinal afferent terminals are also found in the mucosa. These spinal afferents respond to mechanical stimulation and to the chemical environment within the lamina propria, and in particular respond to the changing chemical milieu following injury, ischemia, or infection.

Stimulus–Response Function

The relationship between the intensity of stimulation and the degree of activation of the sensory afferent is known as the stimulus–response function. Afferent information conveyed by spinal, pelvic, and vagal mechanosensitive afferents is somewhat different in its sensory–response function, as revealed by direct electrophysiological recordings of afferent traffic en route to the CNS. The factors that determine sensitivity may include the location of the endings within the bowel wall, the latter being influenced by the extent to which mechanical forces are distributed and dissipated by nonneural structures in the bowel wall. Different mechanosensitive channels may also contribute to their different stimulus–response functions, but these have not been identified.

When the bowel is distended, vagal and pelvic muscle mechanoreceptors have low thresholds for activation, responding to pressure rises of just a few mmHg, and reach maximal responses within physiological levels of distension. These are referred to as low-threshold mechanoreceptors and convey information relating to normal physiological events in the bowel. These endings also respond during contraction and therefore signal to the CNS information relevant to each and every contraction that occurs anywhere along the length of the GI tract. Other spinal afferents also have low thresholds for activation but continue to respond beyond the physiological range and thus encode both physiological and noxious levels of stimulation; these are called wide-dynamic-range fibers. These spinal endings can contribute to signaling visceral pain through some intensity code that recognizes extreme levels of distension or contraction. Other spinal afferents, particularly those with endings in the serosa and mesenteric attachments, respond only to noxious levels of distension (high-threshold mechanoreceptors) and are referred to as nociceptors. These only respond when the bowel is overdistended or during powerful contractions that distort the bowel. An extreme example of mechanical nociception has been described in sensory endings that fail to respond even to extreme levels of distension. These are the so-called sleeping or silent nociceptors that can be awakened to become mechanically sensitive under conditions of injury or inflammation (see later). The latter illustrate the fact that mechanosensitivity is not fixed either in terms of threshold for activation or gain in the stimulus–response relationship, and as such the threshold can be reduced and the gain increased after injury or during inflammation. This leftward shift in the stimulus–response function means that for a given level of stimulation, there is a greater afferent barrage generated. This can give rise to altered perception such that stimuli that are normally innocuous can cause pain while the response to a painful stimulus becomes exaggerated (hyperalgesia).

Transduction by Visceral Afferents

Transduction is the process by which sensory neurons generate trains of action potentials from an adequate stimulus. The conventional understanding is that mechanisms in the neuron produce a generator potential, which in turn evokes a train of action potentials, encoding details of the stimulus such as the timing, rate of onset, amplitude, and duration. While specific transduction mechanisms probably underlie the generator potential, the final pattern of firing is also influenced by accessory mechanisms, including various voltage- and calcium-dependent ion channels. This is analogous to synaptically evoked firing in which the patterned output of action potentials is not simply a frequency code of transmitter-driven membrane potential, but is also powerfully influenced by the density of voltage-dependent sodium, calcium, and potassium channels, by calcium-dependent potassium channels, and potentially conductances from many other sources, especially transient receptor potential (TRP) channels of which TRP vanilloid 1 (TRPV1) has been best characterized in visceral afferents. In most visceral afferent neurons it is not possible to record directly the generator potential, due to the small dimensions of the mechanosensitive endings in peripheral tissues.

Mechanoreceptors at different layers of the gut wall are specialized to encode different aspects of physical stimuli imposed on the gut tissue. It is likely that different transduction mechanisms may be employed by different mechanoreceptors. For visceral mechanoreceptors, there are two major mechanisms which could underlie the generator potential evoked by local distortion of nerve endings. The first is 'indirect,' or 'chemical,' transduction in which another cell type, probably nonneuronal, is activated by the stimulus and which then releases a transmitter or

mediator onto the sensory axon, causing it to fire. Examples of such mechanisms may include Merkel receptors in the skin, hair cells in the inner ear, and glomus cells for some chemosensitive visceral afferents. In contrast, 'direct' transduction occurs when the nerve ending itself contains all of the essential elements required to convert the stimulus into depolarization and firing.

Indirect Mechanotransduction

The transduction in mucosal mechanoreceptors seems to be better explained by an indirect mechanism involving release of mediators than by a direct mechanism involving mechanosensitive ion channels on nerve endings. Mucosal mechanoreceptors do not readily respond to distension (unless there is deformation of the mucosa as a result of over distension) but yet are very sensitive to light stroking of the mucosa, suggesting the transduction site might be on the luminal border of the epithelial.

Thus the transduction process does not occur at the level of the sensory nerve ending itself, but rather in a specialized sense cell in close association with the afferent ending. In this case, the afferent neuron does not respond directly to a particular stimulus, but does so following the release of a mediator from another cell which functions as the sensory detector. This putative mechanism of mechanotransduction is attractive for GI afferents because of both the close association between afferents and other cell types (e.g., mast cells, ICCs, enteric neurons, epithelial cells, enterochromaffin cells) and the expression of a variety of transmitter receptors on the afferent terminals. In this respect particular attention has been paid to enteroendocrine cells in the mucosal epithelium. These cells have an apical tuft of microvilli exposed to the intestinal lumen; this tuft is proposed to be the site of sensory transduction, and in response to an appropriate stimulus, releases the contents of storage granules across the basolateral membrane to stimulate afferent terminals in close proximity within the lamina propria, via a paracrine mechanism. Much recent attention has focused on two such mediators, namely, ATP and 5-hydroxytryptamine (5-HT), which have been shown to play important roles in sensory signaling.

Mechanosensitive Release of Mediators

Mechanosensitive release of 5-HT from the gut wall was classically described by Bulbring in the 1950s. Since then there has been a wealth of literature describing a role for 5-HT in enteric reflex control. However, the role of 5-HT in mechanotransduction in vagal and spinal mechanoreceptors is more controversial, although data are accumulating indicating that under circumstances, such as inflammation, when EC cell hyperplasia occurs and 5-HT reuptake mechanisms are blunted, there is augmented sensitivity to 5-HT, which may impact on sensory signaling. 5-HT can act on a number of G-protein-coupled receptors as well as on the ligand-gated 5-HT_3 channel. Immunohistochemical evidence suggests that 5-HT_3 receptors are present on both dorsal root ganglion (DRG) and nodose ganglion cells that innervate the GI tract.

Burnstock has hypothesized that stretch stimuli in tubular organs may release ATP from epithelial cells and that this then activates sensory nerve terminals through interacting with purinergic receptors. ATP can act either on P2Y receptors, which are G-protein-coupled receptors, or on P2X receptors, which are ligand-gated ion channels. Immunohistochemical evidence exists for P2X receptors ($P2X_3$) on spinal afferents innervating the colon, and on vagal endings ($P2X_{2,3}$) innervating the esophagus and stomach. A role for ATP in sensory signal transduction has been best characterized for the bladder, where urethelial cells release ATP on distension; also, filling-induced bladder afferent discharge and micturition reflex can be blocked by P2 receptor antagonists or when the $P2X_3$ receptor is knocked out. Several lines of evidence also support the purinergic hypothesis for mechanotransduction in the GI tract: (1) mechanosensitive release of ATP from the gut wall has been demonstrated, (2) P2 receptors have been identified on nodose and DRG neurons, (3) exogenous ATP has been shown to activate extrinsic afferent endings, and (4) P2 receptor antagonists reduce pelvic afferent response to colorectal distension in the rat.

Direct Mechanotransduction

Direct mechanosensitivity arises because of the presence of mechanically sensitive ion channels in the nerve terminal membrane. Mechanical deformation of the nerve ending leads to the opening or closing of ion channels that allow charged molecules to pass in or out of the cell, which in turn leads to an alteration in the excitability of the nerve terminal. A variety of mechanosensitive ion channels have been identified, including a class of receptors exemplified by the epithelial amiloride-sensitive sodium channel (ENaC)/degenerin family. Recent data have implicated members of the acid-sensing ion channel (ASIC) family in the modulation of mechanosensory transduction. However, at present, the ion channels and receptors that underlie mechanosensitivity in the GI tract remain unknown.

Identifying the sites at which mechanotransduction occurs has provided some useful insights into afferent function. This has been achieved by locating transduction sites using focal mechanical stimuli (for example, fine probes or von Frey hairs) and marking them for subsequent visualization of the axonal structures associated with mechanosensory 'hotspots.' An extensive description of specialized sensory endings in the skin has been developed using this approach. In the gut, similar studies have been attempted, using anterograde labeling of sensory axons from the extrinsic nerve trunks in which they have been recorded, thus distinguishing their axons from the numerous axons of enteric, sympathetic, and parasympathetic neurons which would otherwise confound identification of sensory endings. Low-threshold vagal mechanoreceptors in the stomach and esophagus have been shown to have mechanotransduction sites corresponding to the IGLEs in myenteric ganglia. They are also exquisitely sensitive to localized distortion of the gut wall with light von Frey hairs. A similar type of ending has been shown to exist for low-threshold, slowly adapting pelvic afferents supplying the rectum. Interestingly, these types of endings are restricted to the rectum and very distal colon, where reflexes necessary for defecation are localized. IGLEs, therefore, represent a class of GI mechanosensory endings involved in transducing low-intensity information.

Transduction Mechanisms

The location of IGLEs in proximity to enteric neurons raises the possibility that they may be activated indirectly following release of chemicals into the synaptic neuropil within the myenteric plexus. To distinguish between 'indirect' and 'direct' mechanisms of transduction, the time course of transduction gives useful insight because 'indirect' mechanisms are likely to be relatively slow – a receptor cell has first to be activated, then must release a chemical mediator, which must then change the membrane potential of the sensory nerve ending to evoke firing. The transduction delays for vagal and rectal low-threshold mechanoreceptors have been measured by subtracting the conduction delay (from an identified transduction site) from the latency of the first action potential evoked by a mechanical stimulus with a sharp onset. For both vagal and rectal mechanoreceptors, the transduction delay required for IGLEs to convert mechanical deformation into an action potential was a few milliseconds. This is rather faster than might be expected for chemical transduction, unless this was mediated via very rapid release of the responsible mediator, which requires active exocytosis. Since exocytotic release of mediators is a calcium-dependent mechanism, the demonstrations that transduction is preserved in solutions with low extracellular calcium and elevated magnesium ion concentrations show that exocytotic release of mediators was not obligatory for mechanotransduction by either vagal or rectal IGLEs. Thus both types of mechanoreceptor probably express the stretch-activated ion channels in their endings and use 'direct' mechanisms of mechanotransduction, although the specific ion channels involved have not yet been identified.

Further support for direct mechanotransduction comes from pharmacological study of mechanosensitivity. A range of compounds known to block stretch-activated ion channels have been applied to both vagal IGLEs and rectal IGLEs. Thus, benzamil, a blocker of a variety of stretch-activated ion channels, reduces mechanosensitivity. Likewise, the TRP channel blocker SKF96,365 also reduces mechanosensitivity by both vagal and rectal mechanoreceptors. However, many such drugs show poor selectivity for stretch-activated ion channels and interpreting their effects is fraught with difficulty. For example, gadolinium ions (Gd^{3+}) have been widely used to block stretch-activated ion channels, although they are known to affect a variety of other ion channels, including voltage-activated sodium channels. While Gd^{3+} certainly reduces the excitability of rectal IGLEs to rectal distension, the effects are entirely accounted for by changes in muscle compliance. Indeed, responses to von Frey hairs, which distort transduction sites in a manner that is largely independent of muscle tone, were not affected by gadolinium.

Mechanonociception

Another major class of mechanoreceptors, which typically have higher activation thresholds, has been described as having endings associated with arterial branch points in the mesentery and serosa of the gut, and in similar locations for many other viscera, including spleen, pancreas, uterus, and ovaries. These mechanoreceptors are considered to be important in nociception but little is known about their mechanisms of transduction. They are well established to respond to a variety of chemical stimuli released during tissue damage (see later). In addition, they may also be activated by ATP, glutamate, and 5-HT; mediators possibly released under more physiological conditions. Despite this, there is little evidence that any of these mediators is essential for transduction, although they are all likely to be involved under pathophysiological conditions. It is well established that distension of the naive (uninflamed) gut causes pain in both humans and animals. The nature of the adequate stimulus for these mechanoreceptors is not well established: they are certainly activated by large distensions of the bowel, but

whether they detect intramural stress or strain is not currently clear. It is also possible that they detect changes in intestinal hemodynamics, responding perhaps to reductions in blood flow due to collapse of vessels when intramural tension exceeds vascular pressure. Such a mechanism may be mediated indirectly, perhaps by release of lipid mediators. Given that pain is such an important symptom of visceral disorders, the importance of these questions is hard to overrate.

Modulation of Visceral Afferent Excitability

In addition to transduction mechanisms, substantial modulation of the excitability of peripheral sensory endings is known to occur, especially in visceral afferents. Modulation is mediated by a wide variety of substances released from nearby and distant cells, including neurotransmitters, cytokines, and autacoids. While it is useful to distinguish transduction from modulation, it should be borne in mind that these mechanisms probably form a continuum. When afferents show spontaneous firing in the absence of a specific stimulus, local release of modulatory substances can directly cause an increase in firing frequency without activating transduction mechanisms.

Sensitization

There is an enormous range of chemical mediators that influence the sensitivity of visceral afferents. Such mediators are usually released under conditions of inflammation, injury, or ischemia from a plethora of cell types (e.g., platelets, leukocytes, lymphocytes, macrophages, mast cells, glia, fibroblasts, blood vessels, muscle cells, and neurons). Each of these specific cells (e.g., mast cells) may release several of these modulating agents, some of which may act directly on the sensory nerve terminal, while others may act indirectly, following release of other agents from other cells, in a series of cascades.

Electrophysiological, immunocytochemical, and molecular biological techniques have revealed the functional expression of receptors to various mediators on the cell bodies of visceral sensory neurons in the dorsal root or nodose ganglia or on their processes in the gut wall. These diverse mediators, which include amines, purines, prostanoids, protease, cytokines, etc., produce their effects on visceral afferent nerves by three distinct processes: (1) by direct activation, which ultimately involves the opening of ion channels present on the nerve terminals, (2) by sensitization, which may occur in the absence of a direct stimulation, but which usually results in afferent hyperexcitability to both chemical and mechanical modalities (this may arise following G-protein-coupled alterations in second-messenger systems, which often lead to phosphorylation of membrane receptors and ion channels that control excitability), and (3) by altering the phenotype of the afferent nerve (e.g., through alterations in the expression of mediators, channels, and receptors, or modulating the activity of these by changing the ligand-binding characteristics or coupling efficiency of other receptors). Neurotrophins, in particular nerve growth factor and glial-derived neurotrophic factor, influence different populations of visceral afferents and play an important role in adaptive responses to nerve injury and inflammation. Voltage-gated sodium channels are one example of a family of ion channels, some of which play an important role in regulating pain thresholds. Under these conditions the afferents are sensitized and this process is believed to be the underlying mechanism of the hypersensitivity observed in some clinical conditions.

Summary

In conclusion, visceral afferents make a number of distinctive, specialized endings in the periphery, each of which is probably tuned to a different afferent stimulus. The afferents have specific mechanisms for transduction of stimuli, but their excitability is also modulated by a wide variety of other chemical mediators released from a range of other cell types under physiological or pathophysiological conditions. While some of these mechanisms are reasonably understood, much remains to be determined about the key factors that control the excitability of visceral afferent nerve fibers.

Medulloblastoma

D Kombogiorgas and S Sgouros, Birmingham Children's Hospital, Birmingham, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The term medulloblastoma was first introduced by Bailey and Cushing in 1925. They used this term to describe a very cellular tumor apparently arising from the roof of the fourth ventricle and projecting into the center of the cerebellum and the cavity of the fourth ventricle. Terms such as neurocytoma, neuroblastoma, sarcoma, and spongioblastoma cerebelli had been used previously occasionally for this histological type. In 1973, Hart and Earle used the term primitive neuroectodermal tumor (PNET) to refer to supratentorial malignant small-cell tumors that were believed to arise from primitive embryonal cells. Ten years later, Rorke and Becker and Hinton suggested separately that all malignant small-cell tumors, including medulloblastoma, should be classified as PNETs and subdivided by location. They suggested the term medulloblastoma for the undifferentiated neuroepithelial round-cell tumors located in the cerebellum. Currently, based on World Health Organization (WHO) classification, the diagnosis of PNET is a generic term for cerebellar medulloblastomas and for neoplasms morphologically indistinguishable from medulloblastomas but located at other sites in the central nervous system (CNS).

Epidemiology

Brain and spinal cord tumors are the second most frequent type of cancer after leukemia in children under 15 years of age. Medulloblastoma is the most frequent brain tumor for both sexes combined after astrocytomas, and it constitutes approximately 20% of childhood cerebral tumors, with a reported male-to-female ratio of 1.5–2:1 and an incidence of two to six cases per million population per year in various countries. In children, medulloblastomas represent 33% of the tumors of the posterior cerebral fossa and 40% of the cerebellar tumors. Mean age at diagnosis is around 7 years of age with peaks at 3 and 7 years.

Histopathology

Classification and Grading

Embryonal (primitive) neuroepithelial neoplasms make up 4–5% of CNS neoplasms. Their features include:

- Predominance in children.
- A tendency to disseminate through cerebrospinal fluid (CSF) pathways.
- A dominant population of small undifferentiated cells.
- High mitotic indices and widespread apoptosis.
- A potential for divergent neuroepithelial differentiation.

Medulloblastoma is a poorly demarcated, pink-purple, soft, friable mass that arises in the cerebellar vermis, usually from the inferior medullary velum (see Figure 1). The tumor may extend through the fourth ventricle into the cerebral aqueduct or into the cisterna magna via the foramen of Magendie. It may invade the cerebellum, brain stem, or cerebellar peduncle. Involvement of the cerebellar hemispheres is uncommon in children, but is more frequent in adults. Brain stem infiltration occurs in 15–36% of patients. There may be foci of hemorrhage or necrosis, but cysts are unusual.

Histologically, childhood and adult medulloblastoma are identical, being highly cellular, malignant, invasive tumors corresponding to WHO malignancy grade IV. They consist of densely packed tumor cells with round to oval or carrot-shaped hyperchromatic nuclei with scanty cytoplasm, high mitotic and apoptotic rates, and usually neuroblastic rosettes in some areas. Microvascular proliferation is relatively uncommon (see Figure 2).

According to the 2002 WHO classification of tumors of the nervous system, the medulloblastoma (i.e., medulloblastoma (classic) (9470/3)) has four variants:

- Desmoplastic medulloblastoma (9471/3).
- Large-cell medulloblastoma (9474/3).
- Medullomyoblastoma (9472/3).
- Melanotic medulloblastoma (9470/3).

The most common variant is the desmoplastic medulloblastoma, which occurs particularly in older children and adults. It constitutes approximately 20% of adult and 10% of childhood medulloblastomas. It tends to be located within the cerebellar hemisphere and is often better demarcated and firmer than other variants, as a result of the greater connective tissue component. It is distinguished from classic medulloblastoma by the presence of an intercellular stromal network, consisting of reticulin and collagen that separates groups of typical medulloblastoma cells into islands. Nodular or desmoplastic medulloblastoma contains centers of dark cells surrounding pale islands, analogous to the germinal centers of a

Figure 1 Magnetic resonance (MR) scans of a 12-year-old girl who presented with a 4-week history of headaches, drowsiness and vomiting and was found to have medulloblastoma: (a) brain axial T1-weighted image without contrast; (b) brain axial T1-weighted image with contrast; (c) brain axial T2 weighted image; (d) brain sagittal T1-weighted image with contrast; (e) spinal sagittal T1-weighted image with contrast; (f) brain MRS spectrum. There is a midline tumor in the posterior fossa, arising from the cerebellar vermis and projecting into the fourth ventricle cavity, which it fills almost entirely (a–d). The tumor is enhanced with gadolinium contrast intravenous injection in (b) and (d). It is well circumscribed and is not causing significance edema in the surrounding brain (b, c). The third ventricle is dilated due to obstructive hydrocephalus caused by the tumor (d). In the spinal views, there is a faint film of enhancement on the pial surface of the spinal cord (e), which denotes the presence of metastatic disease. In the spectroscopy analysis (f), there is a high Cho peak and comparatively lower NAA peak, giving a low NAA:Cho ratio. Cho, choline; Cr, creatine; Cr2, creatine ethyl ester; I:, integral; Ins dd1, inositol; MRS, magnetic resonance spectroscopy; NAA, *N*-acetyl aspartate.

lymph node. It is associated with better prognosis than the classic histological subtype in children, but the converse is true in adults.

Differentiated medulloblastomas with neuroblastic features are distinguished by Homer Wright rosettes. These rosettes are formed by cells surrounding fibrillary structures and characteristically do not encircle blood vessels. The rosettes of neuroblastic medulloblastoma are glial fibrillary acidic protein (GFAP)-negative.

Large-cell medulloblastomas have been characterized recently as a highly malignant variant and represent approximately 4% of medulloblastomas. Commonly, there are findings of large areas of necrosis, high mitotic activity, and high apoptotic rate. They have high tendency for CSF dissemination

Figure 2 Histological slide of a classic medulloblastoma. There are densely packed tumor cells with round to oval-shaped hyperchromatic nuclei with scanty cytoplasm, some mitoses, and some neuroblastic rosettes. Heamatoxylin & Eosin stain, 200×. and also may give lymph node metastasis. A pleomorphic large-cell variant of medulloblastoma is also recognized and has a poor prognosis.

Medullomyoblastomas are rare embryonal tumors of the CNS, arise exclusively in the cerebellum and occur almost always in children younger than 10 years of age. Melanotic medulloblastomas are very rare variants of medulloblastoma with pigmented cells which contain melanin. They consist of anaplastic cells with slight neuronal differentiation, but without the fibrillary background of neuroblastomas, and epithelial islands pigmented with melanin. The latter participate in the spread through the subarachnoid space, but do not extend beyond the dura. Both focal melanin production and evidence of striated muscle differentiation can occur in medulloblastomas, creating the variants melanotic medulloblastoma and medullomyoblastoma.

Staging

Medulloblastoma has a strong propensity to metastasize within the subarachnoid space with microscopic deposits, gross nodules, or en plaque masses, due to the tendency of the tumor to penetrate the ependymal surface. Autopsy series have revealed that cerebrospinal spread occurs in up to 50% of patients. Extraneural metastasis occurs in approximately 5% of patients and most commonly involves the bone marrow.

Chang and colleagues developed an operative staging system based on the TNM (tumor, spread to lymph nodes, and metastasis)-staging designation for the patients with medulloblastoma in 1969 (see Table 1). Because there are no lymphatic channels in the brain, they omitted the class N in their staging system. This system has been in common use worldwide since its introduction.

In 1985, Laurent and colleagues reported a postoperative MAPS (metastasis, age, pathology, and surgery) classification system (see Table 2) to evaluate mainly the prognostic impact of the extent of a residual tumor after the initial definitive surgery as it is assessed by postoperative computerized tomography (CT) scan and to analyze these data in a prospective manner. However, it remains unclear why and how they selected the number 1.5 cm as cut-off for the tumor diameter in the residual tumor-staging classification.

To establish an accurate assessment of disease risk among children with medulloblastoma, Gilbertson and colleagues found that high-molecular-risk patients can be designated as those with high ErbB2 receptor expression ($\geq 50\%$ ErbB2 positive tumor cells) and/or isolated 17p loss, whereas low-molecular-risk patients can be designated as those whose tumors demonstrated neither aberration. They observed no significant relationship between patient age and any molecular abnormality.

Molecular Genetics

Genetic aberrations are believed to contribute to the pathogenesis of medulloblastomas. Approximately 10% of the medulloblastomas carry double minute chromosomes as a cytogenetic sign of amplification of the *C-myc* or *N-myc* genes. Loss of chromosome 17p is the most frequent finding in medulloblastomas (present in up to 50% of the cases), in many tumors related to the occurrence of an isochromosome 17q, suggesting the presence of one or more medulloblastoma-related tumor-suppressor genes on chromosome arm 17p. Interestingly, chromosome 17 alterations are mostly present in medulloblastomas of the classic (nonnodular) type, but are absent in most nodular/desmoplastic-type medulloblastomas. In the latter type, loss of chromosome 9q and inactivation of the Patched (Ptch) tumor-suppressor gene have been described, leading to the hypothesis that there are two distinct entities of medulloblastomas. Other chromosomal aberrations include loss of l0q (in 35% of patients).

Familial adenomatous polyposis (FAP) syndrome arises from mutations in the APC (5q) gene and is associated with medulloblastoma formation. Also, Rubinstein–Taybi syndrome, a condition characterized by short stature, beaked nose, malformed ears, angulated thumbs and toes, mental retardation, and undescended testicles, has also been found to be associated with medulloblastoma. Many of those patients have a

Table 1 Chang classification of medulloblastoma

	Description
T stage	
T1	Tumor <3 cm in diameter and limited to the classic midline position in the vermis, the roof of the fourth ventricle, and less frequently to the cerebellar hemispheres
T2	Tumor >3 cm in diameter, invading one adjacent structure or partially filling the fourth ventricle
T3a	Tumor further invading two adjacent structures or completely filling the fourth ventricle with extension into the aqueduct of Sylvius, foramen of Magendie, or foramen of Luschka, thus producing prominent internal hydrocephalus
T3b	Tumor arising from the floor of the fourth ventricle and filling the fourth ventricle
T4	Tumor further spreading through the aqueduct of Sylvius to involve the third ventricle or midbrain, or tumor extending to the upper cervical cord
M stage	
M0	No evidence of gross subarachnoid or hematogenous metastasis
M1	Microscopic tumor cells found in cerebrospinal fluid
M2	Gross nodular seedings demonstrated in the cerebellar, cerebral subarachnoid space, or in the third or lateral ventricles
M3	Gross nodular seedings in the spinal subarachnoid space
M4	Extraneuroaxonal metastasis

Table 2 MAPS classification of medulloblastoma

	Description
Metastasis	
M0	No evidence of metastasis
M1	Cells present in leptomeninges or cerebrospinal fluid
M2	Nodular seeding demonstrated in supratentorial compartment (enhanced CT scan)
M3	Nodular seeding of spinal compartment (myelogram)
M4	Combined nodular seeding of two compartments (supratentorial and/or infratentorial and/or spinal)
M5	Evidence of systemic seeding (bone marrow, various bone, and viscera organs)
Age	
A1	>3 years
A2	<3 years
Pathology	
P1	Microscopic appearance: benign, classic for tumor type, well-differentiated single cell line
P2	Microscopic appearance: anaplastic, malignant, multiple differentiated cell lines
Surgery[a]	
S0	No tumor
S1	Remaining tumor < 1.5 cm (largest diameter)
S2	Remaining tumor > 1.5 cm (largest diameter)
S3	Remaining tumor (any size) invading brain stem structures (medulla oblongata, pons, midbrain, diencephalon)
S4	Remaining tumor (any size) extending into more than one central nervous system compartment (supratentorial, infratentorial, spinal compartments)

[a]Postoperative residual tumor confirmed by enhanced CT scan of the brain.
CT, computerized tomography; MAPS, metastasis, age, pathology, and surgery.

genetic mutation which has been mapped to chromosome 16p13.3, a genomic region encoding cyclic adenosine monophosphate (cAMP) response element binding protein (CREB) binding protein (CBP).

Ptch is the human homolog of *Drosophila* patched and is a transmembrane receptor for the secreted ligand Sonic Hedgehog (Shh) signaling pathway. The Shh signaling pathway is vital during development for the formation of many vertebrate organ systems, especially the CNS. The Ptch gene has been localized to chromosome 9q, and medulloblastomas are known to have loss of heterozygosity on chromosome 9q, especially medulloblastomas of the desmoplastic subtype. Germ line mutations of Ptch located on chromosome arm 9q causes Gorlin's syndrome (nevoid basal cell carcinoma syndrome). These patients are predisposed to develop basal cell carcinomas and desmoplastic medulloblastomas.

The Shh–Ptch signaling pathway is a major mitogenic regulator of external granular layer (EGL) progenitor cells. Purkinje neurons are the main producers the glycoprotein Shh during cerebellar development. Secreted Shh binds to the receptor Ptch, which is mainly expressed on EGL precursor cells and activates the pathway by relieving the inhibition of Smoothened (Smoh). This results in the activation of target genes,

such as Ptch itself and the Gli family of transcription factors. Signaling leads to translocation of Gli proteins (intracellular effector of Shh signaling) into the nucleus, where they induce the transcription of specific target genes. Medulloblastoma might arise from a deregulation of Shh–Ptch signaling in granule-cell precursors.

The overexpression of Bmi-l and Ptch has been found in a significant fraction of human medulloblastomas, suggesting an activation of the Shh pathway in these tumors. All tumors with low Ptch expression levels did not overexpress Bmi-1, suggesting that Bmi-l is a possible downstream effector of Shh signaling and that Bmi-l overexpression is an alternative or additive mechanism to Ptch mutation in medulloblastoma pathogenesis. The function of Bmi-l downstream of Shh provides a strong link with cell-cycle control. The perturbation of cell-cycle control leads to prolonged proliferation and delayed differentiation.

The Wingless pathway is another developmental pathway, which is involved in the growth of neural progenitors. Mutations of components of this pathway, including its central components β-catenin and Axin1/Axin2, have been identified in medulloblastomas, mostly in the classic subtype. These genetic events lead to a nuclear accumulation of β-catenin and increased expression of specific target genes in medulloblastomas.

Prognostic Factors

Prognosis of patients with medulloblastoma depends on several factors, such as the presence of metastases at diagnosis and the use of radiotherapy or chemotherapy, extent of residual tumor, gender, duration of symptoms, insertion of ventricular-peritoneal shunt within 30 days of the surgical resection of tumor, and genetic profile of the medulloblastoma (high ErbB2 receptor expression and isolated 17p loss). Also, an increase in 18 fluoro-2-deoxyglucose (18 FDG) uptake in the medulloblastoma during positron emission tomography (PET) is a significant negative survival prognostic factor.

Leptomeningeal metastases are usual in children with medulloblastoma and have been reported to be as high as 46% but usually range between 10% and 35%. However, spinal intramedullary metastasis at diagnosis is very rare. Metastatic medulloblastomas have metabolite profiles indicative of increased cell growth and decreased cell death compared with localized tumors, reflecting intrinsic differences in underlying biology. Localized tumors with a magnetic resonance spectroscopy (MRS) metabolite profile similar to those with metastatic disease may be at increased risk of metastatic relapse. Approximately 5% of patients with medulloblastoma may be expected to develop systemic metastases, and the average survival of those patients is approximately 7 months after the appearance of systemic metastases.

Currently, children more than 3 years of age are divided into standard- and high-risk groups. The standard-risk group includes patients with nonmetastatic disease and less than a 1.5-cm^2 residual tumor, based on immediate postoperative gadolinium-enhanced magnetic resonance imaging (MRI) scan of the head and the spine and a negative cytology obtained from a lumbar puncture approximately 10 days after surgical resection of the tumor. The high-risk group includes patients with metastatic disease or those with more than a 1.5-cm^2 residual tumor on immediate postoperative CT or MRI scan, although recent studies (e.g., PNET IV) do not use residual disease as a high-risk feature because some studies have shown this not of prognostic value. Brain stem invasion, which was previously thought to be a high-risk feature, is no longer considered to be so. Gajjar an colleagues reported that there was no difference in progression-free survival (PFS) for patients who underwent gross total resection compared to those with any detectable residual tumor.

Patients with medulloblastoma are at a 5.4-fold excess risk for secondary cancers, including astrocytomas, oligodendrogliomas, salivary gland tumors, cervical and uterine cancer, thyroid tumors, and acute lymphoblastic leukemia, but it is difficult at times to determine the relative impact of radiation versus a possible underlying genetic proclivity to malignancy because most medulloblastoma patients receive cranio-spinal radiation.

Clinical Presentation

Usually, children with medulloblastoma present with the classic triad of symptoms of morning headache, vomiting, and lethargy, which are caused by a posterior fossa mass or associated hydrocephalus. Infants exhibit the classic triad of symptoms less often because of unfused sutures and corresponding compensation for elevated intracranial pressure. Common symptoms in infants include macrocephaly, a full anterior fontanelle, irritability, poor feeding, intermittent vomiting, and the sun-setting sign. Although papilloedema is very common in older children, it is rare in infants. Cerebellar signs include truncal, gait or limb ataxia, or/and dysmetria. Brain stem invasion by the medulloblastoma causes bulbar or facial nerve palsies. Sixth-nerve palsy is usually a result of hydrocephalus. Torticollis may be due to impacted cerebellar tonsils into the foramen magnum. Subsequently, the children tend to maintain a fixed posture, with the head tilted

and partially externally rotated to one side. Passive flexion of the patient forward is actively resisted and results in severe pain. A short duration of symptoms correlates with a higher stage of disease. Symptoms usually last from a few weeks to up to 3 months, although patients presenting with symptoms for 1 year have been reported. Other symptoms include sleepiness, reduced appetite, weight loss, blurred vision, and change in personality.

The most common neurological signs at the time of presentation include ataxia/ataxic gait, nystagmus, cranial nerve palsies, papilloedema, increased head circumference, torticollis, limitation of upward gaze, and reduced visual acquity.

Radiology

Medulloblastomas are usually seen in the midline arising from the anterior portion of the vermis and then growing into the inferior or superior velum of the fourth ventricle. Obstructive hydrocephalus is common and is caused either by filling of the fourth ventricle by the tumor or by compression or sharp angulation of the cerebral aqueduct (see Figure 1). Medulloblastomas have a 10–21% incidence of calcification. Cystic change occurs in 10–20% of children and 59–82% of adults. Hemorrhage within pediatric medulloblastomas is relatively uncommon.

On nonenhanced CT, medulloblastomas appear as homogeneous hyperdense well-circumscribed masses in the midline, associated with the vermis. Increased attenuation on unenhanced scans is felt to correlate with the high degree of cellularity, scanty cytoplasm, and desmoplasia present in these tumors. The homogeneity of density and hyperdensity on a CT scan are the best findings that suggest medulloblastoma over ependymoma.

MRI is the investigation of choice. Sagittal MR images are optimal for visualizing the origin of the medulloblastoma from the vermis. Medulloblastoma is usually hypointense on T-1-weighted and isointense on T-2-weighted images. It is typically very well defined, distorts the fourth ventricle, and does not demonstrate a large amount of associated edema. A spinal MR scan is required preoperatively to assess the presence of spinal metastases (see Figure 1).

The spectroscopic signature of a PNET can distinguish it from other posterior fossa masses in children. PNET tumors show low *N*-acetylaspartate : choline (NAA:Cho) ratio and creatine/ phosphocreatine : Cho-containing compounds (Cr:Cho) ratios compared with low-grade astrocytomas and ependymomas, which have higher NAA:Cho ratios. The Cr:Cho ratio is highest for ependymomas compared to astrocytomas and PNETs. Lactate is usually not present in PNETs, but it is often seen in pilocytic astocytomas and ependymomas (see Figure 1).

Figure 3 Postoperative brain T-1-weighted magnetic resonance (MR) scan with contrast of the patient in Figure 1, obtained 24 h postsurgery. Total surgical excision of the tumor has been achieved.

A routine postoperative cranial MRI is obtained during the immediate postoperative period (see Figure 3). Most chemotherapy protocols require imaging within the first 72 h. Early enhancement has been shown to be associated with residual tumor, which lacks a blood–brain barrier. Imaging of the patients after the third postoperative day may be misleading because dural and operative bed enhancement may simulate a residual tumor or subarachnoid and leptomingeal metastatic disease. Also, the use of hemostatic agents at the tumor bed can be misinterpreted as a residual tumor on early postoperative CT scans.

Metaiodobenzylguanidine (MIBG) is a physiological analog of norepinephrine used in scintigraphy. The 1^{23} I-MIBG single photon emission computerized tomography (SPECT) technique has been reported in the literature as a innovative approach in the diagnosis of medulloblastoma, providing valuable information about the differential diagnosis of medulloblastoma from other posterior fossa tumors and an assessment of the effects of treatment. Another radiological method for the evaluation of patients with medulloblastoma is the 18 FDG PET. High-grade brain tumors accumulate 18 FDG more avidly than normal neurons, enabling their identification amid the background FDG uptake in the brain.

Currently, surveillance MRI of children with medulloblastoma is used routinely in daily clinical

practice to assess the results of treatment and to diagnose an asymptomatic relapse of the disease. The highest risk of relapse is in the first 2 years post-surgery. For this reason, in most protocols MR scans are obtained every 3 months the first year, every 6 months after the second year, and yearly thereafter.

Management

The treatment of patients with medulloblastoma includes maximum surgical resection, followed by adjuvant radiotherapy of whole neuroaxis in patients over the age of 3 years and chemotherapy.

Surgery

Surgical treatment plays an important role in the treatment of medulloblastoma because it establishes the diagnosis, restores the patency of CSF pathways, and reduces the volume of local disease totally or nearly totally in patients with brain stem invasion. It is preferred that a thin film of tumor be left on the brain stem, rather than attempting to excise it, to avoid iatrogenic devastating brain stem injury with bilateral abducent, bilateral facial, or lower cranial nerves palsies. In addition, brain stem invasion (Chang stage T3b), previously considered an indicator of high risk, is now thought not to affect prognosis.

Surgical treatment is usually required on a semi-urgent basis because most patients present with symptoms and signs of increased intracranial pressure. Preoperative administration of corticosteroids decreases the intracranial pressure and brain stem compression, allowing the surgical resection of the tumor to be performed within the next couple of days after admission. In cases of significantly high intracranial pressure in which children present with lethargy, bradycardia, or respiratory collapse, urgent diversion of the CSF is required by the insertion of an external ventricular drain or by endoscopic third ventriculostomy. Permanent treatment of hydrocephalus by the insertion of a ventriculo-peritoneal shunt or by an endoscopic third ventriculostomy is required in 25% of patients under 3 years of age and in 10% of those over 3 years.

Surgical excision of the tumor is performed through a straight midline sagittal suboccipital incision with the patient in prone position and the head flexed. After dissection of the nuchal ligament, the excision of a portion of occipital bone and posterior arch of atlas is performed, followed by the opening of the dura in a Y fashion. The tumor is dissected from the normal cerebellum and removed piecemeal by using the cavitron ultrasonic aspirator (CUSA). It is fundamental for the surgeon to visualize the floor of the fourth ventricle and isolate it from the tumor with a patty, aiming to obtain a dissection plane between the tumor and the brain stem and avoid its injury. It is well documented that patients with total or near-total excision ($<1.5\,cm^2$ of residual tumor in its largest part) on the immediate postoperative MR scan have a better prognosis. In the case of a larger residuum, reoperation is commonly performed, aiming for total or near-total excision. Nowadays, the mortality from surgical resection of medulloblastoma is in the range 1–5%, depending on the preoperative clinical state of the patient.

Most common postoperative complications include hematoma, infection/meningitis, aseptic meningitis, hydrocephalus, pseudomeningocele, CSF leak, cerebellar mutism, cranial nerve palsy, and hemiparesis. Mutism is generally defined as complete absence of speech in a conscious patient, with intact comprehension and no evidence of oral apraxia. The essential anatomical substrate of mutism is probably extensive lesion of the vermian and/or paravermian cerebellar region, as well as the hemispheric cortex, cerebellar peduncles, fibers from the dentate-thalamo-cortical pathway, and part of deep nuclei due to postoperative arterial spasm or retraction injury and edema.

Radiotherapy

Medulloblastoma was a lethal disease for all patients in the pre-radiotherapy era. After the introduction of radiotherapy of cranio-spinal axis, the survival improved to up to 54%. For standard-risk patients, the conventional doses of radiotherapy are around 36 Gy to the cranio-spinal axis, together with a boost of 18–20 Gy to the posterior fossa. Usually, the posterior fossa irradiation of 54–56 Gy is delivered in 30 daily fractions, and the rest of cranio-spinal axis irradiation of 20 Gy is delivered in 20 daily fractions. The 5-year survival of patients receiving such doses has been reported to be between 55 and 70%.

Although radiation is a highly effective therapy for medulloblastoma, it causes severe damage to the developing brain, especially in children younger than 3 years of age. Radionecrosis, mineralizing microangiopathy and calcification of brain, hypopituitarism (growth hormone, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) deficiency), gonadal dysfunction in girls, hypothyroidism, cataract, ototoxicity, reduced perceptual motor-task performance and motor dexterity, and secondary malignancies are well documented long-term complications of radiotherapy for pediatric brain tumors. To reduce the irradiation toxicity to the CNS, hyperfractionated (two daily fractions of) irradiation of cranio-spinal axis has been used in clinical trials (HIT-PNET 4) for the same dose of

radiation as used in conventional radiotherapy. Nowadays, most centers do not administer radiotherapy in patients younger than 3 years of age.

Chemotherapy

In recent years, the combination of surgery with radiotherapy and chemotherapy has improved the prognosis of children with medulloblastoma up to 83%. In the 1980s, the debilitating cognitive and endocrinological sequelae of cranio-spinal radiotherapy coupled with the poor survival for children with residual tumor following surgery led to successive randomized clinical trials by the International Society of Paediatric Oncology (SIOP), Children's Cancer Group (CCG 942), and Pediatric Oncology Group (POG 7909), which introduced chemotherapy to improve survival and reduce radiation dosage. The extent of tumor spread at diagnosis has been always the most robust predictor of outcome. Subsequently, for the patients whose preoperative MR scans do not reveal any metastatic disease, diagnostic lumbar puncture and cytological examination of the CSF are performed to establish the presence of microscopic dissemination of medulloblastoma cells in the CSF. However, the impact of only microscopic tumor cells in lumbar CSF on survival remains debatable. In both CCG 921 and the German trial HIT'91, overall survival was not significantly different in children who were categorized as having no metastasis or microscopic metastasis. Children younger than 3 years are always considered to be at high risk because of their well-established higher rates of recurrence. Chemotherapy in those children is a temporizing agent, allowing their brain time to develop and receive radiotherapy after the age of 3 years. The most commonly used drugs in various chemotherapy schemes include ifosamide, etoposide, methotraxate, cisplatin, vincristine, carboplatine, lomustine, and cyclophosphamide.

Conclusion

With modern multimodality treatment, the outcome of patients with medulloblastoma has improved dramatically. For standard-risk patients (older than 3 years of age, no metastasis, less than 1.5 cm^2 of residual disease), the 5-year progression-free survival varies between 60 and 94% in various clinical series. For high-risk patients (younger than 3 years of age, metastatic disease, more than 1.5 cm^2 of residual disease), the 5-year progression-free survival varies between 43 and 84%. Despite the improvement in survival rate, medulloblastoma remains a challenging disease because those who survive have significant cognitive and physical impairments secondary to both the disease and its treatment. Further understanding of medulloblastoma biology will ultimately lead to the improvement of current therapies and the development of new ones.

Melanocortins: Brain Effects

M Merkestein, W H Gispen, and R A H Adan, University Medical Center Utrecht, Utrecht, The Netherlands

© 2009 Elsevier Ltd. All rights reserved.

The melanocortins (MCs) are a group of proopiomelanocortin (POMC)-derived peptides, sharing a core amino acid motif. The main sites of POMC expression are the arcuate nucleus and the nucleus of the solitary tract (NTS) in the brain, and the anterior lobe of the pituitary gland. Lower amounts of POMC are expressed in peripheral tissues such as skin and certain immune cells.

POMC is cleaved by prohormone convertase 1 (PC1) and 2 (PC2) into the melanocortins, which include α-, β-, and γ-melanocyte-stimulating hormone (MSH) and adrenocorticotropin (ACTH). POMC contains the sequences of the nonMC peptides β-endorphin and lipotropic hormone as well. The MCs share the same signature core amino acid sequence His-Phe-Arg-Trp. This sequence is required for binding to one of the five MC receptor subtypes (MC1–MC5).

MC receptors are seven-transmembrane G-protein-coupled receptors which are positively coupled to adenylate cyclase and, hence, enhance cyclic adenosine monophosphate (cAMP) and protein kinase A signaling. The MC1 receptor MSH receptor, which is mainly expressed on skin melanocytes, plays an important role in the regulation of pigmentation and binds to α- and β-MSH and ACTH. The MC2 receptor (ACTH) receptor, which is expressed in the adrenal gland, binds exclusively to ACTH and controls corticosteroidgenesis in the adrenal cortex. The MC3 and MC4 receptors are the main brain MC receptors, although the MC1 and MC5 receptors have also been found in the brain but at lower expression levels. The MC3 receptor binds to all MCs, including γ-MSH, whereas the MC4 and MC5 receptors bind to all MCs except γ-MSH. MC5 receptor is specifically expressed in the exocrine glands and regulates the synthesis and secretion of exocrine gland products.

This article focuses on the effects of MCs and on the physiological roles of the brain MC system. In addition to the well-known roles of the MC system in the regulation of energy balance, we review its role in fever, the immune system, nerve regeneration, nociception, reward, grooming behavior, stress and anxiety, sexual behavior, and blood pressure and heart rate (Figure 1).

The Brain Melanocortin System

Fifty years ago, the first direct effects of MCs on the brain were described. Central injections of ACTH were shown to affect avoidance and grooming behavior in rats. In the late 1970s, the presence of immunoreactive neurons to MC antibodies was demonstrated, which was a strong indication that the MC system plays a role in the brain. Another indication of the brain MC system was the cloning of the POMC gene and its expression in the arcuate nucleus. Because of difficulties in labeling MCs, it took until the late 1980s before binding sites of MCs could be detected in the brain. The binding of MCs was shown to be restricted to specific areas of the brain. Only slightly later, MC receptors were cloned, and the MC3 and MC4 receptors were shown to be expressed in the brain. The availability of clones of MC receptors accelerated the identification of MC receptor antagonists such as SHU9119, which antagonizes the MC3 and MC4 receptors. This pharmacological tool was very helpful in establishing which effects of MCs were mediated via brain MC receptors.

A unique feature of the MC system is that there are, in addition to endogenous agonists (the MCs), endogenous inverse agonists. An inverse agonist is a ligand that binds to the same receptor-binding site as an agonist and not only antagonizes the effects of an agonist but, moreover, exerts the opposite effect by suppressing spontaneous receptor signaling (when present). A spontaneous gain of function mutation in mice in the agouti locus led to the identification of endogenous inverse agonists for the MC system. This mutation resulted in a yellow fur due to overexpression of agouti protein, which acts as an inverse agonist at the MC1 receptor. Based on its homology to agouti, agouti-related protein (AgRP) was cloned and demonstrated to be expressed in the arcuate nucleus in neurons which are situated close to POMC neurons and project to similar brain areas. AgRP was shown to act as an inverse agonist at the MC3 and MC4 receptors.

Regulation of Energy Balance

The effect of MCs on energy balance was discovered in the mid-1980s, when Bertolini and coworkers and, later, Tsuii and Bray reported that a central injection of MCs reduces ingestive behavior. This was just one of the many effects of MCs reported in that period. In the mid-1990s, the importance of its role in energy balance was underlined by the discovery that the

Figure 1 Overview of the effects of melanocortins in the central nervous system (CNS). The brain melanocortin system affects multiple systems: energy balance, behavior, autonomic system function, and host defense. Dotted arrows indicate a stimulatory effect of the melanocortin system; dashed arrows indicate an inhibitory effect of the melanocortin system.

central MC system acts downstream of leptin, an adipose tissue-derived hormone, released in proportion to body fat content. Physiological levels of leptin result in an increase in energy expenditure and a decrease in energy intake which involves POMC neurons, whereas orexigenic AgRP/neuropeptide Y (NPY) neurons are inhibited. This effect of leptin can be blocked by the administration of the MC receptor antagonist SHU9119. In addition to increasing the firing rate of POMC neurons, leptin also rapidly increases N-acetylation of MSH, which makes MSH more powerful in inhibiting feeding behavior.

Another indication for the role of the MC system in the brain was the observation that mice without the MC4 receptor or the POMC gene have an obese phenotype. Interestingly, humans with mutations in either the POMC or MC4 receptor gene are also susceptible to develop obesity, and nowadays MC4 receptor mutations are the most frequent cause of monogenic obesity in populations of morbidly obese children. Hence, the MC system is also essential for the regulation of energy balance in humans.

The MC system plays a physiological role in the regulation of energy balance. In a state of negative energy balance (e.g., in starvation), leptin levels drop, which results in increased mRNA levels of AgRP in the arcuate nucleus. In a state of positive energy balance (e.g., in overfed rats), POMC mRNA levels are increased, which indicates that the MC system is physiologically involved in counteracting a positive energy balance. The observations that animals with deficits in MC signaling, such as POMC or MC4 receptor knockouts, and rodents chronically infused with MC receptor antagonists develop obesity emphasize this role of the MC system. On the other hand, the administration of a MC agonist, hence activating the MC system, leads to a temporary decrease in food intake and a sustained decrease in body weight.

The MC system affects energy balance not only via the regulation of food intake but also via the regulation of energy expenditure. Rats treated with SHU9119, but pair-fed to controls, show a small increase in body weight which cannot be due to an increase in energy intake. The increase in body weight might be due to the observed decrease in locomotor activity and body temperature in these rats. Furthermore, the inhibition of the MC system suppresses uncoupling protein (UCP) 1 expression in brown adipose tissue, thus inhibiting the conversion of energy into heat production. In addition, analysis of MC4 receptor knockout mice revealed a defect in diet-induced thermogenesis. In contrast to MC4 receptor knockouts, MC3 receptor knockout mice have a normal body weight but an increased body fat percentage. There is an additive effect on body weight in MC3–MC4 receptor double knockouts, indicating that MC3 and MC4 receptors, which are expressed in partially overlapping brain circuits, have different roles in the regulation of energy balance.

Analysis of meal patterns revealed that MCs affect meal termination rather than meal initiation. MC receptor agonists reduce meal size but have no effect

on meal frequency, whereas SHU9119 increases meal size without influencing meal frequency. Furthermore, Benoit and colleagues demonstrated that MC receptor agonists are less potent in suppressing food intake when rats are trained to eat, that is, when they expect a meal or when they have learned to eat large amounts of food in a short time period. MC 4 receptors in the dorsal vagal complex in the brain stem, the brain area which is implicated in the termination of meals (satiety), could well mediate these effects of MCs. Indeed, the application of MCs in the fourth ventricle, near the brain stem, is as potent as its administration into the lateral ventricle, near the hypothalamus. This emphasizes the role of the brain stem in mediating the effect of MCs on food intake. Recently it was demonstrated that MCs increase the sensitivity for the satiety hormone cholecystokinin (CCK) at the level of the dorsal vagal complex. However, the brain stem is certainly not the only brain area where activation of MC receptors inhibits food intake. Local injection of MCs in several brain areas showed that low doses of MCs in the paraventricular (PVN) and dorsomedial (DMH) hypothalamus and the medial preoptic area inhibit food intake as well.

Brain areas which contain and integrate information on taste and palatability, such as the amygdala, NTS, and parabrachial nucleus, also express MC receptors. This provides an anatomical basis for an effect of MCs on food choice. Indeed, MC receptor agonists specifically reduce the intake of fat, but not of protein or carbohydrates, on a three-choice macronutrient diet, whereas the inverse agonist AgRP selectively increases the intake of high-fat diets in rats. Furthermore, mice with mutations in the MC system display an increase in energy intake when fed high-fat foods.

By using a gene therapy approach, it was demonstrated that the overexpression of the MC receptor inverse agonist agouti in different hypothalamic regions results in the development of different obese phenotypes. The overexpression of agouti in the PVN results in hyperphagia and obesity, in the DMH in a late-onset obesity syndrome, and in the lateral hypothalamus in obesity and exaggerated food efficiency but only when the rats are fed a high-fat diet. The exact mechanisms underlying these effects are largely unknown, but may find their origin in the interactions of MC receptors in the different brain regions with downstream effector pathways. In the PVN, the downstream effector pathway probably includes neurons that express corticotropin-releasing hormone (CRH) and thyrotropin-releasing hormone (TRH), which regulate neuroendocrine and autonomic pathways. The effects on energy balance could be similar to adaptations in these systems in response to stress, fasting, physical activity, and cold exposure. Within the DMH, signaling by MC receptors probably involves more chronic changes in energy balance, such as those required for lactation or perhaps chronic food restriction, and probably includes the activation of the orexigenic NPY-containing neuronal cell bodies. Within the lateral hypothalamus, downstream effector pathways activated by MC receptor signaling probably involve brain areas which play a role in motivation. Infusion of the MC receptor antagonist SHU9119 enhances the expression of melanin-concentrating hormone (MCH). Lateral hypothalamic neuronal cell bodies which express MCH project to a wide variety of areas, including the nucleus accumbens (Nac), a forebrain region involved in reward. MCH induces feeding behavior when injected into the Nac. As mentioned earlier, brain areas involved in taste and palatibility specifically increase the intake of fat.

Finally, it has been suggested that the effects of AgRP on food intake, particularly the long-term effects, are dependent on opioid receptor functioning and may involve forebrain regions such as the Nac as well. Whether these effects are specific for AgRP or the effects are just due to changes in MC receptor activity in general is not evident yet.

Eating Disorders

MCs are proposed to play a role in disorders of negative energy balance, such as anorexia nervosa. Indeed, the Ala67Thre AgRP single-nucleotide polymorphism, which reduces the inverse agonism activity of AgRP, occurs more frequently in patients with anorexia nervosa than in controls. Using an animal model for anorexia, the activity-based anorexia model (in which rats have a running wheel in their cage and restricted access to food), Hillebrand and colleagues demonstrated that, despite the reduction in body weight due to food restriction, POMC expression increased in the first days, suggesting increased activity of melanocortinergic neurons. Furthermore, after 1-week exposure to this model, an increased density of MC receptors in the ventromedial hypothalamus was observed. Taken together, these rats are more sensitive to weight loss because of an increased level of POMC, the MC precursor, and more MC receptors; hence, they are more sensitive for the anorectic effects of MCs. However, an enhanced endogenous AgRP expression in the arcuate nucleus was observed as well, which makes it difficult to assess what the net total result on the MC receptors is. In the activity-based anorexia model, additional central administration of AgRP decreased energy expenditure and increased food intake in these rats, which improved their condition, suggesting that increased melanocortinergic tone contributes to anorectic behavior in the

anorexia model. On the other hand, central administration of α-MSH on exposure to the model worsened their condition and accelerated the development of anorexia, in addition to increasing the activity of the hypothalamic–pituitary–adrenal (HPA) axis. Interestingly, in anorexia nervosa patients, the activity of this axis is increased as well.

Regulation of Body Temperature and Fever

The thermoregulatory actions of MCs are dependent on the physiological state. Under normal conditions, MCs modestly increase body temperature, which is probably part of the repertoire of effects by which the MC system controls energy balance. Because MCs, in particular, increase body temperature in the dark phase, when also locomotor activity is increased by MCs, at least part of this thermogenic effect is caused by increased locomotion. However, because MCs also stimulate thermogenesis by stimulating heat production in brown adipose tissue (via the stimulation of UCP-1 expression), other mechanisms contribute to the thermogenic effect of MCs.

In febrile rats, MCs decrease body temperature. Central administration of MCs inhibits a lipopolysaccharide (bacterial endotoxin)-induced febrile response, whereas central administration of SHU9119 increases this febrile response. This effect on the febrile response is mediated via the MC4 receptors in the brain because it can blocked with an MC4 receptor-selective antagonist. Increased levels of endogenous MCs in the septal region are reported during fever in rabbits, suggesting that the endogenous MC system is implicated in the febrile response. In addition, injection of MCs into the septal and preoptic regions in rabbits prevents fever. Moreover, these regions express MC4 receptors and contain thermosensitive neurons, which all suggests that these regions play a role in the effect of MCs on fever.

Regulation of the Inflammatory Response

MCs are potent modulators of inflammation. Central application of MCs inhibits inflammatory responses induced by the injection of interleukin β into the ear or hind paw of rodents, which seem to require an intact sympathetic nervous system. However, peripheral administration of MCs also inhibits inflammatory responses.

MCs have been shown to exert anti-inflammatory responses via MC receptors expressed on blood cells, cells of the immune system, and a variety of other cells. The MC1 receptor has been demonstrated on monocytes, macrophages, neutrophils, mast cells, fibroblasts, and dendritic cells. In addition to the MC1 receptor, MC3 receptors expressed in macrophages and MC5 receptors expressed in lymphocytes have been implicated in the anti-inflammatory effects of MCs. MCs inhibit the release of inflammatory mediators, such as cytokines, even in cells *in vitro*. The cytokine release is affected by MCs via inhibition of activation of the nuclear factor (NF)-κB. NF-κB is a transcription factor that regulates many genes including, cytokines and chemokines, which might explain the broad effects of MCs on mediator production.

α-MSH(11–13), which does not bind to MC receptors, has also anti-inflammatory properties. This indicates that some of the effects of MCs are mediated via a mechanism other than the MC receptors.

Nerve Regeneration

Both systemic and local application of MCs enhances recovery after peripheral nerve injury, provided that the application occurs within days after the injury. The observed neurotrophic effects of MCs are improved nerve regeneration and muscle innervation. *In vitro* studies demonstrated that MCs promote the outgrowth of neurites in cell lines. These effects are also demonstrated *in vivo;* α-MSH stimulates spinal neurite outgrowth after a spinal cord injury. The exact mechanism via which MCs improve nerve regeneration is not known yet. α-MSH affects neurons, but glial cells can also be a target for the MCs.

Because γ-MSH, which activates only the MC3 receptor, does not stimulate nerve regeneration following a sciatic nerve crush lesion, the involvement of the MC3 receptor is ruled out. MT-II, a potent MC receptor agonist that activates MC1, -3, -4, and -5 stimulated nerve regeneration in this model. The MC3/4 receptor antagonist SHU9119 was also shown to stimulate nerve regeneration. SHU9119 is an agonist for the MC1 and MC5 receptors. The acceleration of functional recovery by MCs after peripheral nerve injury is most likely mediated via the MC5 receptor because ligands that were able to activate MC1, but not MC5, receptors were inactive in stimulating nerve regeneration.

Nociception

Both MCs and the opiate β-endorphin are derived form POMC. Opiates are well known for their analgesic effects. MCs also have an effect on the perception of pain, but, in contrast to opiates, MCs are believed to increase the sensitivity to painful stimuli, as demonstrated by the induction of hyperalgesia by the central administration of α-MSH in the tail flick test and the hot plate test in rats. Treatment with

SHU9119, as well as with selective MC4 receptor antagonists, decreases allodynia and nociception in a rat model for neuropathic pain. Also, in the mouse formalin test MC agonists increased nociception, whereas MC antagonists reduced nociception. Upon neuropathic pain, induced by chronic restriction of the sciatic nerve, MC receptor binding increases in areas in the spinal cord which are involved in the transmission of pain. The increased pain perception in this model is mediated by the MC4 receptor because a MC-3-specific agonist has no effect. A MC4-selective antagonist also decreases nociception in this model, further emphasizing the involvement of the MC4 receptor in pain processing. Furthermore, the MC4 is the only MC receptor present in the spinal cord, where the processing of pain takes place. The effects of MCs on nociception can be modulated by opiates. Low doses of the opiate antagonist naloxone inhibit the antinociceptive effect of SHU9119, and when administered together, the effects of the opiate agonist morphine and SHU9119 are additive in rats with neuropathic pain. This indicates that MC receptor antagonists are potential analgesic drugs, which reduce pain perception and increase the effect of morphine. However, they might not function in the long term because the effects on nociception are only transient in the neuropathic pain model. Therefore, it remains to be clarified whether MC receptor ligands are of any use in the treatment of chronic pain.

Interaction with Opiates and the Reward System

In addition to in the modulation of pain as already described, MCs and opiates antagonize one another in several other functions, including feeding behavior. Upon stimulation of POMC neurons and processing of POMC, α-MSH and β-endorphin are stored in the same vesicles and are consequently released at the same time. Because MC receptors couple positively to adenylate cyclase, whereas opiate receptors couple negatively to this pathway, the functional antagonism between these systems is likely to be regulated at this level.

Interestingly, *N*-acetyltransferase acetylates both α-MSH and β-endorphin, making the MC more stable and potent but decreasing the affinity of β-endorphin for opioid receptors. Hence, the regulation of *N*-acetyltransferase activity (e.g., by leptin) has an effect on the balance in efficacy of MCs and β-endorphin after secretion on the activation of POMC neurons. This regulation of efficacy takes also place at the receptor level. Chronic administration of morphine, an opioid, leads to the reduced expression of MC4 receptor mRNA in the nucleus accumbens and the periaquaductal gray, brain regions involved in reward and the reinforcing properties of drugs of abuse. Interestingly, both self-administration of opiates and analgesia caused by opiates can be antagonized by MCs.

Furthermore, MCs modulate the response to addictive drugs because the administration of MC receptor antagonists in the nucleus accumbens inhibits the primary and conditioned reinforcing effects of cocaine. In addition, the MC receptor agonist MTII increases the rewarding effect of amphetamine. These addictive drugs might also affect MC signaling. Chronic cocaine administration, for example, increases the expression of MC4 receptors in the nucleus accumbens, hippocampus, and striatum.

Grooming Behavior

Grooming behavior is displayed by rats as a novelty-induced stress response. It involves activities such as washing, scratching, and licking of the body surface. It is considered that this behavior serves to reduce arousal after stress.

This novelty-induced grooming can be inhibited with MC antagonists, MC antibodies, and antisense POMC nucleotides. MC antagonists are able to inhibit the physiological relevant grooming behavior induced by a novel environment. Intracerebroventricular administration of ACTH and α-MSH induces excessive grooming behavior and stimulates the HPA axis. This excessive grooming behavior seems to be mediated via the MC4 receptor because MC4 receptor-specific antagonists inhibited α-MSH-induced grooming. Furthermore, selective MC4 receptor agonists induce grooming behavior in proportion to their ability to activate the MC4 receptor.

Brain regions which are likely to be involved in the grooming response are the PVN, substantia nigra, and periaqueductal grey because they all express the MC4 receptor and local injections of ACTH in these areas induce excessive grooming behavior.

Anxiety and Stress

MCs have an influence on the stress response because the central administration of MCs stimulates the HPA axis. This could possibly be mediated via stimulation of MC4 receptors present on vasopressinergic/corticotropic neurons in the PVN because plasma levels of stress hormones such as ACTH and corticosterone increase after an injection of α-MSH into the PVN. The increase in plasma corticosterone levels is reduced by the selective MC4 receptor antagonist HS014, supporting the role of the MC4 receptor in the activation of the stress response by MCs. The involvement of the

MC system in the physiological response to stress is demonstrated by the downregulation of AgRP expression and upregulation of POMC and MC4 receptor expression in the arcuate nucleus after footshock stress.

MCs are also thought to have anxiogenic effects, mediated by the MC4 receptor. These anxiogenic effects are demonstrated in the elevated plus maze after an injection of α-MSH into the medial preoptic area and ventromedial nucleus, and in the Vogel test after the administration of α-MSH and MTII. Other supporting evidence for the anxiogenic action of MCs is the decrease in social contact and increased aggressive behavior in the social interaction test after administration of MCs. On the other hand, MC4 receptor antagonists have anxiolytic-like activity in the mouse light–dark exploration test. These anxiolytic-like effects of the MC4 receptor antagonists are clearer in stressful than in nonstressful conditions, which supports the role of the endogenous MC system in a normal stress response. Future research will determine whether MC4 receptor antagonists are potent anxiolytic drugs.

Sexual Behavior

Early studies described the effects of intracerebroventricularly administered ACTH and α-MSH in stimulating penile erections, ejaculation, sexual posturing, and genital licking in male rats but only in the presence of testosterone. In female rats, MCs stimulate lordosis behavior, and the medial preoptic area has been proposed as site of action. In addition, in humans, the superpotent MC agonist MTII induces penile erections and increases sexual desire. Peripheral as well as central MC receptors are considered to be involved in the effects of MCs on sexual behavior. MC5 receptors expressed on preputial glands may play a role in the stimulation of sexual behavior induced by peripheral administration of MCs because MCs stimulate the release of pheromones. However, central administration of MCs affects sexual behavior, in particular penile erection. Injection of MCs into the periventricular hypothalamus, which includes the PVN, stimulates penile erection in rats. Central administration of a MC4 receptor agonist improves sexual function, but has no effect in mice which lack the MC4 receptor. These MC4 receptor-null mice demonstrate a diminished copulatory behavior. Additional evidence for the role of the MC4 receptor in sexual behavior is that, in addition to the spinal cord and brain sites putatively involved in this MC effect, the human and rat penis also express MC4 receptors. However, the effect of MCs on lordosis in female rats could not be blocked by MC4 receptor antagonists. Furthermore, other studies found no effect of MC4 receptor blockage on copulatory behavior in male rats. The MC4 receptor is assumed to play the most important role in the central regulation of sexual behavior by MCs.

Regulation of Blood Pressure and Heart Rate

The effect of MCs on blood pressure and heart rate is rather complicated. Peripheral and central administration of γ-MSH affect heart rate and blood pressure depending on the physiological state. In conscious rats γ-MSH increases blood pressure and heart rate, but in anesthetized rats the opposite effects were observed. The peripheral administration of γ-MSH has a greater effect than its central administration, whereas α-MSH decreases heart rate and blood pressure only when administered centrally. The normal-pressure effect of γ-MSH is not mediated by MC receptors because the effect cannot be blocked with MC receptor antagonists and because even smaller fragments of γ-MSH, such as γ-MSH (6–12), which do not have any affinity for MC receptors, increase blood pressure and heart rate. γ-MSH shares some sequence homology with FMRF-amides, which show a similar effect on blood pressure and heart rate. Hence, the cardiovascular effects of γ-MSH could be mediated via an interaction of γ-MSH and FMRF-amide receptors. However, there is some evidence that a small part of the pressure effect of γ-MSH is mediated via MC3 receptors in renal nerves that are involved in the natriuretic effect of γ-MSH, counteracting salt-sensitive hypertension. Chronic treatment with intracerebroventricular MTII leads to a modestly increased blood pressure and heart rate, which is mediated via the adrenergic system, possibly reflecting effects of central MC receptor activation on sympathetic outflow.

Other MCs are able to affect blood pressure and heart rate via their central receptors. Injection of MCs into the NTS or dorsal motor nucleus of the vagus nerve results in bradycardia and a lower blood pressure, which is inhibited by the co-administration of SHU9119. This depressor effect of MCs is mediated via MC4 receptors, probably located in the NTS.

In summary, MC receptors expressed in the kidney and NTS appear to be involved in the effects mediated by MC receptors on blood pressure and heart rate. FMRF-amide receptors may mediate some of the effects of γ-MSH on increasing blood pressure, heart rate, and cerebral blood flow as well.

Overview

In this article, we briefly outline the mechanisms of melatonin regulation in vertebrates, review effects of endogenous and exogenous melatonin on circadian rhythms, and discuss studies to determine the melatonin receptor subtype(s) mediating circadian responses to the hormone.

Melatonin, a Neuroendocrine Signal of Darkness

Regulation of Pineal Melatonin Production by the Circadian Clock and Light

Melatonin (*N*-acetyl-5-methoxytryptamine) is produced in the pineal gland from serotonin in a two-step enzymatic process. The first step, mediated by arylalkylamine *N*-acetyltransferase (AANAT), is rate limiting in the production of melatonin. AANAT activity is regulated by the circadian system, such that melatonin synthesis is elevated at night in virtually all vertebrate species. In the apparent absence of any storage mechanism, melatonin simply diffuses from the pineal into the circulation and cerebrospinal fluid. AANAT activity is normally high at night, but light exposure during the normal dark period leads to an acute and rapid reduction in AANAT protein levels, cessation of melatonin synthesis, and a rapid decline in blood levels of the hormone. In rodents, a very large-amplitude rhythm in AANAT transcript levels drives rhythmic melatonin production, yet studies of the effects of light exposure at night reveal that there is a fascinating and major posttranscriptional component. In darkness, sympathetic input to the pineal promotes melatonin synthesis and also actively blocks proteosomal degradation of AANAT. With light exposure, proteosomal degradation is disinhibited, leading to very rapid (<10 min) destruction of AANAT despite continued elevation of transcript levels. In primate and ungulate species, the AANAT transcript rhythm is low amplitude, and regulation of proteosomal proteolysis is thought to play a more major role in rhythmic (as well as light-regulated) melatonin secretion than transcriptional regulation. The switch-like regulation of proteosomal proteolysis is achieved through phosphorylation-dependent binding of AANAT to 14-3-3 proteins.

The primary role of melatonin is to provide a biochemical measure of night. Both night-active (nocturnal) and day-active (diurnal) animals produce melatonin at night, so any direct effects of melatonin on behavior are species specific. Although sometimes called the 'hormone of darkness,' melatonin production is not stimulated by darkness, nor does it require the presence of a light–dark cycle to stimulate its 24 h rhythm. The circadian rhythm of melatonin is driven endogenously by the circadian system. Critical structures in this system include the retinae, which detect light and convey lighting information to the circadian clock in the suprachiasmatic nucleus (SCN) of the hypothalamus. From the SCN, a circuitous polysynaptic pathway projects via the spinal cord, entering the cranium as sympathetic postganglionic fibers which are the ultimate mediators of input from the circadian system to regulate melatonin production.

The duration of the nocturnal melatonin secretory episode is related to the duration of the night; therefore, melatonin provides information about changes in photoperiod (season). Changes in the duration of melatonin production result in seasonally appropriate 'photoperiodic responses' including regulation of body composition, thermoregulation, pelage (fur) density and coloration, in addition to reproduction. These photoperiodic responses, mediated by seasonal changes in the melatonin secretory profile, are detailed elsewhere in this encyclopedia.

Extrapineal Sources of Melatonin Production

The rhythms in melatonin levels detected in plasma arise from the pineal in vertebrates, but melatonin is produced (and may have effects) locally in other tissues. In particular, melatonin is also synthesized rhythmically in the retina and influences retinal physiology. In some nonmammalian vertebrates, particularly in avian species, ocular melatonin seeps into the bloodstream and influences circadian function. The gastrointestinal tract can also synthesize melatonin, and here the production of melatonin may be tied more to precursor availability than to circadian or photic regulation of AANAT. Melatonin produced in the gut is not thought to contribute substantially to circulating levels of the hormone in normal circumstances.

Melatonin and Circadian Organization in Nonmammalian Vertebrates

An endogenous circadian system allows an organism to anticipate environmental events, rather than simply reacting to them, so that physiology and behavior are appropriately timed to both internal

and external events. Conceptually, the circadian timing systems can be divided into input, oscillator, and output components. Input pathways relay information about external (and internal) conditions to the pacemaker. The pacemaker oscillates, usually at a period slightly different from 24 h, and the timing of its oscillation can be altered by appropriately timed input stimuli. The output pathways are overt neural and hormonal rhythms that regulate physiology and behavior.

There is a fundamental difference between the role of melatonin in circadian organization in mammalian and that in nonmammalian species. The mammalian circadian timing system is dominated by a strong central circadian pacemaker, located in the SCN of the anterior hypothalamus. The major input pathway is a direct, retinohypothalamic tract that conveys lighting information from the retina. Efferents from the SCN regulate circadian melatonin production and also mediate the acute effects of light to suppress melatonin production. Although the presence of melatonin receptors in the SCN of many species suggests that melatonin could serve as an input, melatonin is viewed largely as an output of the circadian timing system in mammals. The melatonin rhythm is a strongly circadian rhythm that can be measured, for example, in humans with relative ease to determine a subject's biological time (the phase of rhythmicity). In contrast, nonmammalian vertebrates have a more complex circadian organization in which circadian photoreception occurs directly in several tissues in addition to the retina; these directly photoreceptive tissues include the brain and the pineal gland. Rhythmicity in these tissues is important for maintenance of rhythmicity in hypothalamic structures that appear functionally equivalent to the SCN.

Endogenous Melatonin Is Important for Circadian Organization in Nonmammalian Vertebrates

Melatonin plays a key role in coupling oscillators within the circadian timing system of several nonmammalian species. Indeed, the circadian system in several avian species has been described as a neuroendocrine loop, in which neural sites regulate melatonin, and melatonin in turn couples these sites together into a functional pacemaker which subsequently regulates behavior.

Key experiments that demonstrate the role of melatonin in circadian organization have involved removing sources of melatonin (the pineal gland and, in some cases, also the eyes, depending on species) and observing alterations in rhythms in constant conditions. The most compelling data come from sparrows, in which pinealectomy leads to arrhythmicity, and rhythmic melatonin replacement (by injection, feeding, or even transplantation of pineal tissue) leads to restoration of rhythmicity (Figure 1). In other species, changes in the circadian cycle length (period) occur in constant conditions after pinealectomy, and administration of exogenous melatonin can alter rhythm period or phase. This variability between species likely reflects species differences in the level of dependence on melatonin to couple oscillators and the relative autonomy of these areas.

As discussed elsewhere in this encyclopedia, circadian oscillations in vertebrates are based on an intracellular, cell-autonomous, molecular feedback loop. In the absence of melatonin, this transcriptional/translational feedback loop may persist within individual cells of nonmammalian vertebrates, but the coordination among oscillators may be lost, leading to loss of overt, physiological rhythmicity. Alternatively, the absence of melatonin may disrupt the molecular feedback loop within individual cells. Methods for introducing reporter genes into tissues and assessing rhythmic transcription within individual cells have been used to study mammalian cells; application of these methods to putative hypothalamic pacemaker cells from nonmammalian vertebrates will clarify the mechanism of melatonin action on circadian rhythmicity in these species.

Exogenous Melatonin Affects Circadian Rhythmicity in Nonmammalian Vertebrates

Administration of melatonin by means which result in levels sufficiently high to swamp out the endogenous rhythm of melatonin production (thereby removing the rhythmic internal signal that melatonin normally provides) usually leads to dramatic responses in nonmammalian vertebrates. These responses include loss of rhythmicity or significant alteration in circadian cycle length (period). Administration of supraphysiological doses of melatonin at 24 h intervals (by daily infusion, injection, or feeding) to animals with free-running rhythms in constant conditions, however, can lead to synchronization of rhythms to the 24 h period of administration. Although effects of exogenous melatonin on rhythms in nonmammalian vertebrates have been described in many publications, it should be recognized that negative data from similarly designed experiments may not have been published due to the inherent selection for 'positive data' in the peer-review process.

Melatonin Effects on Circadian Rhythms in Mammals

Endogenous Melatonin Has Little Impact on Circadian Rhythmicity in Mammals

As in nonmammalian species, the impact of pineal melatonin on rhythmicity can be assessed by removing

Figure 1 Pineal melatonin is important for circadian organization in house sparrows. (a, b) Perch-hopping activity of sparrows maintained in constant darkness plotted in actogram format. Each horizontal line represents 48 h of data. Data are double-plotted, meaning that each day of data occurs both to the right and below the previous day. Activity is indicated by vertical deflections from the baseline (thicker horizontal lines). (a) A sparrow with a free-running activity rhythm. Note immediate loss of circadian rhythmicity upon surgical removal of the pineal gland. (b) Rhythmicity is restored in a pinealectomized sparrow by transplantation of a pineal gland into the anterior chamber of the eye. The animal was housed in constant darkness except for a brief light pulse at the time of the transplantation surgery. (a) From Gaston S and Menaker M (1968) Pineal function: The biological clock in the sparrow. *Science* 160: 1125–1127. Copyright 1968 AAAS. Reproduced with permission of AAAS. (b) From Menaker M and Zimmerman N (1976) Role of the pineal in the circadian system of birds. *Integrative and Comparative Biology* 16: 45–55. Reproduced with permission from Oxford University Press.

the pineal gland. In contrast to nonmammalian vertebrates, however, pinealectomy has only subtle effects on behavioral circadian rhythms in mammals. In no mammalian species has pinealectomy been reported to lead to loss of rhythmicity or a major change in circadian organization. These data support a model in which the mammalian circadian timing system has a strong central pacemaker (in the SCN) and that coupling within the SCN occurs well even in the absence of melatonin. In this model, endogenous melatonin is relegated primarily to the role of an output rather than being both an output and an input. It should be recognized, however, that the pineal melatonin rhythm is important for regulating rhythmicity within a number of tissues endowed with melatonin receptors. Although these tissues do not contribute to regulation of locomotor activity rhythms, they may impact physiology substantially. For example, rhythmic gene expression in the pituitary pars tuberalis of both mice and hamsters is strongly affected by pineal melatonin. This tissue influences prolactin secretion from the pituitary gland, and in seasonally breeding species this appears to play an important role in regulating annual changes in gonadal status and pelage. Melatonin also appears to act directly in the dorsomedial hypothalamus of seasonal breeders to regulate gonadotrophin secretion. These studies emphasize the physiological importance of the circadian rhythm in pineal melatonin production for photoperiodic responses. Although the pineal melatonin rhythm may not have a striking impact on circadian organization in most mammals, pineal melatonin does have other important physiological functions in species attuned to respond to it.

Removal of melatonin may interfere with responsiveness to other environmental stimuli and therefore have an indirect effect on circadian organization. For example, pinealectomy of rats makes them more susceptible to disruption of their rhythms by constant light. Constant light alone lengthens circadian period and, at high intensities, results in loss of rhythmicity. Alterations in the rate of re-entrainment to

phase-shifted lighting cycles have been reported in pinealectomized animals. Although these results are consistent with a role for melatonin as a coupling agent between oscillators, they are also consistent with an alteration in the sensitivity to light following pinealectomy. These conflicting interpretations also affect studies examining light-induced resetting of the circadian clock, as alterations in sensitivity to light could alter the magnitude of phase shift following a light pulse.

The role of melatonin can also be assessed indirectly by examining animals that do not produce melatonin. Most inbred strains of mice lack the capacity to produce a high-amplitude rhythm in plasma melatonin levels due to defects in the synthetic pathway for melatonin. Despite this, mice have perfectly reasonable rhythms in locomotor activity, temperature, feeding, adrenal hormones, and other output markers of circadian function. Furthermore, mice with targeted disruption of MT1 and MT2 melatonin receptor subtypes have been generated, and these mice also have apparently normal behavioral rhythmicity in constant conditions. These studies indicate that melatonin is not a necessary component of the circadian timing system in mice. Similarly, inhibition of human melatonin production also does not appear to have a major impact on circadian organization. Evidence for this comes from human subjects with spinal cord injuries that disrupt the pathway between the SCN and the pineal gland and from hypertensive patients receiving β-adrenergic receptor antagonists that inhibit melatonin synthesis; in both situations, rhythmic melatonin production is lost, yet circadian rhythmicity persists (Figure 2).

Figure 2 Circadian rhythms persist in humans despite disruption of the melatonin rhythm. The top panels show the melatonin (left) and cortisol (right) rhythms from control subjects ($n = 24$) during a constant routine procedure under dim lighting. Values represent mean ± SEM for data binned by hour for each subject. Normal circadian rhythms in the profiles for both hormones are readily apparent. Habitual sleep times (0:00–8:00 h) are represented by the open box. The lower panels show melatonin (left) and cortisol (right) data from three tetraplegic patients studied under the same conditions. Cervical transections were at C4, C6, and C6/C7. Cervical transection led to complete loss of melatonin secretion, yet the cortisol rhythm is preserved. Adapted from Zeitzer JM, Ayas NT, Shea SA, Brown R, and Czeisler CA (2000) Absence of detectable melatonin and preservation of cortisol and thyrotropin rhythms in tetraplegia. *Journal of Clinical Endocrinology and Metabolism* 85: 2189–2196.

Pharmacological Effects of Melatonin in Mammals

Although pineal melatonin does not play a necessary role in circadian organization in mammals, exogenous melatonin can nevertheless influence circadian rhythms in mammalian species including humans. With respect to melatonin effects on rhythmicity, the most extensively studied mammalian species is the rat. In this species, the free-running period in constant darkness is slightly more than 24 h (e.g., ~24.3 h). Timed, daily injections of melatonin (at 24 h intervals) are essentially without effect on free-running rhythms until the time of the injection slightly precedes the onset of daily activity. When melatonin is injected during this narrow window of sensitivity, it leads to small daily phase advances and thus to synchronization of activity onset to a 24 h period. Injection of saline vehicle does not produce this effect (Figure 3). Upon discontinuation of the daily melatonin injection (or substitution of saline), rats free-run from the time of the last injection, indicating they were indeed entrained by the daily injections (as opposed to being simply excited by the injection, resulting in increased activity every 24 h which could be misinterpreted as entrainment). Studies administering single injections of melatonin to rats free-running in constant conditions further demonstrate that the response depends on the phase of injection. Melatonin causes small (<1 h) phase advances when administered shortly before the time of activity onset. Some studies reveal a second window of responsiveness late at night.

Mice have also been used rather extensively for studies of circadian responses to melatonin, although their response magnitudes are quite small: a single injection at the time of peak sensitivity (CT10) does not cause a detectable phase shift, whereas three consecutive daily injections (at the same projected time, CT10) cause a phase advance averaging approximately 40 min (Figure 4). An additional difficulty in studying mice is that their free-running period is less that 24 h so that repeated administration of melatonin at 24 h intervals at a time that causes a phase advance is not expected to cause entrainment. Thus, additional paradigms (e.g., one to determine whether melatonin accelerates the rate of re-entrainment to a phase-shifted light–dark cycle) have been used in mice (Figure 5). Despite the small

Figure 3 Entrainment of rat locomotor activity rhythms by timed daily injection of melatonin. Panels represent double-plotted actograms of wheel-running behavior. Female rats were initially housed in a 14 h light:10 h darkness (LD) lighting cycle and were transferred to constant darkness (DD) on day 11 of the study. Both rats show free-running rhythms with a cycle length of more than 24 h in DD, as is typical of rats. Beginning on day 34, each rat received one injection per day at 10:00 a.m. The animal receiving daily injections of the saline vehicle (left) continued to free-run throughout the period of study. In contrast, the animal receiving melatonin (100 $\mu g\,kg^{-1}$ subcutaneously) free-ran until the time of injection was approximately coincident with activity onset and then it 'locked on' to the melatonin injections. Entrainment to melatonin is accomplished by small phase advances in response to each daily injection. On day 115, daily injections of saline commenced; the animal lost entrainment despite continued handling and saline injection. These representative records show that melatonin can lead to phase-dependent and reversible entrainment of activity rhythms in rats. From Thomas EM and Armstrong SM (1988) Melatonin administration entrains female rat activity rhythms in constant darkness but not in constant light. *American Journal of Physiology* 255: R237–R242. Reproduced with permission of the American Physiological Society.

Figure 4 Melatonin can phase shift free-running circadian rhythms in mice. (a, b) Representative single-plotted actograms showing the phase-shifting effect of melatonin injections in mice. Mice were free-running in constant darkness and received injections (purple circles) of vehicle (VEH) (a) or melatonin (MLT; 90 μg per mouse) (b) on three consecutive days. Injections occurred at circadian time 10 (2 h before projected activity onset). Activity onsets (red circles) were determined for each circadian cycle, and the magnitude of phase shift for each animal was determined by comparing the time difference, on the day of treatment, between a line through activity onsets before treatment (green line) and a line through activity onsets after treatment (blue line). (c) Average responses ($n = 9$ per treatment). The asterisk indicates a significant difference between the two treatment groups ($p < 0.001$). C57BC WT refers to the strain origin of the animals; they were wild-type mice generated by intercrossing heterozygous MT1-deficient mice with a primarily C57BL/6J genetic background. From Dubocovich ML, Hudson RL, Sumaya IC, Masana MI, and Manna E (2005) Effect of MT1 melatonin receptor deletion on melatonin-mediated phase shift of circadian rhythms in the C57BL/6 mouse. *Journal of Pineal Research* 39: 113–120. Reproduced with permission from Blackwell Publishing.

Figure 5 Melatonin accelerates re-entrainment of mice to a phase shift of the light–dark cycle. (a, b) Single-plotted actograms of representative animals receiving vehicle (VEH) (a) or melatonin (MLT; 90 μg/mouse/day) (b) in a re-entrainment paradigm. The original lighting cycle is shown at the top of the panel, whereas the shifted lighting cycle is shown at the bottom. Injections (purple circles, indicated by arrows) were administered 30 min prior to lights-out of the new lighting cycle, beginning on the first day of the advanced cycle and continuing for 3 days. Activity onsets (red) are indicated for each day, and fitted lines through onsets before and after the phase advance shift of the lighting cycle are shown. (c) Average responses. Data points are mean ± SEM hours of advanced activity onset on each day after the shift ($n = 20$ and 27 per treatment). The asterisk indicates a significant difference between the two treatment groups ($p < 0.05$). C57BC WT refers to the strain origin of the animals; they were wild-type mice generated by intercrossing heterozygous MT1-deficient mice with a primarily C57BL/6J genetic background. From Dubocovich ML, Hudson RL, Sumaya IC, Masana MI, and Manna E (2005) Effect of MT1 melatonin receptor deletion on melatonin-mediated phase shift of circadian rhythms in the C57BL/6 mouse. *Journal of Pineal Research* 39: 113–120. Reproduced with permission from Blackwell Publishing.

magnitude of circadian responses to melatonin in mice, studies in this species have been prompted by the availability of genetically modified mice with disruption of melatonin receptor subtypes.

A third nocturnal rodent species in which the effects of melatonin have been examined is the Syrian hamster. There is considerable discrepancy in the literature regarding the effects of melatonin in this

species. Studies using very large doses of melatonin report melatonin-induced alterations in circadian rhythms, whereas one study reveals that there is no greater response to melatonin than to vehicle and that the response attributed to melatonin in other work could be due to the effects of arousal related to injection.

Rhythmic administration of melatonin has also been found to entrain diurnal rodent species, including the Indian palm squirrel and the Nile grass rat. In these animals, there appear to be two windows of sensitivity so that entrainment can occur by either phase advances or phase delays. However, another diurnal species, the chipmunk, appears to be insensitive to entrainment by melatonin injections. Information on melatonin receptor subtype, distribution, and sensitivity is not available for these species, and the reasons for these large interspecies differences are unknown.

Melatonin Entrains Developing Hamsters

The most robust entrainment response to melatonin in mammals is the impact of melatonin on the developing Syrian hamster. In this species, and in several other rodents, maternal cues are able to set the phase of the circadian oscillator in the fetal SCN. This prenatal entrainment results in within-litter synchrony of circadian phase, which can be detected as synchronization of rhythms within the fetuses of a litter. Alternatively, synchronization can be detected by rearing the pups in constant conditions and then assessing the phase of rhythms during the postnatal period. Pineal *N*-acetyltransferase rhythms in 10-day-old rat pups and locomotor activity rhythms in several other species have been used to detect within-litter synchronization. Cross-fostering studies reveal that the major influence of the mother on the pups occurs during the prenatal and early postnatal periods. Destruction of the maternal SCN early in gestation leads to a litter in which the pups are not temporally coordinated, showing that the synchronization that normally occurs is not just due to the developing clocks being started or synchronized by a developmental event that the developing offspring share, such as birth.

Melatonin from the maternal circulation readily crosses the placenta, and rhythms in maternal melatonin are paralleled by rhythms in fetal melatonin levels. Furthermore, melatonin passes from mother to pup via the milk. Thus, melatonin is an attractive candidate for a hormonal cue that could mediate maternal effects on pup rhythmicity. Indeed, prenatal transfer of melatonin from mother to fetus has profound effects on pubertal development in Siberian hamsters. Studies in several species indicate that melatonin is not necessary for maternal entrainment of the fetus, however. Whereas endogenous melatonin does not appear necessary for entrainment of the developing circadian clock, exogenous melatonin has a profound entraining effect during development in Syrian hamsters. An elegant series of studies by Fred Davis and colleagues assessing entrainment of pups of SCN-lesioned mothers showed that (1) melatonin and D1-dopamine receptor activation entrain the developing circadian clock to opposite phases; (2) the minimal melatonin treatment is a single injection; and (3) there is a developmental window for the effect of melatonin, with loss of sensitivity to melatonin late in the first week of life. There is a marked downregulation in melatonin receptor density in the Syrian hamster SCN in the first week after birth, and this downregulation of receptors may limit the responsiveness of the SCN at later ages. Alternatively, there may simply be a transition of the SCN away from sensitivity to melatonin, similar to the loss of sensitivity to dopaminergic activation that occurs in rats during a comparable, early postnatal period. The efficacy of melatonin in synchronizing the pup phase in the offspring of SCN-lesioned dams indicates that melatonin is one important signal for entraining the developing circadian oscillator, but it is clearly not the only signal. The intrauterine environment is rich in other temporal cues (e.g., temperature, nutrients, and other hormones) and it appears that multiple redundant signals usually lead to entrainment of the fetus.

Experimental and Therapeutic Uses of Exogenous Melatonin in Humans

Studies demonstrating the impact of melatonin on rhythms in other species, and the presence of specific, high-affinity receptors for melatonin within the human SCN, have fuelled interest in the use of melatonin as a chronobiotic (an agent for resetting the oscillator regulating behavioral rhythms). One proposed application of melatonin is to facilitate re-entrainment after a phase shift of the light–dark cycle caused by transmeridian flight (e.g., a jet-lag pill). Of greater general importance is the proposed use of agents such as melatonin to rapidly facilitate adaptation to changes in the light–dark cycle induced by shift work. In view of the increasing prevalence and the negative health impact of shift work, this application looms very large in terms of the scope of the population that could benefit. The much smaller populations afflicted with other circadian rhythm sleep disorders, such as advanced and delayed sleep phase syndrome, and particularly totally blind people (who commonly suffer from non-24 h sleep–wake syndrome), could also benefit from a safe and effective chronobiotic.

Melatonin can indeed cause small phase shifts in humans, and phase–response curves describing both advances and delays have been published. The

maximum phase advance in response to melatonin occurs during the late afternoon to early evening, and the peak response is on the order of approximately 30 min. Phase delays occur when melatonin is administered in the early morning, with a similar magnitude of response. The mechanism of action of melatonin remains unclear, however. Melatonin has also been described as a sleep-promoting agent, and alteration in sleep regulation directly, or alteration of light–dark exposure when subjects close their eyes to sleep, may have a feedback effect on circadian clock function. Although melatonin could influence sleep by reducing the firing rate of SCN neurons, it could also do so by effects on the peripheral vasculature leading to changes in thermoregulation; thermoregulatory adjustments play an important role in sleep induction.

One situation in which even small phase shifts can be critically important is in the case of humans who are totally blind. In the absence of light information reaching the SCN, the circadian pacemaker cycles at its endogenous period, which is usually slightly more than 24 h (averaging ~24.5 h in blind subjects). Although a small minority of blind people without conscious light perception retain circadian photoreception, the majority do not and thus are insensitive to light both visually and circadianly. In these people, and in the majority of individuals lacking eyes (e.g., as a result of injury or surgical resection of cancer), the resultant lack of synchronization between the internal non-24 h circadian system and the external 24 h environment induces a chronic condition, non-24 h sleep–wake disorder. The disorder is characterized by cyclic episodes of good sleep, followed by poor nighttime sleep and excessive daytime sleepiness, as the individual free-runs and thus experiences alternating periods of his or her biological day being coincident with, and later being out of phase with, the 24 h day. In these individuals, a chronobiotic that achieves a daily phase advance equal to the difference between their free-running period and the 24 h day (e.g., 0.5 h per day, on average) can lead to stable entrainment, immediately correcting the debilitating sleep disorder. Indeed, this has been found in some studies involving daily melatonin administration (Figure 6(a)). Notably, remarkable variation between blind subjects has been noted in the response to timed daily melatonin administration (Figure 6). The initial phase of treatment, the dose of melatonin, and the individuals' circadian period all appear to influence the ability of blind subjects to entrain to daily melatonin administration. Smaller doses (0.5 mg or lower) appear to be at least or even more effective than larger doses (5 mg or higher), and at such higher doses entrainment appears to depend on initiating treatment at the correct phase. Individuals with a period closer to 24 h also may be more likely to respond positively due to the relatively smaller daily shift required to entrain to a 24 h period. Entrainment to timed daily melatonin administration remains the only treatment available to totally blind subjects with non-24 h sleep–wake disorder, and although the small number of trials conducted to date are not all consistent, melatonin treatment has been proven in principle and is a promising solution to this particular disorder.

The small magnitude of phase shift caused by melatonin would seem to be inconsistent with proposed therapeutic applications of melatonin that require a much larger amplitude of response (e.g., for achieving a 5 h phase shift after a transatlantic flight). However, melatonin and light exposure may synergize in their effects on the circadian clock in sighted individuals. The phase–response curves to melatonin and light are approximately opposite and the light responses are larger than the effects of melatonin. Melatonin has been shown to hasten re-entrainment to a phase-shifted lighting cycle in simulated (and actual) jet lag and shift work paradigms. Whether this action is due to direct effects on the SCN circadian clock and/or via changes in sleep–wake or light–dark cycles remains to be established. Given the dual effects of melatonin, its administration should be timed to enhance both its chronobiotic and its potential sleep-facilitating effects.

Melatonin Receptors

Identification of Melatonin Receptor Subtypes

Radioactively labeled 2-iodomelatonin (2-[^{125}I]iodomelatonin, ^{125}I-Mel) has been used to identify and characterize high-affinity melatonin binding sites ($K_D < 200$ pM). High-affinity melatonin receptors are coupled to G-proteins because GTP analogs inhibit high-affinity ^{125}I-Mel binding. Autoradiographic methods to localize sites of ^{125}I-Mel binding led to detection of site-specific distribution of binding sites, including a high concentration of melatonin receptor binding in the SCN of most (but not all) species (Figure 7(e)). Melatonin affects second messenger pathways, particularly G_i-mediated inhibition of forskolin-stimulated cAMP accumulation, in those tissues in which the receptor concentration is relatively high.

In addition to high-affinity sites, a lower affinity 2-[^{125}I]iodomelatonin binding site with K_D values in the 1–2 nM range was identified in hamster tissues, with a fundamentally different pharmacological profile, most notably a relatively higher affinity for *N*-acetylserotonin and prazosin, and guanine nucleotides do

Figure 6 Variable responsiveness of blind humans to daily melatonin treatment. (a and b) Two totally blind men with free-running circadian rhythms received melatonin (5 mg melatonin *per os* at 21:00 h) (open circles) and no treatment/placebo (solid circles) for at least one full circadian cycle. Horizontal lines indicate transitions between treatments. Data points represent the peak times of the urinary cortisol rhythm, assessed by weekly collections of urine at 4 h intervals (8 h at night) for 24–48 h. Lines represent the period of the cortisol rhythm during various phases of treatment, determined using best fit linear regression. Period estimates from the cortisol rhythm were comparable to period estimates based on melatonin metabolite rhythms before treatment. (a) Subject 31 initially had a free-running rhythm with a period of 24.57 h. Melatonin treatment began at 21:00 h, at a time that corresponded to an internal circadian time (CT) of CT16, approximately 2 h after the onset of endogenous plasma melatonin production and at a phase known to cause an advance shift. Melatonin treatment entrained the cortisol rhythm to a 24 h (24.0 ± 0.2 h) period and to a normal phase (12.9 ± 1.2 h). One week after cessation of melatonin treatment (day 83), the cortisol phase occurred at 17.1 h, indicating that the subject reverted to a free-running period of more than 24 h after discontinuation of melatonin treatment. (b) Subject 45 initially had a free-running rhythm with a period of 24.87 h as determined by the urinary cortisol rhythm. Melatonin treatment began at 21:00 h, at a time corresponding to CT5 (approximately 9 h before the onset of endogenous plasma melatonin production). Melatonin treatment failed to entrain the cortisol rhythm (period during melatonin treatment, 25.22 ± 2.59 h) despite being administered for nearly two full circadian cycles. Based on data from Lockley SW, Skene DJ, James K, et al. (2000) Melatonin administration can entrain the free-running circadian system of blind subjects. *Journal of Endocrinology* 164: R1–R6.

not affect binding to these sites. The first melatonin receptor nomenclature was introduced to distinguish high-affinity sites that correlated with functional activity (ML-1) from the lower affinity, prazosin-sensitive sites (ML-2).

Work by Steve Reppert and colleagues led to the isolation and characterization of cDNAs encoding a family of high-affinity G-protein-coupled melatonin receptor subtypes, all of which fall within the pharmacologically characterized ML-1 receptor class and all of which inhibit forskolin-stimulated cAMP accumulation when expressed in cell lines. Thus, the melatonin receptors called Mel1a (now MT1) and Mel1b (now MT2), as well as the nonmammalian Mel1c receptor subtype, are all 'ML-1' type by the older nomenclature. Mice with targeted disruption of the MT1 and MT2 receptor subtypes have been generated and used to assess receptor subtypes mediating responses to melatonin.

The unique pharmacological profile of the ML-2 site allowed development of a specific radioligand and the eventual purification of the ML-2 site, leading to its identification as the enzyme, quinone reductase type 2 (QR2). In the current receptor nomenclature, the 'ML-2' binding site was renamed the MT3 melatonin binding site. That QR2 binding accounts for the MT3 binding sites is most conclusively shown by the absence of MT3 type binding in QR2 knockout mice.

A mammalian melatonin receptor-related receptor (now called GPR50) has also been identified. This receptor is structurally related to the family of G-protein-coupled melatonin receptors, having a similar amino acid sequence and an identical exon/intron structure. Human, mouse, and sheep homologs of this receptor have been identified, but none is capable of binding ^{3}H-melatonin or 2-[^{125}I]iodomelatonin; GPR50 remains an orphan receptor.

Figure 7 Melatonin receptor gene expression and receptor binding in mouse brain. (a–d) Brain sections processed for *in situ* hybridization. Panels (a) and (c) were hybridized with the antisense probe to detect MT1 melatonin receptor transcript, whereas panels (b) and (d) are adjacent sections hybridized with the sense probe (as a control). Expression of MT1 receptor mRNA is present in areas that coincide with regions containing melatonin receptor binding (see (e) and (g)). (e–l) Melatonin receptor binding assessed by incubation of brain sections with 100 pM 2-[^{125}I]iodomelatonin. Panels (e–h) are sections from a wild-type mouse, whereas panels (i–l) are from an MT1 receptor knockout mouse. Sections shown in panels f, h, j, and l were incubated with 100 pM 2-[^{125}I]iodomelatonin plus an excess (1 μM) of melatonin to determine nonspecific binding. Mice with targeted disruption of the MT1 receptor gene lack readily detectable melatonin receptor binding by autoradiographic methods. AHA, anterior hypothalamic area; PT, pars tuberalis; PVT, paraventricular nucleus of the thalamus; SCN, suprachiasmatic nucleus. Panels (a–d) are based on unpublished data of S Haddady, CM Lambert, and DR Weaver confirming findings reported in Roca AL, Godson C, Weaver DR, and Reppert SM (1996) Structure, characterization, and expression of the gene encoding the mouse Mel-1a melatonin receptor. *Endocrinology* 137: 3469–3477. Panels (e–h) are based on experiments conducted by DR Weaver and reported in Liu C, Weaver DR, Jin X, et al. (1997) Molecular dissection of two distinct actions of melatonin on the suprachiasmatic circadian clock. *Neuron* 19: 91–102.

Melatonin Receptor Subtype Expression in SCN

As noted previously, there are two high-affinity, G-protein-coupled receptors for melatonin in mammals – the MT1 and MT2 receptor subtypes. The MT1 receptor transcript is expressed in mammalian brain and pituitary (pars tuberalis) in a manner that agrees well with the distribution of detectable melatonin receptor binding sites (Figure 7). Furthermore, mice with targeted disruption of the MT1 receptor lack detectable melatonin receptor binding by autoradiographic methods (Figures 7(i) and 7(k)), whereas mice with disruption of the MT2 receptor have no detectable decrement in melatonin receptor binding. The MT2 receptor transcript appears to be broadly but weakly expressed, and the MT2 receptor protein appears to be present at rather low levels. Thus, the majority of melatonin receptor binding is due to MT1 rather than MT2 receptor expression.

Molecular Dissection of Circadian Effects of Melatonin

Four SCN-mediated responses have been examined in an effort to dissect the melatonin receptor subtype(s) affecting the SCN. One robust SCN response to melatonin is an acute inhibition of electrical activity, detected by multiunit recording from SCN slices maintained *in vitro* (Figure 8). This inhibitory response to melatonin is mediated by the MT1 receptor. The response is completely absent in MT1 receptor knockout mice and is unaffected in MT2 receptor knockout mice. A second *in vitro* SCN response to melatonin involves monitoring the phosphorylation state of calcium and cyclic AMP response element binding protein (CREB). Exposure of SCN slices to pituitary adenylate cyclase activating peptide (PACAP) late during the subjective day leads to an increase in the number of neurons in which CREB is phosphorylated. Pretreatment of SCN slices with melatonin at concentrations of 1–10 nM blocks the PACAP-induced increase in CREB phosphorylation. Mice with targeted disruption of the MT1 receptor respond normally to PACAP but do not respond to melatonin (1 nM) (Figure 9). At higher concentrations of melatonin, however, inhibition of CREB phosphorylation occurs even in MT1 receptor-deficient mice. This higher threshold response to melatonin is blocked by the MT2 receptor antagonist 4P-PDOT and is also

Figure 8 Melatonin inhibits SCN neuronal firing through the MT1 melatonin receptor. Schematic of representative data. Slices containing the SCN were prepared from a wild-type (MT1+/+) and an MT1 receptor-deficient mouse (MT1−/−) and were monitored by multiunit recording of electrical activity for approximately 36 h. The rate of firing (in spikes per second) is indicated by the black line with gray fill below. On the second day *in vitro*, the slices were exposed for 30 min intervals to vehicle (gray box) and then to melatonin (black box) at escalating doses (0.1, 1, 10, and 100 nM) during the circadian day. Inhibition of electrical activity occurs in the slice from the wild-type mouse but not in the slice from the MT1 receptor-deficient mouse. The lighting cycle to which the animals were exposed before slice preparation is shown at the bottom of each panel. Based on data reported in Liu C, Weaver DR, Jin X, et al. (1997) Molecular dissection of two distinct actions of melatonin on the suprachiasmatic circadian clock. *Neuron* 19: 91–102.

Figure 9 Melatonin inhibits PACAP-induced CREB phosphorylation through the MT1 receptor at low concentrations and through the MT2 receptor at higher concentrations. SCN slices from mice of the genotypes shown were treated with PACAP 2 h before lights-out and fixed 15 min later. Phospho-CREB immunoreactive nuclei in the SCN were assessed by immunohistochemistry. Data represent the percentage inhibition in the number of phospho-CREB-labeled neurons in the SCN. Percentage inhibition is expressed relative to slices treated with PACAP alone (0% inhibition) or the vehicle alone without PACAP (100% inhibition). Standard error values were within 10% for each experiment and are not shown for clarity. To combine data from experiments reported in two different publications, the results of the MT1−/− groups from the two papers have been averaged. Responses to low concentrations (1 nM) of melatonin require the MT1 receptor. A response to higher melatonin concentrations (100 nM) occurs in the absence of the MT1 receptor; this response is blocked by an MT2 receptor antagonist (4P-PDOT) and is absent in double-knockout mice. Asterisks indicate significant inhibition ($p < 0.05$). Based on data reported in von Gall C, Weaver DR, Kock M, et al. (2000) Melatonin limits transcriptional impact of phosphoCREB in the mouse SCN via the Mel_{1a} receptor. *NeuroReport* 11: 1803–1807; and Jin X, von Gall C, Pieschl RL, et al. (2003) Targeted disruption of the mouse Mel_{1b} melatonin receptor. *Molecular and Cellular Biology* 23: 1054–1060.

absent in MT1/MT2 double-knockout mice (Figure 9). Thus, the regulation of CREB phosphorylation state is controlled primarily by the MT1 receptor, with the MT2 receptor having an influence only at higher melatonin concentrations.

Curiously, a third *in vitro* response of the SCN to melatonin suggests a primary role of the MT2 receptor. This paradigm involves application of melatonin to slices prepared from the SCN, followed by monitoring the electrical activity of single SCN neurons over the following day to determine the time of the peak in single unit firing rate. In this assay system, melatonin produces a 3 or 4 h phase advance when applied during a sensitive window during late subjective day (at CT10). This response to melatonin is preserved in MT1 receptor knockout mice, but it is blocked by pertussis toxin, suggesting involvement of a G-protein-coupled receptor (presumably the MT2 receptor). Studies in rats suggest that this *in vitro* phase-shifting response is blocked by a competitive MT2 receptor antagonist. However, Siberian hamsters (which naturally have a defect in the MT2 gene leading to the absence of functional MT2 receptors) also respond to melatonin in this assay. A very peculiar aspect of the single unit response to melatonin is the inexplicably high potency of melatonin: 3–10 pM concentrations of melatonin will cause a phase shift in the single unit assay, yet concentrations 300- to 3000-fold higher (1–10 nM) are required for most other responses assessed in SCN slices *in vitro*. It is not clear why the response to melatonin in the single unit assay is so much larger than the *in vivo* response, or why it occurs at concentrations of melatonin that are so low. Furthermore, the receptor mechanism for this *in vitro* phase-shifting response does not seem consistent with results obtained *in vivo*. The single unit assay may monitor a subset of SCN

neurons that are very highly responsive to melatonin but that appear not to correlate well with other *in vitro* responses to the hormone.

Phase-shifting responses to melatonin have also been described in intact mice. As noted previously (Figure 4), three consecutive daily injections (at the same projected time) cause a phase advance averaging approximately 40 min in wild-type mice. Dubocovich and colleagues have shown that this response to melatonin is absent in MT1 receptor-deficient mice. Similarly, this group reports that the modest acceleration of re-entrainment to a phase-shifted lighting cycle (Figure 5) is absent in MT1 receptor-deficient mice. In contrast, an earlier study using antagonist administration indicated that the MT2 receptor was necessary for the phase advance in response to melatonin injections. As noted previously, the most profound circadian response to melatonin administration in mammals occurs in developing Syrian hamsters, a species that naturally lacks a functional MT2 receptor. Thus, the literature is contradictory with respect to the receptor subtype most important for SCN responses to melatonin. Although there are exceptions, studies aimed at identifying the receptor subtypes responsible for responses to melatonin generally indicate that the major effects of melatonin are mediated by the MT1 melatonin receptor subtype. There has been interest in melatonin and in the development of melatonin analogs for chronobiotic and sleep-promoting effects. It is not clear whether there would be any advantage of subtype-selective pharmaceuticals affecting melatonin receptors.

Memory Consolidation: Cerebral Cortex

B Bontempi, Université de Bordeaux 1, Talence, France

Introduction

Converging evidence from clinical and animal research supports the idea that our memories of everyday life – of people, places, and events – are not formed instantaneously but are gradually stabilized over time via a process called memory consolidation. Müller and Pilzecker were the first to adopt the term consolidation in 1900; just as in the definition in the dictionary, it means to make stronger or firm. However, the consolidation process must not be considered to be a unitary and passive mechanism enabling new memories to be transformed from an initially labile state to a more permanent state. On the contrary, memory consolidation is a highly dynamic process that involves large-scale reorganization at both the synaptic and entire interconnected brain system levels.

Recent studies have shed light on the dynamics of hippocampal–cortical interactions that allow recently acquired memories to be transformed into enduring memories in distributed cortical networks. Here we review these recent advances by presenting experimental evidence that forms the bases for two competing models of memory consolidation. Mechanisms underlying cortical storage are also briefly discussed, with a particular emphasis on the role of the prefrontal cortex, which seems to play a privileged role in processing remote memories.

Time Course of Memory Consolidation

Two main forms of consolidation can be distinguished on the basis of their temporal dynamics. Synaptic consolidation primarily involves morphological changes within localized neuronal circuits, such as the restructuring of existing synaptic connections or the growth of novel ones. Such changes, which occur rapidly after a learning episode (within minutes to several hours), are triggered by a cascade of different metabolic events which include activation of central receptors, release of different neurotransmitters and second messengers, activation of transcription factors and associated target genes, and ultimately the synthesis of a plethora of proteins directly responsible for the observed structural changes. Over the past decade, much has been learned about the cellular and molecular bases of this process. By contrast, system consolidation is a much slower process which can last for weeks to months, or even up to several decades, depending on the species. Consolidation in this case refers to a gradual process of reorganization and a differential involvement of the brain regions that support memory processing. For instance, the brain regions that are crucial for processing recently acquired information are not necessarily identical to those that are important for later memory recall. The mechanisms underlying this reorganization are largely unknown.

What are the brain regions critical for recent and remote memory processing? A pioneer in the field was the French psychologist Ribot, who pointed out as early as 1881 that memory loss after a brain trauma was often related to the age of the memory. He concluded, based on clinical observations, that retrieval of recent memory was typically more impaired than that of older (or more remote) memory, suggesting that memories may be reorganized in a time-dependent manner. It is only later, during the mid-twentieth century that refined anatomical approaches made it possible to identify damage to the medial temporal lobe, including the hippocampus, as being responsible for the occurrence of this typical graded amnesia. Certainly one of the most famous patients in the field of cognitive neuroscience is patient H.M., who suffered from intractable epileptic seizures whose focus was located within the medial temporal lobe. It was decided at the time to excise large amounts of his medial temporal lobe bilaterally. Although the surgery was successful in abolishing the epilepsy, one of the unexpected consequences was that H.M. exhibited severe retrograde amnesia, that is, the loss of memory for information acquired prior to the onset of amnesia. H.M.'s surgery also produced persistent anterograde amnesia, or the inability to form new memories. Particularly interesting was the fact that H.M.'s retrograde amnesia was temporally graded just as previously described by Ribot – memories acquired recently were more affected than memories acquired longer ago during his childhood. This particular pattern of memory impairment together with other case studies was interpreted as showing that the hippocampus and related structures of the medial temporal lobe have a time-limited role in memory storage and that memories, once consolidated, must be stored elsewhere. This idea forms the central tenet of most contemporary views of system consolidation; the hippocampus acts as a temporary consolidation organizing device, but storage of enduring memories depends on broadly distributed extra-hippocampal networks, presumably located within the cortical regions.

Models of Memory Consolidation

In the standard model of memory consolidation, illustrated in Figure 1, the hippocampus is believed to rapidly integrate and bind information from distributed cortical neurons that support the various features of a whole experience to form a coherent memory trace. Consolidation of this new memory trace at the cortical level then occurs slowly via reactivation of hippocampal–cortical networks, eventually leading to the increase in the strength and stability of cortical–cortical connections. Over time, as memories mature, the role of the hippocampus gradually diminishes until structured cortical networks become capable of retrieving remote memories independently.

However, it has been argued that not all the experimental evidence supports this model. First, retrograde amnesia is not always temporally graded. Flat gradients where both recent and remote memories are similarly impaired have been observed. Second, certain gradients have been reported to last for decades or up to almost the entire human life span in some amnesic patients. These observations have prompted some researchers to challenge the standard model of memory consolidation and to propose an alternative view, known as the multiple trace theory, in which the hippocampus is necessary for memory recall as long as memories are viable. According to this theory, each memory trace, which corresponds to a specific conscious experience, consists of a cohesive hippocampal–cortical ensemble. Each time that a particular event is recalled, this event is recoded in the form of multiple related memory traces dispersed over larger areas of the hippocampus. Consequently, the relative sparing of remote memories in amnesic patients is a function of the extent of hippocampal damage, with limited damage producing temporally graded retrograde amnesia and extensive lesions resulting in a flat gradient for retrograde amnesia. Another interesting feature of this model is that the form of memory being processed is thought to determine the time course of hippocampal engagement during consolidation. Whereas the standard model favors a disengagement of the hippocampus regardless of the type of declarative memory (memory allowing the conscious recollection of facts and events) being processed, the multiple trace theory predicts that complete hippocampal lesions will produce temporally graded retrograde amnesia only for semantic (general knowledge of facts) but not episodic (richly detailed recollection of specific events) memory. Some case studies, for instance, patient E.P., who has extensive bilateral lesions of the medial temporal lobe but excellent autobiographical memories from his youth, do not support this prediction.

Figure 1 The standard model of memory consolidation. Perceptual, motor, and cognitive information is initially processed by a large number of specialized primary and associative cortical areas represented here by cortical modules. The medial temporal lobe, including the hippocampus, integrates the various features of an experience and binds them rapidly into a coherent memory trace. System consolidation then occurs slowly over time and involves a hippocampal–cortical dialog to gradually strengthen cortical–cortical connections. This involves the strengthening of existing cortical–cortical connections and the creation of new connections between previously unconnected neurons. As cortical memories mature and gain stability, the role of the hippocampus gradually diminishes allowing structured cortical networks to retrieve remote memories independently. A key feature of this model is that changes in the strength of hippcampal–cortical connections are fast but short-lasting whereas changes within cortical–cortical connections are slow but long-lasting. Plasticity phenomena at both hippocampal and cortical sites are likely to involve Hebbian-like mechanisms, that is increased synaptic strength between two neurons where the first neuron repeatedly stimulates the second one. From Frankland PW and Bontempi B (2005) The organization of recent and remote memories. *Nature Reviews Neuroscience* 6: 119–130.

Furthermore, there are several examples of temporal gradients in animals even after complete hippocampal lesions. A central issue is whether remote episodic memories following extensive hippocampal lesions are as detailed and vivid as those in control subjects.

Experimental Evidence

In Animals

Temporally graded retrograde amnesia has been shown across a variety of species, suggesting that time-dependent memory reorganization is an evolutionarily conserved process. Designing experiments in laboratory animals to study this phenomenon offers a numbers of advantages. First, what is learned and when it is learned can be rigorously controlled across times in a prospective manner, which is difficult to achieve in humans, in which studies rely almost exclusively on retrospective questionnaires. Perhaps even more important, it is possible to produce discrete brain lesions restricted to specific regions of interest. Close analysis of the literature reveals that the length of the retrograde amnesia gradient seems to be a function of several factors including the species, the complexity of the memory paradigm, the level of mastery of the task and the type, and the extent and location of the brain lesion.

Although lesion approaches have brought a great deal of information about the potential roles of the different regions of the medial temporal lobe in memory processing, they tell us nothing about the contribution of the hippocampus when this region was intact at time of retrieval. To circumvent this problem, functional brain imaging techniques similar to positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) in humans have been developed and applied to studying memory processes. One such technique is the (^{14}C)2-deoxyglucose autoradiographic method, which allows for regional measurements of levels of glucose consumption, and thereby neuronal activation, in the entire brain. This technique was applied to spatial discrimination learning in mice (**Figures 2(a) and 2(b)**). In accordance with the standard model of memory consolidation, lengthening the retention interval from 5 days (recent memory) to 25 days (remote memory) resulted in decreased metabolic activity in the hippocampus and a concomitant increase in several cortical areas (**Figure 2(c)**).

More recently, cellular imaging experiments have used the expression of activity-dependent genes such as c-fos and zif-268 as markers of brain activity. Using these approaches, it has been possible to track changes in the organization of spatial and contextual memories. Again, a converging and consistent pattern of neuronal reorganization emerged – the retrieval of recent memory engaged the hippocampus, whereas the retrieval of remote memories was associated with increased activity in cortical regions such as the prefrontal, anterior cingulate, and retrosplenial cortices. More refined reorganization of neuronal activity across cortical layers was also observed, for instance, in the parietal cortex. Recruitment of these different cortical regions may reflect their increasing roles in memory storage, effortful recall, performance monitoring, and use of consolidated remote memories. Consistent with these imaging data, pharmacological inactivation of different cortical sites specifically disrupts recall of remote, but not recent, memories.

In Humans

Temporal gradients of retrograde amnesia have been reported in humans, and these case studies are well documented. One striking difference from animal studies concerns the length of the gradient. Most often, amnesia extends back across a period of several years and, in some cases, for several decades. Both remote semantic memory for facts and remote episodic memory for autobiographical events appear to be spared even though some hippocampal patients have been diagnosed as having difficulties in recollecting detailed episodes from their early life, possibly because of extensive damage outside the medial temporal lobe.

Results from functional brain imaging studies have proven to be more controversial, in part because of the technical difficulties in recording activity across subjects accurately and in designing appropriate comparative baseline control tasks in order to isolate neuronal activity associated with nonspecific aspects of the testing procedure. A recent fMRI study by Takashima and colleagues, however, appears to be quite consistent with the imaging data obtained in animals. The authors were successful in studying remote memory in a prospective manner, just like the experimental designs classically used in animals. Healthy adult subjects were asked to memorize a series of photographs of various landscapes. Recognition of these photographs was then probed during a testing session that occurred either 1 day, 1 month, or 3 months later. The correspondence with the imaging results obtained in animals is striking. Not only was the recall of remotely acquired pictures independent of the hippocampus and dependent on the medial prefrontal cortex, but this dramatic reorganization occurred at a rapid pace that was of a magnitude comparable to that observed in animal's studies of retrograde amnesia.

Figure 2 System consolidation as revealed by functional brain imaging in mice: (a) testing procedure; (b) imaging procedure; (c) color-coded autoradiographs of coronal sections of mice tested for recent memory (left), remote memory (center), or remote memory in the new context (right). As illustrated in (a), mice were first submitted to spatial discrimination testing in the eight-arm radial maze, wherein they were trained to locate and remember the spatial positions of three constantly baited arms. Following 9 days of training to acquisition criterion (80% correct responses), memory performance was then assessed either 5 days (recent test) or 25 days (remote test) later. An additional group of mice was tested 25 days later with a similar maze but located in a different room. As illustrated in (b), following intravenous injection of the (^{14}C)2-deoxyglucose (2DG) radioactive tracer, mice were submitted to recent or remote retention testing in the

Mechanisms Underlying System Consolidation

Over the last decade, multidisciplinary approaches in animals have contributed to the elucidation of many of the cellular and molecular mechanisms underlying memory processing in hippocampal networks during synaptic consolidation. Much less is known, however, about the dynamics of hippocampal–cortical interactions that allow these memories to be transformed into remote memories in cortical networks. Memory reactivation remains the core mechanism in most models of system consolidation. Repeated activation of hippocampal networks is thought to reinstate, in a coordinated and synchronized manner, activity in different cortical networks. Reactivation can be induced either during online states of conscious recollection (or quiet wakefulness) or during offline states such as sleep. Marr was among the first to suggest that offline replay of previous waking pattern of neural activity during sleep may drive consolidation and ensure a gradual stabilization of cortical memory traces. A role for sleep in memory consolidation is now well documented. Although exceptions exist, a gain in performance after overnight sleep has been reported. Conversely, sleep deprivation can interfere with, and even prevent, memory consolidation. At the molecular level, sleep has been associated with the upregulation of approximately 100 known genes (and ~400 unidentified ones) independent of circadian rhythm. It is reasonable to assume that at least some of these genes, either directly or indirectly via triggering of specific signaling pathways, mediate incremental changes in synaptic plasticity within cortical networks.

In the hippocampus, rapid encoding is likely to predominantly involve changes in weight between existing connections via long-term potentiation (LTP) and long-term depression (LTD) (or weight plasticity). In the cortex, however, where network reorganization occurs slowly, an additional form of plasticity may involve the creation of new synaptic connections between previously unconnected neurons. In the animal brain imaging studies already mentioned, it is this form of wiring plasticity that was observed. Long-term storage of spatial and contextual information was accompanied by the generation of novel synapses in specific areas of the prefrontal and anterior cingulated cortices, thus indicating that wiring plasticity most likely contributed to changing the organization and architecture of distributed cortical networks supporting remote memory storage (Figure 3). Such morphological changes appear to be crucial because α-calcium/calmodulin-dependent

Day 1 Day 30

Figure 3 Remote memory storage in the cortex involves wiring plasticity. The expression of growth-associated protein 43 (GAP-43), a presynaptic protein that controls axon growth and sprouting and that is used as a marker of newly formed synapses, was examined in the anterior cingulate cortex (aCC) of animals tested either 1 day (recent memory) or 30 days (remote memory) following spatial discrimination in a five-arm maze (top image). Cortical consolidation of the spatial position of the baited arm of the maze was accompanied by an increase in GAP-43 staining on day 30 as compared with day 1 (bottom images). Nuclei appear in blue, GAP-43 fluorescent staining is green. This finding supports that cortical networks undergo structural changes as memories mature over time. Scale bar = 10 μm.

eight-arm radial maze. Their brains were rapidly removed on completion of testing and prepared for autoradiography, which allowed for quantitative measurement of testing-induced changes in neuronal activation in various brain regions. In (c), the lower section of each panel shows a magnified view of the dorsal hippocampus (dHPC), which includes the CA1, CA3, and dentate gyrus (DG) regions. Increasing the retention interval from 5 to 25 days resulted in a significant decrease of metabolic activity in the hippocampus and a concomitant increase of activity in several cortical regions such as the frontal (FC) and anterior cingulate (aCC) cortices. These data point to a time-limited role of the hippocampus in remote memory storage. Over time, as memories mature, distributed cortical areas become capable of mediating the retrieval of remote memories independently. However, when mice are confronted with a different context at the remote time, the hippocampus is reengaged, indicating that this brain region is required to encode novel information. HPC, hippocampus; PC, parietal cortex; pCC, posterior cingulate cortex. From Frankland PW and Bontempi B (2005) The organization of recent and remote memories. *Nature Reviews Neuroscience* 6: 119–130.

protein kinase II mutant mice exhibiting normal hippocampal plasticity (but lacking cortical plasticity) are unable to form enduring memories. The hippocampus has been conceptualized as a fast learner and the cortex as a slow learner. Differences in the relative prevalence of weight versus wiring plasticity may underlie this apparent division of labor. Slow incremental changes in cortical networks may help prevent catastrophic interference, as emphasized in current connectionist models; protect existing cortical memories from being erased; and ensure constant updating of these cortical memories.

One question that often comes to mind is how the hippocampus manages to reactivate the right network of cortical neurons related to a specific experience. Because hippocampal–cortical projections are topographically organized, several researchers have suggested that the hippocampus might store some sort of indices of all the relevant neocortical synapses that need to be strengthened as memories mature. Although still speculative at present, identification of cortical synapses could be achieved via the setting of synaptic tags at all relevant synapses that were activated at the time of initial encoding in the primary sensory as well as associative cortices.

A Crucial Role for the Prefrontal Cortex in Processing Remote Memory

There is new evidence from both animal and human studies in favor of a crucial role for the prefrontal cortex in remote memory recall. Classically, the prefrontal lobe has been implicated in mediating effortful monitoring and response selection during retrieval. Forgetting, which may reflect a partially degraded memory trace, is inevitably associated with long-term memory storage, and we are all familiar with the increased difficulty in retrieving information acquired long ago compared to recently acquired information. The prefrontal lobe may also have additional roles in retrieval processes. The prefrontal cortex consists of several highly interconnected regions, including the prelimbic, inframimbic, and anterior cingulate areas. These regions are reciprocally connected to the sensory, motor, and limbic cortices and are therefore ideally suited to integrate complex information from different sensory sources. This potential for integration has led to the hypothesis that the ability of the prefrontal cortex to process remote memories might mirror that of the hippocampus to process recent information. At the time of encoding, the hippocampus is thought to integrate information from various independent cortical modules that represent the various features of an experience and then to rapidly fuse these features into a coherent memory trace. As memories become gradually consolidated in the cortex, this integrative function may be transferred to the prefrontal cortex, which then become capable of integrating information embedded within other distributed cortical networks (Figure 4). More challenging is the recent view that the prefrontal cortex might modulate hippocampal activity during memory storage. Intriguing functional brain

Figure 4 A privileged role of the prefrontal cortex (PFC) in systemic consolidation: (a) recent memory; (b) remote memory. The PFC is thought to have multiple roles in remote memory storage and retrieval. At the time of encoding, memories are encoded in hippocampal–cortical networks. The hippocampus is crucial in integrating information from distributed cortical modules, each representing individual components of a memory. As memories mature over time, cortical–cortical connections are strengthened, allowing cortical regions, and particularly the PFC, to ensure retrieval of remote memories independently and to assume the integrative role initially exerted by the hippocampus. Consistent with this, the inactivation of the PFC blocks the expression of remote memory, but spares recent memory, in rodent tests of contextual and spatial memory. The prefrontal cortex might also modulate hippocampal activity during remote memory recall. The hippocampus is normally active when processing the outside environment. However, when incoming information matches previously stored cortical information, the PFC inhibits hippocampal activity by direct or indirect pathways to prevent the encoding of redundant information. In the presence of a mismatch situation, no inhibition is exerted and the hippocampus is engaged as usual. From Frankland PW and Bontempi B (2005) The organization of recent and remote memories. *Nature Reviews Neuroscience* 6: 119–130.

imaging results, indeed, point to the inhibition of hippocampal activity when remote memories are successfully recalled, suggesting that the prefrontal cortex might exert a top-down inhibitory control over hippocampal activity and prevent the consolidation of existing (i.e., already corticalized, and thereby redundant) information (Figure 4). This view is consistent with the existence of match and mismatch comparator neurons in the cortex, especially in the prefrontal cortex.

Concluding Remarks

Since the first clinical observations of Ribot more than a century ago, we have made considerable progress in unraveling the neurobiological bases of memory consolidation. The consolidation process is no longer seen as a simple passive phenomenon but as a dynamic process of neuronal reorganization that affects extensive hippocampal and cortical networks over timescales much longer than initially envisioned. Functional brain imaging techniques coupled with multiple cell recording have allowed new breakthroughs in the identification of the different brains regions and neuronal network supporting recent and remote memory storage. Yet, despite dramatic advances in the field of functional genomics and proteomics, we are still far from understanding all the precise cellular and molecular mechanisms underlying memory reorganization within cortical networks.

Memory Consolidation: Systems

K A Paller, Northwestern University, Evanston, IL, USA

The Consolidation of a Memory

At the moment when we perceive an event, the journey of memory storage begins. In a sense, such an event may exist for many years before finally being remembered – where is it, what is it, and how does it manage to persist?

Whereas memory is revealed by an organism's behavior at the time of retrieval, neural substrates of memory storage assume some persistent form during the entire retention interval. The ability to remember an event is made possible by changes in neurons and in networks of neurons – neural plasticity. Yet, these changes are quite unlike when a liquid is poured into a mold and solidifies as plastic or when clay is shaped and fired to form pottery. A memory trace is not a static entity. It does not remain in a fixed state, like a file in a file drawer or on a computer. Rather, further neural changes can transpire during the time period between acquisition and retrieval as a memory is associated with other stored information and potentially becomes more stable.

What is the fate of the neural plasticity first set into motion when an event is experienced? An understanding of the concept of memory consolidation requires understanding the form of memory traces (engrams) both in neural and cognitive terms, as well as specifying how memory traces change over time.

Memory Distinctions

Memory storage and memory retrieval mechanisms are known to differ in fundamental ways according to the type of memory in question. Likewise, memory consolidation proceeds differently for different types of memory.

A long-standing distinction in research on human memory allows for separate mechanisms for short-term storage lasting seconds, perhaps minutes, and long-term storage lasting much longer. Donald Hebb's seminal proposal stated that reverberating neural circuits can keep an experience in mind for a short time, whereas structural changes in neuronal ensembles underlie storage that persists over longer periods. Mental representations of perceptual and conceptual information can be actively maintained through rehearsal. In this sense, short-term storage cannot be defined by a characteristic time span. Rehearsal can continue for an indefinite amount of time. The term immediate memory aptly draws attention to this aspect of memory and is akin to what William James termed primary memory. In contrast, secondary memory refers to information brought back to mind after earlier leaving one's awareness, rather than information kept in mind through rehearsal. The length of the retention interval, short term versus long term, is thus not a suitable way by itself to differentiate between types of memory. Immediate memory (also known as working memory) belongs in a class by itself due to its dependence on the rehearsal of information.

Aside from immediate memory, there are several distinct ways in which behavior comes under the influence of past experience. Of central relevance for major territories of human cognition, declarative memory pertains to memory for complex facts and personally experienced events, and can be distinguished from a diverse set of memory phenomena collectively known as nondeclarative memory. Nondeclarative memory includes skill learning, habit learning, simple forms of conditioning, various types of priming that can be measured in implicit memory tests, and nonassociative forms of learning like habituation and sensitization.

Some of the molecular building blocks of memory storage are common across these different types of memory. Elaborate layers of molecular machinery can require some passage of time so as to complete the process of memory formation. In many cases, neural plasticity induced during learning can be modulated by subsequent events. Release of epinephrine and cortisol, for example, can allow emotional significance to regulate memory strength. Selective gene activation and protein synthesis also play key roles in stabilizing synaptic changes.

These aspects of memory fall in a category called synaptic consolidation. Relevant molecular changes can require minutes to hours. On the other hand, the present discussion focuses on neural mechanisms of systems-level consolidation that are specific to declarative memory and that tend to occur over a much longer timescale.

Consolidating Declarative Memories

Declarative memory concerns the ability to bring back to mind factual and episodic information. Each of us maintains a colossal but changing record of facts and events to access when needed. This information can potentially stay with us for so many years that one might say that declarative memories can last a lifetime. One general principle of memory storage is that cortical networks specialized for processing specific types of information are the very same

networks involved in storing that information as fragments of declarative memories. Those fragments must be linked together in order for any particular declarative memory to exist.

Although we have learned much about the brain mechanisms responsible for declarative memory, and about ways to assess this type of memory using recall and recognition tests, pinpointing the exact neural substrates of any one specific autobiographical event or fact is beyond current technology. Indeed, a declarative memory does not reside in a single location, but rather, it depends on a dynamic network of neurons. Lively controversy surrounds questions about how consolidation operates on such a network, the precise length of time consolidation requires, and whether these memories assume a labile form under special circumstances.

Empirical evidence that can be brought to bear on theories of consolidation comes from multiple sources. Neuropsychological studies of patients with amnesia, in particular, suggest that declarative memories can change to become resistant to disruption and that this change is a by-product of consolidation. Critical brain damage in amnesia tends to include midline diencephalic or medial temporal structures, including the hippocampus and adjacent cortical regions, though the distinct memory functions presumably mediated by these different regions are currently unclear. Studies of animal models have also been designed to identify the neuroanatomical basis of this critical contribution to memory.

Evidence from Human Memory Disorders

Memory impairment tends to comprise both anterograde amnesia, a pronounced difficulty in learning new information, and retrograde amnesia, a disruption of the ability to remember information that had been learned prior to the onset of symptoms. In either case, patients experience difficulty remembering factual as well as event information (though dissociations are possible, at least in retrograde amnesia). Some amnesic patients exhibit severe anterograde amnesia and severe retrograde amnesia; some exhibit mild anterograde amnesia and mild retrograde amnesia. Given that neurological insult can produce correlated anterograde and retrograde amnesia in this manner (even though there are important exceptions), standard accounts specified a single mechanism that led to both effects. In particular, a core defect in a protracted consolidation process required for declarative memory storage could result in both types of impairment; new learning would not be normal without consolidation, and old memories would not be retrieved normally if their consolidation had not run its course.

In analyses of retrograde amnesia, it is useful to take into account the age of memories that might be retrieved (i.e., the length of the retention interval) by distinguishing between recent memory and remote memory. Indeed, a prevalent characteristic of retrograde memory impairment, described in 1882 by Theodore Ribot and known as Ribot's law, states that the dissolution of memory is inversely related to the recency of the event. Numerous cases of retrograde amnesia have been described in which the impairment was taken to be limited to recent memories, with preservation of remote memories. Patterns of temporally graded retrograde amnesia have been demonstrated using a variety of tests (**Figure 1**).

Implications of Temporally Graded Retrograde Amnesia

The notion that consolidation progresses over an extended period of time is consonant with evidence from retrograde amnesia, given the following scenario. To the extent that memories were formed recently, consolidation processes would have as yet been insufficient to produce a stabilized cortical memory. These memories become inaccessible in the absence of retrieval mechanisms that depend on hippocampus and related structures. This standard neuroanatomical account of consolidation thus characterizes recent memories as those that depend on both cortical and hippocampal networks.

In contrast, to the extent that an old memory has been subject to sufficient consolidation, it can be retrieved via cortical retrieval mechanisms. Whether hippocampal participation remains critical for some remote memories in some patients, however, is currently controversial.

This standard conceptualization of consolidation is as a process whereby declarative memories outgrow their dependence on corticohippocampal networks to become cortically self-reliant. This metamorphosis may involve increased connectivity among the components of the memory in the cortex; accordingly, the process has sometimes been referred to as cross-cortical consolidation. Cross-cortical consolidation may also involve the formation of new cortical representations that function to represent the gist or higher-order meaning of the memory while simultaneously enhancing the coherence of the set of neocortical storage sites (**Figure 2**).

Testing such speculations about how declarative memory representations change as a result of consolidation will require new sources of neurophysiological and neuroanatomical evidence. Before delving into this sort of evidence, we must examine doubts that have been raised about the evidence from retrograde amnesia.

Figure 1 Forgetting curves showing temporally graded retrograde amnesia. (a) Recall was tested using questions about news events that occurred in preceding years (1950–2002) in five patients with damage limited primarily to the hippocampal region and 2–3 control subjects matched to each amnesic patient. The time period labeled AA (anterograde amnesia) represents recall deficits for information acquired after the onset of amnesia. (b) Recognition was tested for TV shows that were broadcast for only one season in preceding years (1957–72) in 16 patients who were given a course of electroconvulsive therapy (ECT) as treatment for depressive illness. Subjects were required to select actual TV show titles presented among fabricated titles, and the guessing rate was 25%. This test is advantageous because TV show titles were learned in a specific year and were unlikely to be rehearsed repeatedly afterwards. ECT was given three times per week and testing occurred before the first treatment and 1 h after the fifth treatment. These memory deficits did not result from medications or depressive illness *per se*. Memory abilities improved within a few weeks after ECT was completed. Adapted from Manns JR, Hopkins RO, and Squire LR (2003) Semantic memory and the human hippocampus. *Neuron* 38: 127–133; and from Squire LR, Slater PC, and Chace PM (1975) Retrograde amnesia: Temporal gradient in very longterm memory following electroconvulsive therapy. *Science* 187: 77–79.

Controversies and Challenges in Studies of Retrograde Amnesia

The extant literature on retrograde amnesia presents a complicated story that does not uniformly support this standard account of consolidation. Temporally graded retrograde amnesia has been observed reliably in patients with closed head injury, Korakoff's syndrome, and other disorders of memory. Observations by Scoville and Milner in 1957 of patient HM, who became amnesic following bilateral medial temporal lobectomy for medically intractable epilepsy, showed retrograde amnesia for autobiographical memory of roughly 2 years in duration. However, an insidious disease onset, as is likely in Korsakoff's syndrome, or factors like epilepsy or certain medications, could lead to apparent retrograde deficits that actually resulted from poor encoding during those years.

Conventional methods for assessing remote memory also have limitations. Whereas tests of anterograde amnesia concern information delivered systematically to the patient under well-controlled conditions, tests of retrograde amnesia tend to probe information acquired under unknown circumstances. When testing memory for historical events or celebrities, for example, it can be difficult to determine the patient's premorbid knowledge. To attempt to overcome this problem, experimenters can learn about important life events from informants or create specialized tests for specific information.

In constructing retrograde tests, it can be helpful to select test items such that various factors are equivalent across time periods. In this way, for example, difficulty might be equated such that an observed forgetting curve would reflect true forgetting rather than greater difficulty for older items. However, equating difficulty may lead to other differences across items, as the most remote items may tend to concern factual rather than episodic knowledge. Interpretations of retrograde gradients thus require careful attention to the makeup of test materials.

Another interpretive limitation results because most people show superior autobiographical retrieval for events from their early adulthood. One explanation is that these years often include people's most momentous experiences and so have a powerful influence on their life story and personality. Events from these times may also be extensively intertwined with other relevant information such that they are not easily lost.

Importantly, many reports of retrograde amnesia have demonstrated impairments not limited to a few years, but spanning one or more decades. Some patients lose essentially their whole life, in that they are unable to retrieve many autobiographical memories from any past time period. In contradistinction to the temporally graded period of retrograde amnesia shown in Figure 1, these patients show no gradient. A process of gradual consolidation does not

Figure 2 A speculative account of cross-cortical consolidation represented schematically. Initially (stage 1), a fact or event is encoded via representations in multiple cortical regions with binding and cognitive control provided by prefrontal cortex. A selection of neocortical ensembles is figuratively shown in red (allied subcortical networks are omitted). At the same time, high-level features in this dispersed representation involve hippocampal networks (stage 2). These hippocampal networks trigger pattern completion such that the set of dispersed cortical fragments can later be activated together. Over time (stage 3) and with the aid of hippocampal networks, coherence ensembles begin to form in various cortical regions such as medial temporal cortex or other limbic-associated cortex (e.g., entorhinal, perirhinal, parahippocampal, posterior cingulate, and medial prefrontal cortex). These coherence ensembles ultimately become part of the memory representation, taking on a superordinate role. Network connections become strengthened when the memory is retrieved and/or related to other stored information. By this account, a coherence ensemble is a cortical network that functions to maintain cohesiveness among the various parts of a declarative memory, and that ultimately (stage 4) takes over the binding role of the hippocampus. Adapted from Paller KA (2001) Neurocognitive foundations of human memory. In: Medin DL (ed.) *The Psychology of Learning and Motivation*, vol. 40, pp. 121–145. San Diego, CA: Academic Press.

seem to supply a viable explanation for such extensive memory loss. Moreover, dense retrograde impairments have been found in some patients with minimal anterograde amnesia, although this phenomenon is controversial and may be explained in some cases by other factors, such as psychogenic amnesia. Another complication is that retrograde impairments can disproportionately affect episodic versus semantic knowledge. Some patients display poor memory primarily for remote autobiographical information, some primarily for remote factual information.

One theoretical view developed to account for extensive episodic memory loss is known as multiple trace theory. By this view, the hippocampus contributes to episodic memory retrieval for all time periods. This contribution provides episodic retrieval with the contextual detail that supports the ability to approximate re-living a past event. Memories for factual information do not include this contextual detail and become hippocampal-independent after sufficient consolidation. The idea that episodic memories do not become independent of the hippocampus provides an explanation for retrograde amnesia for episodes across all time periods.

Interpretations of these intriguing patterns of retrograde impairment, however, must take into account the fact that retrograde amnesia can arise from several fundamentally different causes. Although consolidation provides a viable explanation for some instances of retrograde amnesia, memories can also be lost when pathology disrupts cortical areas responsible for the storage of this information. Whereas declarative memories are dispersed across multiple cortical regions, some of the multimodal and multidimensional knowledge critical for retrieving certain memories may depend on the integrity of special convergence zones in the brain, perhaps including medial temporal cortex (i.e., entorhinal, perirhinal, and parahippocampal), orbitofrontal cortex, medial prefrontal cortex, parietal cortex, and posterior cingulate cortex. As described above, a new representation formed in one of these regions may become part of the declarative engram by virtue of the consolidation process. Further research is needed to delineate the type of information stored in such regions. Conceivably, decades of retrograde amnesia can arise when storage sites in these critical regions are disrupted, in which case the evidence would have no bearing on specifying the time span of consolidation. Brain damage to some of these regions could conceivably result in extensive retrograde amnesia with minimal anterograde amnesia if the hippocampus and some adjacent medial temporal cortex remained intact.

Another explanation for dense retrograde amnesia must also be considered. Cross-cortical consolidation may not be the culprit when retrograde amnesia

across all time periods results from a profound defect in retrieval. Indeed, various sorts of evidence now point to a critical role of the frontal lobes in orchestrating retrieval. Full-blown memories of distinct autobiographical episodes can require extensive memory search. The planning, organization, and evaluation processes required for retrieval can become extremely challenging after frontal brain damage. Also, dissociations in the type of information that can and cannot be retrieved could arise from deficits based on either corrupted storage sites or disabled retrieval.

The interpretation of long periods of remote memory loss must also be informed by evidence for systematic relationships between the length of the retrograde loss and sites of brain damage. More evidence of this sort is needed, but results from postmortem histological analysis for several cases suggest that partial hippocampal damage produces limited retrograde impairment (1–2 years), whereas more extensive damage to the hippocampus and entorhinal cortex produces broader retrograde impairment (15–25 years).

In sum, the literature includes an inconsistent mix of reports of retrograde amnesia that either extends over decades or is limited to a recent period not longer than a few years. In cases of temporally extensive retrograde amnesia, storage and retrieval accounts must be carefully evaluated. Perhaps all old memories in healthy people are subject to steady reorganization. If so, an interesting but untested possibility is that the longer a patient has amnesia, the more dense their retrograde amnesia will be. At any rate, further research will hopefully expand our understanding of the range of retrograde deficits that can be observed and clarify when such memory disorders arise from a consolidation defect.

Problems with Specifying the Age of a Memory

A further theoretical concern haunts the evaluation of all data on remote memory in amnesic patients. How should we conceptualize an episodic memory that is 20 or more years old?

An episodic memory is defined with reference to one specific event that was experienced in a unique spatiotemporal context. If a person is capable of remembering an event from 20 years ago, it can reasonably be assumed that this memory was also retrieved multiple times in the intervening years. Nevertheless, researchers commonly refer to this as a 20-year-old memory. If intervening retrieval influences memory storage, it might be more appropriate to regard the effective retention interval as much shorter than 20 years. Although an individual may recall an event from 20 years ago, the memory itself could be largely based on modifications made more recently. Indeed, past episodes not retrieved and elaborated upon multiple times over many years may be the ones we tend to forget.

Even younger memories are subject to concerns about effects of intervening retrieval. Once we acknowledge that memories are accessed in sleep, which now seems undeniable, we cannot rule out the idea that every instance of remote memory retrieval is a function of storage events at multiple time points.

By the present account of consolidation, each time a memory for an episode is retrieved, there is a possibility that the information in question is associated with other information so as to expand the operative nature and meaning of the memory. Retrieved memories are regularly reevaluated and related to new information in mind at the moment of retrieval, including the context of the new retrieval episode. Moreover, new events can provoke the reinterpretation of past events. Thus, the memory trace should be conceived of as product of memory storage operations engaged during various retrieval experiences. Unless intervening retrieval can be ruled out, it is problematic for the age of an episodic memory to be defined simply on the basis of when the original event occurred.

This reconceptualization of remote memories provides an important point of contact between multiple trace theory and the standard model of consolidation. A recalled episode may be tantamount to a retelling of prior re-tellings of the same story, rather than a replay of an ancient story set in stone long ago.

There are thus two reasons an amnesic patient's retrograde impairment cannot be specified by a simple duration. First, consolidation for various factual and episodic memories may proceed at a different rate depending on the type of information and the ways in which it is retrieved and associated with other information. Second, as underscored by the preceding discussion, specifying a single operative age for a given memory is problematic.

Memory Transformation due to Consolidation

Connections to the cortical storage sites that comprise a declarative memory may be formed via the hippocampus at initial encoding, and then used when that memory is subsequently retrieved. In this way, memories may be subject to continual hippocampal-dependent restructuring for some time. Some remote memories may ultimately reach a state in which any further changes are relatively minimal, even though these memories may retain their episodic quality.

Whereas consolidation can produce a hippocampal-independent memory, it can also change the representational quality of a memory. In some cases of

Figure 3 Several demonstrations of temporally graded retrograde amnesia following damage to the hippocampal region. Learning took place at multiple times before surgery. Two groups of animals were tested in each experiment, normal animals (N) and animals with either lesions of the hippocampus (H), lesions of hippocampus plus surrounding cortex (H+), or lesions of entorhinal cortex (EC). repeated retrieval of an event memory, contextual details are lost so that the event itself comes to be represented only abstractly. That is, specific episodic information can become extraneous through a process of decontextualization. Although these memories start out as contextually rich episodic memories, vivid perceptual and contextual details gradually become unavailable – factual information about the event becomes the only part of the memory that can be recalled. In this manner, an episodic memory can be said to have changed into a semantic memory. Decontextualization may produce an enduring semantic memory in conjunction with a shift in memory storage from neocortical/hippocampal to only neocortical.

Computational models of consolidation have implemented procedures that theoretically could lead to the formation of decontextualized memories. In the Complementary Learning Systems framework, for example, hippocampal networks implement fast links among neocortical components. Memory representation in the neocortex, in contrast, changes more slowly. This scheme keeps neocortical memories safe from interference that would result if networks changed based on each new piece of episodic information. Instead, slow neocortical changes can lead gradually to the buildup of semantic knowledge. The time course of consolidation can then be conceived as a reflection of the time-consuming training of cortical networks by hippocampal networks.

Evidence from Prospective Studies, Neuroimaging, and Sleep Research

Müller and Pilzecker introduced the term consolidation (*Konsolidierung*) in 1900 and proposed that memories could change over time from a fragile, labile form to a fixed form. In 1903, Burnham took up consolidation in the context of the retrograde difficulties experienced by amnesic patients and combined the notion of retrieval and association with the idea of neural reorganization. However, we have only limited opportunities to observe these consolidation-based changes directly. Such opportunities will increase as we (1) begin to understand the physiological changes inscribed in brain networks responsible for

declarative memories and (2) develop ways to overcome the methodological and interpretative limitations discussed above. Prospective studies offer the opportunity to analyze well-controlled memory storage over a certain time period. Instead of relying on memory tests for retrospective information acquired under unknown circumstances, the circumstances of encoding can be controlled such that a range of retention intervals can be systematically examined.

In animal studies of consolidation, a variety of approaches have been used in prospective studies, with lesions created surgically to encompass specific regions (Figure 3). Many of these studies have obtained results supporting the hypothesis that medial temporal damage produces temporally graded retrograde amnesia (although there are also some exceptions). These observations of retrograde amnesia in multiple species and with multiple types of testing procedure also attest to the feasibility of future efforts to delineate the precise causes of retrograde memory impairment, and in this way clarify how these memories are consolidated.

Human neuroimaging has also been used in studies designed to examine how hippocampal contributions to retrieval may change as a function of the time since initial encoding. Interpretations must contend with many of the limitations discussed above. Hippocampal activity for recent and remote memories, in particular, can be engaged due to retrieval processing *per se* and/or due to encoding of the new recollective experiences prompted by the retrieval cues. The possibility of superimposed encoding activity can thus pose difficulties for conclusive interpretations of the role of the hippocampus in recent versus remote memory retrieval in these studies.

Prospective methods have also been used in some neuroimaging studies. In one such study, subjects viewed a series of 320 landscape photographs and were tested up to 90 days later. Brain activations for recognized pictures were examined at four retention intervals (Figure 4). Consolidation apparently led to a change in the anatomical basis of memory storage, in line with predictions based on temporally graded memory deficits due to hippocampal damage. The hippocampal contribution appeared to decrease with time while an anterior medial prefrontal contribution increased with time. Evidence from animal studies

Figure 4 Results from an fMRI experiment in which brain activations for confident recognition responses were compared as a function of whether initial encoding took place 1, 2, 30, or 90 days earlier. (a) A region of ventral prefrontal cortex showed increased activity with increasing study–test delay. (b) Bilateral hippocampal regions showed decreased activity with increasing study–test delay. These findings suggest that hippocampal networks play a temporary role in memory storage, and that this role may be transferred to cortical regions such as medial prefrontal cortex. This experiment also included a rest period about 3 h after encoding, during which polysomnographic recordings were made, and those individuals who exhibited a greater amount of slow-wave sleep during this period tended to demonstrate superior memory for the photographs on later tests. Reproduced from Takashima A, Petersson KM, Rutters F, et al. (2006) Declarative memory consolidation in humans: A prospective functional magnetic resonance imaging study. *Proceedings of the National Academy of Sciences of the United States of America* 103: 756–761. Copyright (2006) National Academy of Sciences, USA.

also supports the idea that this region of prefrontal cortex, which receives information from many other cortical regions, may play a key role in memory reorganization.

Evidence from multiple sources supports the idea that consolidation can occur both during waking and during sleep. Hippocampal and cortical neurons in animals show evidence of memory replay during postacquisition waking and sleep. Plasticity-related gene expression in medial temporal regions is altered systematically during sleep. Hippocampal theta during sleep may also index memory processing, perhaps involving temporal coupling across brain regions. Sleep spindles in cortical electroencephalogram (EEG) recordings at 12–15 Hz become more plentiful after periods of declarative memory encoding during waking, and together with hippocampal sharp wave/ripple EEG patterns may reflect hippocampal–neocortical dialog. Depth EEG recordings have also implicated interactions between hippocampus and medial temporal cortex in memory processing during sleep. Various physiological events that have yet to be deciphered may support memory processing during multiple stages of sleep. Many dreams occur together with eye movements, and these rapid eye movement (REM) periods have some clear ties to memory, perhaps emotional memories in particular. However, some evidence suggests that REM may not be the only time, or even the foremost time, for memory reprocessing. Another stage, slow-wave sleep (SWS), which is prevalent early in the night, may play a vital role in hippocampal–neocortical interactions that promote declarative memory consolidation. During SWS, reduced cholinergic activation and/or cortisol feedback in the hippocampus may promote hippocampal information flow to the neocortex. One possible sign of the processing of declarative memories during SWS is a buildup of slow negative potentials over frontal cortex, and correlations have been observed between SWS and later performance on declarative memory tests for information learned prior to going to sleep. Although many questions remain about memory processing during sleep, this research area will undoubtedly be a source of much new thinking on consolidation in the coming years.

Memory Disorders

A Fradera and M D Kopelman, King's College London, London, UK

© 2009 Elsevier Ltd. All rights reserved.

Varieties of Amnesic Syndrome

The amnesic syndrome can be defined as an abnormal mental state in which memory and learning are affected out of all proportion to other cognitive functions in an otherwise alert and responsive patient. Various disorders can give rise to an amnesic syndrome, including the alcoholic Korsakoff syndrome, herpes encephalitis, severe hypoxia, certain vascular lesions, head injury, deep midline tumors, basal forebrain lesions, and occasionally the amnesic variant of mild cognitive impairment Alzheimer's dementia. These syndromes can produce both anterograde amnesia (AA), whereby memory is affected for events following the onset of the disorder, and retrograde amnesia (RA), affecting events from before the onset.

Korsakoff Syndrome

Korsakoff syndrome is the result of nutritional depletion (i.e., thiamine deficiency, due most commonly to alcohol abuse). Diagnosis typically follows an acute Wernicke encephalopathy involving confusion, ataxia, nystagmus, and ophthalmoplegia; however, onset can also be insidious, with little history of these features. Korsakoff patients will show intact short-term memory over spans of seconds but severe impairment for learning over longer periods, together with a retrograde memory loss that typically covers years or decades. Reasoning is broadly intact but patients will often exhibit some abnormal facets of cognition, including repetitive questioning and a dysexecutive profile that may alter behavior – for example, apathy or irritability – together with disorientation in time and its attribution; patients may also confabulate. Consistent with this, some degree of general cortical atrophy is usually observed, particularly in the frontal lobes.

The Korsakoff syndrome is notable in that there is a distinct neurochemical pathology, with important implications for treatment. Research on animals and on malnourished prisoners-of-war established thiamine depletion as the pathological basis for the acute Wernicke episode, and the subsequent (Korsakoff) memory impairment. The mechanisms by which thiamine depletion acts to produce the Wernicke–Korsakoff neuropathology is not fully understood, nor is the genetic contribution to acquiring the condition. Along with the mamillary bodies, the thalamus is considered the critical site of damage in producing the amnesia; early research suggested that damage to the medial dorsal nucleus was key, but more recent evidence points to the anterior principal nucleus.

Herpes Encephalitis

Herpes encephalitis (HSE) can give rise to a severe form of amnesic syndrome. The onset is typically abrupt, arising either from primary infection or reactivation of the virus from an earlier infection, and accompanied by acute fever, headache, nausea, and, in some cases, seizures and behavioral changes. Diagnosis is by the polymerase chain reaction (PCR) test or a raised titer of antibodies to the virus in the cerebrospinal fluid (CSF), but sometimes a presumptive diagnosis is made on the basis of the clinical picture as well as severe signal alteration in the temporal lobes on brain magnetic resonance imaging (MRI), associated with loss of tissue volume, hemorrhage, and edema.

The disorder will usually produce extensive temporal lobe damage that is usually bilateral, together with some general cortical atrophy and changes in orbitofrontal regions and surrounding frontal lobe. The medial temporal lobe structures are usually particularly severely affected (see Figure 1) including the hippocampi, amygdalae, and the entorhinal, perirhinal, and parahippocampal cortices – areas critical to memory formation. The disease may also implicate basal forebrain structures which give cholinergic outputs to the hippocampi.

Herpes encephalitis and the Korsakoff syndrome lead to a very similar memory disorder that reflects the fact that the hippocampi are linked to the thalami and mamillary bodies by several neural connections. These patients show similar forgetting rates. However, herpes patients typically show more severe involvement of early retrograde memories, a particular impairment for spatial memory (especially when the right hippocampus is implicated, which can result also in an impairment in face recognition) and a greater degree of semantic memory loss from concomitant damage to inferolateral temporal structures. These patients may, however, have a better insight into their memory disorder.

Severe Hypoxia

Severe hypoxia can give rise to an amnesic syndrome following carbon monoxide poisoning, cardiac and respiratory arrests, or suicide attempts by hanging or by poisoning with the exhaust pipe from a car. Drug overdoses may precipitate prolonged unconsciousness and cerebral hypoxia, and this quite commonly occurs in heroin abusers. The consequences of this can be quite variable, but typically severe hypoxia

Figure 1 Three-dimensional surface renderings of the hippocampi (top) and the combined parahippocampal and hippocampal structures (bottom) in a healthy control volunteer (left) and in a herpes encephalitis patient (right). These images are taken from planimetric segmentations of the structures from three-dimensional magnetic resonance images. Reproduced from Kopelman MD, Lasserson D, Kingsley DR, et al. (2003) Retrograde amnesia and the volume of critical brain structures. *Hippocampus* 13: 879–891, with permission.

involves changes in the hippocampi, with evidence of loss of pyramidal cells in the CA1 region reported. Fluorodeoxyglucose–positron emission tomography (FDG–PET) studies have also shown reduced glucose metabolism in the thalamus.

Vascular Disorder

Vascular disorders can particularly affect memory, as opposed to general cognitive functioning, in cases of (1) thalamic, medial temporal, or retrosplenial infarction or (2) subarachnoid hemorrhage. Thalamic damage produces amnesia when there is anterior thalamic involvement, as this is where the mamillothalamic tract projects into the thalamus. The features of this disorder are an anterograde amnesia with a limited retrograde component (although when frontocortical projections are affected, a more extensive retrograde amnesia may be observed). Hippocampal damage is due to disruption of the supply from the anterior and posterior choroidal arteries, the latter being a branch of the posterior cerebral circulation; bilateral damage will produce a global amnesia whereas unilateral damage produces a more material-specific memory loss. The retrosplenium is also supplied from the posterior cerebral artery, and infarction or hemorrhage can produce amnesia by disrupting connections to the anterior thalamus, entorhinal, and parahippocampal cortices.

Subarachnoid hemorrhage following rupture of an aneurysm can result in memory impairment, whether the anterior cerebral or posterior cerebral circulation in the Circle of Willis is involved. Ruptured aneurysms in the anterior communicating artery can implicate the basal forebrain and ventromedial frontal structures. To produce a persistent amnesic syndrome it is thought critical that damage occurs to the septal nucleus of the basal forebrain, which provides cholinergic projections to the hippocampi.

Head Injury

Following head injury both transient and persisting amnesias can arise. Posttraumatic amnesia (PTA) is assumed to reflect the degree of underlying diffuse brain pathology (axonal shearing and tearing) resulting from rotational forces, but other pathological mechanisms include contrecoup damage, hypoxia, and intracranial hemorrhage. During PTA patients show accelerated forgetting of material, and following recovery from head injury memory impairments (in new learning) are the slowest cognitive function to improve. Head injury can also produce an RA which is usually fairly brief, but may be extensive in severe cases. Although most patients with head injury show a recovery over the course of 1–3 months, a proportion will show deficits that extend well beyond this. It appears that amnesia following head injury does not insulate against posttraumatic stress disorder (PTSD) for the event, as windows of experience tend to be preserved that allow the reexperiencing of emotionally harrowing elements of the event.

Transient Global Amnesia

Transient global amnesia (TGA) occurs over a period of several hours (average 4–6 h, up to 12 h), in which the sufferers (typically older males) retain their sense of personal identity but show a profound anterograde amnesia together with some degree of RA, typically more pronounced for episodes than for facts. This episode is sometimes preceded by headache or nausea, a stressful life event, a medical procedure, intense emotion, or vigorous exercise, and an episode of migraine may be a precipitating factor. TGA is currently understood to be due to transient dysfunction in limbic–hippocampal circuits, crucial to memory formation.

Transient Epileptic Amnesia

Transient epileptic amnesia refers to a small minority of TGA patients in whom epilepsy appears to be the

underlying cause. Standard electroencephalogram (EEG) and computed tomography (CT) scan findings are often normal, but abnormalities may be found on sleep EEGs. Episodes may be ictal or postictal in nature. Memory deficits between attacks are sometimes reported, both for new learning and particularly gaps in past memory. One possible explanation for these gaps is that brief runs of seizure activity at a clinically undetectable level have disrupted normal encoding. Another is that the current epilepsy somehow prevents the retrieval of old, autobiographical memories. Automatisms and postictal confusional states that can arise from epilepsy are also associated with memory disruption: automatisms involve limbic structures that are otherwise responsible for memory formation, and hence amnesia for these periods is always present and is usually complete.

Summary of Amnesic Syndrome

The preceding examples of amnesic syndrome do not, of course, comprise a comprehensive list of the disorders which give rise to transient or persistent amnesia. What they have in common is the neuroanatomical basis for the memory disruption: temporary or permanent dysfunction or damage in medial temporal/diencephalic circuitry, or damage to the basal forebrain cholinergic inputs to that circuitry. Our discussion now turns to the different components of memory that can be affected by damage to this circuitry, and interactions with frontal lobe and temporal neocortical structures. These are anterograde and retrograde episodic memory deficits (see Figure 2), semantic memory deficits, and confabulatory episodes.

Various aspects of anterograde memory can be affected in amnesic disorders. Anterograde memory encompasses working memory – which holds information for brief periods of time (a matter of seconds) and allocates resources – and the more permanent episodic memory – which is explicit and refers to specific learned events. It also covers forms of memory whereby information is decoupled from its learning context, such as semantic memory for facts and knowledge, and implicit memory in the form of classical conditioning, procedural learning of perceptuo-motor skills, and priming effects.

Episodic Memory Deficits

There has been much debate about the nature of the episodic memory impairment in amnesia. An overview of the basic processes of memory is illustrative: memories must initially be registered in some way (encoded); they must be stored in an effective fashion, and they must be able to be recovered from the memory system (retrieval). Amnesia could in principle be due to problems at any or all of these stages.

It now seems unlikely that initial encoding is failing in amnesia, as memory performance is largely unaffected by conditions that maximize encoding support for studied items; also, working memory can be preserved in the presence of profound amnesia. A more credible account is that disruption occurs later, during the transition of memories into long-term storage, termed consolidation, which may involve processes operating over hours as well as months or even years. The hippocampus has been identified as a critical site in terms of this consolidation, but the process and nature of the process are still under debate, particularly with regard to the implications of a longer term consolidation process for retrograde amnesia (discussed more fully later). Memories that are successfully consolidated into the store may be threatened by the failure of storage itself: this would be reflected by accelerated rates of forgetting. Following work with

Figure 2 The taxonomy of episodic memory loss due to amnesia (PTA, posttraumatic amnesia). Lines with higher gradients denote better memory for that period.

the medial temporal lobe patient HM and others, this account was put forward to distinguish hippocampal from diencephalic amnesia, but subsequent, more stringent studies found that differences in the forgetting rate of patients from controls were restricted to recall rather than recognition memory, and that this was true across both types of pathology.

A further account is that amnesia reflects a specific deficit in the acquisition of contextual information, in terms of the spatial and temporal information tying an item to the environment in which it was encountered. Such specific deficits are indeed found in amnesics, but not in all cases, and the patterns differ substantially across groups. In terms of the hippocampal lesion sites associated with amnesia, the account has been reformulated as a deficit in binding complex associations or relations (not merely between item and position, but between very different types of items, such as pairing words and pictures); amnesia is thought to disrupt the flexible association of items, and the composition of these items with respect to one another.

Finally, the impairment may lie at the final stage of memory processing, the retrieval of items from storage. The case for the pure retrieval hypothesis is made on the basis of findings showing that amnesics clearly have memory information but produce it inappropriately – for example, producing true memory items on a task that requires another type of item, as well as evidence that retrieval cues can improve performance. However, this pattern can also be seen in the performance of healthy participants, suggesting that it may be a consequence of poor memory rather than its cause. Cueing effects may also simply reflect priming effects – that is, an advantage to memory that is purely implicit in nature.

In summary, the balance of evidence seems to favor a primary role for an acquisition/consolidation problem, some slighter impairments in retention (forgetting), detectable only on recall testing, and a possibly secondary deficit in retrieval processes. Basic research has demonstrated a biological mechanism for consolidation and its disruption, and primate work indicates that medial temporal lobe damage disrupts pair-coding neuronal responses, a mechanism likely to be critical in the support of long-term memory representations. The disruption of acquisition in amnesia may be particularly characterized by a deficit in binding different types of material, including contextual information, and this relates to various distinctions drawn within episodic memory, which is now considered.

Explicit and Implicit Memory

Relative to explicit memory, implicit memory is generally much better preserved in amnesia. Patients show preserved perceptuo-motor skills, and respond appropriately to simple forms of classical conditioning (such as the eye-blink response). They also show priming effects (a more rapid response to an item on the basis of its prior presentation, or that of a similar item), suggesting that this process does not rely on diencephalic/medial temporal brain structures, but rather upon cortical regions. Cases have been described whereby perceptual priming is impaired, even in the face of preserved explicit memory; a role for occipital lobe circuits has been implicated in these cases. However, amnesic patients do show impaired priming in certain experimental conditions (e.g., in difficult tasks when baseline responding has been controlled) or in associative learning. This implicates a contribution of medial temporal/diencephalic structures to priming in these circumstances.

Recall and Recognition Memory

The distinction in memory between recall (items are directly retrieved from memory with little support from cues) and recognition (information is provided to an individual who must simply make a judgment as to whether it has been previously experienced) is of great current interest in contemporary research. At issue is whether amnesic patients may show a disproportionate impairment for one form over the other, suggesting that there may be distinct neural loci underlying these processes. One position is that recall is subserved by a set of neural structures comprising the hippocampi, fornices, mamillary bodies, mamillothalamic tract, and anterior thalami – structures which are crucial in attributing contextual information, including time and spatial location, to memory items, thereby allowing the items to be distinguished and retrieved in the manner required for recollection. Recognition is supported by brain regions (including the perirhinal cortex) which are critical for familiarity judgments. There is some evidence that hippocampal damage disproportionately affects recall memory, as in some cases of developmental amnesia.

An opposing position is that both recall and recognition are served by medial temporal lobe structures and that dissociations across recall and recognition tasks reflect the severity of amnesia. Particular support for this position is given by studies showing that damage limited to the hippocampal formation has produced impairments in recognition memory. This is a touchstone issue which is continuing to preoccupy researchers.

Remembering and Knowing; Recollection and Familiarity

Gardiner and Richardson-Klavehn have distinguished between the subjective states of remembering and

knowing. Remembering (R) involves the reexperience of 'intensely personal experiences of the past,' whereas knowing (K) is when 'we are aware of knowledge that we possess but in a more impersonal way,' without the experience of reliving the acquisition of this knowledge. Do these types of memories arise from a single unitary process, from two independent but overlapping processes, or from entirely exclusive processes? Evidence that the same memory items can be variously experienced as R or K, depending on the passage of time, has been used to argue that the processes are not exclusive. Extensive work has examined how these concepts map onto the recall and recognition divisions of memory. It seems likely that both familiarity and recollection can contribute to recognition, with characteristics of performance varying according to the experience supporting it (e.g., judgments that rely upon recollection show greater levels of subjective confidence). Familiarity is not accompanied by the contextual detail required to spontaneously evoke a piece of memory information, whereas recall necessarily relies upon recollection. An analysis of data from several studies of amnesia (due to hippocampal or diencephalic damage) suggests that recollection is disrupted to a greater extent than is familiarity. This evidence leads to the possibility that a defining feature of amnesia is the loss of contextual/associational information, leading to a memory experience that is both impoverished and lacking the subjective experience of 'mental time travel' – the rich and fluid memorial reexperiencing of an event.

Semantic Memory Deficits

Semantic memory comprises knowledge of facts, concepts, and language, stored without corresponding information about the initial learning experience. The cognitive neuroscience of semantic memory – in particular, its relation to episodic memory – is an issue of current theoretical interest. There are several ways in which this issue has been investigated.

Semantic Dementia

Semantic dementia is a degenerative disorder that causes a progressive loss of semantic knowledge which can occur across both verbal and nonverbal domains. In the verbal domain, this leads to loss of word comprehension and naming, and increasingly degraded and empty speech, though the latter remains fluent and grammatical in output. Perceptual and reasoning abilities are also intact, and episodic memory is relatively preserved, as are some classes of knowledge, such as numerical information. The underlying pathology is generally confined to inferior and lateral temporal gyri, more commonly left-lateralized, although right-lateralized atrophy can occur, producing impairments in visual semantics.

Patients often show impaired knowledge of subordinate meaning categories relative to superordinate categories, such as loss of 'dog' but preservation of 'animal'; over time, however, superordinate knowledge may also succumb to the disease. This has been taken as evidence for a hierarchical organization of semantic memory, but it may reflect a more secure neural underpinning for the superordinates, due to their higher usage frequency or their greater degree of connectedness to other concepts. Crucial to the debate on memory systems is the fact that, when compared with amnesic disorders, there can be a classic double dissociation, in that semantic dementia results in semantic impairments with preserved episodes, whereas amnesia leads to episodic impairments with relatively preserved semantic information.

New Learning of Semantic Material in Amnesia

Individuals who suffer severe amnesia provide the opportunity to assess whether the acquisition of semantic material depends upon the episodic memory system. In principle, if new semantic knowledge can be acquired despite a very severe episodic memory deficit, it implies a separation of the neurobiological systems underlying semantic memory and episodic memory. A number of studies in the past 10 years suggested that patients who show severe episodic memory impairments may show significantly better performance on tasks of new vocabulary or recognizing public figures and events. For example, a densely amnesic individual with almost complete bilateral destruction of the hippocampi and severe atrophy of the perihippocampal tissue was tested on knowledge of vocabulary and famous individuals that had arisen since the onset of amnesia; he demonstrated access to explicit semantic knowledge in these domains, albeit at lower levels than within matched controls. However, this finding has been contested, due to some cases of medial temporal lobe amnesia apparently showing little ability to acquire new knowledge.

Cases of developmental amnesia have been studied recently, again offering the opportunity to assess current semantic memory when the acquisition of new episodic memories has been severely impaired. For example, the patient Jon, amnesic due to neonatal injury, is impaired on recall tasks and does not describe any subjective sense of episodic recollection. However, he has been able to perform relatively well in mainstream education – developing competencies in speech, reading, and writing, and scores within the normal range on measures of comprehension, world knowledge, and vocabulary that tap semantic information.

Retrograde Amnesia

In this section, we address amnesia for past events: its nature in different kinds of memory disorder, its implications for theories of memory storage, and whether it can occur in the absence of broader memory impairment.

Temporal Gradients

Investigations of remote memory loss have often striven to assess Ribot's law, expressed in 1882:

> The progressive destruction of memory follows a logical order . . . it begins at the most recent recollections which, being . . . rarely repeated and . . . having no permanent associations, represent organization in its feeblest form. (Théodule Ribot, 1839–1916)

This is reflected in a temporal gradient whereby the most recent memories are lost but more remote ones are intact. Such temporal gradients have been reported in a number of patients with amnesia of both temporal lobe and diencephalic origin, and a more gentle gradient is also observed in Alzheimer's dementia (see Figure 3).

What is the basis of these gradients? In Korsakoff patients, one possible explanation is that prolonged heavy drinking leading up to the Wernicke episode might result in a progressive anterograde memory loss over this period. However, this view is not supported by cases in which memories lost due to the syndrome are known to have been in the awareness of the individual prior to onset (e.g., memories were described in diary entries), nor by the fact that severity of drinking does not correlate with severity of retrograde deficit. Drinking may, at best, explain the relative steepness of the gradient compared with other syndromes, but not the gradient itself.

Consolidation theory suggests that the medial temporal/diencephalic system is responsible for both memory formation and consolidation of memories into permanence over a period of years, whereas older memories are permanently distributed through the neocortex. This consolidation/structural reallocation account is supported by findings of minimal RA when lesions are confined to the diencephalon or medial temporal lobe, whereas more substantial RA is underpinned by more extensive pathology, which at its extreme (when there is widespread damage of the kind observed in HSE or Alzheimer dementia) produces a flat temporal gradient. However, this consolidation process would operate over a much longer duration than that involved in transfer from short-term to long-term memory, and an extensive temporal gradient, going back 20–30 years, would imply that physiological consolidation occurs over very long durations, which is problematic for this account.

Another account is the multiple trace theory (MTT), in which the hippocampi are assumed to be continuously involved in the storage and retrieval (reactivation) of memory traces. This model proposes that activations within neocortical and other structures represent information, and that these are bound into a memory trace by hippocampal neurons, acting as an index or marker of the distributed memory information. Each reactivation of a memory trace results in the formation of multiple traces indexed by the hippocampus, and the extraction of more generalized factual information into semantic memory stores. In turn, the existence of multiple traces results

Figure 3 Temporal gradients across different tasks. Remote memory curves on different types of tasks obtained in healthy control participants, Korsakoff patients, and Alzheimer patients. (a) Autobiographical incident recall. (b) Personal semantic fact recall. (c) News event recall. Adapted from Kopelman MD (1989) Remote and autobiographical memory, temporal context memory, and frontal atrophy in Korsakoff and Alzheimer patients. *Neuropsychologia* 27: 437–460, with permission from Elsevier.

in temporal gradients with relative preservation of older (more rehearsed) memories, and the extent of RA would depend upon the size of the hippocampal lesion (with severe atrophy/damage leading to a flat gradient). However, past factual information is not coupled to the hippocampus and hence semantic memories can show a temporal gradient, even when severe hippocampal pathology results in a flat gradient for episodic memories.

A third theory is that, over time, episodic memories are recomposed in a semantic form, losing their vividness and contextual (episodic) aspects: a transformation of memories, rather than their replication. Semantic memories are better insulated from loss in brain damage, as they are presumably stored in more widespread and interconnected networks.

At the time of writing, these various positions remain as credible alternative theories of retrograde amnesia. In support of MTT are reports of patients with steep gradients for personal semantic facts together with flat autobiographical memory gradients, following medial temporal lobe damage. However, many such patients also have extensive damage elsewhere, and other patients with damage confined to the medial temporal lobe or diencephalon show a brief, graded RA – the latter is more consistent with the structural reallocation account of RA. Meanwhile, the episodic-to-semantic memory account – wherein early semanticized memories are easier to retrieve under suboptimal conditions – is consistent with evidence of a retrieval deficit in RA, and the weakness of the relationship between anterograde and retrograde deficits. However, temporal gradients can also be found within the semantic domain, such as for new word learning.

Focal Retrograde Amnesia

A number of cases in the literature have been reported to show a profound RA, with anterograde amnesia slight or absent. However, closer examination of these cases show they provide only limited evidence for the existence of a neurological focal retrograde amnesic syndrome. In a review of the literature, Kopelman found that in many cases the anterograde component was substantial, in others modest but certainly present, and that effort has not always been made to equate the difficulty of retrograde and anterograde tests, which may differentially rely on specific cognitive processes such as visual imagery. Accounts of focal RA have relied on impairments in semantic, autobiographical, or public event knowledge, and may have overemphasized isolated dips in performance in the absence of a more generalized impairment. Moreover, a thorough assessment of psychiatric state is rarely reported; this is relevant, as the retrograde impairment may reflect a psychological or simulated component (see Figure 4). The more convincing cases have included those who showed an initial anterograde amnesia which then abated, and cases of transient epileptic amnesia; however, the former may be better characterized as instances of failure to recover retrograde amnesia, and the latter could be explained as the consequence of periods of faulty encoding across the life span due to brief runs of seizure activity. Cases in which a psychological component made a substantial contribution are interesting in their own right and pose issues both for the clinician and for the researcher of memory. There is continuing debate as to whether psychogenic cases are underpinned by a neurophysiological component – such as in frontal control mechanisms – or whether their understanding is best attempted at a more cognitive or psychosocial level, such as memory suppression mechanisms deployed in response to certain stressors.

Confabulation and Memory Distortion

Confabulation was defined by Berlyne as "falsification of memory occurring in clear consciousness in association with an organically derived amnesia." He argued that it can arise either in a momentary fashion or as spontaneous outbursts from the patient. The former is far more common, and is characterized by the confabulated content being produced as a response to a demand for memory information unavailable to the subject. These provoked confabulations can be viewed as an extension of the kind of intrusion errors seen in recall memory performance by healthy individuals, as well as occasional fill-ins and guesses intended to smooth over awkwardness. Spontaneous confabulation is rarer, but when it occurs it tends to persist either over a short period of time, such as within a confusional state, or over more extended periods, in which case it is usually associated with ventromedial frontal lobe pathology.

A number of theories of spontaneous confabulation have been proffered. One is that the memory errors are the consequence of misattribution of context to memories, such that memories associated with a certain location or time are attributed to another (such as recalling a bank transaction and relocating this event to the current environment of a hospital). This idea originates from Korsakoff's descriptions of confabulations that were essentially confusions in time. Another possibility is that the fault lies not in context memory but within a broader evaluation of the origin of memories. According to this view, much of the patients' memorial information is impoverished or uncoupled from details of where or when it originated, from whom it was given, and

Figure 4 Social factors and brain systems influencing autobiographical memory retrieval and personal identity. The diagram shows frontal lobe processes (gray box) involved in confabulation (trace specification/verification; context memory/source monitoring), and social factors (ovals, circle) and brain systems (rectangles) involved in psychogenic amnesia: Inhibition leads to impaired retrieval of incidents and facts, and severe inhibition affects orientation in person. Adapted from Kopelman MD (2000) Focal retrograde amnesia and the attribution of causality: An exceptionally critical review. *Cognitive Neuropsychology* 17: 585–621.

whether the experience occurred at all, or was simply imagined. According to both of these views, the fault lies with the amount of memory information that is retrieved, whereby degraded information, or that uncoupled from associated information, results in confabulatory errors.

A further theory is that the stages of memory search and retrieval are disrupted such that memories are poorly selected, and then verified without adequate monitoring of their appropriateness. Initial memory search suffers either because of introduced noise or overbroad search criteria. Subsequent retrieval stages are also prone to failure, including checking that the memory accords with the initial goal of searching for it, as well as whether it is implausible or otherwise problematic. The patient thus produces erroneous memories that a healthy memory system would have halted within its verification system. Plausibility is given to this account by the fact that memory retrieval, information assessment, and judgments are all cognitive processes associated with frontal lobe function. There is also experimental evidence that confabulators make errors in memory judgments that are not dependent on context, but which depend upon accurate strategic retrieval, such as recalling details of fairy tales and bible stories.

Schnider has argued that the problem in confabulation is not in memory *per se*, but in a component of the brain's reward system that acts to suppress memory traces that do not pertain to current ongoing reality. According to this view, evoked memories are accompanied by mental associations to other more tangential memories; these are normally easily distinguished and inhibited when the individual wants to act or make a decision, but for confabulators these persist with a strong experiential sense of relevance (see Figure 5 for a depiction of this). Schnider notes that a neuroanatomical site common to spontaneously confabulating patients is the orbitofrontal cortex, part of the anterior limbic system which orchestrates communication between the neocortex and the subcortical reward system, directly via the ventral striatum. He also provides data which demonstrate that spontaneous confabulators fail an experimental test distinguishing currently relevant from irrelevant memories. Later, they pass this test once their confabulating has resolved. However, some recent evidence contests the specificity of this linkage.

There has been recent evidence that confabulations may be biased toward emotionally motivated content. Patients will produce information that is self-enhancing – that they are younger than they truly are,

Figure 5 Model of 'now representation' in thinking. Any letter is meant to indicate an event or memory trace. The sizes of the letters indicate their saliency in thinking. Letters outside the boxes are external cues. In normal memory, traces are activated by external cues and associations with other activated cues. When the system is required to adapt to ongoing reality (a fresh cue), these items are then suppressed, with weaker (more tangential) traces fading quicker than recently seen ones; thus, the healthy brain remains in the 'now' but has access to the past. In amnesics, this process occurs, but the trace relating to the recently viewed item is lost at a rate similar to that for more tangential items, trapping amnesics in the 'now.' Spontaneous confabulators are unable to suppress the memories that are no longer currently relevant, allowing a tumult of traces to ensue.

that dead or distant relations are alive or near, or that the severity or awkwardness of their current situation is minimized. This may be because the damage to the executive system has eroded the distinctions between the idealized representation of self and the actual sense of self, such that idealizing distortions are more likely to be accepted than in healthy individuals.

Summary

The state of our understanding of memory disorders continues to develop. The natures of the various etiologies are well established and currently the focus of interest is upon the conceptual issues that underpin memory formation, loss, and confusion. The roles of the hippocampi in recollection and in recall memory and the putative hippocampal role in the reactivation or consolidation of memories are of crucial interest, as are formation of semantic memories and whether this depends upon the episodic memory store. The psychological contribution to memory disorders is likely to garner increasing attention, not just in psychogenic fugue and focal retrograde amnesia, but also in interaction with clearly neurological factors, as will the deficits that give rise to pathological false memory. Progress will be made through neuropsychological studies of patients, together with neuroscientific techniques – preferably employed in concert – resulting in better understanding of the causes of memory disorders.

Introduction

During the course of everyday life, we are nearly continuously forming new memories – and then retrieving them on demand. Some of these memories are only short-lived, like memoranda (e.g., a telephone number when dialing); without rehearsal, they are gone from our mind within a few seconds. This type of memory is called short-term memory or, in other words, working memory, in that it is thought to be critical for thinking or higher cognitive functions. Other memories are long-lasting and accumulate in our brains. These include personal memories of past experiences (episodic memory; e.g., "you had a good dinner with your friend last weekend") and knowledge about the world (semantic memory; e.g., "a dog has four legs and wags its tail"). This type of memory is classified as long-term memory or, more precisely, long-term declarative memory, which can be consciously recollected. Both short-term memories and long-term declarative memories are thought to be represented and retained in the cerebral cortex. There are also other memory systems, including priming, procedural learning, classical conditioning, and emotional learning, which are collectively termed implicit or nondeclarative memory. These memory systems work unconsciously, and the results of their processing are expressed in behavior or performance of tasks. Although the cerebral cortex also plays a key role in nondeclarative memory systems, in this article we will focus on representation of short-term memory and long-term declarative memory, which will be described mainly based on animal studies carried out using macaque monkeys.

Short-Term Memory Representation during Working Memory Tasks

Short-term memory is thought to be represented in a network involving several cortical regions, including the prefrontal cortex and the posterior sensory cortices. Within this network, the prefrontal cortex is thought to play a pivotal role by controlling and making use of the subsidiary posterior cortices to enable retention of short-lived information that is relevant for goal-directed behavior at that moment. Our understanding of the role played by the prefrontal cortex derives from several observations. (1) Monkeys with prefrontal lesions show an impaired ability to perform delayed response tasks or delayed alternation tasks, in which they must retain a sample position or previously selected position for brief periods to get rewards. Moreover, monkeys with mid-dorsolateral prefrontal lesions show an impaired ability to perform working memory tasks, such as self-ordered tasks in which they must keep in mind their previous selections and utilize the information for subsequent correct responses. For instance, in one self-ordered task the monkey faced three food containers, each with a distinctly different shape and color. In the first trial, all three containers had a reward inside, and the monkey could select any container to get a reward. In subsequent two trials, however, the monkey would be rewarded only if he selected a container that was not selected in an earlier trial. Thus, especially in the third trial, he had to keep in mind his previous selections and refer to them to correctly avoid vacant containers. (2) During short-term memory tasks or working memory tasks, the prefrontal cortex exhibits sustained neuronal activity during delay periods in which monkeys are required to hold information in memory in order to perform their tasks. This sustained activity is maintained across intervening distractors as long as the information in short-term storage is task-relevant and necessary. (3) Neurons in the prefrontal cortex are able to encode a variety of types of information depending on the situation; they are not restricted to specific modalities. Prefrontal neuronal activity has been associated with short-term storage of information about stimulus identity, about stimulus position and about their concatenation, and even about more abstract notions, such as a task mode (which rule to adopt) and category (which category stimuli belong to). Prefrontal neurons also encode prospective information, including target identity or positions for impending responses. (4) Several prefrontal areas are further activated in imaging studies when required to manipulate the contents held in short-term memory. Moreover, a population of prefrontal neurons is involved in instructed shift of spatial short-term memory or in transformation from sensory-derived information to motor-related information. A keyword to describe the nature of prefrontal neuronal activity is thought to be 'relevance' – that is, neurons in the prefrontal cortex appear to be able to encode anything relevant to goal-directed behavior at that moment. That said, some mild tendency toward regional modal specificity is suggested in the prefrontal cortex: the dorsolateral region is associated with spatial information, the ventrolateral region with object information. This tendency is consistent with differences in corticocortical

connections between specific regions of the prefrontal cortex and the posterior sensory cortices.

The macaque inferior temporal (IT) cortex is one of the aforementioned posterior sensory cortices and plays a part in representing short-term memory of visual objects. The IT cortex is known to be the highest region in the object vision pathway, through which external objects are analyzed in a stepwise fashion from retinal visual inputs toward object identity. IT neurons respond to visual features which vary from moderately complex shapes (e.g., a spiny starlike shape or a striped triangle) to combinations of such shapes with color or texture. One early study revealed that IT neurons show sustained activity during the delay periods in a delayed matching-to-sample (DMS) task making use of colored stimuli. During the task, the monkeys were required to retain a sample color in mind for 16 to 20 s, after which they had to discriminate a matching choice color from a distractor color. Some of these delay-responsive neurons exhibited different levels of activity depending on the color of the stimuli, which suggests that this activity is a neuronal representation of color information that the monkeys retained in short-term storage while performing the task (**Figure 1**). In later studies, it was demonstrated that a population of neurons in the macaque IT cortex exhibit strong selectivity for complex computer-generated visual patterns. This selective activity was observed not only during stimulus presentation but also after offset of the stimulus, during the delay period when monkeys were required to keep the stimulus information in mind. For instance, when monkeys were trained to perform a DMS task involving a large set of fractal patterns and a 16 s delay period, it was found that individual anteroventral IT neurons commonly exhibited strong delay period activity only after presentation of certain stimuli making up a small fraction of the stimulus set (**Figure 2(a)**). Notably, this selective delay period activity was independent of the physical attributes of the sample stimuli – that is, it was unaffected by the size, orientation, color, and position of the stimuli (**Figure 2(b)**). Thus delay period activity in these IT neurons probably represents short-term information about the stimulus identity.

Figure 1 Activity of an IT neuron during a DMS task using four sample colors. Sample (S) and matching (M) periods are indicated by horizontal bars below the horizontal axis. Every line represents the mean firing rate during four to six trials with each of the four sample colors. The delay period activity of this neuron differed depending on the color of the sample. The neuron also exhibited color-dependent differences in activity during the sample and matching periods. The brain schemas on the right show area TE and the position of the neuron (black dot) in a cross-section of area TE (shaded). Reprinted with permission from Fuster JM and Jervey JP (1981) Inferotemporal neurons distinguish and retain behaviorally relevant features of visual stimuli. *Science* 212: 952–955. Copyright [1981] AAAS.

Figure 2 Response properties of macaque anteroventral IT neurons in a DMS task using a large set of colored fractal patterns. (a) Distribution of the responses of a neuron to 64 different fractal patterns. For each fractal pattern, the neuronal activity during the delay periods was averaged over more than four trials in which the fractal patterns were presented as sample stimuli. The horizontal axis indicates response strength in terms of firing rates, and the vertical axis indicates the number of fractal patterns. Examples of the fractal patterns used are also shown, with arrows indicating the neuronal responses they elicited. This neuron responded highly selectively to a few optimal stimuli (two examples are on the right-hand side) and only poorly to the others (the examples on the left-hand side). (b) Responses of another neuron. This neuron shows invariance in its responses after altering the size, orientation, or color of the stimulus: the original fractal patterns (original) were reduced in size by half (size), rotated 90° clockwise (rotation), or transformed from color to monochrome by referring to a pseudo-color lookup table (Monochrome). The averaged delay activities are plotted against stimulus transformation. This IT neuron discharged during the delay after one particular fractal pattern (closed circles) but not after others (the other markers), irrespective of pattern size, orientation, or color. Most of the neurons tested showed similar response invariance: size invariance was observed in 16 of 19 neurons, orientation invariance in 5 of 7 neurons, and color invariance in 15 of 20 neurons. With the neurons that did not show response invariance, manipulation of the most effective pattern reduced or abolished delay activity. The closed circles represent responses to the original optimal fractal pattern and its transformed patterns (shown at the bottom of the figure). Error bars indicate standard deviations for 4–15 trials. The other markers denote responses to the original suboptimal fractal patterns and their transformed patterns. Reproduced from Miyashita Y and Chang HS (1988) Neuronal correlate of pictorial short-term memory in the primate temporal cortex. *Nature* 331: 68–70, with permission from Nature.

Long-Term Memory Representation in the Macaque IT Cortex

Emergent Stimulus Selectivity in IT Neurons

Neurons in the IT cortex show a high degree of plasticity with respect to their selectivity for visual stimuli. As described in the previous section, a substantial population of macaque IT neurons responds highly selectively to computer-generated geometric stimuli (Figure 2(a)), even though these artificial stimuli were completely unfamiliar to naive monkeys. Since it is highly unlikely that the IT cortex inherently contains neurons that are tuned to these computer-generated stimuli, their strong selectivity is thought to be newly acquired through repeated experience. Consistent with this idea, IT neurons have been shown to respond more selectively after training than before training to some types of stimuli,

Figure 3 Responses of neurons in the perirhinal cortex and adjacent cortical areas to visual stimuli during a serial recognition task. (a) Responses of a recency neuron. The neuronal responses to the first (top row) and repeated (bottom row) presentations of novel (left) and familiar (right) stimuli are shown as peristimulus time histograms of the neuronal discharge and rastergrams denoting individual discharges in several trials. Note that the responses to the stimuli were significantly larger upon the first presentation in the session than they were upon repeated presentations, regardless of the stimulus familiarity – that is, these responses signaled whether the stimulus had

including fractal patterns, Fourier descriptors, baton-like stimuli, and animal-like stimuli. Training also increases the proportion of neurons that will selectively respond to a particular visual stimulus. Moreover, visual experience increases the similarity of the responses of nearby neurons to a particular visual stimulus. This emergent stimulus selectivity within the IT cortex appears to result from the reorganization of neural connections through experience or learning, which probably boosts perceptual processing of appropriate stimuli and leads to the development of expertise when monkeys are trained on a task. In that sense, the strong emergent stimulus selectivity of IT neurons can be said to be an expression of long-term memory representation.

Neuronal Correlates of Recognition Memory

Recognition memory, which is a type of long-term memory that includes an episodic aspect, is the ability to judge whether an item was recently encountered or not. This memory is thought to be largely dependent on the perirhinal cortex, which is situated in the anteroventral part of the IT gyrus neighboring the hippocampus, and contains neurons exhibiting activity that is modulated by the recency and familiarity of visual stimuli. For instance, when monkeys performed a serial recognition task in which they were required to discriminate novel or unfamiliar stimuli from familiar or recently seen stimuli, three types of neuronal responses were observed in the perirhinal cortex and adjacent cortical areas, including the entorhinal cortex and area TE (Figure 3). One group of neurons appeared to encode recent presentation of a visual stimulus: the neurons showed diminished responses to repeated presentation during a daily session or after 24 h, irrespective of stimulus familiarity. Another group of neurons appeared to encode the familiarity of a visual stimulus: these showed diminished responses to familiar stimuli, irrespective of the recency of presentation. A third group appeared to encode a combination of recency and familiarity: these neurons showed specific responses to the first presentation of novel stimuli. The proportions of these three neuronal types are similar in the perirhinal cortex and adjacent cortical areas, and their responses are thought to be highly important for performance of recognition memory tasks. Thus, reduced neuronal activity within the perirhinal cortex and adjacent cortical areas, related to the recency and familiarity of visual stimuli, may be neuronal correlates of visual recognition memory.

Neuronal Correlates of Semantic-Like Long-Term Memory

The stimulus selectivity of neurons in the macaque IT cortex may also support formation of long-term associative representations among disparate visual stimuli. For example, in an electrophysiological study, monkeys were trained on a DMS task making use of a large stimulus set of about 100 fractal patterns that were always presented in a predetermined order (Figure 4). After a 16 s delay period following presentation of a fractal sample, the monkeys were required to discriminate a matching choice pattern from a distractor pattern. Single-unit recordings made after overtraining on the task revealed that a population of anteroventral IT neurons exhibited correlated responses to sample patterns that had no geometrical similarity (Figure 4(a)) but were repeatedly presented in close proximity along the predetermined order of the stimulus set (Figure 4(b)). This suggests that, guided by the close temporal proximity of the presented visual stimuli, IT neurons form representations of the temporal relationships between stimuli.

Other evidence of associative representations among stimuli within the IT cortex comes from the findings of a later electrophysiological study which demonstrated that a population of anteroventral IT neurons learned to encode semantic-like relationships between pairs of visual stimuli that are geometrically unrelated and have no other relationship to one another, except that they are operationally associated in the experiments. Specifically, monkeys were trained on a pair-association (PA) task, which is a well-known neuropsychological test that is widely used to assess dysfunction of the medial temporal lobe memory system in humans (usually, the test is composed of tens of word pairs). In a visual PA task using pairs of Fourier descriptors, one member of a pair was presented as a cue stimulus at the beginning of a trial, then after a

been seen recently, but not its relative familiarity. (b) Responses of a familiarity neuron. Responses to novel stimuli were significantly larger than they were to familiar stimuli, regardless of whether the stimuli had been presented once or repeatedly during the session – that is, these responses signaled the relative familiarity of the stimulus, but not whether it had been seen recently. (c) Responses of a novelty neuron. Responses to the first presentations were significantly larger than they were to the repeated presentations of novel stimuli; maximum responses to familiar stimuli were comparable but the firing duration was greatly shortened – that is, this neuron responded best to the first presentation of novel stimuli, and its responses signaled both the relative familiarity of a stimulus and whether it had been seen recently. Reproduced from Xiang JZ and Brown MW (1998) Differential neuronal encoding of novelty, familiarity and recency in regions of the anterior temporal lobe. *Neuropharmacology* 37: 657–676, with permission from Elsevier.

Figure 4 Correlated responses of macaque anteroventral IT neurons to disparate fractal patterns presented in close proximity along a predetermined sequence. (a) While monkeys performed a DMS task in which colored fractal patterns were presented in a predetermined order, single-unit recordings were made from the anteroventral part of the IT cortex. These six pairs of fractal patterns respectively elicited the two highest levels of delay activity in six different neurons. Note that there is no similarity between the geometric patterns of the two optimal stimuli. (b) Correlated responses were observed to disparate fractal patterns in close proximity along the serial position numbers in a learned sample set, but not in a new one. Of 206 IT neurons recorded while monkeys performed the task, 57 showed shape-selective delay activities. For each of those 57 neurons, autocorrelation coefficients for the responses to learned and new sample sets of fractal patterns were calculated and then plotted against the 'distance' between the serial position numbers used to calculate the coefficients. The correlation between neuronal responses was high for fractal patterns in close proximity within the learned set, but was nearly zero for both distantly positioned learned patterns and novel patterns. (●, ○) Average autocorrelation coefficients for the learned and new stimulus sets in 17 neurons that were successfully tested using both sets. (▲) Coefficients for the learned set in the 57 neurons. (■) Coefficients for the learned set in the 28 neurons for which the nearest-neighbor correlation for the serial position number was significant ($P < 0.05$) according to Kendall's test. Error bars are standard errors. Three vertical stars indicate $P < 0.001$; two vertical stars indicate $P < 0.01$; one star, $P < 0.05$ vs. the value for new stimulus list (Kolmogorov–Smirnov test). Reproduced from Miyashita Y (1988) Neuronal correlate of visual associative long-term memory in the primate temporal cortex. *Nature* 335: 817–820, with permission from Nature.

following delay period the monkeys are required to choose the other member of the pair. Single-unit recordings from the anteroventral part of the IT cortex made while the monkeys performed the task revealed that a population of neurons showed comparable or correlated responses to two Fourier descriptors arbitrarily paired in the task (Figure 5); they clustered within 'hot spots' in the region. This correlated selectivity for paired visual stimuli develops while the monkey is learning the relationships between the stimuli. In addition, single-unit recordings also revealed that lesions in the perirhinal and entorhinal cortices, which comprise the interface between the IT cortex and the medial temporal lobe memory system, reduced correlated selectivity for trained paired stimuli in the anteroventral IT cortex (more precisely, anteroventral part of area TE; TEav), even though the neuronal responsiveness to individual stimuli used in the visual PA task was maintained. Moreover, the lesions also impaired formation of correlated selectivity for new pairs in the region. Thus, semantic-like association of one visual image with another, which can be regarded as an elemental unit for the elaborate semantic memory network, is thought

Figure 5 Associative coding of two disparate Fourier descriptors in the macaque anterior IT cortex. (a) Twelve pairs of Fourier descriptors (pictures 1 and 1′ to 12 and 12′) were used as stimuli in a visual PA task for monkeys. The monkeys learned to retrieve the other member of the pair when one member was presented as a cue stimulus. (b) Sequence of trial events in the visual PA task. Lever: lever press by the monkey to initiate a new trial. Warning: green square (1 s). Cue: one of 24 pictures serving as a cue stimulus (1 s). Delay: green square (4 s). Choice: a choice array of two stimuli, the paired associate of the cue and a distractor from a different pair. Reward: fruit juice reward for correctly selecting the associate. (c) Responses of an IT neuron to the 12 pairs of Fourier descriptors. Shown are mean discharge rates elicited by each picture during the cue presentation period relative to the spontaneous discharge rate (indicated by the arrowhead). Cue stimuli are labeled 'pair number' on the horizontal axis. For instance, in pair 1, the left bar indicates the response to picture 1, the right bar the response to picture 1′. The error bars indicate SEM. This neuron responded highly selectively to both pictures in pair 12, even though pictures 12 and 12′ had no apparent geometrical similarity (see panel (a)). Reproduced from Sakai K and Miyashita Y (1991) Neural organization for the long-term memory of paired associates. *Nature* 354: 152–155, with permission from Nature.

to be formed and represented in the neuronal responses of the IT cortex, probably supported by the medial temporal lobe memory system.

Molecular Biological Aspects of Memory Representation

The neuronal plasticity involved in formation of semantic-like associative representations in the anteroventral part of the IT cortex is thought to be supported by reorganization of the synaptic connections among neurons. Consistent with this idea are the findings of a study in which the use of tracer agents was combined with single-unit recording to reveal that divergent neuronal projections from the lateral portion of the anteroventral IT cortex (TEav) to the medial portion (area 36 in the perirhinal cortex; A36) differ depending upon the stimulus selectivity of the projecting TEav neurons. Specifically, when trained on a visual PA task, TEav neurons showing stimulus selectivity for computer-generated patterns (Fourier descriptors) have a greater tendency to project only to a hot spot of A36 neurons encoding semantic-like relationships between the paired patterns than do TEav neurons without selectivity for the trained patterns (these are probably responsive for other visual stimuli not used in the task). Such anatomical and physiological coupling – that is, less

Figure 6 *In situ* hybridization of BDNF mRNA. (a–d) Distribution of BDNF mRNA in the IT gyrus of the PA and control hemispheres. BDNF mRNA accumulated in a patchlike cluster in area 36 (36) of the PA hemisphere (framed area in (a)), but not in area 36 of the control hemisphere (b). The framed areas in (a) and (b) are enlarged in (c) and (d), respectively. BDNF mRNA-positive cells were observed in layers V/VI and II/III of the PA hemisphere (c). En, entorhinal cortex; 35, area 35; TE, area TE; rs, rhinal sulcus. Arrowheads mark the boundaries between different cortical areas. (e–g) Cells positive for BDNF mRNA in layers II/III of the PA hemisphere. The cell indicated by an arrow in (c) is enlarged and shown in darkfield (e), brightfield (f), and brightfield with epi-illumination (g). Silver grains were concentrated around lightly Nissl-stained neuronal nuclei. Cortical layers in area 36 are indicated along the margin of (d). Scale bars = 1 mm (a, b), 250 μm (c, d), and 50 μm (e–g). Reproduced from Tokuyama W, Okuno H, Hashimoto T, et al. (2000) BDNF upregulation during declarative memory formation in monkey inferior temporal cortex. *Nature Neuroscience* 3: 1134–1142, with permission from Nature.

divergence coupled with stimulus selectivity – suggests that synaptic connections were pruned in the course of training on the visual PA task.

In a similar vein, several molecular biological studies demonstrated that while monkeys are learning semantic-like relationships in the PA task, expression of messenger ribonucleic acids (mRNAs) encoding proteins involved in synaptic plasticity is upregulated in the anteroventral IT cortex. In these studies, quantitation of mRNA using reverse transcription polymerase chain reaction (RT-PCR) was combined with a split-brain preparation in which the anterior commissure and the entire extent of the corpus callosum were transected. This enabled comparison of mRNA expression in a PA hemisphere and a control hemisphere within the same monkey, thereby eliminating genetic and cognitive variations between individuals. The experimental results revealed that mRNAs encoding brain-derived neurotrophic factor (BDNF) and the immediate-early gene *zif268* product (Zif268, also known as the transcriptional regulatory factor early growth response 1 (EGR1)) were upregulated in A36, where semantic-like associative memories were reflected within neuronal activity. Moreover, the results of *in situ* hybridization analyses demonstrated that cells positive for BDNF (Figure 6) and Zif268 mRNAs form a patchlike cluster in A36. These observations suggest that upregulation of BDNF and Zif268 mRNAs contributes to the neuronal reorganization that results in formation of semantic-like visual associations encoded within the neuronal activity in the anteroventral part of the macaque IT cortex. A likely scenario is that BDNF induces morphological changes in axonal and dendritic complexity, depending on neuronal activity, while Zif268 triggers a cascade of gene activation leading to synaptic reorganization.

Conclusion

The findings summarized in this article suggest that the prefrontal cortex works as a pivot or control center for short-term neuronal representations, while subsidiary domain-specific posterior cortices are employed to specify the physical features or object identity of the contents held in short-term memory. Visual recognition memory may be reflected by diminished neuronal activity within the perirhinal cortex and adjacent cortical areas, while semantic-like visual associative memories can be formed and represented within the neuronal activity of the anteroventral part of the IT cortex, probably supported by functions of the medial temporal lobe memory system. Viewed from a molecular biological standpoint, such semantic-like associations are thought to be formed through synaptic

reorganization, as mRNAs involved in synaptic plasticity are selectively upregulated in cortical areas where associations are encoded during semantic-like learning. Thus, the cerebral cortex, which processes and analyzes external sensory inputs, also represents and stores short-term and long-term memories in a domain-specific fashion – that is, memories are represented in the corresponding cerebral areas that processed the initial information from which the memories originated.

Memory: Computational Models

M W Howard, Syracuse University, Syracuse, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Computational models of memory are constrained from a number of directions. A physically accurate model of memory must simultaneously describe the details of behavioral performance and the mechanistic neural processes that support such performance. Such a model should simultaneously explain both changes in behavior due to manipulations of the neural substrate, such as lesions or pharmacological manipulations, and the detailed neurophysiology of the underlying structures, as measured by functional magnetic resonance imaging (fMRI), electroencephalogram/event-related potentials (EEG/ERP), and the activity of single neurons. We are far from such a comprehensive view of the neural basis of the types of memory typically studied by cognitive psychologists. However, some progress has been made toward this ideal in several domains. This work can be divided into content areas, distinguished by the types of memory and brain region supporting them, or the level of approach. This article describes the levels of approach that are possible in constructing computational models of memory and reviews progress in one content area – computational models of working memory.

Approaches to Modeling Memory

An endstate comprehensive neural model of cognition must be formulated at several levels of analysis, from the molecular to the very abstract. The question, however, is where to start in this vast endeavor. Presumably we can start from an accurate projection of the correct comprehensive model at any particular level of description and work at redescribing the model at adjacent levels of description. Appropriately, then, computational models of memory have been constructed at several levels of description.

Formal or mathematical models of memory are typically focused on describing behavioral performance in as near to complete detail as possible. Typically models in this tradition start from some simple but abstract low-level structure from which asymptotic or average behavior can be inferred. Although it is clearly desirable that this implementation be interpretable as some neural process, concerns of neural realism have not historically been considered diagnostic in this tradition. For instance, stimulus sampling theory, an early example of this approach developed in the 1950s, postulated that a stimulus was represented by a set of abstract stimulus elements. Learning a stimulus–response association consisted of binding a subset of the elements corresponding to a stimulus to a response. With repeated presentation of a stimulus, a new sample of elements is conditioned to the appropriate response, resulting in learning that gradually approaches an asymptote. An elaborated version of this simplified model was developed to describe changes in the strength of retention with different retention intervals and presentation schedules by postulating that the set of stimulus elements available to be conditioned fluctuated gradually over time. Although the abstract processing elements of stimulus sampling theory do not map simply on to any known neural process, or even brain region, closed-form analytic solutions can be derived for a number of important quantities that map on to behavioral observables. Mathematical models of memory have grown more elaborate since the 1950s, so that computer simulation is usually required to develop complete behavioral predictions.

To provide a more concrete idea of how such ideas might be actualized, Figure 1(a) illustrates some of the basic assumptions of stimulus sampling theory. A set of abstract elements, represented by filled or open circles, are available to represent a stimulus on each trial. The set of such elements used to represent the stimulus on a trial is represented by the set S. The remainder of the set of stimulus elements, which are unavailable, is referred to as S'. On the first learning trial, shown on the left, all of the elements in S are conditioned to the response. Conditioned elements are shown as large open circles, whereas unconditioned elements are shown as small filled circles. Over a delay, abstract processing elements shift from S to S', and vice versa, with transition probabilities defined by j and j'. These fluctuations lead to a forgetting of the conditioned response as conditioned elements used to describe the stimulus transition from the active set to the inactive set.

Connectionist approaches to memory modeling adopt a somewhat intermediate level of description. Rather than relying on completely abstract processing elements, connectionist models rely on sets of interconnected units that are often mapped explicitly on to specific brain regions. These units typically have a scalar activation at each time step that corresponds to the firing rate, perhaps averaged over a group of physical neurons and connections, perhaps modifiable, between units that correspond to synapses or at least to pathways between brain regions. Although we can find counterexamples to all such generalizations, connectionist models of memory focus less on a quantitative description of behavior than do

Figure 1 Approaches to computational models of memory: (a) mathematical model; (b) connectionist model; and (c) biophysical model. In (a) Estes's stimulus sampling model exemplifies mathematical models; they generate behavioral predictions from a small set of mathematical rules that need not map on to actual neural processes. In (b), Norman and O'Reilly's model of item recognition exemplifies connectionist models; they describe memory performance using a set of quasineural processing elements. In (c), Wang et al.'s model of working memory exemplifies biophysical models of memory; they attempt to provide a realistic description of the cellular processes that contribute to memory performance. CA3 and CA1, subfields of the hippocampus; DG, dentate gyrus; ECin, input layer of the entorhinal cortex; ECout, output-layer of the entorhinal cortex; P, pyramidal cells; PV, CV, CR, subpopulations of interneurons; SR, stimulus-response interaction; STS, short-term store. (b) Adapted from Norman KA and O'Reilly RC (2003) Modeling hippocampal and neocortical contributions to recognition memory: A complementary learning systems approach. *Psychological Review* 110(4): 611–646.

mathematical models. These models are evaluated as much on the basis of their neural plausibility, given what is known about the anatomical circuits and physiology underlying the regions. These constraints can come from correctly describing the qualitative effects of physiological manipulations, such as brain lesion or pharmacological manipulations.

Figure 1(b) shows an example of a connectionist model of item recognition memory, a memory task in which the subject is given a probe item and asked whether it was presented as part of a study episode. In this model, a set of interconnected abstract processing elements are identified with brain regions. In this case, an input pattern is presented to a set of processing elements identified with input layers of the entorhinal cortex (EC). These processing elements are connected to other elements identified with other brain regions – in this case the dentate gyrus (DG) and the subfields of the hippocampus (CA3 and CA1). The model's memory for a recognition probe can be assessed by examining the degree to which the pattern in the output layer of the EC (EC_{out}) resembles the input pattern presented to the input layer (EC_{in}) when the pattern is repeated as a probe item after learning.

At a yet more detailed physical level, biophysical models of memory attempt to describe memory processes using models of neural activity that are not merely plausible but as close to physically accurate as possible. Typically model neurons in these simulations fire individual spikes, with a set of realistic conductances taken from experimental data. The goal of biophysical models of memory is typically not to model behavioral data *per se* but rather to show how a mechanism believed to relate to some cognitive mechanism supporting some type of memory performance could be physically implemented. These models are typically evaluated in terms of their ability to accurately describe the currents and firing rates observed in neurons during performance of a task believed to be related to the cognitive processes that are under study.

Figure 1(c) shows a biophysical model designed to capture aspects of working memory maintenance, a mechanism believed to be required to retain information in attention for a short time. In this simulation, there are several subtypes of simulated neurons that are interconnected to one another. Figure 1(c) shows the response of each of the types of model neurons to a transient injected current. Simulated pyramidal cells (P) are interconnected with three types of interneurons. The pyramidal cells are modeled as three-compartment neurons – that is, at the subcellular level. The pyramidal cells and interneuon populations differ in their intrinsic properties, synaptic properties, and network connectivity. In this simulation, the traces labeled PV, CB, and CR correspond to three different subpopulations of interneurons. This model is primarily evaluated on the basis of its ability to describe the detailed behavior of neurons of the different classes observed in the prefrontal cortex during the maintenance phase of a working memory task in which a monkey must remember a spatial location.

These three examples illustrate a number of differences among mathematical, connectionist, and biophysical approaches. They can be seen as lying on a

continuum in terms of several variables. The spatial scale over which these models are specified obviously varies, from the behavior of the whole organism in the case of mathematical psychological models to sets of cells identified with brain regions in the case of connectionist models to subcellular processes in the case of the biophysical model. These approaches also differ with respect to the temporal scale over which the models are specified. Whereas mathematical models often treat memory in units of stimulus presentations, which may be several seconds, connectionist models typically measure time in tenths of seconds. In contrast, biophysical models often describe somatic voltage at the submillisecond timescale.

In addition to the (often considerable) difficulty associated with getting a model to work within a particular level of description, there is an additional level of difficulty in constructing models that make contact across levels of description. We use the term memory to encompass a very broad range of phenomena, including everything from an aplysia learning to retract its gill to a person consciously recollecting the sounds and sights of a specific event given, say, a familiar odor as a cue. These phenomena, and others, are typically studied separately, with the range of phenomena under examination organized by a putative memory system, or perhaps the specific brain region (or regions) believed to be crucial in a particular task. A great many such problems that have been addressed using computational models of memory at one or more levels of investigation. Some of the more notable topics that have benefited from computational models of memory include categorization, delay and trace conditioning, cognitive control, associative learning, and hippocampal-dependent memory. A thorough survey of these diverse problems is impossible given the space constraints of this article. Instead, we restrict the content of our discussion severely and discuss computational models of working memory maintenance. This area is perhaps particularly well suited to giving the reader a flavor of the different approaches that are possible using computational models of memory. The models that have been developed to study working memory are also perhaps notable in that a number of attempts have been made to bridge multiple levels of analysis.

Models of Working Memory

To cognitive psychologists, the term working memory is used to describe the set of cognitive processes required to store information actively in attention for a short period of time and make decisions based on that information. Ideas about working memory have evolved from previous conceptions of short-term memory. These models pay differing amounts of attention to the necessity of, on the one hand, storing information for a short period of time and, on the other, controlling what information enters into short-term storage and how it might be manipulated.

The 1960s and 1970s saw the development of very successful mathematical models of short-term memory. The most prominent of these was the Atkinson and Shiffrin (AS) buffer model (**Figure 2(a)**). In this model, attentional control processes gate information into and out of a labile, but limited-capacity, short-term store (STS). Activity in short-term store is closely associated in this view with the process of rehearsal, in which subjects actively and consciously repeat to-be-remembered materials to themselves. For instance, suppose that someone tells you a phone number that you must remember for a few seconds before you can write it down. A common strategy in this situation is to repeat the digits to yourself to keep them fresh in your memory. Subjects in human verbal learning studies frequently adopt a rehearsal strategy to help them remember the study items. Formally, STS was conceived of as a small number of slots, typically two to four, into which study items could be copied. There are a small integral number of slots, and an item can either be present or absent in the buffer – no partial activation was allowed. The relatively small capacity of STS means that decisions must be made about what information to prioritize. In the AS model, these decisions are assumed to be under conscious strategic control, although the rules for deciding what information should be maintained or discarded were not explicitly modeled but rather assumed to reflect specific strategies appropriate to a particular task. Finally, STS serves as a gateway for information to be stored in long-term store (LTS). The longer an item remains active in STS, the better the chances that it will be successfully stored and later recovered from LTS.

The AS model and its successors were extraordinarily successful at describing human behavioral data in a relatively wide variety of experimental paradigms, including a continuous paired-associates task and the free recall task, in which subjects are presented with a list of words and then instructed to recall them in any order they think of them. As a consequence, ideas about short-term memory from the AS model, including the notion of a short-term store that retains an integral number of stimuli in a discrete fashion, have persisted and been implemented in a variety of biophysical and connectionist models of working memory.

Connectionist models of working memory have emphasized the importance of maintenance of information as a subprocess in the service of cognitive

Figure 2 Approaches to models of working memory: (a) buffer model; (b) Lisman–Idiart–Jensen (LIJ) model; (c) bifurcation plot of dynamics in a multistable biophysical model; (d) biophysical simulation of multistability observed in layer V cells in the entorhinal cortex. In (a), incoming information is stored in one of a discrete number of working memory buffers; information is either present or absent in these buffer slots. In (b), the LIJ model is a biophysical instantiation of the buffer model in which neurons representing different items coactive in the buffer occupy different subcycles of an ongoing theta oscillation. A raster plot from a biophysical simulation is shown. Neurons corresponding to each of several items are presented, and patterns of activated items are either in the buffer or not. For instance, item 7 is initially present in the buffer, but then falls out when item 8 is presented. In (c), the multistable biophysical model exploits network properties to implement bistability. The network consists of cell assemblies with excitatory recurrent connections and inhibitory lateral connections. The *y* axis plots the firing rate of one of the assemblies and the *x* axis plots its external input current. The stable states of the dynamics are shown with solid lines. When the input current exceeds a threshold (approximately 0.4 in the figure), the activity of the assembly jumps from the value on the lower line to the value on the upper line (curved arrow). After this takes place, the cell remains active even after the external current is removed (dashed line). A sufficiently large inhibitory current can cause the assembly to return to rest (left side of figure). In (d), under appropriate conditions, layer V cells respond to a depolarizing input with a sustained nonzero firing rate. As additional inputs are presented, the cell adopts a new stable firing rate (B and C). This property does not depend on recurrent connections because it was observed under conditions of synaptic isolation. In the biophysical simulation shown here, multistability is a consequence of a fixed-point attractor, the location of which can be changed by changes in the number of activated channels, a process which is triggered by sufficiently large changes in Ca^{2+} concentrations. Note the long time scale.

control. For instance in the Stroop task, subjects are presented with a color name in a colored font that may be inconsistent with the named color; for instance, the word red written in blue. In this task, subjects are instructed to read the word rather than report its actual color. Subjects are much slower to read the name, and they make more errors, when the physical color is inconsistent with the written color name (e.g., the word red written in blue) than when it is consistent (e.g., the word red written in red). Neuropsychological data indicate that the ability to inhibit the tendency to say the name of the physical color depends on an intact prefrontal cortex. A number of closely related connectionist models of working memory describe the ability to control the inappropriate response by means of active attentional maintenance of a rule representation (i.e., say-the-name-of-the-word). This rule representation modulates, or gates, the appropriate behavioral response to the physical stimulus. For the rule representation to remain active, it must be actively maintained in a short-term buffer in prefrontal cortex. In these connectionist models, then, the concept of active maintenance is retained, but the emphasis is more on the maintenance of rules than on information to be committed to long-term memory.

Biophysical models of working memory have focused on the mechanisms of active maintenance rather than on either the role of this maintenance in executive processing or its potential role in transferring

information to long-term memory. A variety of biophysical mechanisms have been proposed for working memory maintenance in at least two distinct regions. These models can be roughly divided into two classes: those that rely on network properties to allow persistent firing and those that rely on intrinsic properties of individual neurons that allow them to maintain firing over long durations. A goal of many of these efforts has been to implement bistability – a population of neurons that have two stable states, one with a high sustained firing rate and one with a much lower firing rate. In this sense, these models have retained the idea of all-or-none activation present as early as the AS buffer model.

Network models rely on the idea that a population of neurons is divided into cell assemblies with strong exitatory connections within an assembly and inhibitory connections between neurons from different cell assemblies. If the parameters of the model are chosen appropriately, the network will have the property that, if an assembly is given a sufficiently large external input, the recurrent connections sustain a high level of firing that can persist even when the external input is removed. The assembly will then remain active until a sufficiently large inhibitory input, either an inhibitory external input or an excitatory input to another assembly, causes it to return to the rest state (Figure 2(c)). Network models are widely believed to describe the basis of sustained activity observed in neurons in the prefrontal cortex. The anatomical organization of the dorsolateral prefrontal cortex, with interconnected pyramidal cells and a spatially distributed network of interneurons, suggests that it may be organized into columns that serve as cell assemblies.

Cellular mechanisms for bistability that do not depend critically on recurrent connections have also been proposed. The Lisman–Idiart–Jensen (LIJ) model proposes that large afterdepolarizations observed in some cells may be sufficient to cause a cell to fire again. If an initial spike can cause a second spike, then the cell will continue firing for a macroscopic time interval. In order to allow for multiple items to be maintained simultaneously, the LIJ model proposes that brain oscillations play a role in organizing the firing of patterns of spikes corresponding to separate items that are activated in memory. In the LIJ model, theta oscillations, large 4–12 Hz oscillations in the local field potential that are especially prominent in the hippocampus, serve to provide a temporal frame for the item representations such that spikes corresponding to each of the items active in working memory fire once per theta cycle. The patterns corresponding to different items are kept separate from one another because the patterns are constrained to fire on different cycles of gamma (40–80 Hz) oscillations (see Figure 2(b)).

Using nested gamma and theta oscillations, the LIJ model has been used to model most of the features of the AS model in a biophysically plausible way. For instance, the biophysical model allows patterns of activity to drop out of the buffer in an all-or-none fashion (note the fate of pattern 7 in Figure 2(b)). Inclusion of synaptic plasticity via *N*-methyl-D-aspartate (NMDA) channels has been shown to lead to long-lasting changes in the strength of the connections between items active in short-term memory, analogous to the transfer from STS to LTS, critical in the AS model. The major application of the LIJ model to directly describing cognitive data has been the Sternberg task. In the Sternberg task, the participant studies a list consisting of no more than a handful of stimuli. At the end of the list, the participant is given a probe item and must decide if the probe was part of the list or not. The key finding is that the amount of time it takes the subject to decide if the item was on the list or not increases linearly with the number of items on the list, at least for small list lengths. The LIJ explains this linear slope because of the strict temporal ordering of the items active in memory. In addition to the fact that the slope, typically around 40 ms/item, is on the order of what we would expect if we had to wait for a gamma cycle for the next item to come up, variants of the LIJ model have been shown to describe human performance in the Sternberg task in remarkable detail. Moreover, since the LIJ was first proposed, a wealth of data implicating theta and gamma oscillations in working memory and the Sternberg task in particular have been discovered. The LIJ provides a biophysical implementation of the assumptions of the AS model and also of Sternberg's ideas about how subjects scan through a short list of items to reach a decision on the probe. As such, it provides a remarkable example of a model that bridges multiple levels of description.

More elaborate forms of persistent neural activity that do not depend on interconnections between cells have been observed in the EC. Cells in layer V of the EC have been shown to be able to produce extremely long-lasting persistent firing in the absence of synaptic input. Moreover, these cells are able to gradually change their firing to reflect the summation of their inputs. That is, a first stimulus might cause the cell to fire steadily at a given rate. A second stimulus would cause the neuron to jump to a new steady firing rate. The mechanisms underlying this remarkable ability are a topic of intense investigation. It is known that persistent firing depends on a Ca^{2+}-sensitive nonspecific cation (CAN) channel that remains open for long periods. The firing rates a cell can sustain are

apparently graded, rather than discrete, and are observed even when intracellular stores of Ca^{2+} are depleted. One theory of how this remarkable behavior is possible is that at any time the current dynamics are controlled by a fixed-point attractor that is insensitive to small perturbations. However, sufficiently large (in terms of amplitude and/or duration) changes in the internal Ca^{2+} concentration cause the location of this fixed state to gradually change. The exact intracellular mechanisms of how this is accomplished are not known, but a plausible multicompartment model implementing these ideas is able to simulate the behavior of multistable integrator cells in remarkable detail (see **Figure 2(d)**).

Intrinsic persistent activity is an extremely important property for a general working memory system to have. If the ability to maintain information in working memory requires a preexisting synaptic network, as in the recurrent networks supporting bistable cell assemblies such as those shown in **Figure 2(c)**, then, because cell assemblies must support one another, the number of patterns that can be maintained (at different times) must be less than the number of neurons. In contrast, if neurons can maintain their own firing for arbitrarily long periods of time without network connections, then the number of distinguishable patterns that can be maintained at different times can even exceed the number of neurons. This property is extremely useful for a working memory buffer in the spirit of the AS model that should be able to store at least all the words in the English language.

The other unique property of multistable cells is their ability to support a gradual decay of information rather than the precipitous all-or-none dropout rule of the AS model that is implemented in the bistable biophysical models. This gradual decay of information in working memory is a characteristic of a more recent mathematical model of working memory maintenance and storage of information into long-term memory – the temporal context model (TCM). Much like the AS model, TCM was formulated as a mathematical model of experiments in which participants learn and recall lists of words. As such, it has predicted and explained several findings that would be counterintuitive if the AS model were a literally accurate description of maintenance and storage of recently presented information. TCM differs from the AS model in two respects: (1) rather than decaying in an all-or-none fashion, information decays gracefully from the working memory store in TCM, which is referred to as a temporal context vector, allowing TCM to describe gradual forgetting over much longer time scales than the AS model can, a property that is consistent with some behavioral data; (2) in TCM the input to the working memory store caused by an item is not fixed over time, as in the AS model, but can change to reflect the temporal context in which the item was presented. This ability to bind items to the temporal contexts they are encoded in turns out to have several important implications.

Recently, proponents of TCM made a bridging hypothesis to connect the abstract mathematical model with the actual neural substrate. They proposed that the temporal context vector should correspond to the pattern of activity across cells in extra-hippocampal medial temporal lobe regions, in particular the EC. They showed that a population of multistable cells, such as those illustrated in **Figure 2(d)**, if subject to cortical gain control, could implement the equation for the change of temporal context in such a way as to allow the gradual decay of information in the temporal context vector. Continuing the mapping between TCM and the brain, the function of the hippocampus proper is to enable items to be bound to and subsequently to recover the temporal context or state of activation in the EC, that obtained when they were studied. This assumption made it possible for the model to account for the effect of hippocampal lesions on learning tasks in rats.

The approach of models exploiting the bistability property introduced by the AS model and the multistability property exploited by TCM differ considerably in their behavioral predictions and the range of potential implementations. It might be nice if one could declare one approach correct and the other incorrect. A more likely outcome is that both reflect some insight into how working memory maintenance behaves in different circumstances. One means of reconciliation is to note that the connectionist view of working memory maintenance as something that retains goal states in prefrontal cortex does not overlap particularly strongly with the view of a gradually changing representation of recent experience in extra-hippocampal medial temporal lobe cortical areas. Perhaps both are accurate descriptions of related but distinct phenomena. In this case, bistable maintenance of goal states would not typically have much to do with how we remember recent events, whereas a gradually changing state of temporal context would not be much use in performing the Stroop task.

Computational models of memory can be roughly divided into three classes that differ in their level of realism and commitment to explaining cognitive versus neural data: formal or mathematical models, connectionist models, and biophysical models. Although each of these approaches is valid in its own right, the fact that recent models are attempting to bridge these levels is a promising development. Computational models of working memory at all three levels have been reviewed, but it should be kept

in mind that similar developments are taking place in the study of many types of memory and many different brain regions.

Memory: Genetic Approaches

J Z Tsien, Boston University, Boston, MA, USA

© 2009 Published by Elsevier Ltd.

Introduction

It is widely believed that memory is formed and stored in the brain by modification of the physiological or physical features of synapses, the specialized junctions where neurons connect with each other, a notion that can be traced back to Santiago Ramon y Cajal at the end of the nineteenth century. The foundations for exploring the molecular and genetic basis of learning and memory were further laid in 1949, when Canadian psychologist Donald O Hebb came up with what is known as Hebb's rule. In essence, he postulated that a memory is produced by coincident neural activity; when two connected nerve cells are active simultaneously, the strength of their synaptic connection increases; this confers a basis for the persistence of memory.

To understand whether the brain actually uses 'coincidence-detection' logic to modify synaptic efficacy and store information, researchers have focused on the hippocampus, a region shown to be essential for memory formation, and have found that high-frequency electrical stimulation can produce a persistent increase in synaptic efficacy, a process termed long-term potentiation (LTP). Although LTP was initially discovered in the hippocampus by Bliss and Limo, subsequent studies have shown that it can be elicited in many brain regions. As a result, LTP becomes a major experimental model for the investigation of molecular and cellular mechanisms of synaptic plasticity.

A series of investigations have revealed that the *N*-methyl-D-aspartate (NMDA) receptor is a crucial molecular switch for the induction of LTP. The activation of the NMDA receptor requires both the release of glutamate from the presynaptic neurons and the deplorization of the postsynaptic cells (**Figure 1(a)**). Thus, the NMDA receptor is an ideal to implement the Hebb's rule at the synaptic level. The opening of the NMDA receptor channel allows the influx of calcium, which then activates its downstream signaling molecules such as Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII), PKC, PKA, and MAP kinase. Through a yet less defined process, it eventually leads to long-term modifications in synaptic transmission efficacy.

Hebb's Rule, NMDA Receptor Coincidence-Detection, and Memory Formation

To examine the role of those signaling molecules in the actual memory process, researchers have used two major approaches, namely pharmacological inhibition and genetic manipulation. For example, pharmacological investigations in the late 1980s and early 1990s reported that infusion of NMDA receptor antagonists into brain ventricles resulted in animals' poor performance in the Morris water maze. At the first glimpse this seemed to provide evidence for the role of hippocampal LTP in memory formation. However, careful analyses revealed that poor performances in the water maze tests could be a result of drug-induced side effects including sensorimotor disturbances. In addition, chronic APV exposure to neurons has been shown to upregulate NMDA receptors including the NR2B subunit, thus raising the question as to what chronic APV infusion in the brain is actually doing to NMDA receptor sensitivity and function.

The complications from pharmacological approach have compelled the researchers to use gene knockout methods to investigate the role of candidate molecules in learning and memory. However, conventional gene knockout, a method which deletes a gene of interest in every cell of the body starting from embryonic day 1, has its own limitations. For example, the knockout of the NMDA receptor 1 subunit (NR1), a key subunit essential for the channel activity, led to the mice dying within 12 h of birth. In many other cases, knockout often leads to developmental abnormality and altered brain structures. Therefore, the lack of tissue and temporal specificity in conventional gene knockout has limited its application in analyzing gene function in cognition and behavior.

To overcome those limitations, conditional gene knockout techniques were developed by Tsien and his colleagues in 1996. This second-generation gene knockout employs Cre/loxP-mediated recombination system to restrict deletion of any gene of interest to specific cells, tissues, or organs in mice. By applying its powerful technique, researchers knocked out the NR1 gene specifically in the CA1 region of the hippocampus in young adult mice. Analyses revealed that the knockout of the NMDA receptor prevented all forms of NMDA receptor-mediated synaptic plasticity in the CA1 region, and those CA1-specific NR1 knockout mice exhibited profound deficits in

Figure 1 The NMDA receptor as a cellular coincidence-detector for memory formation. (a) Sketch of brain cells linked in vast networks, with zoom in at synapses showing the NMDA receptor, NR2B subunits, intracellular signaling molecules, etc. Activation of the NMDA receptor requires the binding of glutamate (from presynaptic terminals) and the removal of Mg from its pore (by postsynaptic depolization). (b) Creation of smart mice, Doogie, has stringently validated the Hebb's rule. Figure adapted from Tsien JZ (2000) Building a brainier mouse. *Scientific American* 282: 62–68.

a variety of spatial and nonspatial memory tests including the hidden-platform water maze, novel object recognition, contextual fear conditions and social transmission of food-preference, etc. Additional knockout of the NR1 in the CA3 region also shows that it can lead to memory deficits, although less pronounced in CA3-specific knockout than that of CA1-specific knockout. Thus, those conditional gene knockout experiments strongly suggest the important role of hippocampal NMDA receptors in controlling the formation of hippocampal-dependent learning and memory.

Interestingly, daily exposures of these CA1-specific NR1 mice to enriched environments can significantly alleviate some of those learning and memory deficits. Later studies showed that daily enrichment produces significant changes in the expression of several hundred genes, as well as an increase in dendritic

spines in the brains of those mutant mice, suggesting the beneficial effects of enriched environments. However, similar enrichment seems to be incapable of rescuing the memory deficits in the forebrain-specific NMDA receptor knockout, suggesting that the enrichment may exert its effects through a cortical NMDA receptor-mediated mechanism.

While the conditional gene knockout experiments are supportive of a role of the NMDA receptors in memory process, those experiments did not necessarily represent the most stringent evidence for linking the synaptic coincidence-detection feature of the NMDA receptor to memory formation. The knockout of the NR1 gene removes the physical channel structure from the synapses and disables all function of the NMDA receptor, thus resembling the sledge-hammer approach.

In 1999, researchers were able to fine-tune the coincidence-detection function of the NMDA receptor by manipulating the NR2B subunit of the NMDA receptor channel complex and creating the smart transgenic mice, nicknamed 'Doogie' (Figure 1(b)). Those NR2B transgenic mice have exhibited superior learn and memory functions in at least six different behavioral tests. Therefore, a series of stringent genetic experiments have unequivocally demonstrated that NMDA receptor-mediated coincidence-detection plays an essential role in memory formation. In addition, genetic manipulations of NMDA receptor-downstream molecules, such as CaMKII, PKA and MAP kinases, have also affected learning and memory performances.

Molecular Mechanisms Underlying Memory Consolidation and Storage

Memory process can be generally divided into four distinct stages: learning, consolidation, storage, and retrieval. Studies of amnesiac patients and brain lesions in experimental animals have revealed that memory consolidation requires the hippocampus to continue its engagement for an additional period of time after learning – estimated to be days and week(s) in rodents and months to year(s) in primates. The consolidation process is believed to be crucial for converting short-term labile memory into long-term stable memory in the brain.

It is generally agreed that long-term memory is ultimately expressed in the form of structural and physiological changes in synapses. Until recently, the dominant view in the field was that this structural modification of synapses is the result of a learning-triggered molecular cascade consisting of receptor activation, transient changes in protein phosphorylation levels, new protein synthesis, and new gene expression. However, a variety of emerging evidence suggests that this 'single cascade hypothesis' cannot fully account for the formation and consolidation of long-term memory in the mammalian brain. First, the timescales for a molecular cascade, which typically occurs on the timescale of minutes to hours, do not fit with the timescale of memory consolidation, which operates on the timescale of week(s) in rodents and years in humans. Second, although protein synthesis inhibitors seem to produce long-term memory deficits (often tested within a day or days of training), spontaneous recovery or reminder-induced recovery of memory over the time course of a week or weeks has been reported in animals initially thought to be amnesic. Finally, individual synaptic receptor and structural protein molecules have relatively short lifetimes, in brain as in other organs. For example, a recent study shows that synaptic NMDA receptors are degraded within 5 days in brains of freely behaving mice. Such turnover rates of synaptic receptors and their associated signaling and structural proteins would inevitably lead to deleterious drifts in synaptic efficacy, thereby destabilizing the stored memory traces, in the absence of restorative mechanisms. Thus, the observed metabolic turnovers of synaptic proteins raise a fundamental question: how can the structural changes at synapses, as envisioned by the Hebb's biochemical cascade, sustain memories over long periods of time in spite of such dynamic turnover?

An alternative mechanism to account for both the molecular and system-level consolidation of long-term memory comes from the application of third-generation gene knockout techniques. In 2000, researchers developed inducible, reversible, and CA1-region specific NR1 knockout mice (iCA1-KO) by combining the tTA and Cre/loxP recombination system in an effort to test whether the NMDA receptor activity is required during the memory consolidation stage. Surprisingly, the deletion of the CA1 NMDA receptor in the post-learning period produced severe impairment in memory consolidation. It further revealed that the first two posttraining weeks constitute the critical time-window during which the NMDA receptor reactivations are required. Since the NMDA receptor in the CA1 region is known to be not involved in basal synaptic transmission, those experiments have led the researchers to postulate that NMDA-reactivation during the postlearning period is to trigger the repeated synaptic reentry–reinforcement (SRR) process to consolidate the newly acquired memory trace at the synaptic level (Figure 2).

Consistent with the requirement of NMDA receptor-reactivation for memory consolidation, it has been found that memory consolidation is also dependent

Figure 2 Synaptic reentry–reinforcement (SRR) process for memory consolidation and storage. (a) Reactivations of the NMDA receptor during the consolidation period trigger the repeated synaptic reentry–reinforcements of synaptic memory traces initiated by original learning. (b) Hippocampus also serve as the coincidence-regenerator for coactivating the cortical neurons belonging to different sensory modules, resulting in the SRR-based strengthening of cortical synaptic efficacies, primarily between cortical modules A and B, as well as within each module. Once fully consolidated, the cortically stored memories across all modules can be retrieved by partial cues. The cortical storage of remote memories also requires NMDA receptor reactivation-based SRR process to counteract the synaptic turnover-related draft in synaptic efficacy Figure adapted from Wittenberg GM and Tsien JZ (2002) An emerging molecular and cellular framework for memory processing by the hippocampus. *Trends in Neuroscience* 25: 501–505.

Figure 3 Bump-and-hole-based inducible protein knockout strategy. By integrating convergent protein engineering and rational inhibitor design, researchers developed an *in vivo* conditional protein knockout and/or manipulation technology. This method is based on the creation of a specific interaction interface between a modified protein domain and sensitized inhibitors. By introducing this system into genetically modified mice, we can readily manipulate the activity of a targeted protein, such as αCAMKII, on the timescale of minutes in specific brain subregions of freely behaving mice Part of the figure adapted from Wang H, Shimizu E, Tang YP, et al. (2003) Inducible protein knockout reveals temporal requirement of CaMKII reactivation for memory consolidation in the brain. *Proceedings of the National Academy of Sciences of the United States of America* 100: 4287–4292.

on reactivations of CaMKII, the key intracellular mediator for the NMDA receptor activation, during the first postlearning week. Using inducible protein knockout technique (Figure 3), researchers have found that mice with either the normal or higher level of CaMKII activity can learn and consolidate fear memories equally well. However, switching back and forth between two different levels of CaMKII activity within the first postlearning week severely disrupts synaptic consolidation of 1 month long-term fear memories. In other words, memory consolidation needs to occur at the same level of CaMKII activity as the one used during memory acquisition. Interestingly, similar alterations in the CaMKII expression level during the second, third, and fourth posttraining weeks were no longer capable of disrupting memory consolidation, again illustrating that memory consolidation has a critical time period during which precise reactivation of NMDA receptor-mediated cascades is required.

Additional genetic experiments suggest that the SRR process is also crucial for the consolidation of hippocampal-independent memory. For example, inducible gene knockout has demonstrated that the consolidation of conditioned taste aversion memory depends on the presence of the NMDA receptor in the cortex during the postlearning weeks. Therefore, SRR may present a common off-line mechanism for memory consolidation at both synaptic and systems levels in the brain.

The latest genetic analyses further suggest that the SRR process also plays a key role in memory storage. As mentioned before, it is generally believed that long-lasting memory is stored in the form of structural synaptic modifications triggered by original learning. Such structural changes, once laid down, were previously assumed to confer the long-term stability of stored memories. But since molecular and structural machineries at the synapse are recently shown to undergo routine metabolic turnovers, it prompted researchers to further investigate whether

the NMDA receptor-mediated SRR process serves as a quality-control mechanism for preventing the draft in synaptic efficacy.

Using forebrain-specific and inducible gene knockout technique, researchers reported that the 9 month retention of both contextual and cued fear memories can be profoundly impaired if the NR1 was temporarily knocked out by feeding mice with doxcycline (which induced disabling of NMDA receptor function) for 30 days during the seventh month after its initial memory acquisition. Interestingly, transient knockout of the NR1 (feeding doxycycline for 7 days) did not produce memory storage deficits, suggesting that synaptic draft is an accumulative process and that the prolonged absence of the NMDA receptor is detrimental to the long-term stable storage of remote memories in the brain. Therefore, the emerging view is that this NMDA receptor reactivation-mediated SRR process serves as a crucial and general cellular mechanism in linking the consolidation and storage of long-term memories from the molecular level to the systems level.

The hypothesis that the SRR process can account for both molecular and systems-level memory consolidation and storage has been further elaborated by the computational modeling. The computational analysis shows that in the presence of repeated NMDAR-mediated synaptic modification, SRR is fully capable of consolidating long-term memory traces (Figure 2). In contrast, in the absence of SRR, synaptic efficacy cannot be stably consolidated and preserved; consequently, the synaptic circuits gradually become unreliable, thereby undermining long-term stability of the neural circuits and information storage in the brain.

It is important to point out that the synaptic reactivation is different from the reactivation of memory at the cognitive level, in that the SRR-mediated off-line strengthening of synaptic connections requires only pairwise reactivation between two activated neurons. One conceivable triggering mechanism could be that conscious recall can initiate the SRR process. This is consistent with common experience, where the more frequently a particular event is recalled, the better and longer it will be remembered. Other triggering mechanisms could be the spontaneous reactivation of the brain network in either the awake or sleep state.

Network-Level Memory Patterns and Memory-Coding Units

One fundamental goal of neuroscience is to understand the organizing principles and the cellular network basis by which the brain encodes mnemonic information in real time. Although enormous information has been obtained by lesions and molecular techniques, there is little understanding of the network-level encoding mechanisms underlying information processing. Recently, researchers used a large-scale ensemble recording array to investigate the activity patterns of over 200 individual neurons in the mouse hippocampus during the encoding process of episodic memories. The large-scale ensemble recordings have revealed that various robust episodic experiences, such as free-fall inside a plunging elevator (drop), a sudden gush of air to the back of an animal's back (air blow), or an earthquake-like shake of the home cage (earthquake), have evoked diverse changes in the firing of some of the hippocampal CA1 cells (Figure 4).

Pattern-classification algorithms, namely multiple discriminant analysis (MDA) and principal component analysis (PCA) reveal that various startle-triggered ensemble responses of CA1 neurons form distinct patterns in a low-dimensional encoding subspace (Figure 5). Further application of a sliding-window technique to MDA or PCA methods enables the researchers, for the first time, to directly visualize and dynamically monitor real-time network memory encoding patterns. Moreover, the method also permits the detection and quantification of postlearning processing and reactivations of newly formed ensemble patterns (Figure 4).

Application of agglomerative hierarchical clustering and sequential MDA methods further reveals that the network-encoding power is actually derived from a set of functional coding units, termed neural cliques – a group of neurons with the similar response property and selectivity, in the CA1 cell population. For example, 'the general startle neural clique' consists of individual cells capable of responding to all types of startling stimuli including the elevator drop, earthquake, and air blow, whereas the 'subgeneral startle cliques' are neural groups that respond to a combination of two types, not all, of startling events. In addition, there are neuron groups which exhibit high specificity toward one specific type of startling events, such as elevator drop (the drop-specific neural clique), earthquake ('earthquake-specific neural clique'), or sudden air-blow events ('air-puff specific neural clique').

The key feature of neural cliques is that the individual neurons belonging to a given clique exhibit 'collective co-spiking' temporal dynamics. This collective co-spiking dynamics among neural clique members enables the memory coding units to achieve real-time network-level encoding robustness by overcoming the response variability of individual neurons.

Figure 4 Visualization and dynamical monitoring of network-level memory patterns in the hippocampus. Two hundred and sixty simultaneously recorded single units from a mouse during a period of 0.5 s prior to and 1 s after the occurrence of startling episodes ($t = 0$ marked with vertical red line) forms distinct ensemble patterns during awake rest (dots, yellow ellipsoid), air-blow (circles, green ellipsoid), drop (triangles, blue ellipsoid) and earthquake (stars, magenta ellipsoid) epochs (shown in a three-dimensional sub-encoding space obtained using MDA). Dynamical monitoring of memory trace formation and reactivations are shown as trajectories of the ensemble encoding patterns. The initial response to an air-blow or drop events (black lines) is followed by two large spontaneous excursions (red and green lines for two air-blow reactivations, and purple line for drop pattern reactivation). Please note that the reactivated traces occurred as co-planar, geometrically similar lower amplitude trajectories (directionality indicated by arrows). Part of figure adapted from Lin L, Osan R, Shoham S, Jin W, Zuo W, and Tsien JZ (2005) Identification of network-level coding units for real-time representation of episodic experiences in the hippocampus. *Proceedings of the National Academy of Sciences of the United States of America* 102: 6125–6130.

Hierarchical Organization of Memory-Encoding Neural Clique Assemblies

Through examining the overall organization of neural clique assembly involved in startle memory encoding, it seems that the internal CA1 representations of any given startle episode involve a combinatorial set of neural cliques, invariantly consisting of the 'general startle clique', 'subgeneral startle clique', 'startle identity-specific clique', and context-specific startle clique. As such, each clique assembly is invariantly organized in a categorical hierarchy manner and is consisted of a 'feature-encoding pyramid' (Figure 5): starting with the neural clique representing the most general and common features (to all categories) at the bottom layer, followed by neural cliques responding to less general features (covering multiple, but not all, common categories), and then moving gradually up toward more and more specific and discriminating features (responding to a specific category), and eventually with the most discriminating feature clique (corresponding to context-specificity) on the top of the feature-encoding pyramid.

According to this hierarchical structure of network-level memory encoding (Figure 5), the 'general startle neural clique' represents the neurons engaged in the extraction of the common features among various episodes (e.g., encoding abstract and generalized knowledge that 'such events are scary and dangerous', by integrating neural inputs from the amygdala). The 'subgeneral neural cliques' are involved in identifying sub-common features across a subset of startling episodes (e.g., perhaps, the 'earthquake and drop-specific clique' for encoding the semantic memory of the fact that 'those events involve shaking and motion disturbances', by integrating inputs from the vestibular system); whereas the 'startle identity-specific cliques'

Figure 5 Hierarchical and categorical organization of memory coding units. Memory-encoding neural cliques are organized in a hierarchical and categorical fashion, and any given startling episode is encoded by a combinatorial assembly of a series of neural cliques, invariantly consisting of the general startle clique, sub-general startle clique, startle identity-specific clique, and context-specific startle clique. In this feature pyramid of the encoding clique assembly, the neural clique representing the most general, abstract features (to all categories) is at the bottom and it forms a common building block for all types of startle event encoding. The next layer of the pyramid is made by neural cliques responding to less general features (covering multiple, but not all, categories), those sub-general cliques are present in a subset of the neural clique assemblies. Moving up along this encoding feature pyramid, neural cliques become more and more specific. The neural clique at the top of the pyramid encodes the most specific and highly discriminate features, thereby defining a particular event or experience. Please note that the number of neurons for each clique does not necessarily correspond to its position in the feature pyramid. In other words, the neural clique encoding the general features does not necessarily have more neurons than the neural cliques encoding more specific features. Figure adapted from Lin L, Osan R, and Tsien JZ (2006) Organizing principles of real-time memory encoding: Neural clique assemblies and universal neural codes. *Trends in Neuroscience* 29: 48–57.

encode discriminative information about startle types (defining 'what type' of events have happened); and the 'startle context-specific cliques' provide even more specific features, such as contextual information about where a particular startling event has happened.

This invariant 'feature-encoding pyramid' of neural clique assemblies reveals four basic principles for the organization of memory encoding in the brain (Figure 5): first, the neural networks in the memory systems employ a categorical and hierarchical architecture in organizing memory coding units. Second, the internal representations of external events in the brain through such a feature-encoding pyramid are achieved not by recording exact details of the external event, but rather by recreating its own selective pictures based on the importance for survival and adaptation. Third, the 'feature-encoding pyramid' structure provides a network mechanism, through a combinatorial and self-organizing process, for creating seemingly unlimited numbers of unique internal patterns, capable of dealing with potentially infinite numbers of behavioral episodes that an animal or human may encounter during its life. Fourth, in addition to its vast memory storage capacity, this neural clique-based hierarchical extraction and parallel binding processes also enable the brain to achieve abstraction and generalization, cognitive functions essential for dealing with the complex, ever-changing situations.

The finding that the memory-encoding neural clique assembly appears to invariantly contain the coding units for processing the abstract and generalized information is particularly revealing. It provides crucial insights into how the formation of daily episodic memories is intrinsically linked to the formation of semantic memories – memories of facts, concepts, and generalized knowledge.

The observed 'feature-encoding pyramid' structure of the neural clique assembly is likely to represent a general mechanism for memory encoding across different animal species. For example, single unit recordings in human hippocampus show that some hippocampal cells fire in response to faces, or more selectively, to certain types of human facial emotions, others seem to exhibit highly selective firing to one specific person regardless (e.g., 'actress Halle Berry cell' which fires selectively to her photo portraits, Catwoman character, and even a string of her name).

Although those cells were not recorded simultaneously, the findings are nonetheless consistent with the general-to-specific feature pyramid structure. In addition, it is also reported that while some place cells in the rat hippocampus exhibit location-specific firing regardless of whether the animals engage in a random forage or goal-oriented food retrieval (or make a left-or right-turn in a T-maze), others seem to fire selectively at their place fields only in association with a particular kind of experience.

Universal Neural Codes Across Individuals and Species

With the identification of the neural clique as a basic coding unit and the feature-encoding pyramid within the clique assemblies, researchers can now mathematically convert those distinct ensemble representations observed in a low-dimensional encoding-subspace into a string of binary activation codes with 1's and 0's. This binary assignment, 1 for the active state and 0 for the inactive state of neural cliques, is based on the idea that the activity state of a neural clique can be monitored by downstream neurons using a biologically plausible binary activation function. This mathematical conversion of the activation patterns of the neural clique assembly into a binary code of 1's and 0's creates a simple and convenient way for universally comparing and categorizing network-level representations from brain to brain of the same species and even across animal species.

It is important to point out the fundamental differences between the neural clique pattern-based brain codes and the nucleotide-based genetic codes. Specifically, the neural clique-based brain codes have at least four distinct properties:

1. *Uninheritable*. Genetic codes are directly transferred through reproductions; whereas brain codes, by and large, are not inheritable and can only be acquired through experiences (perhaps with exceptions of those neural codes for controlling the primitive functions such as breathing, heartbeat, and knee-jerk reflex, etc.; those may have been genetically programmed).
2. *Self-organizing*. Genetic codes act like predetermined scaffolds, providing blueprints for the development and basic functionality of the organism, whereas brain codes are dynamical and self-organizing, arising out of internal structures and connectivity of neural networks upon behavioral experiences.
3. *Variable sizes*. The numbers of genes are exactly fixed for each individual and species, whereas the number of brain codes is highly variable in each brain, and in theory, it is only limited by the network capacity (which is determined by the convergence and divergence in connectivity), as well as the amount of behavioral experiences that an individual encounters.
4. *Modifiable*. Unless mutated, the genetic code remains static, whereas the membership of individual neurons within a given neural clique is modifiable by experience-dependent synaptic plasticity or disease states.

Thus, the above features of the brain codes are set apart in a fundamental way from the genetic codes.

The identification of neural cliques as memory coding units in the hippocampus prompts us to entertain the concept that neural cliques as basic, self-organizing

Figure 6 The hierarchical-extraction and parallel-binding process in the brain. Under this neural clique coding process, the brain achieves coherent internal encoding and processing of the external events. For example, when a person experiences a sudden earthquake, neural cliques in his primary visual cortex encode the decomposed features about edge orientation, movement, and eventually shapes of visual objects, whereas the neural cliques in the vestibular nuclei detect sudden motion disturbances. As information is processed along its pathways into deeper cortex such as the inferior temporal cortex (IT), neural cliques begin to exhibit complex encoding features such as houses. By the time it reaches high association cortices such as the hippocampus (HP) and temporal medial cortex (TMC), the neural clique assembly encodes earthquake experience and its location, with 'what and where' information. At this level, some more abstract and generalized information in experiencing the earthquake event (e.g., semantic memories of 'the earthquake is dangerous and scary') have emerged. As information is further processed into other cortical regions involving decision-making and motor-planning, a series of phased firing among various neural clique assemblies lead to adaptive behaviors, such as screaming and running away from the house or hiding under a dining table. The figure is adapted from Lin L, Osan R, and Tsien JZ (2006) Organizing principles of real-time memory encoding: Neural clique assemblies and universal neural codes. *Trends in Neuroscience* 29: 48–57.

processing units may be applicable to many, if not all, neural networks in the brain. Under this neural clique code model (Figure 6), the functionality implemented by neural cliques in a given network depends on the specializations of the corresponding regions. In primary sensory regions, neural cliques in those regions (perhaps, organized in the forms of cortical columns) encode piecemeal information by decomposing external events into various basic features (e.g., the primary visual cortex for detecting edge orientation, color or size of visual objects, whereas the vestibular nuclei for detecting motion). As information is further processed along its pathways into deeper regions, neural cliques (although no longer organized in their anatomically distinguishable maps or columns) start to encode more complex features (e.g., shapes and complex objects such as houses and faces in the inferior temporal cortex). By the time it reaches high association cortices such as the hippocampus, neural cliques have already contained both specific and generalized mnemonic information about events, places, and people with a significant amount of abstraction and generalization. Eventually, the brain areas involved in decision making, executive function, and motor planning may start coherent and phased firings among various neural cliques, thereby generating behaviors.

The emergence of a variety of new technologies, ranging from molecular genetics to high-density recording arrays, has begun to provide researchers an unprecedented opportunity to investigate the relationship between genes, brain, and mind. The latest identification of memory coding unit assemblies and their hierarchical organization in the brain has revealed as to how and why memory, semantic knowledge, abstraction, and generalization are coherently generated. It gives scientists not only a mathematical solution to translate neural activity into universal binary codes for the assembly of the codebook of the mind, but also a potential strategy for designing truly intelligent computers and robots.

Metabolic Syndrome and Sleep

Introduction

Simply observing people – at the beach, at a shopping mall, walking down a crowded street, at a sports stadium, or in the workplace – will lead the observant individual to the inescapable conclusion that there is a major medical problem in the United States: obesity. Obesity is a disease that in just the past few decades has been increasing dramatically in developed countries, and it has reached epidemic levels in the United States. Color maps of the United States provided by the US Centers for Disease Control and Prevention, depicting the prevalence of overweight people in individual states, reveal in a dramatic fashion just how rapidly the 'obesity invasion' has occurred and the enormity of the epidemic. ('Overweight' refers to a body mass index, or BMI, between 25 and 30, and obesity is a BMI > 30; this measure of obesity is calculated as weight in kilograms divided by the square of height in meters.) The obesity epidemic is not limited to adults, as there are numerous epidemiological studies demonstrating an alarming increase in obesity in children. This increase is even leading diabetologists to rethink the term 'adult-onset diabetes,' to differentiate adult-onset (type 2) from juvenile-onset (type 1) diabetes, as many juveniles are now being diagnosed with insulin resistance and type 2 diabetes. Furthermore, this epidemic of obesity is not limited to the developed, food-rich countries of the world, as increased signs of obesity and diabetes are being found in less developed countries, including the two most populous countries, China and India.

Besides the social stigma attached to obesity, the upward trends in BMI are cause for concern because of risks of secondary complications, including signs of what has been referred to as the 'metabolic syndrome' (formerly referred to as syndrome X), including insulin resistance, hyperglycemia, dyslipidemia, hypertension, inflammation, and coagulation disorders. Obesity and the metabolic syndrome have been linked to heart attack, stroke, diabetes, cancer, and arthritis, all of which are responsible in part for some of the major health problems facing the industrialized world today.

While less easy to observe by just watching people walk down the street, in the United States there has been a parallel epidemic – an epidemic many have attributed to the fast pace of our '24/7' industrial societies – involving chronic partial sleep loss. Voluntary chronic sleep loss represents an increasingly common condition in industrialized societies and is due primarily to socioeconomic and cultural pressures. The incidence of symptoms of insufficient sleep has been increasing since about 1950. Around-the-clock operations imply chronic partial sleep loss for the large population of shift workers, and schedules compressing the workweek by the use of extended work shifts (for example, 12 h workdays) and unscheduled overtime have become routine in a number of industries.

The relationship between the rise in obesity and the loss of sleep, hypothesized to be 'interacting epidemics,' is depicted in Figure 1. However, are these epidemics interacting or are they simply correlated, with no cause-and-effect relationship to one another? The following discussions provide both epidemiological and clinical research results which indicate that long-term partial chronic sleep loss is indeed an underlying cause of obesity, diabetes, and the metabolic changes associated with the metabolic syndrome. In addition, data from animal models supporting the connection between sleep loss and metabolic dysfunction are provided, in addition to a discussion of how the two interacting epidemics could be connected on a mechanistic level. It should be noted that we are at an early stage in our understanding of how the obesity and chronic sleep loss epidemics are linked to one another, as their possible dependency on one another has only emerged in the past few years.

Sleep Loss and Metabolic Syndrome: Interacting Epidemics – Epidemiological Studies

There are now numerous epidemiologic surveys indicating a strong association between sleep disturbances, or shortened sleep durations, and cardiovascular disease, diabetes mellitus, and respiratory disorders. Indeed, as of 2006, there were at least 35 epidemiological studies linking short sleep periods with adverse health outcomes, including obesity, diabetes, and cardiovascular disease. For example, individuals who sleep less than 5 h a night have a threefold increased risk of heart attacks, and patients with coronary heart disease had more complaints of disturbed sleep than did patients without coronary heart disease. Another example is sleep apnea, which has been shown to increase the risk of cardiovascular disease and diabetes mellitus. In turn, cardiovascular and metabolic disorders, most notably hypertension, congestive heart failure, coronary heart disease, and diabetes mellitus, are associated with a higher prevalence of sleep apnea.

Figure 1 Time lines for the epidemics of obesity and sleep loss in the United States. The figures have been redrawn from data collected for the Centers for Disease Control and Prevention National Health and Nutrition Examination Study (obesity) and from National Sleep Foundation polls (sleep duration).

Recent studies indicate that the relationship between short sleep duration and obesity extends beyond urban settings to rural populations, for whom lifestyle factors, nutrition, physical activity levels, and work hours are often different than for city dwellers.

For individuals with type 2 diabetes mellitus, sleep disturbances may be related to obesity and sleep apnea, and recent studies have also demonstrated a strong association between obesity, impaired glucose tolerance, insulin resistance, and sleep apnea. Results from both short-term physiological and epidemiologic studies consistently suggest that decreased sleep duration or quality may increase the risk for diabetes mellitus. Indeed, in patients with type 2 diabetes mellitus, decreased subjective sleep duration and quality are predictive of poorer glycemic control. These are notable findings for health care professionals and patients because they indicate not only that voluntary chronic partial sleep deprivation may increase the risk for diabetes mellitus, but also that continuing this pattern renders it more difficult to treat the condition.

In another study that analyzed 924 patients from four primary care practices in Virginia, a reduced amount of sleep was associated with overweight and obese status, with patients in the obese group showing a near inverse linear relationship between weight and reported sleep time. Findings from the Amsterdam Growth and Health Longitudinal Study, which began collecting data on study participants at 13 years of age, on factors such as fatness, fitness, and lifestyle, revealed these factors to be important determinants of the metabolic syndrome in 10% of the studied population by the age of 36 years – an indication that the obesity epidemic in young people is not confined to the United States. An alarming statistic defines a major problem among North American youth: between 1980 and 2000, the percentage of obese young people has risen from 5% to 15%, and another 15% has moved into that classification in young adulthood. While this epidemic in such a young population has received national attention, less well known is the finding that children of all ages in the United States are sleeping 1–2 h less per night than they need, according to a recent poll taken by the National Sleep Foundation. While insufficient sleep has often been associated with the elderly population, the increasing demands and lifestyles of modern society have imposed restricted sleep regimens on youth as well. It is now critical to determine the importance of a lack of sufficient sleep during the early formative years, and how that may be involved in putting the young on a trajectory toward obesity and the metabolic syndrome – a trajectory that could be altered in some cases, if sleep loss is indeed playing a role in this epidemic.

Sleep Loss and Obesity and the Metabolic Syndrome: Interacting Epidemics – Clinical Research Studies

Van Cauter and colleagues published a pivotal study in 1995 that demonstrated in humans that sleep loss has clear negative consequences for the body, beyond the brain. In this laboratory experiment, 6 days of restricted time (4 h per night) in bed in young men was associated with alterations in glucose metabolism that, over the long term, could increase the risk of developing diabetes. A similar study demonstrated that even short-term chronic sleep loss was associated with alterations in the levels of two hormones involved in appetite regulation: leptin and ghrelin. These alterations led to increased appetite, raising the possibility that such changes could ultimately increase the risk of weight gain. Similar associations between sleep duration and leptin and ghrelin were observed in a larger sample from the Wisconsin Sleep

Cohort Study, providing further evidence for the link between sleep and appetite regulation. Such studies in chronically sleep-deprived humans has renewed interest in the role of insufficient sleep as a cause of many of the metabolic abnormalities associated with sleep apnea. However, while there is a growing awareness among some sleep, metabolic, cardiovascular, and diabetes researchers that insufficient sleep could be leading to a cascade of disorders, few in the general medical profession or in the lay public have yet made the connection.

Sleep Loss and Obesity and the Metabolic Syndrome: Interacting Epidemics – Evidence from Animal Studies

Unfortunately, most of the weight-conscious public, and even many in the health care professional community, still view weight control as a biological black box and ascribe obesity to laziness and a lack of will. However, the experience of those whose body weight is 'defended,' even though they are dieting and trying to lose weight, suggests that body weight regulation is more complex than just will power. Indeed, it is controlled much like a thermostat, with fluctuation around a programmed set point that can be altered after weight gain. The magic bullet for preventing obesity has proved elusive because, like other complex diseases (e.g., hypertension, hyperlipidemia, and cancer), multiple genetic and environmental factors contribute to body weight dysregulation and its secondary complications. An important goal in developing new therapies for obesity and the metabolic syndrome is to elucidate the elaborate pathways that regulate appetite, food intake, and energy expenditure, and to determine how interactions between behavior, metabolism, and the environment contribute to long-term energy balance. It is of particular interest to determine the cellular and neural mechanisms that underlie the effects of acute and/or chronic sleep loss on metabolism.

Genetic and clinical observations both point to interconnections between sleep and metabolic regulation. A major finding that set the stage for investigating neural interconnections linking sleep and metabolic homeostasis was the discovery of the orexins (also called hypocretins). These neuropeptides are part of signaling pathways within the energy center of the brain. A major discovery by Mignot and colleagues was the identification of the orexin receptor as the causative genetic defect in the most common form of canine narcolepsy. While these two fundamental systems appear to have distinct functions in human physiology, the discovery of overlapping molecular components suggests a co-regulation that may have coordinated the alternance between periods of fasting and sleep and periods of wakefulness, food seeking, and energy storage. A lack of sleep may perturb the homeostatic coordination of these pathways, activating metabolic pathways that trigger energy conservation (increased food intake and decreased expenditure) in excess of the energy cost of increased wakefulness. Indeed, our recent analysis of leptin-deficient animals suggests that leptin *per se* may be necessary for consolidated sleep, since animals with a genetic absence of leptin display markedly increased sleep fragmentation and experience increased periods of microsleep during the active period. In view of observations, from experimental models and human clinical studies, on the relationship between the sleep–wake cycle and fuel homeostasis, it may well be that interventions to improve sleep may ameliorate some of the metabolic deficits associated with overweight and obesity.

Recent genetic studies in mice have also provided strong evidence for there being important linkages between the sleep and body weight regulatory systems. We have recently discovered that homozygous *Clock* mutant mice have a greatly attenuated diurnal feeding rhythm, are hyperphagic and obese, and develop a metabolic syndrome of hyperleptinemia, hyperlipidemia, hepatic steatosis, and hyperglycemia, with insufficient compensatory insulin production, a hallmark of type 2 diabetes mellitus. In addition, levels in the expression of hypothalamic peptides associated with energy balance were greatly attenuated in the *Clock* mutant animals. The *Clock* gene is a major component in the transcriptional–translational feedback loops that make up the molecular circadian clock in mammals. Taken together, these results indicate that the circadian clock gene network plays an important role in mammalian energy balance involving a number of central and peripheral tissues, and that disruption of this network can lead to obesity and the metabolic syndrome in mice.

Chronic sleep loss is often associated with disrupted circadian rhythms. This is particularly true in shift workers, who not only have disturbed circadian rhythms as they continually shift their sleep and wake times to different times of the 24 h day, but who also do not obtain sufficient sleep often over the course of many years. In view of recent findings indicating that disrupted rhythms can lead to metabolic dysfunction in animal models, and that at the molecular level circadian clock genes also interact with other genes that regulate glucose and lipid metabolism, adverse effects on metabolism may in some cases be due to a combination of sleep loss and disrupted rhythms. Distinguishing between adverse metabolic outcomes as a function of sleep loss as opposed to disturbed rhythms can be problematic, since for many animal

models both sleep loss and circadian disruption occur simultaneously. For example, while we concluded that decreased longevity in cardiomyopathic hamsters exposed to a light–dark cycle that was reversed on a weekly basis was due to the chronic disruption of the normal circadian organization, it could be expected that such forced re-entrainment on a weekly basis would have adverse effects as well on the quantity and/or quality of sleep. Similarly, while the development of obesity and signs of the metabolic syndrome in the *Clock* mutant animal have been attributed to circadian dysfunction at the organismal and/or molecular levels, *Clock* mutant animals show reduced sleep of 1–2 h per day; such chronic loss of sleep could also be contributing to the adverse metabolic events. While it will be important to determine the underlying links between disturbed rhythms and/or sleep loss on metabolic function from a mechanistic point of view, from a health perspective, the finding that loss of sleep and/or circadian disruption on a chronic basis, for whatever reason, can have severe adverse metabolic consequences, has important health implications that need to be addressed as our society faces an unprecedented epidemic in obesity, diabetes, and associated diseases.

Summary

Many fingers are being pointed at the possible multitude of causes for the obesity epidemic: not enough exercise, high-fat foods, poor eating habits, watching too much television, genetics, family history, fast-food hysteria, or exposure to advertising luring us to eat unhealthy foods. Even our early prenatal and postnatal environments may be putting us on a trajectory for an unhealthy metabolic state later in life, as many studies have now demonstrated that nutritional state early in life predicts how one will respond to dietary inputs later in life. Our genes evolved in humans engaged in high levels of physical activity (much of it chasing and looking for food), with eating habits requiring them to eat as much as possible (and as much meat and fat as possible) when a meal became available (i.e., rarely); today, many humans have food available all of the time, and this modern 'food everywhere' environment is a reality that may predispose modern humans to obesity.

It is hoped that the book by Kiess and colleagues, *Obesity in Childhood and Adolescence,* has raised the clinical community's awareness of the causes, consequences, and therapies of obesity in the young. However, it is noteworthy that none of the 21 chapter titles in that book contain the word 'sleep,' indicating that the connection between sleep loss and obesity is still not a major consideration in the war on obesity. The Institute of Medicine recently published a report titled *Sleep Disorders and Sleep Deprivation: An Unmet Public Health Problem*, in which it was stated, "The cumulative effects of sleep loss and sleep disorders represent an under-recognized public health problem and have been associated with a wide range of health consequences." Thus the alarm has been sounded – will people and health care professionals wake up?

Metabotropic Glutamate Receptors (mGluRs): Functions

B A Grueter and D G Winder, Vanderbilt University School of Medicine, Nashville, TN, USA

© 2009 Elsevier Ltd. All rights reserved.

Metabotropic Glutamate Receptors

In the mid-1980s, glutamate was shown to stimulate inositol 1,4,5-trisphosphate (IP_3) production, indicating the potential existence of a 'metabotropic,' or non-ion-channel-forming, glutamate receptor. This led to the distinction between ionotropic and metabotropic glutamate receptors (mGluRs). There are eight subclasses of mGluRs that have been identified and cloned. mGluRs belong to family C of the G-protein-coupled receptor superfamily, which includes calcium-sensing and γ-aminobutyric acid B ($GABA_B$) receptors and act to modulate neuronal excitability in many brain regions. Eight separate gene products (mGluRs 1–8) comprise the mGluR family of receptors, several of which can exist as alternatively spliced variants. These subtypes are classified into three groups based on pharmacology, similarities in coupling mechanisms, and sequence homology (Table 1). mGluRs of the same group show about 70% sequence identity, whereas between groups this percentage decreases to about 45%. Group I receptors (mGlu1 and mGlu5) are linked to G_q, whereas, group II (mGlu2 and mGlu3) and group III (mGlu4, mGlu6, mGlu7, and mGlu8) receptors are coupled to $G_{i/o}$. Intracellularly, the large C-terminus of mGluRs can interact with a variety of signaling systems.

G-Protein-Coupled Receptors

G-protein-coupled receptors (GPCRs) are seven-transmembrane-domain (7TM) proteins that interact with G-proteins. Receptor activation leads to associated guanosine triphosphatase (GTPase) activity and ultimately to activation or inhibition of an effector protein. G-protein regulation of effectors, particularly in neurons, occurs through two broad mechanisms. One is direct G-protein binding to ion channels. More traditionally, G-proteins function to activate or inhibit second-messenger-forming enzymes, leading to direct second messenger binding to ion channels, second messenger activation of kinases or phosphatases that phosphorylate/dephosphorylate ion channels, or alterations in protein–protein interactions involving an ion channel. These mechanisms constitute the major routes for mGluR signaling, although it should be noted that these receptors have also been reported to signal through G-protein-independent ways through as yet unclear mechanisms.

Structure of mGluRs

mGluRs are composed of two main domains, a large extracellular domain (ECD), and a 7TM region, and share very little sequence homology with other GPCRs. Proposed models confirmed by X-ray crystallography suggest the unique ECD contains two globular lobes separated by a cleft which contains the orthosteric ligand-binding site. While glutamate is commonly thought to be the primary ligand at this site, it is important to note that many excitatory amino acids are present in neural tissue, many of which can also activate mGluRs. In addition, allosteric binding sites have also been identified in the 7TM region. The second intracellular loop of mGluRs infers selectivity for G-protein coupling while a highly conserved third loop plays a crucial role in G-protein activation. Interactions among the first loop, third loop, and C-terminal tail are thought to control efficacy of G-protein coupling. The intracellular C-terminal region of mGluRs plays a major role in regulation and trafficking.

Regulation of mGluR Signaling

mGluR signaling is tightly regulated by both homologous and heterologous mechanisms. Both agonist-induced (homologous) and heterologous forms of regulation of mGluRs have been observed. Phosphorylation by several different kinases can alter mGluR signaling. For instance, protein kinase C (PKC)-dependent phosphorylation of mGluRs, particularly group I mGluRs, is thought to serve as a major mechanism of desensitization. β-Arrestin-induced desensitization of mGluRs has also been described. The $\beta\gamma$ subunits of G-proteins are thought to target G-protein-coupled receptor kinases (GRKs) to mGluRs, resulting in β-arrestin-mediated sequestration and ultimately desensitization.

Group I mGluR expression at the plasma membrane and the functional coupling of group I mGluRs to intracellular signaling molecules are dependent upon scaffolding proteins. The Homer family of proteins is a major example of this. There are three genes encoding Homer proteins. Homer 1a is an immediate-early gene product while Homer 1b/c, Homer 2, and Homer 3 are constitutively expressed. Homer proteins link group I mGluRs through the C-terminal tail to signaling molecules such as the IP_3 receptor, and to scaffolding components of the postsynaptic density, such as Shank. It is suggested that Homer

Table 1 Classification of mGluRs

Family receptor	*Coupling*	*Group/subtype-selective pharmacological agents*[a]
Group I		
mGluR1	G_q-coupled	Agonists: DHPG, ACPD, quisqualate Antagonist: LY393675 Inverse agonist (allosteric antagonist): LY367385

Group II		
mGluR2	$G_{i/o}$-coupled	Agonists: DCG-IV, LY354730, ACPD Antagonist: LY341495
mGluR3	$G_{i/o}$-coupled	Agonists: DCG-IV, LY354730, ACPD Antagonist: LY341495
Group III		
mGluR4	$G_{i/o}$-coupled	Agonists: L-AP4, L-SOP Antagonists: MSOP, MAP4
mGluR6	$G_{i/o}$-coupled	Agonists: L-AP4, L-SOP Antagonists: MSOP, MAP4
mGluR7	$G_{i/o}$-coupled	Agonists: L-AP4, L-SOP Antagonists: MSOP, MAP4
mGluR8	$G_{i/o}$-coupled	Agonists: L-AP4, L-SOP, DCPG Antagonists: MSOP, MAP4

[a]ACPD, (1*S*,3*R*)-1-amino-1,3-cyclopentanedicarboxylate; L-AP4, L-2-amino-4-phosphonobutyric acid; CHPG, (*R*,*S*)-2-chloro-5-hydroxyphenylglycine; DCG-IV, (2*S*,2′*R*,3′*R*)-2-(2′,3′-dicarboxycyclopropyl)glycine; DCPG, (*S*)-3,4-dicarboxyphenylglycine; DHPG, 3,5-dihydroxyphenylglycine; MAP4, α-methyl-2-amino-4-phosphonobutyrate; MPEP, 2-methyl-6-(phenylethynyl)pyridine; MSOP, methylserine-*O*-phosphate; L-SOP, L-serine-*O*-phosphate.

proteins may regulate the expression and function of group I mGluRs at multiple levels, including targeting, surface expression, clustering, physical linkage to other synaptic and subsynaptic complexes, and modulation of constitutive activity. Interestingly, biochemical evidence suggests the C-terminus of Homer 2a interacts with the Rho family of small GTPases, in a GTP-dependent manner. Homer proteins have also been shown to form complexes with Shank proteins, which act as scaffolding proteins and link group I mGluRs with other proteins in the postsynaptic densities (PSDs), such as Dynamin2, an important molecule implicated in endocytosis, and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor (AMPAR)–glutamate receptor-interacting protein (GRIP) complexes.

Expression of mGluRs

mGluRs have unique but overlapping distributions throughout the central nervous system (CNS). In addition, mGluRs have been reported to function in the peripheral nervous system and elsewhere. For example, mGluRs have been shown to play an important role in nociceptive transmission, as will be described in a later section.

Glutamate Sources from Which mGluRs Can Be Activated

mGluRs are often located in the areas adjacent to the synapse. Functionally, their location suggests that they become activated in situations of repeated stimulation of afferents, which results in considerable glutamate accumulation in the synaptic cleft coupled to spillover to extrasynaptic sites. In addition to the frequency and duration of synaptic activity, the extracellular concentration of glutamate also depends on the efficacy of neuronal and glial uptake, which is dictated by the number of glutamate transporters (GluTs). GluTs, along with passive diffusion, are the primary means of glutamate removal from the extracellular space. The ability of mGluRs to participate in signaling is thought to be tightly regulated by GluT activity.

Another potentially important contributor to extracellular glutamate levels is the cystine–glutamate exchanger. The nonsynaptic cystine–glutamate antiporter exchanges extracellular cystine for intracellular glutamate with a minimal contribution of synaptic glutamate release. It has been suggested that one form of cocaine-induced neuroadaptation may be due to a decrease in basal levels of extracellular glutamate in the *N*-acetylcysteine (NAc) after several weeks of withdrawal from cocaine, an effect attributed to a reduced function of the cystine–glutamate transporter.

mGluR Function

Neuromodulation

Neuromodulation is a subtle influence on synaptic efficacy or neuronal excitability. Neuromodulation

can also involve longer-lasting changes such as alterations in gene expression. The 'fine tuning' of neuronal function by neuromodulation makes receptors and pathways attractive therapeutic targets for many diseases and disorders. mGluR activation serves as a major source by which glutamatergic transmission can modulate synaptic efficacy, neuronal excitability, and gene expression.

Synaptic Plasticity

Persistent alterations in synaptic efficacy initiated by transient stimuli are referred to as forms of synaptic plasticity. Changes in synaptic efficacy can occur by presynaptic mechanisms such as altered neurotransmitter release as well postsynaptic mechanisms. Activation of mGluRs can play an important role in facilitation of multiple forms of synaptic plasticity. mGluR activation can induce long-term depression (LTD) at many glutamatergic synapses. Further activation, primarily of group I mGluRs at some synapses, can positively modulate *N*-methyl-D-aspartate receptor (NMDAR)-dependent long-term potentiation (LTP) induction.

Group I mGluRs

Group I receptors (mGluR1 and mGluR5) are linked to activation of phospholipase C (PLC), leading to phosphoinositide hydrolysis, calcium release, and PKC activation. Activation of group I mGluRs can also indirectly regulate adenylyl cyclase, leading to increased cyclic adenosine monophosphate (cAMP) formation, as well as cyclic guanosine monophosphate (cGMP) accumulation, phospholipase A, and extracellular signal-regulated kinase (ERK) activation.

Although highly homologous, studies suggest mGluR1 and mGluR5 receptors have distinct functions in regulating synaptic transmission. This implies differential regulation of these receptors and potential divergence in effector systems. Conversely, at some synapses only one type of group I mGluR is functionally important: for instance, only mGluR1 has been shown to function in the ventral tegmental area and cerebellum.

Synaptic Locus of Group I mGluRs

Mechanisms underlying group I mGluR function vary across brain regions and synapses. Much information on the function of these receptors can be gained by determining the synaptic locus of action of these receptors. Immunohistochemical and electrophysiological results reveal that group I mGluRs localize and function presynaptically, postsynaptically, and on glia. However, group I mGluRs are predominantly located at the periphery of the postsynaptic density (perisynaptically). Activation of group I mGluRs causes postsynaptic effects such as neuronal depolarization, excitation, and spike frequency adaptation in a number of brain regions. For instance, selective activation of group I mGluRs with the agonist 3,5-dihydroxyphenylglycine (DHPG) increases postsynaptic membrane excitability in hippocampus, cortex, striatum, amygdala, subthalamic nucleus, and hypothalamic nuclei.

Increases in neuronal excitability via activation of group I mGluRs are thought to occur in large part through modulation of K^+ channels. Specific activation of group I mGluRs induces net inward currents by inhibiting K^+ channel conductance in neurons in the hippocampus and hypothalamus. For instance, K^+ channels are a major target of mGluRs, and many diverse types of K^+ channels are inhibited following activation of mGluRs. Activation of mGluRs has been shown to block the I_{AHP} (I_{AHP} is an outward, Ca^{2+}-activated, K^+ current with slowly activating and inactivating ($\sim$2 s) kinetics) and to thereby reduce accommodation of spike firing in hippocampal CA1 pyramidal cells, CA3 pyramidal cells, the dentate gyrus, cultured cerebellar Purkinje cells, and basolateral amygdaloid nucleus.

Activation of group I mGluRs has also been shown to modulate voltage-gated calcium channels (VGCCs). Alterations in VGCCs can occur either presynaptically, consequently changing vesicular release probability, or postsynaptically, leading to changes in intracellular calcium levels. Although mGluR-dependent modulation of channels has been shown to be a consequence of direct G-protein-linked action – for example, inhibition of Ca^{2+} channels – many other effects occur as a result of activation of intracellular messenger pathways. Group I, in contrast to group II, mGluRs can use several distinct signal transduction pathways to inhibit Ca^{2+} channels, both Ca^{2+} intracellular-independent and -dependent mechanisms.

In addition to the postsynaptic modulation of synaptic transmission by alteration of neuronal excitability, group I mGluRs have been reported to function presynaptically. One example is in the hippocampus, at the level of the synapses between Schaeffer collaterals and CA1 pyramidal cells. Consistent with presynaptic function, an increase in paired pulse facilitation has been observed upon activation of mGluR5, suggesting a decrease in vesicular release probability.

Retrograde Signaling

Cannabinoids Of great interest in the mGluR field was the finding that endocannabinoid synthesis can be

triggered by activation of group I mGluRs. Retrograde signaling through the endocannabinoid system helped explain biophysical evidence suggesting a presynaptic change in probability of neurotransmitter release, with immunochemical data suggesting that group I mGluRs are primarily localized to postsynaptic structures.

Use of pharmacological tools as well as genetic manipulations has provided evidence for a role of arachidonic acid metabolites – more specifically, the 12-lipoxygenase metabolite of arachidonic acid, 12(*S*)-hydroxyeicosa-5(*Z*),8(*Z*),10(*E*),14(*Z*)-tetraenoic acid (HETE) – in inducing group I mGluR LTD in the hippocampus. Direct application of this metabolite mimicked and occluded mGluR5-dependent LTD at these synapses; mGluR5-dependent LTD in the hippocampus is absent in mice lacking the 'leukocyte type' 12-lipoxygenase, and group I mGluR LTD-inducing stimuli promote 12-lipoxygenase activity. A suggested potential downstream target of 12-lipoxygenase is p38 kinase. p38 kinase, like ERK, is a member of the mitogen-activated protein kinase (MAPK) family and has been implicated in group I mGluR LTD. For instance, in the dentate gyrus, group I mGluR LTD is dependent on p38 kinase signaling and in the CA1 of the hippocampus activation of group I mGluRs results in AMPA receptor endocytosis (which will be discussed in greater detail in a subsequent section) and is dependent on p38 kinase signaling as well as protein synthesis.

Kinases Involved in Group I mGluR Function

Group I mGluRs are linked to the activation of multiple kinases. Consistent with coupling of group I mGluRs with G_q and Ca^{2+} signaling, activation of these receptors can lead to activation of the Ca^{2+}/diacylglycerol (DAG)-dependent PKC family. mGluR-induced activation of PKC can lead to phosphorylation of a multitude of downstream targets, ultimately resulting in neuronal modifications such as LTP or LTD. One such target of mGluR-stimulated PKC activity is the MAPK/ERK pathway. The ERK pathway is a signaling cascade that plays a crucial role in a variety of cell regulatory events, including cell proliferation, differentiation, and survival, as well as an involvement in long-term synaptic changes and behavior. In neurons, ERK activation has been shown to be involved in processes associated with synaptic remodeling and long-term changes in synaptic efficacy. These processes include protein synthesis, changes in gene expression, dendritic spine stabilization, modulation of ion channels, and receptor insertion.

The ERK cascade is activated by a variety of extracellular agents, including growth factors, hormones, and neurotransmitters, and serves as an important point of convergence for the PKC and protein kinase A (PKA) pathways. PKC regulates ERK activity through an interaction with either Ras or Raf-1, leading to activation of mitogen-activated protein extracellular kinase (MEK) and consequently ERK. Additionally, it was discovered that DAG, another second messenger product of PLC activity, is capable of activating ERK independent of PKC activation.

Consistent with a role for PKA and PKC in some forms of group I mGluR LTD, group I mGluR LTD in the hippocampus, bed nucleus of the stria terminalis (BNST), and cerebellum is dependent on ERK activation. In addition to these kinases, receptor tyrosine phosphatases have also been shown to play an integral role in the group I mGluR-induced removal of AMPARs from the synapse, resulting in LTD of excitatory synaptic transmission.

Pharmacology of Group I mGluRs

The recent development of mGluR-selective ligands (e.g., phenylglycine derivatives acting either as agonists or as antagonists) has helped begin the elucidation of the functional roles of mGluRs in brain and behavior. The pharmacological profile of group I mGluRs has been determined in mammalian heterologous expression systems on cloned mGluRs. The rank order of potency of the most common agonists is quisqualate > DHPG = glutamate > (1*S*,3*R*)-1-amino-1,3-cyclopentanedicarboxylate (ACPD). The specific agonist for group I mGluRs used in the studies presented in the following sections is DHPG, which is devoid of activity at other mGluRs. An agonist for mGluR5 – (*R*,*S*)-2-chloro-5-hydroxyphenylglycine (CHPG) – has been reported, although it is not very potent.

The first antagonist described for group I mGluRs was α-methyl-4-carboxyphenylglycine (MCPG). However, MCPG also antagonizes group II mGluRs. There are several drugs that selectively inhibit mGluR5; the most widely used is the noncompetitive antagonist 2-methyl-6-(phenylethynyl)pyridine (MPEP), with the caveat that at high concentrations it blocks NMDA receptors.

Group I mGluRs and Plasticity

Group I mGluRs have been shown to potentiate either NMDAR- or AMPAR-mediated responses. However, a major function of group I mGluR activation is to produce a persistent weakening of glutamatergic transmission at synapses in the CNS. There appear to be at least two mechanisms through which this is accomplished. One involves the recruitment of endocannabinoid signaling and presynaptic alterations, and has been observed in the dorsal and ventral striatum.

A second major mechanism is through endocannabinoid-independent signaling mechanisms, and has been heavily studied in the hippocampus and cortical regions. Both presynaptic and postsynaptic mechanisms have been described for endocannabinoid-independent forms of group I mGluR LTD.

Group I mGluRs Can Alter iGluR Function

Group I mGluRs have been shown to modulate iGluRs in several ways. Activation of mGluRs can lead to changes in neuronal excitability and therefore influence NMDAR activity. For instance, membrane depolarization via group I mGluR stimulation can enable enhanced NMDAR-mediated synaptic plasticity. Additionally, through activation of kinases/phosphatases, group I mGluRs can alter the signaling properties of iGluRs and can influence trafficking of these receptors into and out of the synapse.

PKC phosphorylates NMDA and AMPA receptors. The activation of PKC by mGluRs might therefore modulate the phosphorylation state of these two ionotropic receptors, resulting in a potentiation of the response. Activation of group I mGluRs can lead to a removal of AMPA receptors from the membrane, resulting in a depression of synaptic transmission. More specifically, following activation of group I mGluRs there is a reduction in the density of postsynaptic AMPARs.

Group II mGluRs

Group II mGluRs (mGluR2/3) are widely distributed throughout the CNS, where they are moderately to highly expressed in brain regions that are commonly associated with anxiety disorders, including the hippocampus, prefrontal cortex (PFC), and amygdala. mGluR2 is generally localized at the periphery of the presynaptic terminal, suggesting a role for these receptors at instances of spillover of glutamate beyond the synaptic cleft in response to repetitive stimulation. By contrast, mGluR3 is more diversely localized, including both pre- and postsynaptic localization on neurons, as well as relatively heavy localization on glial cells. Group II mGluRs most commonly function presynaptically to decrease the probability of synaptic vesicle release, but at multiple synapses within the CNS postsynaptic mechanisms have been reported. Voltage-dependent Ca^{2+} channels are likely to be involved in the presynaptic inhibition mediated by mGluRs. Additionally, it has been suggested that K^+ channels mediate some of the effects induced by activation of group II or III mGluRs.

LY354740 ((1*S*,2*S*,5*R*,6*S*)-(+)-2-aminobicyclo[3.1.0] hexane-2,6-dicarboxylic acid) and several related compounds are potent and selective agonists at mGluR2 and mGluR3, with an EC_{50} of 1050 nM in the rat cortex, hippocampus, and striatum, and 10 or 30 nM in cells expressing recombinant mGluR2 or mGluR3, respectively. LY341495 ((2*S*)-2-amino-2-[(1*S*,2*S*)-2-carboxycycloprop-1-yl]-3-(xanth-9-yl) propanoic acid) is an antagonist of mGluRs, with nanomolar potency against group II mGluRs and micromolar potency against group III mGluRs.

LTD of excitatory transmission can be induced by activation of group II mGluRs in several brain regions. For example, group II mGluR LTD has been shown presynaptically in the basolateral amygdala (BLA), the nucleus accumbens, the BNST, and the striatum. In contrast, it was shown that stimulation of thalamic inputs to the lateral nucleus of the amygdala induces a group II mGluR-mediated postsynaptic LTD. Additionally, in the dentate gyrus and the medial PFC it was found that group II mGluR activation induced a postsynaptic LTD that was PKA and PKC dependent.

Behavioral studies of mice lacking mGluR2 or mGluR3 support earlier findings of a role of these receptors in anxiety behaviors. Consistent with the role of these receptors in various animal models of anxiety/stress, group II mGluR agonists have been considered promising candidates as therapeutic agents for the treatment of anxiety as well as other brain disorders.

Group III mGluRs

Like group II mGluRs, group III mGluRs are coupled to inhibition of cAMP production, and modulation of ion channels. However, in contrast to the other groups, group III mGluRs are primarily located at presynaptic active zones at the axon terminal. As with the group II mGluRs, the group III mGluRs inhibit neurotransmitter release, resulting in a reduction in glutamatergic or GABAergic synaptic transmission. Unfortunately, there are few pharmacological tools with the desired receptor subtype selectivity ideal for testing the significance of the subtypes of group III mGlu receptors. L-2-Amino-4-phosphonobutanoate (L-AP4), the most commonly used selective group III agonist, has a high affinity for mGluR4, mGluR6, and mGluR8 and a low affinity for mGluR7. One of the most promising drugs available for group III mGluRs is the positive allosteric modulator of mGluR4, (–)-*N*-phenyl-7-(hydroxyimino)cyclopropa[*b*]chromen-1a-carboxamide (PHCCC). (*S*)-3,4-Dicarboxyphenylglycine (DCPG), a more recently described group III mGluR agonist, is a relatively specific mGluR8 agonist.

While group III mGluR function has been reported in brain regions such as the BLA, central nucleus of the amygdala, BNST, and hippocampus using an agonist

pharmacology approach, behavioral analysis of specific receptor mutant mice has also proved useful. In combination with the limited pharmacology, mutants of mGluR4, mGluR7, and mGluR8 have all been shown to have behavioral phenotypes. For instance, consistent with a dysregulation of the hypothalamic–pituitary–adrenal (HPA) axis, mice with targeted deletion of mGluR7 show changes in animal behavior paradigms predictive of antidepressant and anxiolytic action. They also exhibit a deficit in fear responses and learning paradigms. Interestingly, administration of the mGluR4 allosteric potentiator, PHCCC, also has anxiolytic-like effects, implicating a role for this receptor in anxiety as well. mGluR4 knockout (KO) mice have altered glutamate and GABA release and, interestingly, mGluR4 activation protects against neurodegeneration. mGluR8 has been implicated in conditioned fear, and similar to the other group III mGluRs, mice lacking mGluR8 have an increased anxiety phenotype.

Of the mGluRs, mGluR6 has the most restricted expression. These receptors are expressed postsynaptically at ON bipolar cells in both rod and cone systems and function as the main excitatory receptor responsible for relaying synaptic signals in these retinal cells. Consistent with their important functional role in visual processing, genetic targeting of mGluR6 impairs detection of visual contrasts.

Diseases

Many psychiatric as well as neurological diseases have been linked to alterations in neuronal excitability via the glutamatergic system. As mGluRs function to regulate a large number of synapses, and are known to play a role in pathophysiological conditions, compounds that act on these receptors are prime targets for a number of therapeutic applications. For instance, drugs targeting mGluRs have been shown to prevent certain forms of pain and anxiety. There are positive potential therapeutic effects of mGluR compounds in treating Parkinson's disease as well as the conditions of drug dependence and withdrawal. Also, activating or potentiating mGluRs may help in treatment of schizophrenia and Alzheimer's disease. An interesting model suggests a specific role for group I mGluRs in fragile X mental retardation. Intense investigation reveals a role for mGluRs in nociception both centrally and peripherally. For instance, group I mGluRs have been implicated in the processes of central sensitization and persistent nociception, whereas activation of group II mGluRs is effective against neuropathic or inflammatory pain.

Pharmacology/Therapeutic Utility of mGluRs

An exciting new direction in the pharmacological targeting of mGluRs has been the development of subtype-selective allosteric modulators. An advantage of allosteric modulators over traditional compounds is that allosteric modulators rely on activation by the endogenous transmitter released in an activity-dependent manner. mGluRs are prominent targets as both positive and/or negative allosteric modulators with unique pharmacological properties. Allosteric modulators, as compared to orthosteric ligands, appear to show a unique degree of selectivity.

Background

The first challenge to the general belief that all glutamate receptors were ligand-gated ion channels was the demonstration by Sladeczek, Pin, Recasens, Bockaert, and Weiss that glutamate stimulates polyphosphoinositide (PI) hydrolysis in cultured striatal neurons. Similar data were obtained in brain slices, where the PI response to glutamate is maximal in the early postnatal life and declines progressively during postnatal development. The term 'metabotropic glutamate (mGlu) receptors' was introduced in 1987 by H Sugiyama and colleagues, who examined responses to excitatory amino acids in *Xenopus* oocytes injected with rat brain mRNA. Cloning of the first mGlu receptor subtype by S Nakanishi and colleagues in 1991 was the milestone for any further development of the field.

Classification of mGlu Receptors

mGlu receptors form a family of eight subtypes subdivided into three groups based on their sequence similarities and G-protein coupling.

Group I mGlu Receptors

Group I includes mGlu1 (variants: mGlu1a, -1b, -1c, -1d, and -1e) and mGlu5 (variants: mGlu5a and -5b) receptors, which are primarily coupled to G_q/G_{11} proteins (Figure 1). Secondary coupling involves G_s and the pertussis toxin-sensitive G_o. Activation of both subtypes in recombinant cells stimulates PI hydrolysis with an ensuing formation of the two intracellular second messengers, inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 releases Ca^{2+} from intracellular stores, whereas DAG activates protein kinase C (PKC). Activation of group I mGlu receptors can also stimulate cyclic adenosine monophosphate (cAMP) formation, arachidonic acid release, the mitogen-activated protein kinase (MAPK) pathway, and the phosphatidylinositol 3-kinase (PI3K) pathway. The mGlu1 receptor is negatively coupled to a variety of K^+ channels and to the C1 type of transient receptor potential (TRP) channels.

Homologous desensitization of group I mGlu receptors involves phosphorylation mechanisms mediated by either PKC or G-protein-coupled receptor kinases (GRKs). Different GRK isoforms, including GRK2, GRK4, and GRK5, have been found to desensitize mGlu1 receptors in recombinant cells. GRK4 is also required for desensitization of native mGlu1 receptors expressed by cerebellar Purkinje cells. While desensitization by GRK4 is mediated by receptor phosphorylation, desensitization by GRK2 is independent of phosphorylation and may involve a direct interaction with activated $G_{\alpha q}$. The mGlu5 receptor is selectively desensitized by members of the GRK2 family (GRK2 and GRK3) through a mechanism that involves phosphorylation of the Thr840 residue in the C-terminus domain of the receptor. The Regulator of G-protein signaling, RGS4, which acts as effector antagonist by increasing the GTPase activity of $G_{\alpha q}$, inhibits mGlu1 and mGlu5 receptor signaling.

Group II mGlu Receptors

Group II includes mGlu2 and mGlu3 receptors, which are coupled to G_i/G_o proteins (Figure 1). Their activation inhibits cAMP formation, inhibits L- and N-type voltage-sensitive Ca^{2+} channels, activates K^+ channels, and stimulates the MAPK and PI3K pathways. The latter two effects are presumably mediated by the $\beta\gamma$ subunits of G_i. Activation of group II mGlu receptors can also amplify the stimulation of cAMP formation by β-adrenergic receptor agonists in cultured astrocytes, and the stimulation of PI hydrolysis by mGlu1/5 receptor agonists in brain slices.

Group III mGlu Receptors

Group III includes mGlu4, mGlu6, mGlu7 (variants: mGlu7a and -7b), and mGlu8 (variants: mGlu8a, -8b, and -8c) receptors, which are all coupled to G_i/G_o proteins (Figure 1). Activation of mGlu4, mGlu7, and mGlu8 receptors inhibits cAMP formation and N-type voltage-sensitive Ca^{2+} channels. In cells expressing mGlu4 receptors, GRK2 attenuates agonist-stimulated MAPK activation without affecting inhibition of adenylyl cyclase. Activation of mGlu6 receptors inhibits cGMP-dependent cation channels in ON bipolar cells of the retina (see later).

Structure and Mechanisms of Activation of mGlu Receptors

mGlu receptors belong to class C G-protein-coupled receptors (GPCRs), which also includes γ-aminobutyric acid B ($GABA_B$) receptors, the Ca^{2+}-sensing receptor

Figure 1 The mGlu receptor family. PtdIns-4,5-P_2, phosphatidylinositol 4,5-bisphosphate; Ins-1,4,5-P_3, inositol 1,4,5-trisphosphate; DAG, diacylglycerol; PKC, phosphokinase C; PLC, phospholipase C.

expressed parathyroid cells, the taste receptors that detect sweet and umami, and some pheromone receptors. mGlu receptors are formed by (1) a large N-terminus extracellular domain (about 600 amino acids) containing the glutamate binding site and a Cys-rich region, (2) a seven-transmembrane (7TM) domain, and (3) an intracellular C-terminus domain that varies in length depending on the receptor subtype/splice variant. mGlu1a, mGlu5a, and mGlu5b receptors have long C-terminus domains, which favor their interaction with adaptor and scaffolding proteins (see later). In the mGlu1b and -1d variants, the 313 C-terminus amino acids are substituted by 20 (mGlu1b) and 22/26 (mGlu1d human/rat) amino acids. The mGlu1e isoform corresponds to the soluble extracellular domain of the mGlu1 receptor. The mGlu5b variant differs from mGlu5a for the presence of 39 amino acids inserted 49 residues downstream of the seventh TM domain. The existence of truncated forms of mGlu3 and mGlu6 receptors, corresponding to the extracellular portion of the receptors, has been demonstrated in human tissue. In the mGlu7b variant, the last 16 amino acids of mGlu7a are substituted by 23 different residues.

The elegant report by Kunishima and colleagues in 2000 has afforded insights into the structure

and mechanism of activation of mGlu receptors. Glutamate binds to a 'venus fly trap' (VFT) region of the N-terminus domain constituted by two globular lobes separated by a hinge. The lobes oscillate between a close/active conformation and an open/inactive conformation. Agonist binding to the hinge facilitates the closure of the two lobes, whereas binding of competitive antagonists stabilizes the open conformation. Similarly to other class C GPCRs, mGlu receptors function as dimers. Dimerization involves a hydrophobic interaction between lobe I of the VFT in each monomer, and is stabilized by a disulfide bond. The use of receptor chimeras containing the C-terminus domains of type 1 and type 2 $GABA_B$ receptors (which form obligatory heterodimers) has allowed to establish that the mGlu receptor dimer can be activated by a single molecule of orthosteric agonist, but that binding of two molecules (one to each monomer) is required for full receptor activation. In contrast, it appears that only one 7TM domain is required for effective G-protein activation. The 7TM domain contains the binding sites for positive allosteric modulators ('potentiators' or 'enhancers'), which amplify receptor activation only in the presence of an orthosteric agonist – that is, in an activity-dependent manner. One enhancer molecule per dimer is needed for full amplification of mGlu receptors. The 7TM domain also bears the binding sites for negative allosteric modulators, which inhibit mGlu receptors independently of the concentrations of ambient glutamate.

mGlu receptors interact with a variety of adaptor and scaffolding proteins, which regulate receptor expression and coupling with other receptors or enzymes. Homer proteins, which contain both postsynaptic density/disc/zonula occludens (PDZ) and Ena/vasodilator-stimulated phosphoprotein homology-1 (EVH-1) domains, bind to a proline-rich motif in the C-terminal region of mGlu1a and mGlu5 receptors. Constitutively expressed, long isoforms of Homer proteins (Homer 1b, -1c, -2, and -3) have a C-terminal coiled-coil domain that mediates self-multimerization and allows the interaction of mGlu1a/5 receptors with other Homer-interacting proteins, such as the IP_3 receptor (Figure 2(a)). This interaction is disrupted by the short inducible isoform of Homer (Homer 1a), which lacks the coiled-coil domain. Interestingly, Homer 1a is encoded by an early inducible gene, which is expressed in response to synaptic activation. The interaction between Homer and the long isoform of the PI3K enhancer, PIKE, mediates the stimulation of PI3K by mGlu1 receptor activation. mGlu1 receptors functionally interact with ephrin-B2, a member of the ephrin/Eph receptor family of transmembrane proteins which mediate processes of cell-to-cell interaction during development and in the adult life. This interaction might have interesting implications for processes of developmental plasticity. Other proteins interacting with group I mGlu receptors are the E3 ubiquitin ligase, Seven in absentia homolog 1a, protein phosphatase 1c, tubulin, and tamalin. Protein phosphatase 2C binds selectively to, and dephosphorylates, mGlu3 receptors. mGlu7 receptors interact with calmodulin, protein interacting with PKC 1 (PICK 1), glutamate receptor-interacting protein 1 (GRIP 1), syntenin, α-tubulin, filamin A, and the catalytic γ subunits of protein phosphatase 1C. A simultaneous or exclusive binding to these proteins tightly regulates mGlu7 receptor signaling. mGlu8 receptors interact with sumo1 and other components of the sumoylation cascade, such as ube2a, Pias1, Piasγ, and Piasxβ.

Cell Biology, Pharmacology, and Implications for Human Pathology

The three groups of mGlu receptor ligands (Figure 3) have potential clinical applications, as outlined in Table 1.

mGlu1 Receptor

The mGlu1 receptor consists of 1194 amino acids in humans and 1199 amino acids in rats and mice; accession numbers are Q13255 (human), P23385 (rat), and P97772 (mouse). The gene is named *GRM1* (human) and *Grm1* (rat, mouse); chromosomal locations are 6q24 (human), 1p13 (rat), and 10 A2 (mouse).

At a subcellular level, mGlu1 proteins are mostly found in postsynaptic elements at the periphery of the postsynaptic density (PSD). This contrasts with the distribution of *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors, which are localized in the central region of the PSD. mGlu1 receptors are expressed by Purkinje cells of the cerebellar cortex, where they participate in the induction of long-term depression (LTD) at the parallel fiber–Purkinje cell synapse. LTD is a particular form of synaptic plasticity that, in the cerebellum, underlies motor learning. Mice with genetic deletion of mGlu1 receptors are ataxic and show persistent multiple climbing fiber innervation of cerebellar Purkinje cells. Interestingly, anti-mGlu1 receptor antibodies are found in a subset of patients with Hodgkin's lymphoma and paraneoplastic ataxia. The mGlu1 receptor is also expressed in the olfactory bulb, pars compacta of the substantia nigra, hippocampus, and thalamic nuclei. In the hippocampus, activation of mGlu1 receptors inhibits GABA release and mGlu1 receptor antagonists are protective against excitotoxic and hypoxic/ischemic neuronal death. Unexpectedly, that

Figure 2 Synaptic localization of mGlu receptors. (a) mGlu1 and mGlu5 receptors are found at the periphery of postsynaptic elements. mGlu1a, mGlu5a, and mGlu5b receptors interact with scaffolding and adaptor proteins, including Homer. (b) mGlu2/3 and mGlu4/7/8 receptors are predominantly found in presynaptic terminals, where their activation inhibits neurotransmitter release; mGlu3 and mGlu5 receptors are also found in glial cells. (c) Activation of mGlu6 receptors by the glutamate released from photoreceptor cells inhibits the activity of ON bipolar cells. Glut, glutamate; IP3R, inositol 1,4,5-trisphosphate receptor; ER, endoplasmic reticulum; EAAT, excitatory amino acid transporter; PP2B, protein phosphatase 2B; TRPC, transient receptor potential-C. ectopic expression of mGlu1 receptors in melanocytes promotes the development of multiple melanomas in mice. Because mGlu1 receptors are found in human melanomas but not in benign nevi, it is possible that receptor activation contributes to neoplastic transformation of melanocytes.

There are no selective agonists of mGlu1 receptors. 3,5-dihydroxyphenylglycine (DHPG) activates both mGlu1 and mGlu5 receptors, although it has no activity at other glutamate receptor subtypes. The following drugs are examples of competitive mGlu1 receptor antagonists (in the rank order of affinity): LY367385 = 4C3HPG > 4CPG > AIDA. Compounds Ro01–6128 and Ro67–7476 are mGlu1 receptor enhancers with nanomolar potency, whereas BAY36–7620 and CPCCOEt are negative allosteric

Table 1 Potential clinical applications of mGlu receptor ligands

Group	*Application*
Group I	Chronic pain (mGlu1/5, Ant/NAM)
	Anxiety disorders (mGlu5, Ant/NAM)
	Drug addiction (mGlu5, Ant/NAM)
	Fragile X syndrome (mGlu5, Ant/NAM)
	Parkinsonism (mGlu5, Ant/NAM)
	Schizophrenia (mGlu5, PAM)
	Brain ischemia (mGlu1, Ant/NAM)
Group II	Generalyzed anxiety disorders and panic attack (mGlu2/3, Ago/PAM)
	Drug addiction (mGlu2/3, Ago/PAM)
	Schizophrenia (mGlu2/3, Ago/PAM)
	Chronic pain (mGlu2/3, Ago/PAM; mGlu2 inducers)
Group III	Epilepsy (mGlu4/7/8, Ago/PAM)
	Parkinsonism (mGlu4, Ago/PAM)
	Anxiety (mGlu8, Ago/PAM)

Ago, agonist; Ant, competitive antagonist; PAM, positive allosteric modulator; NAM, negative allosteric modulator.

CPCCOEt, 7-(hydroxyimino)cyclopropa[*b*]chromen-1a-carboxylate ethyl ester.)

mGlu5 Receptor

The mGlu5 receptor consists of 1212 amino acids in humans and 1203 amino acids in rats; accession numbers are P41594 (human) and P31424 (rat). The gene is named *GRM5* (human) and *Grm5* (rat, mouse); chromosomal locations are 11q14.2 (human), 1q32 (rat), and 7 D3 (mouse).

Activation of recombinantly expressed mGlu5 receptors induces oscillatory increases in intracellular Ca^{2+} release. This property, which is not shared by mGlu1 receptors, relies on the presence of a Ser residue in the C-terminus domain, which is phosphorylated by PKC, and places the mGlu5 receptor at the core of basic processes in cell biology. Similar to the mGlu1 receptor, the mGlu5 receptor is localized in postsynaptic elements, where it is physically linked to NMDA receptors via a chain of interacting proteins, which include PSD-95, Shank, guanylate kinase-associated protein (GKAP), and Homer (**Figure 2(a)**). Activation of mGlu5 receptors facilitates the opening of NMDA-gated ion channels, and activation of NMDA receptors amplifies mGlu5 receptor function by inhibiting receptor desensitization. Because of their functional interaction with NMDA receptors, mGlu5 receptors are involved in the induction of long-term potentiation (LTP), a putative electrophysiological substrate of associative learning. mGlu5 knockout mice show a defective LTP in the hippocampus and an impaired spatial learning. Activation of mGlu5 receptors also mediates a non-NMDA-dependent form of LTD in the hippocampus.

mGlu5a and mGlu5b variants show an opposite developmental pattern of expression in the central nervous system (CNS). mGlu5a receptors are abundantly expressed early after birth, and mediate the robust PI response to excitatory amino acids in the first 2 weeks of postnatal life. Expression of mGlu5b receptors increases with age and is prominent in the adult hippocampus, striatum, and cerebral cortex. mGlu5 receptors are also found in peripheral cells, including thymocytes, hepatocytes, melanocytes, cells of the male germinal line, osteoblasts, and insulinoma cell lines, where their function begins to be explored. Remarkably, mGlu5 receptors are present in both embryonic and neural stem cells, and their activation supports proliferation and self-renewal of these cells. A dysfunction of mGlu5 receptors has been associated with the fragile X syndrome, the most frequent form of inherited mental retardation. This syndrome is caused by the absence of the fragile X mental retardation protein (FMRP), an RNA-binding protein which functions as a negative regulator of protein synthesis. LTD mediated by mGlu5 receptors is enhanced in mice lacking FMRP, and pharmacological blockade of mGlu5 receptors partially corrects neurological and behavioral abnormalities in these mice.

mGlu5 receptors are selectively activated by 2-chlorohydroxyphenylglycine (CHPG), which, however, is a relatively weak agonist. No selective competitive antagonists are currently available. 2-Methyl-6-(phenylethynyl)pyridine (MPEP), 6-methyl-2-(phenylazo) pyridin-3-ol (SIB-1757), and (*E*)-2-methyl-6-stryrylpyridine (SIB-1893) are prototypes of a growing list of negative allosteric modulators of mGlu5 receptors, which includes 3-[(2-methyl-1,3-thiazol-4-yl)ethynyl] pyridine (MTEP) and the anxiolitic drug, fenobam. Compounds 3,3'-difluorobenzaldazine (DFB), *S*-(4-fluorophenyl)-{3-[3-(4-fluorophenyl)-[1,2,4] oxadiazol-5-yl]-piperidin-1-yl}methanone (AD X47273), 3-cyano-*N*-(1,3-diphenyl-1*H*-pyrazol-5-yl) benzamide (CDPPB), and *N*-{4-chloro-2-[(1,3-dioxo-1,3-dihydro-2*H*-isoindol-2-yl) methyl]phenyl}-2-hydroxybenzamide (CPPHA) are example of mGlu5 receptor enhancers which amplify receptor function in an activity-dependent manner. mGlu5 receptor ligands are of potential interests for the treatment of psychiatric and neurological disorders, such as anxiety, schizophrenia, parkinsonism, and neuropathic pain. Systemic administration of MPEP produces anxiolytic effects in a number of tests, including fear-potentiated startle, auditory and contextual fear conditioning, the elevated plus maze, conflict tests, and stress-induced hyperthermia. These effects are mediated by mGlu5 receptor blockade in the hippocampus and in the central nucleus of the amygdala, two regions that are actively involved in the acquisition and expression of fear conditioning. Pharmacological blockade or genetic

deletion of mGlu5 receptors disrupts prepulse inhibition of the acoustic startle reflex in rodents, thus mimicking the deficit in sensorimotor gating typical of schizophrenic patients. Administration of MPEP also enhances the cognitive deficit induced by the psychotomimetic drug, phencyclidine. Hence, mGlu5 receptor enhancers are currently developed as potential antipsychotic agents.

mGlu5 receptors are highly expressed in all stations of the basal ganglia motor circuit, and regulate the 'indirect pathway' of motor control by opposing the action of dopamine released from nigrostriatal terminals. The activity of this pathway is negatively regulated by the dopamine released from nigrostriatal fibers, which acts on D_2 inhibitory receptors located on medium-size spiny GABAergic neurons that project to the external portion of the globus pallidus (GP_e). In striatal projection neurons, mGlu5 receptors physically interact with A_{2A} adenosine receptors, and act synergistically with them in antagonizing the inhibitory control exerted by D_2 receptors. In addition, activation of mGlu5 receptors inhibits GP_e neurons by a mechanism of cross-desensitization with mGlu1 receptors, and stimulates neurons of the subthalamic nucleus. Pharmacological blockade or genetic deletion of mGlu5 receptors protects mice against nigrostriatal damage produced by the parkinsonian toxin, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), or the psychostimulant, methamphetamine. This raises the attractive possibility that mGlu5 receptor antagonists/negative modulators behave as antiparkinsonian agents by relieving motor symptoms and reducing the ongoing degeneration of nigrostriatal neurons at the same time.

mGlu5 and mGlu1 receptors are implicated in the pathophysiology of chronic pain. Both receptor subtypes are localized on peripheral unmyelinated sensory afferents, and their activation increases the sensitivity to noxious heat, a phenomenon termed 'thermal hyperalgesia.' Activation of mGlu5 receptors in peripheral nociceptors stimulates PI hydrolysis and arachidonic acid release from DAG, leading to prostaglandin formation. Autocrine or paracrine stimulation of prostanoid receptors by prostaglandins in nociceptors results into an increased sensitivity of vanilloid TRPV1 receptors, thus inducing thermal hyperalgesia. Group I mGlu receptors also contribute to the regulation of nociceptive transmission and plasticity in the dorsal horns of the spinal cord, and perhaps in other stations of the pain neuraxis. Antagonists/negative modulators of mGlu5 and mGlu1 receptors produce analgesic effects in models of inflammatory and neuropathic pain.

Finally, mGlu5 receptors have been implicated in the synaptic mechanisms underlying drug addiction. These receptors positively regulate brain reward function and drive drug consumption. Blockade of mGlu5 receptors by MPEP elevates the intracranial self-stimulation threshold, decreases cocaine and nicotine self-administration, and attenuates naloxone-induced somatic signs of morphine withdrawal.

mGlu2 and mGlu3 Receptors

The mGlu2 receptor consists of 872 amino acids in humans, rats, and mice; accession numbers are Q14416 (human) and P31421 (rat). The gene isnamed *GRM2* (human) and *Grm2* (rat, mouse); chromosomal locations are 3q21.31 (human), 8q32 (rat), and 9 (mouse).

The mGlu3 receptor consists of 877 amino acids in humans and 879 amino acids in rats and mice; accession numbers are Q14832 (human), P31422 (rat), and Q9QYS2 (mouse). The gene is named *GRM3* (human) and *Grm3* (rat, mouse); chromosomal locations are 7q21.1–q21.2 (human), 4q32 (rat), and 5A1-h (mouse).

mGlu2 and mGlu3 are highly homologous and have a similar functional and pharmacological profile. Both receptors are predominantly localized in the preterminal region of the axon, and, if present in glutamatergic nerve terminals, can only be activated by amounts of glutamate sufficient to escape the clearance mechanisms around the synapses (**Figure 2(b)**). Activation of group II mGlu receptors attenuates neurotransmitter release as a result of a reduced cAMP formation and inhibition of voltage-sensitive Ca^{2+} channels. In brain slices, activation of mGlu2/3 receptors fails to stimulate PI hydrolysis *per se*, but amplifies the stimulation of PI hydrolysis mediated by group I mGlu receptors. The functional significance of this mechanism is unknown. mGlu3 receptors are also found in astrocytes, where their activation stimulates the MAPK and PI3K pathways and leads to the production of tropic factors (**Figure 2(b)**).

Both mGlu2 and mGlu3 receptors are activated by 2*R*,4*R*-4-aminopyrrolidine-2,4-dicarboxylic acid (APDC; (a selective agonist with micromolar affinity), and by the cyclopropan derivatives, 2*S*,2′*R*,3′*R*)-2-(2′,3′-dicarboxycyclopropyl)glycine (DCG-IV) and (2*S*,1′*S*,2′*S*)-2-(carboxycyclopropyl)glycine (L-CCG-I). Both drugs activate mGlu2 and mGlu3 receptors in the mid-nanomolar range; however, DCG-IV is also an NMDA receptor agonist, whereas L-CCG-I can also activate group I mGlu receptors. (1*S*,2*S*,5R,6*S*)-(+)-2-Aminobicyclo[3.1.0]hexane-2,6-dicarboxylic acid (LY354740) and (–)-2-oxa-4-aminocyclo[3.1.0]hexane-4,6-dicarboxylic acid (LY379268) are conformationally constrained glutamate analogs in which the glutamate backbone is locked into a fully extended state by incorporation into a bicycle[3.1.0]

hexane ring system. Both compounds are potent and selective mGlu2/3 receptor agonists with affinity in the low nanomolar range, and are systemically active. LY354740 and its prodrugs are currently under clinical development for the treatment of anxiety and panic disorders (see later). (1*R*,2*S*,5*S*,6*S*)-2-Amino-6-fluoro-4-oxobicyclo[3.1.0]hexane-2,6-dicarboxylic acid monohydrate (MGS0028) is another potent and selective agonist of mGlu2/3 receptors. Compounds (2*S*,1′*S*,2′*S*)-2-(9-xanthylmethyl)-2-(2′-carboxycyclopropyl)glycine (LY341495) and (1*R*,2*R*,3*R*,5*R*,6*R*)-2-amino-3-(3,4-dichlorobenzyloxy)-6-fluorobicyclo[3.1.0]hexane-2,6-dicarboxylic acid (MGS0039) are mGlu2/3 receptor antagonists with nanomolar affinity. However, LY341495 recruits other mGlu receptor subtypes at micromolar concentrations and is considered as a pan-mGlu receptor antagonist. There are only a few tools that can help discriminate mGlu2 from mGlu3 receptors. No subtype-selective mGlu2 receptor agonists are available. *N*-Acetyl-aspartyl-glutamate (NAAG) is an endogenous compound that activates mGlu3 receptors and has no activity at mGlu2 receptors. However, NAAG displays a low potency and is also active at NMDA receptors. A growing number of positive allosteric modulators, such as 2,2,2-trifluoro-*N*-[3-(2-methoxyphenoxy)phenyl]-*N*-(3-pyridinylmethyl)-ethanesulfonamide (3-MP PTS) and 2,2,2-trifluoro-*N*-[3-(cyclopentyloxy)phenyl]-*N*-(3-pyridinylmethyl)-ethanesulfonamide (cyPPTS), selectively amplify responses mediated by mGlu2 receptors. No mGlu3 receptor enhancers are currently available.

The development of mGlu2/3 receptor agonists or enhancers is aimed at the treatment of a number of psychiatric disorders, such as anxiety disorders, schizophrenia, and drug addiction. The agonist LY354740 is effective in all animal models of anxiety, and is also active in humans in preventing CO_2-induced anxiety and panic attacks and relieving symptoms of generalized anxiety disorder (GAD). Remarkably, pharmacological activation of mGlu2/3 receptors does not produce adverse effects, such as sedation, ataxia, and dependence, that are typical of benzodiazepines and other CNS depressants, although it may disrupt memory processing. mGlu2 and mGlu3 receptors are highly expressed in limbic regions, and may regulate transmission at the synapses between the basolateral nuclei and the central nucleus of the amygdala. A final effect of LY354740 appears to be an enhanced GABAergic activity within the central nucleus of the amygdala, as shown by an increased Fos protein expression in GABAergic neurons. It appears that both mGlu2 and mGlu3 receptors are necessary for the anxiolytic effect of LY354740, although selective mGlu2 enhancers can also relieve anxiety.

mGlu2/3 receptor agonists or mGlu2 receptor enhancers are active in models predictive of antipsychotic activity, including the disruption of working memory, motor activity, sensory–motor gating (only mGlu2 enhancers), and glutamate efflux induced by phencyclidine or amphetamine. In addition, there is a functional antagonism between mGlu2/3 receptors and serotonin 5-HT_{2A} receptors, which mediate the psychotomimetic action of LSD and other hallucinogenic drugs. Thus, there is a common pathway for the action of mGlu2/3 receptor agonists and atypical antipsychotic drugs, such as clozapine or olanzapine, which act as 5-HT_{2A} receptor antagonists. Although there is no association of polymorphism in the mGlu2 receptor gene with schizophrenia, an increased expression of mGlu2/3 receptors is found in the prefrontal cortex of schizophrenic patients. Thus, one expects that the brain of schizophrenic patients is highly responsive to drugs that activate mGlu2/3 receptors.

mGlu3 receptors are present in astrocytes and microglia, where their activation stimulates the synthesis of neurotropic factors, such as transforming growth factor-β (TGF-β), nerve growth factor (NGF), and brain-derived neurotropic factor (BDNF). An increased secretion of TGF-β from astrocytes mediates the neuroprotective activity of group II mGlu receptor agonists in culture. mGlu3 receptors are also found in neural stem cells and human glioma cells, and their blockade inhibits cell proliferation by dampening the stimulation of the MAPK and the PI3K pathways.

Group II mGlu receptors have been recently shown to play a role in the synaptic adaptations that occur during the development of drug dependence. Activation of mGlu2/3 receptors negatively regulates brain reward function, as agonists elevate the intracranial self-stimulation threshold and decrease relapse to drug-taking behavior during abstinence, thus regulating the negative affective state observed during withdrawal.

Finally, mGlu2/3 receptors mediate analgesic effects via a variety of mechanisms, including a reduced sensitivity of TRPV1 channels in peripheral nociceptors, and a reduced neurotransmitter release at the synapses between primary afferent fibers and second-order neurons in the dorsal horn of the spinal cord. L-Acetylcarnitine, a drug currently used for the treatment of painful neuropathies, induces the expression of mGlu2 receptors in dorsal root ganglia neurons by amplifying the activity of transcription factors of the nuclear factor-kappa B (NF-κB) family.

mGlu4, mGlu7, and mGlu8 Receptors

The mGlu4 receptor consists of 912 amino acids in humans, rats, and mice; accession numbers are Q14833 (human), P31423 (rat), and Q68EF4 (mouse). The gene is named *GRM4* (human) and

Grm4 (rat, mouse); chromosomal locations are 6p21.3 (human), 20p12 (rat), and 17 A3.3 (mouse).

The mGlu7 receptor consists of 915 amino acids in humans, rats, and mice; accession numbers are Q14831 (human), P35400 (rat), and Q68ED2 (mouse). The gene is named *GRM7* (human) and *Grm7* (rat, mouse); chromosomal locations are 3p26.1 (human), 4q42 (rat), and 6 E3 (mouse).

The mGlu8 receptor consists of 908 amino acids in humans, rats, and mice; accession numbers are O00222 (human), P70579 (rat), and P47743 (mouse). The gene is named *GRM8* (human) and *Grm8* (rat, mouse); chromosomal locations are 7q31.3–q32 (human), 4q22 (rat), and 6 A3 (mouse).

These three receptor subtypes are preferentially, although not exclusively, located in the terminal region of the axons and share the ability to inhibit neurotransmitter release at various synapses in the CNS. Their location in the vicinity of the active zones of neurotransmitter release makes these subtypes as putative glutamate autoreceptors (Figure 2(b)). L-2-Amino-4-phosphonobutanoate (L-AP4) and the endogenous compound L-serine-*O*-phosphate (L-SOP) are prototypical orthosteric agonists of all group III mGlu receptors. (+)-4-Phosphonophenylglycine (4-PPG) activates receptors with the following rank order of potency: mGlu8 > mGlu4 >> mGlu7. (*S*)-3,4-Dicarboxyphenylglycine (DCPG) is an agonist with greater affinity for mGlu8 than for mGlu4, whereas (1*S*,3*R*,4*S*)-1-aminocyclopentane-1,3,4-tricarboxylic acid (ACPT-I) activates mGlu4 and mGlu8 receptors with equal potency. Neither DCPG nor ACPT-I has any effect at mGlu7 receptors. (*R*,*S*)-α-Cyclopropyl-4-phosphonophenylglycine (CPPG) and (*S*)-α-methyl-2-amino-4-phosphonobutanoic acid (M AP-4) are competitive antagonists with higher affinity for mGlu8 receptors. CPPG has no apparent activity at mGlu7 receptors. (–)-*N*-Phenyl-7-(hydroxyimino) cyclopropa[*b*]chromen-1a-carboxamide (PHCCC) is an enhancer with high selectivity for mGlu4 receptors. At high concentrations, PHCCC may also recruit mGlu1 receptors because of its similarity with CPCCOEt (see earlier). A selective agonist of mGlu7 receptors, *N*,*N*′-dibenzhydrylethane-1,2-diamine dihydrochloride (AM N082), has recently been synthesized. This compound is atypical because it does not bind to the VFT (like all classical mGlu receptor agonists), but to a site located in the 7TM domain of mGlu7 receptors.

Activation of mGlu4 receptors is neuroprotective and mGlu4 receptor agonists/enhancers have been proposed as potential therapeutic agents in Parkinson's disease for their ability to reverse parkinsonian symptoms in animal models. This action appears to be mediated by the inhibition of GABA release in the GP_e, which lies along the 'indirect pathway' of the basal ganglia motor circuit. Activation of mGlu4 receptors is also protective against experimental parkinsonism induced by MPTP in mice. mGlu4 receptors are highly expressed by cerebellar granule cells, and are also found in medulloblastoma cells, which derive from granule cell neuroprogenitors. Interestingly, activation of mGlu4 receptors inhibits proliferation of medulloblastoma cells and limits the spontaneous growth of medulloblastomas in the cerebellum of tumor-prone mice.

The function of mGlu7 and mGlu8 receptors is only partially known. Both receptors have been proposed as drug targets in treatment of anxiety and stress-related disorders, but there are some caveats. The mGlu7 receptor agonist, AMN082, relieves anxiety, but genetic deletion of mGlu7 receptors does the same. In contrast, mGlu8 knockout mice show an increased level of anxiety, similar to that found in animals subjected to stressful conditions.

Finally, mGlu4, mGlu7, and mGlu8 receptors have been considered as potential targets for the experimental therapy of epilepsy. Drugs that activate mGlu4 or mGlu8 receptors reduce generalized seizures in epilepsy-prone mice and rats and chemically induced seizures. In addition, mice lacking mGlu7 or mGlu8 receptors show an increased susceptibility to chemically induced seizures. Expression of mGlu4 receptors is increased in the dentate gyrus of mice with a low susceptibility to seizures and of patients with temporal lobe epilepsy. In contrast, activation of mGlu4 receptors is required for the induction of absence seizures in mice.

mGlu6 Receptor

The mGlu6 receptor consists of 877 amino acids in humans and 871 amino acids in rats and mice; accession numbers are O15303 (human), P35349 (rat), and Q5NCH9 (mouse). The gene is named *GRM6* (human) and *Grm6* (rat, mouse); chromosomal locations are 5q35 (human), 10 (rat), and 11 B1.3 (mouse).

This is a peculiar receptor; it is exclusively localized in the dendrites of ON bipolar cells of the retina and responds to the glutamate released from rod and cone photoreceptor cells in the dark. Activation of mGlu6 receptors leads to hyperpolarization of ON bipolar cells by closing cGMP-dependent cation channels. This effect may involve a receptor coupling with G_o and activation of the Ca^{2+}-dependent protein phosphatase, calcineurin (Figure 2(c)). Light reduces glutamate stimulation of mGlu6 receptors, leading to opening of cation channels and depolarization of ON bipolar cells. Mice lacking mGlu6 receptors show a loss of ON response but unchanged responses to light. Interestingly, mutations in the gene encoding

the mGlu6 receptor are associated with night blindness and abnormal electroretinogram ON responses in humans. The mGlu6 receptor shows the same pharmacological profile of other group III mGlu receptors, being activated by L-AP4, L-SOP, and 4-PPG, and antagonized by CPPG, MSOP, and MAP-4.

Metal Accumulation during Aging

H M Schipper, McGill University, Montreal, QC, Canada

Introduction

Central nervous system (CNS) senescence has been implicated as the most robust risk factor for a host of human neurodegenerative disorders, including sporadic (nonfamilial) Alzheimer's disease (AD), Parkinson's disease (PD), and amyotrophic lateral sclerosis (ALS). Thus, a thorough understanding of intrinsic brain aging mechanisms and their relationship to intervening neuropathological processes is essential for the development of therapeutic modalities that successfully prevent, ameliorate, interrupt, or reverse neuronal attrition and clinical decline in these conditions. Over the past two decades, oxidative stress (OS) and free radical damage, altered patterns of transition metal (especially iron) deposition, and mitochondrial insufficiency (bioenergetic failure) have been abundantly documented in the aging and degenerating mammalian CNS. Although the tendency has been to investigate these changes as disparate histopathological features of neural senescence and disease, we hypothesize that OS, abnormal iron mobilization, and mitochondrial dysfunction combine inextricably to yield a single neuropathological 'lesion' that serves as a vital link between normal brain aging physiology and neurodegeneration. In this article, support for this unifying perspective is reviewed based on evidence adduced from investigations of rodent astroglial senescence, experimental models of aging-associated neurodegenerative disorders, and human neuropathological studies. Several scientific and clinical implications of this formulation are considered.

Free Radicals, Transition Metals, and OS

Free radicals are atoms containing unpaired electrons in their outer orbitals. In the course of normal aging, and to a greater extent in disease states, free radicals and other reactive oxygen species (ROS), reactive nitrogen species (RNS), and reactive sulfur species (RSS) generated endogenously or derived from environmental sources may overwhelm tissue enzymatic and nonenzymatic antioxidant defenses (a condition broadly referred to as 'OS') and incur molecular damage to various cellular substrates, including proteins, lipids, carbohydrates, and nucleic acids. Among the transition metals (d-block elements listed between Group IIA and Group IIB of the periodic table), iron, copper, manganese, mercury, and cadmium are redox-active and are capable of mediating significant injury upon deposition within neural tissues. Ferrous iron (Fe^{2+}) and cuprous copper (Cu^{+}), the predominant transition metals in mammalian tissues, play pivotal roles in cellular redox chemistry by reducing H_2O_2 to the highly cytotoxic hydroxyl ($OH^{\bullet}$) radical (Fenton catalysis) or by behaving as nonenzymatic peroxidases that bioactivate benign compounds into toxic free radical intermediates. Within the CNS, ROS in turn may promote aberrant cell signaling and electrophysiological derangements; bioenergetic failure; proteosomal dysfunction, protein aggregation, and inclusion formation; protoxin bioactivation; and neuronal synaptolysis, apoptosis, and necrosis. Pathological transition metal deposition and attendant OS constitute an important pathway for cellular dysfunction and death (and hence a potential therapeutic target) in a host of human neurological (Table 1) and medical disorders, and may contribute to the senescence-dependant decline in cognition and other CNS activities. This article focuses primarily on mechanisms of brain iron sequestration and the relationship of the latter to the prevailing 'free radical–mitochondrial' theory of aging in the context of human neurodegenerative disorders.

The Free Radical–Mitochondrial Theory of Aging

In 1956, Denham Harman first proposed a 'free radical' theory of aging which posits that "free radical reactions are involved in the aging changes associated with the environment, disease and intrinsic aging processes." The theory gained momentum upon recognition that mitochondria are both a leading source of ROS generation and a prime target of oxidative molecular damage in aging eukaryotic cells. The free radical–mitochondrial theory states that oxidative damage to mitochondria, instigated by intrinsic metabolic processes and/or environmental insults, leads to cascading infidelity of electron transport and a self-propagating spiral of increased ROS generation within the inner mitochondrial membrane. The latter, in turn, elicits bioenergetic deficits (ATP loss and failure of ATP-dependent processes) and progressive tissue aging. Evidence supporting this theory has been garnered from a broad range of experimental and observational studies involving intact animal and *in vitro* models that span the entire phylogenetic spectrum. The theory suggests that (1) any injury or disease that exacerbates mitochondrial ROS production may accelerate senescence of the

affected tissue or organ and (2) normal, aging tissues compromised by a progressively unfavorable mosaic of healthy and ROS-generating mitochondria (termed 'heteroplasmy') may become increasingly vulnerable to aging-associated conditions such as atherosclerosis, neurodegeneration, and cancer.

Iron Deposition in the Aging CNS

Iron is indispensable for normal neural development and physiology and contributes to a diverse spectrum of cellular functions, including myelination, biogenic amine metabolism, electron transport, antioxidant enzyme activity, and cytokinesis. To facilitate these vital functions, while at the same time limiting the metal's propensity to mediate toxic Fenton reactions (*vide supra*), iron homeostasis in neural and peripheral tissues is tightly controlled by an orchestra of proteins governing its absorption, valence configuration, extracellular transport, cellular flux, chemical signaling activities, and intracellular storage (Table 2). Despite this elaborate regulation, iron progressively accumulates in the mammalian CNS as a function of advancing age, and a portion of the metal in the brain parenchyma and cerebrospinal fluid (CSF) is maintained in a redox-active state. In the normal human CNS, the sequestered metal exhibits an affinity for the basal ganglia, hippocampus, certain cerebellar nuclei, and other, largely subcortical, brain regions. In these aging brain loci, the iron deposits co-register with multiple markers of oxidative substrate modifications and genetic, biochemical, and morphological indices of enhanced mitochondrial damage. Moreover, there appears to be a fairly consistent exacerbation of these co-localizing pathological features in most, if not all, of the major aging-related human neurodegenerative disorders and in some inflammatory, ischemic, and infectious CNS conditions.

Table 2 Some key proteins implicated in mammalian iron homeostasis

Protein name	*Function*
ATP-binding cassette protein, ABC7	Nonheme Fe export from mitochondria(?)
ABC-me (mitochondrial erythroid)	Mitochondrial transport related to heme synthesis
Ceruloplasmin	Ferroxidase activity/cellular Fe export
Divalent metal transporter (DMT1)/ Nramp2	Membrane transport for Fe^{2+}
Duodenal cytochrome *b*	Ferric reductase (provides Fe^{2+} for DMT1 in duodenum)
Ferritin (H and L)	Cellular Fe storage
Ferrochelatase	Fe^{2+} insertion into protoporphyrin IX (heme synthesis)
Ferroportin 1/MTP1/Ireg1	Cellular Fe export
Frascati	Mitochondrial Fe transport
Frataxin	[Fe–S] cluster synthesis
Heme oxygenase (1 and 2)	Recycling of heme Fe/cell survival
Hemojuvelin (repulsive guidance molecule C)	Unknown/cardiac and striated muscle Fe metabolism(?)
Hepcidin	Inhibitor of intestinal Fe absorption and macrophage heme Fe recycling
Hephaestin	Ferroxidase activity/enterocyte Fe export
Hereditary hemochromatosis protein	Modulates tissue Fe uptake via interaction with TfR(?)
Iron regulatory protein (1 and 2)	Cellular Fe sensors/regulators of Fe uptake and storage proteins
Lactoferrin	Fe-binding protein/antibacterial and antiviral activities
Melanotransferrin	Unknown/Fe binding protein
Mitochondrial ferritin	Mitochondrial Fe storage(?)
Sideroflexin 1	Mitochondrial transport related to Fe metabolism
Steap3	Endosomal ferrireductase
Transferrin	Plasma Fe(III) carrier
Transferrin receptor (TfR1 and 2)	Membrane receptor for diferric-Tf

Iron Deposition in Alzheimer's and Parkinson's Diseases

Aging remains the most robust risk factor thus far identified for the development of sporadic (nonfamilial) AD and idiopathic PD, two of the most common and devastating neurodegenerations in aging populations of the industrialized world. AD is a dementing condition characterized by progressive neuronal degeneration, gliosis, and the accumulation of extracellular amyloid (senile plaques) and intraneuronal inclusions (neurofibrillary tangles) in discrete regions of the basal forebrain, hippocampus, and association cortices. Idiopathic PD is an extrapyramidal (movement) disorder featuring gradual attrition of dopaminergic neurons in the substantia nigra pars compacta, formation of intraneuronal fibrillar inclusions (Lewy bodies) in this cell population, and variable depletion of noradrenaline and serotonin in other brain stem nuclei. Oxidative damage and mitochondrial insufficiency have been amply documented in the affected brain of AD and PD patients and in transgenic mouse models of these conditions. Neuropathological and magnetic resonance imaging studies have demonstrated augmented iron deposition in the cerebral cortex and basal ganglia of AD and PD patients, respectively. In both the AD and PD brain, increased expression of the intracellular iron storage protein, ferritin, parallels the distribution of the excess iron and largely implicates nonneuronal (glial, endothelial) cellular compartments. In AD, moreover, redox-active iron co-localizes to senile plaques and neurofibrillary tangles and may contribute to the biogenesis of these hallmark inclusions via free radical mechanisms. Interestingly, local concentrations of transferrin-binding sites in these neurodegenerative conditions remain unchanged or vary inversely with the elevated iron stores. Thus, although important for normal iron delivery to most systemic tissues, the transferrin pathway of iron mobilization appears to contribute little to pathological brain iron trapping in these aging-related neurodegenerations. As discussed later, experiments conducted in our laboratory have implicated the enzyme heme oxygenase-1 (HO-1) as a putative transducer of aberrant mitochondrial iron trapping under conditions of OS that likely prevail in the senescent CNS and, to a greater extent, in AD- and PD-affected neural tissues. Other iron-mobilizing proteins, such as lactoferrin, melanotransferrin (p97), ceruloplasmin, and the mutant hereditary hemochromatosis protein (encoded by the *HFE* gene), may also participate in the pathogenesis of these common neurodegenerative diseases.

Iron Deposition in Other Human CNS Disorders

Although most vigorously investigated in AD and PD, OS, mitochondrial lesions, and disturbances in iron homeostasis have also been described in other aging-related human neurodegenerative conditions, including ALS, progressive supranuclear palsy, corticobasal degeneration, Huntington's disease, and aceruloplasminemia. This pathological triad may also compromise neural tissues affected by multiple sclerosis (MS), HIV-1 encephalitis, ischemic or hemorrhagic stroke, and cerebral trauma. The extent to which transferrin-dependent and -independent pathways contribute to pathological iron mobilization in these diverse conditions remains to be determined.

Hypothesis

On the basis of their frequent co-occurrence within the aging and diseased neuraxis, we posit that OS, augmented iron deposition, and mitochondrial insufficiency represent a single cohesive neuropathological 'lesion,' with the advent of one constituent obligating the appearance of the others. If confirmed, this formulation may (1) establish a novel conceptual bridge between normal brain senescence and neurodegeneration in the context of the free radical–mitochondrial theory of aging, (2) impact our understanding of the pathogeneses and regional predilections of various senescence-dependant human neurological afflictions, and (3) possibly inform strategies for therapeutic intervention that target the molecular pathways serving to bind the components of this tripartite lesion. In the following section, a model of glial senescence is presented that lends support to our central hypothesis and provides a useful experimental paradigm for delineation of key events favoring pathological iron deposition and mitochondrial injury in the aging and degenerating CNS.

Glial Iron Sequestration in Brain Aging and Disease

Astrocytes

Astrocytes, the most abundant and diversified of the neuroglia, subserve a broad range of adaptive functions. Under certain circumstances, however, astrocytes may mediate dystrophic effects within the CNS and thereby contribute to neurological decline. Examples of the latter include the bioactivation of proneurotoxins; the release of excitotoxic amino acids following tissue hypoxia, metal exposure, and OS; formation of epileptogenic scar tissue in response to

CNS injury; and neoplastic transformation and malignant behavior. Astrocyte hypertrophy, accumulation of glial fibrillary acidic protein (GFAP)-positive intermediate filaments, and possibly hyperplasia (reactive gliosis) are characteristic pathological features of the major aging-related neurodegenerative disorders including AD, PD, Huntington's disease, and ALS. Gliosis also occurs, to a lesser extent, in the course of normal brain aging. Increases in monoamine oxidase B (MAO-B) activity accompany reactive gliosis in the aging mammalian brain, in AD, and in experimental models of PD. Under these circumstances, neuronal injury may be fostered by excessive H_2O_2 derived from the accelerated oxidative deamination of dopamine (DA) and other monoamines.

Iron Deposition in Subcortical Astroglia

In the course of normal aging, a subpopulation of astrocytes residing within the mammalian hippocampus, basal ganglia and other subcortical brain regions progressively accumulates cytoplasmic granules replete with ferrous iron and occasionally other transition metals such as copper and chromium. For reasons discussed earlier, the accumulation of these iron-rich inclusions may render the senescent nervous system increasingly prone to free radical-mediated degeneration. We have determined that the gliosomes are derived from damaged, metal-laden mitochondria engaged in a complex macroautophagic process. In turn, the gliosomes may give rise to corpora amylacea (CA), glycoproteinaceous inclusions that accumulate in astrocytes and the extracellular space in subpial and periventricular regions of the aging and degenerating human brain. In rodents, the appearance of this senescent glial phenotype can be accelerated *in vivo* and/or *in vitro* by dietary iron and copper supplementation, cranial X-irradiation, mechanical trauma, cysteamine (CSH) administration, and, in certain hypothalamic nuclei, chronic estrogenization. We have also garnered evidence that intracellular OS is a 'final common pathway' leading to the transformation of normal astrocyte mitochondria to peroxidase-positive inclusions *in vitro* and in the intact aging brain. Thus, the pathological triad of OS, iron sequestration, and mitochondrial damage is fully manifest in the development of this senescent gliopathy. The topography and intensity of endogenous glial peroxidase activity (iron-laden mitochondria) may denote CNS regions that are particularly susceptible to OS during normal aging and under pathological conditions.

In rat astroglial cultures, the pro-oxidant effects of CSH, hydrogen peroxide, menadione, DA, β-amyloid$_{40/42}$, tumor necrosis factor-α (TNF-α), and interleukin-1β (IL-1β) promote the uptake of non-transferrin-derived $^{59/55}$Fe, but not diferric-transferrin-derived $^{59/55}$Fe, by the mitochondrial compartment. These findings are commensurate with the fact that pathological iron accumulation in the degenerating human CNS appears to be a transferrin-independent process. Moreover, the targeting of excess cellular iron to mitochondria may readily explain why bioenergetic failure is a ubiquitous feature of neural tissues exhibiting iron overload. As discussed in the following section, the heme-degrading enzyme, HO-1, may be a pivotal factor promoting the establishment of this aging-associated gliopathy.

Heme Oxygenase-1: Transducer of Mitochondrial Iron Deposition in 'Stressed' Astroglia

Heme Oxygenase

Heme oxygenases reside within the endoplasmic reticulum where they catalyze, in collaboration with reduced nicotinamide adenine dinucleotide phosphate (NADPH) cytochrome P450 reductase, the oxidative cleavage of heme to biliverdin, free ferrous iron, and carbon monoxide (CO). Biliverdin is metabolized further to the bile pigment, bilirubin, via biliverdin reductase (**Figure 1**). At least two isoforms of heme oxygenase, HO-1 (also called HSP32) and HO-2, are expressed in mammalian cells. Basal HO-1 expression in the normal rodent brain is restricted to small groups of neurons and neuroglia, whereas HO-2 protein is widely distributed throughout the neuraxis. Diverse response elements in the mammalian *ho-1* promoter and enhancer regions render the gene highly inducible by numerous pro-oxidant and inflammatory stimuli, including H_2O_2, transition metals, ultraviolet light, T helper cell (Th1) cytokines, prostaglandins, lipopolysaccharide, dopamine, β-amyloid, and the natural substrate, heme. By promoting the conformational modification and accelerated degradation of vulnerable tissue hemoproteins, SW Ryter and RM Tyrrel surmised that OS may transiently increase the intracellular 'free heme pool.' In these stressed cells, the upregulation of HO-1 may confer protection by accelerating the conversion of pro-oxidant heme to the radical-scavenging bile pigments, biliverdin and bilirubin. In many tissues overexpressing HO-1, potential toxicity resulting from the intracellular liberation of heme-derived ferrous iron is mitigated by co-induction of apoferritin synthesis, a major iron sequestration pathway. However, the Piantadosi lab and others have shown that heme-derived iron and CO may at times exacerbate intracellular OS and substrate damage by facilitating ROS

Figure 1 The heme catabolic pathway. The heme products – ferrous iron (Fe II), carbon monoxide, and biliverdin/bilirubin – may behave as either pro-oxidants or antioxidants, accounting for the disparate influences of heme oxygenase expression on cellular survival (symbolized by Janus faces). In the structures depicted, M is methyl, V is vinyl, and P is propionate. Adapted from Ryter SW and Tyrrell RM (2000) The heme synthesis and degradation pathways: Role in oxidant sensitivity. Heme oxygenase has both pro- and antioxidant properties. *Free Radical Biology & Medicine* 28: 289–309, with permission.

production within the mitochondrial and other subcellular compartments.

HO-1 and Mitochondrial Iron Sequestration

In rat astroglial cultures, we have observed that HO-1 mRNA, protein, and/or activity levels increase within hours of treatment with CSH, DA, β-amyloid$_{40/42}$, TNF-α, or IL-1β. After 3–6 days of exposure to these stimuli, uptake of non-transferrin-derived $^{59/55}$Fe (but not diferric transferrin-derived iron) is significantly augmented by the mitochondrial compartment relative to untreated control cultures. Coadministration of antioxidants (ascorbate, melatonin, or *trans*-resveratrol) suppresses the HO-1 response to CSH, DA, and the proinflammatory cytokines, indicating that OS is a common mechanism mediating glial *ho-1* gene induction under these experimental conditions. HO-1 overexpression appears necessary and sufficient for the mitochondrial iron trapping in oxidatively challenged astroglia because the latter can be (1) attenuated by tin mesoporphyrin (SnMP), a competitive inhibitor of heme oxygenase activity, or dexamethasone (DEX), a transcriptional suppressor of the *ho-1* gene and (2) recapitulated by transient transfection of the human (h) *ho-1* gene.

HO-1, Intracellular OS, and the Mitochondrial Permeability Transition

We have demonstrated that mitochondrial iron trapping by hHO-1-transfected glia and cells exposed to DA, TNF-α, or IL-1β is abrogated by co-treatment with cyclosporin A or trifluoperazine, inhibitors of the mitochondrial permeability transition pore. These findings suggest that, in 'stressed' astroglia, engagement of this membrane megachannel facilitates the import of cytosolic iron (and possibly other metal ions) to the mitochondrial matrix. We determined that (1) treatment with SnMP or antioxidants (ascorbate, melatonin or resveratrol) blocks the compensatory induction of the redox-sensitive *mnsod* gene in astrocytes challenged with DA or transiently transfected with hHO-1 cDNA and (2) hHO-1 transfection significantly augments levels of protein carbonyls (protein oxidation), 8-epiPGF2α (lipid peroxidation), and 8-OHdG

(nucleic acid oxidation) in glial mitochondrial fractions relative to sham-transfected controls and hHO-1-transfected cells incubated with SnMP. These findings indicate that HO-1 overexpression in astroglia amplifies intracellular OS that, in turn, favors mitochondrial permeability transition and iron influx into this organelle. Of note, Bruce Ames' group and U Rauen et al. have provided evidence that increases in chelatable cytosolic iron facilitate permeability transition in hepatocyte mitochondria.

HO-1 Expression in Human CNS Aging and Disease

Normal aging In 2003, W Hirose and colleagues reported that numbers of neurons and neuroglia immunoreactive for HO-1 in the normal human hippocampus and cerebral cortex increase progressively between 3 and 84 years of age. In earlier studies, we calculated that 6.8% and 12.8% of GFAP-positive astrocytes co-express immunoreactive HO-1 protein in the normal senescent human hippocampus and substantia nigra, respectively. HO-1 expression also increases in optic nerve astrocytes and in retinal ganglion cells and photoreceptors of the human eye between the second and the seventh decades of life. In the normal elderly, our group and George Perry's lab noted HO-1 staining to be particularly prominent in choroid plexus epithelial cells, ependymocytes, cerebrovascular endothelial cells, many glial and extracellular CA, and the olfactory neuroepithelium. On the basis of the previously discussed evidence and the tenets of the free radical–mitochondrial theory of aging, we propose that a self-reinforcing cascade of ambient OS, glial HO-1 expression, and mitochondrial iron deposition may contribute to the gradual depletion of high-energy substrates in aging human neural tissues.

Alzheimer's disease In the AD hippocampus, we have calculated that ~86% of GFAP-positive astrocytes exhibit HO-1 immunoreactivity, whereas only 6–7% of hippocampal astroglia in age-matched normal control tissue express this stress protein. In collaboration with David Bennett's group in Chicago, we observed significant induction of astroglial HO-1 expression in the brains of individuals with amnestic mild cognitive impairment (a harbinger of incipient AD), indicating that glial HO-1 upregulation is an early event in the pathogenesis of this dementing disorder. To the extent that our *in vitro* data can be extrapolated to the intact human brain, it is conceivable that the perturbed CNS iron homeostasis and mitochondriopathy characteristic of AD may be downstream effects of chronic HO-1 overproduction in the diseased neural tissues.

Parkinson's disease In 1998, we reported that dopaminergic neurons of the substantia nigra in both normal and PD human brain exhibit moderate HO-1 immunoreactivity. In the PD specimens, cytoplasmic Lewy bodies within affected dopaminergic neurons were prominently decorated with annular HO-1 staining, confirming an earlier observation by R Castellani and colleagues. In our study, the fraction of GFAP-positive astrocytes expressing HO-1 protein in the PD nigra was substantially increased (77.1%) relative to age-matched control preparations (12.8%). In both the PD and control specimens, relatively low levels of glial HO-1 expression were observed in other subcortical nuclei, such as the caudate, putamen, and globus pallidus. In accord with the data and our central hypothesis, sustained augmentation of HO-1 activity in nigral astroglia may promote the pathological deposition of nontransferrin iron, intracellular OS, and mitochondrial electron transport (complex I) deficits reported in the substantia nigra of PD patients.

Other disorders In MS, an autoimmune demyelinating disorder of central white matter, we have observed that astroglial HO-1 expression is significantly increased in spinal cord plaques (57.3% of GFAP-positive cells) relative to that computed in the spinal white matter of normal individuals (15.4%). As argued in the cases of AD and PD, enhanced intraglial heme degradation catalyzed by HO-1 may contribute to the aberrant iron deposits and mitochondrial lesions reported in human MS and in rodent models of this condition. Robust HO-1 induction has also been documented in the brains of patients with Pick disease, corticobasal degeneration, progressive supranuclear palsy, ischemic and hemorrhagic stroke, and *Plasmodium falciparum* malaria. The triad of oxidative substrate damage, deregulated iron homeostasis, and bioenergetic failure occurs in most, if not all, of these conditions and may be secondary to the antecedent overexpression of HO-1 in 'stressed' astroglia.

Conclusions and Implications

The mechanisms responsible for the augmented deposition of iron and other redox-active transition metals in the aging and diseased CNS remain incompletely understood. On the basis of a considerable body of neuropathological and experimental data, we propose that oxidative molecular damage, the deposition of nontransferrin iron (and possibly other metals), and mitochondrial insufficiency in these conditions are causally interdependent phenomena and inextricable components of a single cytopathological 'lesion.' This central hypothesis predicts that iron

homeostasis will invariably be perturbed in CNS tissues harboring mitochondrial lesions, that neural tissues manifesting iron overload will exhibit obligatory bioenergetic failure, and that at least some of the aberrant metal deposits will co-localize to the mitochondrial compartment. We have reviewed evidence that induction of the heme-degrading enzyme, HO-1, in astroglia stressed by aging or disease may represent a 'final common pathway' for the sequestration of nontransferrin iron by the mitochondrial compartment and transformation of these organelles into peroxidase-positive inclusions and CA, structural biomarkers of the senescent mammalian CNS. Given the exquisite sensitivity of the glial *ho-1* gene to ambient OS and other noxious stimuli, it is not surprising that pathological iron deposition and mitochondrial damage are a fairly consistent response of neural tissues to a broad range of genetic and acquired metabolic disturbances. Thus, OS accruing from an excessive amyloid burden or the elaboration of proinflammatory cytokines may be responsible for glial HO-1 induction, iron sequestration, and bioenergetic failure in the AD forebrain. Dopamine-derived ROS, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-like xenobiotics, endoneurotoxins, nitric oxide, and Th1 cytokines are plausible inducers

Figure 2 A model for pathological iron deposition, OS, and mitochondrial insufficiency in brain aging and disease. Extracellular pro-oxidant stressors and intrinsic aging processes upregulate heme oxygenase-1 (HO-1) in astrocytes, liberating heme-derived free ferrous iron (Fe^2) and carbon monoxide (CO). The latter generate intraglial OS that promotes opening of mitochondrial permeability transition pores and influx of (non-transferrin-derived) iron into the mitochondrial matrix. The redox-active iron augments oxidative damage to the electron transport chain machinery (mitochondrial DNA (mtDNA), cytochromes), resulting in a vicious spiral of mitochondrial ROS generation and injury in accord with the prevailing free radical–mitochondrial theory of aging. This progressive state of astroglial mitochondrial heteroplasmy endangers nearby neuronal constituents by several mechanisms: (1) The mitochondrial ferrous iron catalyzes the bioactivation of protoxins (e.g., catechols, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)) to potent neurotoxins (*o*-semiquinones, MPP^+). The latter may be extruded to the extracellular space and exert direct dystrophic effects on susceptible neuronal targets. Diminished ATP levels accruing from glial bioenergetic failure may further predispose to neuronal degeneration by (2) augmenting extracellular glutamate concentrations (excitotoxicity), (3) curtailing glutathione (GSH) delivery to the neuronal compartment, and (4) limiting the degradation of potentially toxic protein aggregates by the ubiquitin–proteosome system. Neuronal degeneration stimulates microglial activation, resulting in the release of ROS, nitric oxide (NO), and proinflammatory cytokines. The latter further induce the *ho-1* gene in indigent astroglia, completing a self-sustaining loop of pathological cellular interactions, perpetuating oxidative damage and mitochondrial insufficiency within senescent and degenerating neural tissues. Genetic and environmental risk factors may confer disease specificity by superimposing unique pathological signatures on this core lesion. In the case of AD and PD, for example, β-amyloid deposition in the hippocampus and dopamine (DA) release from dying nigrostriatal projections, respectively, feed into the pathological cascade by stimulating HO-1 activity in regional astroglia. Progressive derangement of astroglial iron mobilization and mitochondrial insufficiency would then drive the primary neurodegenerative process regardless of its etiology. H_2O_2, hydrogen peroxide; IL-1β, interleukin-1β; TNF-α, tumor necrosis factor-α. Adapted from Schipper HM (2004) Brain iron deposition and the free radical-mitochondrial theory of aging. *Aging Research Reviews* 3: 265–301.

of the astroglial heme oxygenase–mitochondrial iron axis in the PD nigra, and iron-mediated mitochondrial injury in MS may be secondary to the upregulation of glial HO-1 by IL-1β, TNF-α, and/or myelin basic protein within the affected white matter.

Importantly, neuron-like PC12 cells co-cultured with rat astrocytes replete with mitochondrial iron (induced by CSH pretreatment) or overexpressing the human *ho-1* gene were found to be far more vulnerable to OS-related killing than were PC12 cells grown atop control ('iron-poor') astroglia. Thus, the accumulation of iron-laden, metabolically deficient astroglia may seriously compromise the integrity and viability of nearby neuronal constituents and thereby promote neurological dysfunction and disease. In our model, pathological, mutually reinforcing glial–neuronal interactions may perpetuate oxidative damage, pathological iron deposition, and mitochondrial insufficiency within senescent and degenerating neural tissues long after initiating insults may have dissipated (**Figure 2**). As a putative transducer of mitochondrial iron deposition in 'stressed' astroglia, the augmented glial HO-1 activity may provide a rational target for therapeutic intervention in a host of human neurodegenerative and neuroinflammatory conditions.

Metaplasticity

Introduction

Metaplasticity Defined

Metaplasticity refers to an activity-dependent and persistent regulation of subsequently induced synaptic plasticity, such as long-term potentiation (LTP) or long-term depression (LTD). Essentially, metaplasticity entails a change in the physiological or biochemical state of neurons such that the ability to generate synaptic plasticity is altered. A key feature of metaplasticity is that this change, once established, outlasts the triggering ('priming') bout of activity and persists until a second bout of activity occurs to induce LTP or LTD (Figure 1). It is this persistence feature that is critical for the phenomenon, and that distinguishes it from more conventional forms of neuromodulation which occur during the induction of synaptic plasticity. There is no agreed criterion for the degree of persistence required to meet the definition of metaplasticity, but commonly studied effects have ranged from many minutes to many days. The 'meta' part of the term reflects the higher order nature of the plasticity, that is, the plasticity of synaptic plasticity.

In principle, metaplasticity can be induced by a range of priming events: cell firing, synaptic activity, paracrine signals, or endocrine signals. It is most clearly observed when the priming event by itself generates no observable LTP or LTD, because the modulation of subsequent plasticity cannot be attributed simply to a change in synaptic drive during the second bout of activity. However, the generation of plasticity during the priming episode does not preclude the simultaneous induction of metaplasticity.

When metaplasticity is induced by synaptic activity, two classes of phenomena can be distinguished: homosynaptic metaplasticity and heterosynaptic metaplasticity. Metaplasticity is homosynaptic when the priming synaptic activity regulates subsequent plasticity only at those same synapses. In contrast, heterosynaptic metaplasticity occurs when plasticity is regulated for a range of synapses terminating on a postsynaptic neuron, regardless of whether they participated in the priming activity.

BCM Model

Metaplasticity was conceptualized at a theoretical and computational level by the Bienenstock–Cooper–Munro (BCM) model of synaptic plasticity in the visual cortex, well before the term was actually coined. In this model, the degree of LTD or LTP generated by a given bout of synaptic activity is a nonlinear function of the degree of postsynaptic activation. Synaptic activity that occurs moderately above the resting level generates LTD, but if sufficiently high levels of activity occur, LTP is generated instead. The level of activity at which the plasticity function switches from LTD to LTP is known as the modification threshold (Figure 2). This model incorporates a form of metaplasticity, in that the modification threshold is itself a function of the degree of cell firing recently generated by the postsynaptic neuron. If the neuron has recently been very active, presumably as driven by synaptic inputs, then the modification threshold shifts to the right, making it harder to generate LTP and easier to induce LTD (Figure 2). Equally, if the neuron has recently been very inactive, then the modification threshold shifts to the left. This modeled form of metaplasticity is fundamentally heterosynaptic in nature, because it is immaterial which synaptic inputs drove the initial cell firing that shifted the modification threshold. The frequency–plasticity function is then set for all excitatory synapses on the postsynaptic neuron.

Metaplasticity Induction

Metaplasticity Induced by Synaptic Stimulation

The study of metaplasticity in the hippocampus has revealed that both LTP and LTD may be modified by prior synaptic activity according to the receptor systems that are activated (see the section titled 'Receptor mechanisms') and the pattern of that activation. Hence, stimulation protocols which would typically induce LTP may fail to do so if preceded by bouts of stimulation which by themselves do not induce conventional synaptic plasticity. For example, in area CA1, LTP can be completely suppressed if the LTP-inducing high-frequency stimulation (HFS) is preceded 20 min earlier by multiple weak trains of HFS. This form of metaplasticity is homosynaptic and lasts for at least 30 min. On the other hand, if multiple strong trains of HFS are delivered to an input pathway, heterosynaptic metaplasticity can be induced

Figure 1 Time line of events during metaplasticity. Metaplasticity is defined as a lasting after-effect of an initial bout of neural activity which changes the state of the participating neurons such that the ability to induce synaptic plasticity at a later time is altered.

Figure 2 Bienenstock–Cooper–Munro (BCM) model. The ability of presynaptic activity to induce synaptic plasticity is a nonlinear function (Φ) of postsynaptic activity. The modification threshold (θ_M) is the crossover point between LTD and LTP. The modification threshold dynamically varies based on time-averaged postsynaptic cell firing. In this example, sufficient prior postsynaptic activity drives the modification threshold to the right, changing the Φ function from the dashed line to the solid line.

Figure 3 An example of mGluR-dependent synaptic priming of LTP in hippocampal CA1 slices. In control hippocampal slices, theta-burst stimulation (thin arrow at 60 min) delivered to the Schaffer collaterals in area CA1 induced a decaying form of LTP. Priming stimulation of group I metabotropic glutamate receptors (mGluRs) (thick arrow at 40 min) during *N*-methyl-D-aspartate receptor (NMDAR) antagonist AP5 application significantly enhanced the induction and persistence of LTP induced by theta-burst stimulation 20 min later. Data are mean ± S.E.M. of the field excitatory postsynaptic potential (fEPSP) slopes expressed as a percentage of baseline values (dotted line). Adapted with permission from Raymond CR, Thompson VL, Tate WP, et al. (2000) Metabotropic glutamate receptors trigger homosynaptic protein synthesis to prolong long-term potentiation. *Journal of Neuroscience* 20: 969–976. Copyright 2000 by Society for Neuroscience.

Figure 4 An example of NMDAR-dependent priming of LTD induction in hippocampal CA1 slices. An initial bout of low-frequency stimulation (LFS) to the Schaffer collaterals in area CA1 produces at best a weak short-term depression, but primes the synapses to respond with a much larger LTD when a second identical LFS is delivered 10 min later. Data are mean ± S.E.M. of the field excitatory postsynaptic potential (fEPSP) slopes expressed as a percentage of baseline values (dotted line). Adapted from Mockett B, Coussens C, and Abraham WC (2002) NMDA receptor-mediated metaplasticity during the induction of long-term depression by low-frequency stimulation. *European Journal of Neuroscience* 15: 1819–1826.

such that the induction of LTP is inhibited and the induction of LTD is facilitated for all tested pathways terminating on those postsynaptic neurons. In the dentate gyrus, priming stimulation applied to the medial perforant path raises the LTP threshold heterosynaptically in the lateral perforant pathway for up to several weeks. Although metaplasticity typically entails a change in the initial induction of synaptic plasticity, under some conditions a stimulus protocol can suppress selectively the late phase of subsequent LTP (lasting hours or more), without affecting its induction.

In contrast to the inhibitory effects of prior stimulation on LTP, priming stimulation under other conditions can facilitate LTP (Figure 3). This effect is generally homosynaptic, lasts at least 1 h, and occurs under conditions which favor the activation of metabotropic glutamate receptors (mGluRs) during the priming stimulation (see later). Prior synaptic stimulation can also regulate LTD. For example, an initial mild low-frequency stimulation (LFS) protocol primes synapses to exhibit a large LTD upon being given a second identical LFS (Figure 4). The metaplastic effect of the first LFS is input specific, effective for at least 1 h, and by itself entails little or no observable change in transmission at the primed synapses.

Behavioral Induction of Metaplasticity

While metaplasticity can be induced in its different forms by electrically stimulated synaptic activity, such protocols are not particularly naturalistic. However, metaplasticity can also be induced by environmental stimuli such as changes in sensory input, learning, and

stress. As predicted by the BCM model of synaptic plasticity, changes in visual input during development *in vivo* can cause metaplasticity of LTP and LTD as assessed *in vitro*. In slices of visual cortex from visually deprived (dark-reared) rats, the modification threshold is shifted to the left compared to light-reared animals, such that LTP and LTD are induced by a lower than normal range of stimulation frequencies (Figure 5). Similarly, olfactory discrimination learning makes LTP in rat olfactory cortex more difficult to induce in slices, while at the same time enabling LTD induction that does not normally occur in slices from untrained animals. Noxious stimuli can also affect plasticity; stress induced *in vivo* causes impairment of subsequent LTP in both CA1 and the dentate gyrus, plus an enhancement of LTD, as assessed *in vitro*. This metaplasticity can last several days after the stress occurs.

There is an exception to the general principle that increased sensory input makes LTP more difficult to attain; if a brief exposure to a novel environment is given temporally close to the induction of LTP, then its induction *in vivo* in CA1 is enhanced. This indicates that under some conditions an increase in sensory input is followed immediately by a short window of time during which synapses are in a metaplastic state, such that LTP induction is facilitated rather than inhibited.

Receptor Mechanisms

The stimulation protocols just described achieve their metaplastic effects by activation of specific postsynaptic receptors, primarily glutamatergic. These receptors then initiate a series of intracellular events through activation of second messengers or entry of calcium (see the section titled 'Signal transduction pathways'). *N*-Methyl-D-aspartate receptors (NMDARs) and mGluRs have attracted the most attention as triggers for evoking metaplasticity events in the hippocampus. Priming activation of NMDARs by either electrical stimulation of afferent pathways or by direct NMDA application inhibits the induction of LTP while promoting the development of LTD. Furthermore, NMDAR antagonists block the ability of multiple weak tetani to inhibit subsequent LTP. Similarly, NMDAR antagonists block the priming of LTD by a mild LFS. In the stress model of metaplasticity, the inhibition of LTP and facilitation of LTD are both mediated by NMDAR activation during the stressful experience, as NMDAR antagonists given during the stress block these metaplastic effects.

Figure 5 Visual experience can induce metaplasticity. In visual cortical slices from rats that have been visually deprived (filled circles), LTP and LTD (measured in layers 2/3 and evoked by layer 4 stimulation) can be induced by lower than normal stimulation frequencies *in vitro*. Note that stimulation at 0.5 Hz induces greater LTD in visual cortex of dark-reared rats compared with light-reared rats (data point not shown). Adapted from Philpot BD, Espinosa JS, and Bear MF (2003) Evidence for altered NMDA receptor function as a basis for metaplasticity in visual cortex. *Journal of Neuroscience* 23: 5583–5588. Copyright 2003 by Society for Neuroscience.

The consequences of prior mGluR activation on subsequent synaptic plasticity largely depend on the subtype activated and the brain region in which they are located. For example, in area CA1, group I mGluR activation facilitates LTP induced by a subsequent mild HFS, while prior activation of group II mGluRs inhibits LTD induction without affecting LTP. In contrast, the priming effect of mGluR activation on subsequent LTP/LTD in the dentate gyrus is less predictable and appears to be determined by a range of experimental variables. For example, at medial perforant path–granule cell synapses *in vitro*, activation of group I and II mGluRs by strong HFS blocks subsequent group I receptor function, and hence inhibits group I-dependent LTD/depotentiation, while activation of mGluRs in response to a weak HFS inhibits subsequent HFS-induced LTP. The latter effect requires a synergistic interaction between group I and group II mGluRs and coactivation with NMDARs. The outcome of mGluR activation also depends on the nature of the experimental preparation. Thus, while activation of group II mGluRs in freely moving rats facilitates synaptically induced LTD, *in vitro* this treatment facilitates LTP induction.

Some priming effects have been reported for other receptor types, such as the β-adrenergic and dopamine receptors. Dopamine D1/D5 receptors, for example, are involved in mediating the consolidation of tetanus-induced LTP in CA1 of freely moving rats by prior exposure to novel objects. Interestingly, *in vitro* studies show that this is a highly regional effect within the hippocampus, as similar regulation is absent in the dentate gyrus. However, in the case of β-adrenergic receptor-mediated priming, a reversal of this pattern occurs with increased persistence of tetanus-induced LTP observed in the dentate gyrus, but not in CA1. While these priming effects are of considerable physiological relevance, comparatively little work has been done to characterize the mechanisms involved in mediating these responses or their integration with other plasticity-inducing factors.

Signal Transduction Pathways

Like synaptic plasticity, metaplasticity relies on cascades of intracellular signaling molecules to turn synaptic activation of membrane-bound receptors such as mGluRs and NMDARs into lasting changes in the cell (Figure 6). Group I mGluRs couple to phospholipase C (PLC) via a $G_{\alpha q}$-type G-protein. PLC then liberates diacylglyerol (DAG) and inositol trisphosphate (IP_3) from membrane phospholipids, the former activating protein kinase C (PKC) and the latter binding to receptors on intracellular Ca^{2+} stores, causing Ca^{2+} release into the intracellular compartment. NMDARs, in contrast, act more directly by virtue of their relatively high permeability to Ca^{2+}: under conditions favorable to NMDAR activity, Ca^{2+} enters the neuron and acts as a trigger for subsequent biochemical events. A prime example of a signaling enzyme that is triggered by a rise in intracellular Ca^{2+} levels is Ca^{2+}/calmodulin-dependent kinase II (CaMKII). CaMKII is a key component not only in the induction of LTP but also in metaplasticity. This kinase is initially activated by Ca^{2+}/calmodulin complex, but once activated it autophosphorylates at the Thr-286 site and becomes active independent of Ca^{2+}. However, if CaMKII

Figure 6 Schematic diagram showing some of the receptors and signal transduction pathways involved in metaplasticity. Presynaptic stimulation of an appropriate magnitude and temporal pattern causes the release of glutamate, which binds to *N*-methyl-D-aspartate receptors (NMDARs), α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPARs), and metabotropic glutamate receptors (mGluRs). Both NMDARs and mGluRs can initiate metaplasticity in response to different patterns of synaptic stimulation (HFS, LFS, high- and low-frequency stimulation). NMDARs act by allowing direct Ca^{2+} influx into the cell and thereby triggering a signaling cascade involving enzymes such as Ca^{2+}/calmodulin-dependent kinase II (CaMKII), whereas mGluRs induce metaplasticity by coupling to signaling pathways via a G-protein. These actions then contribute to processes such as glutamate receptor-associated changes (receptor function, expression, location, or subunit composition), changes in intrinsic excitability, and presynaptic changes which place the synapse in a metaplastic state. Additionally, metaplasticity can entail increased local translation and somatic transcription of proteins involved in plasticity induction and consolidation, and setting of a 'synaptic tag' to allow capture of newly synthesized plasticity-related proteins transported from the soma. GABA, γ-aminobutyric acid; PLC, phospholipase C; PIP_2, phosphoinositol bisphosphate; IP_3, inositol trisphosphate; DAG, diacyglycerol; PKC, protein kinase C; PKA, protein kinase A; AC, adenylate cyclase; cAMP, cyclic AMP.

autophosphorylates at the Thr-305/306 site, it inhibits its own activity. This dual regulation allows CaMKII to be involved in both mGluR- and NMDAR-dependent metaplasticity. For example, the mGluR-dependent 'molecular switch' that facilitates later LTP induction at CA3–CA1 synapses is dependent on activation of CaMKII. On the other hand, NMDAR-dependent homosynaptic inhibition of LTP by prior activity at lateral perforant path synapses in dentate gyrus relies on autoinhibition of CaMKII.

PKC is also common to several types of metaplasticity. This enzyme is activated by the second messenger DAG, but the activity of some PKC isotypes is also modulated by Ca^{2+}. PKC mediates several types of mGluR-dependent metaplasticity; at CA3–CA1 synapses both the 'molecular switch' and priming of LTP involve PKC (following $G_{\alpha q}$ and PLC activation in the latter case). Similarly, at medial perforant path synapses in the dentate gyrus, inhibition of NMDAR-dependent LTP and mGluR-dependent LTD by prior high-frequency stimulation relies on PKC. Other signaling molecules, such as p38 MAP kinase, protein phosphatase 1, and protein phosphatase 2A, have been implicated in metaplasticity.

A form of metaplasticity which deserves separate mention because of its unusual signal transduction is the mGluR- and endocannabinoid-dependent facilitation of LTP at CA1 synapses. This form of metaplasticity is dependent on activation of PLC but not a rise in intracellular calcium, instead relying on production of the endocannabinoid, 2-arachidonoyl glycerol (2-AG), from DAG. Another unusual aspect of this form of metaplasticity is the fact that it is not restricted to the postsynaptic neuron; instead, 2-AG is released to retrogradely inhibit presynaptic GABAergic synapses (Figure 6).

Metaplasticity Expression

Changes in Glutamate Receptor Function and Expression

Metaplasticity is expressed in many cases by changes in glutamate receptor function and expression. For example, some protocols which metaplastically inhibit LTP induction act by suppressing NMDAR currents and therefore Ca^{2+} flow into the spine during LTP-inducing HFS. Similarly, NMDAR function is downregulated during maturation of rat cortex through changes in NMDAR subunit composition from predominantly NR2B-containing to predominantly NR2A-containing, the latter being less Ca^{2+} permeable. Although normally a slow developmental process, this change can occur very rapidly, as exemplified by the subunit switch occurring in the rat visual cortex of dark-reared animals 2 h after light exposure. The net effect of having more NR2A-containing receptor is a rightward shift in the modification threshold such that higher stimulus frequencies are needed to induce LTP and LTD compared to non-light-exposed rats Figure 5. Similarly, olfactory training makes LTP in rat olfactory cortex more difficult to induce in slices, in conjunction with an increase in the expression of the NR2A subunit relative to the NR2B subunit of the NMDAR.

At many glutamatergic synapses, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPARs) provide the majority of current flow into the postsynaptic cell in response to presynaptic glutamate release under normal conditions, and thus any modification of receptor function or synaptic expression will manifest itself as an overt change in synaptic transmission (i.e., synaptic plasticity). On the other hand, regulation of AMPARs may also be involved in the expression of metaplasticity, such as a change in the threshold for addition of new AMPARs to the existing synaptic pool. Emerging evidence indicates that this can be accomplished by protein kinase A (PKA)-dependent priming of AMPAR movement into the extrasynaptic membrane. Subsequent LTP-related NMDAR activity then triggers their rapid delivery into the synaptic membrane as functional receptors.

Changes in Protein Synthesis

In some models, the expression of metaplasticity requires *de novo* protein synthesis as an intermediate step. For example, priming of LTP at CA1 synapses by activation of group I mGluRs initiates the synthesis of new proteins, and inhibitors of translation but not transcription inhibit the priming effect. This indicates that the proteins are synthesized by preexisting mRNA, probably localized to dendrites or synapses. The identities of the key proteins are not yet known. In another paradigm, a weak decaying form of LTP generated by a mild HFS in one pathway can be converted to a stable form of LTP if it can capture proteins generated in response to a strong HFS in a neighboring pathway.

How are the new proteins captured at the synapse for use? In mGluR priming of LTP, the proteins are made locally near the synapses and thus are already close to their site of action. In the case of somatodendritically localized protein synthesis, proteins, are captured through a process known as 'synaptic tagging.' Here, a mild HFS delivered to one set of synapses sets a 'tag' at those synapses to identify them as activated. Although the identity of this tag is also currently unknown, its role is to sequester newly

synthesized somatic and dendritic plasticity-related proteins into the synapse as they are transported throughout the cell, and thereby enhance the persistence of the initially weak plasticity. Synaptic tagging is an example of a heterosynaptic metaplastic process in which weakly activated synapses exhibiting decremental plasticity are primed for the capture of plasticity-related proteins necessary for consolidation of LTP/LTD (Figure 6).

Metaplasticity at Individual Synapses – Synaptic States

Although metaplasticity is usually studied in populations of synapses, individual synapses within a group could have very different histories of activity. In organotypic slice cultures, synapses between pairs of individual hippocampal neurons can exist in one of several possible 'synaptic states,' the particular state being determined by the synapse's recent history of activity. One of these states, termed 'silent,' describes a synapse that possesses functional NMDARs but no AMPAR response, probably due to a lack of (or few) AMPARs in the membrane. When triggered by appropriate synaptic activity, a silent synapse can become 'active' and exhibit an AMPAR-mediated response. From this active state, LTP and LTD can be generated. A further state, neither potentiated nor depressed, has been termed 'recently silent.' Recently silent synapses have only just acquired an AMPAR response due to recent synaptic activity but have not yet fully transitioned into the active state. Despite having a normal AMPAR response and being capable of potentiation, these synapses are temporarily immune from LTD caused by endocytosis of AMPARs that would occur at an active synapse in response to LFS. Thus two synapses with apparently identical strength but different histories of activity can differ greatly in their ability to undergo synaptic plasticity.

Plasticity of Intrinsic Excitability

Under some conditions, action potentials generated in or near the soma by summation of synaptic potentials can back-propagate into the dendrites and affect synaptic function. The relative timing between the arrival of synaptic input and the back-propagating spikes can influence the strength and direction of synaptic plasticity at a given synapse. In addition, dendrites are capable of generating spikes, which may also be important in regulating synaptic plasticity. Therefore, any persistent plasticity of intrinsic cell excitability (i.e., the ability to generate and propagate a spike) in response to activity provides a potentially powerful means of metaplasticity expression.

In several types of neurons, the ability to fire action potentials is modifiable by synaptic stimulation. For example, HFS of deep cerebellar nucleus neurons causes a persistent NMDAR-dependent increase in the number of spikes fired in response to a depolarizing current pulse. Also in cerebellar neurons, theta-burst stimulation of mossy fibers causes a persistent increase in excitability, expressed as an NMDAR-dependent increase in input resistance and decrease in spike threshold. In cortical neurons, moderate-frequency synaptic stimulation causes a highly persistent increase in spike firing in response to a depolarizing stimulus. This is due to an mGluR-dependent downregulation of the Ca^{2+}-activated K^+ channels underlying the spike afterhyperpolarization (AHP) (Figure 7). Importantly, downregulation of the AHP facilitates the induction of subsequent LTP.

Figure 7 Synaptic or pharmacological activation of mGluRs can cause potentiation of intrinsic excitability. Potentiation of intrinsic excitability in layer V pyramidal neurons can be induced by tetanic stimulation of glutamatergic synaptic inputs at 10 Hz in the presence of ionotropic receptor antagonists. Upper panel: Number of action potentials (AP) evoked by a constant current pulse before and after tetanic stimulation. Traces a and b, respectively, recorded before and 25 min after a 10 Hz stimulation. Lower panel: A similar modification of intrinsic excitability induced pharmacologically by the mGluR agonist aminocyclopentane dicarboxylic acid (ACPD) (50 μM). Adapted from Sourdet V, Russier M, Daoudal G, et al. (2003) Long-term enhancement of neuronal excitability and temporal fidelity mediated by metabotropic glutamate receptor subtype 5. *Journal of Neuroscience* 23: 10238–10248. Copyright 2003 by Society for Neuroscience.

A key characteristic of the plasticity of intrinsic excitability is its ability to either localize to specific regions in the neuron or to be cell-wide. For example, a burst of back-propagating action potentials fired by depolarization of rat CA1 pyramidal neurons persistently depresses voltage-dependent Ca^{2+} channels in individual dendritic spines, prevents subsequent LTP. Also in CA1 neurons, LTP is accompanied by a persistent increase in dendritic excitability which manifests as an amplification of back-propagating action potentials due to a downregulation of A-type K^+ channels. Crucially, this change in intrinsic excitability is limited to the local dendritic region containing the stimulated synapses. Conversely, a persistent change in somatic spike-generating ability should influence subsequent synaptic plasticity in a more generalized way. Indeed, LTP-inducing synaptic activity at one set of synapses on a CA1 pyramidal neuron can cause a persistent increase in the AHP and a reduction in spike firing, which inhibits the induction of subsequent LTP at a separate set of synapses on the same neuron.

Persistent plasticity of intrinsic cell excitability measured *in vitro* is also associated with *in vivo* learning. For example, hippocampus-dependent learning results in persistent suppression of the AHP and an increase in spike firing measured subsequently *in vitro* in both hippocampal and olfactory cortex neurons. Similar changes in intrinsic excitability as a result of learning tasks have also been observed in invertebrates such as *Aplysia*. Importantly, learning of either a hippocampus-dependent olfactory or spatial task is enhanced by prior olfactory learning, and this enhancement occurs only within the time frame of the increase in intrinsic excitability. It is therefore likely that the persistent increase in intrinsic excitability that accompanies learning is a real-life form of metaplasticity which allows an improvement in the ability to learn a subsequent task.

Presynaptic Mechanisms

In addition to the sizable body of literature devoted to postsynaptic mechanisms of metaplasticity, there is also evidence that a persistent change in the release probability of presynaptic glutamatergic terminals due to prior activity is one way in which metaplasticity is expressed. In cultures of hippocampal neurons, a chronic reduction in synaptic activity increases the release probability and physical size of synapses, and either chronic reduction in activity or chronic blockade of AMPA receptors increases the pool of available glutamate-containing vesicles. Further, a chronic reduction in either activity or Ca^{2+} influx modifies synapses such that their number of releasable vesicles and presynaptic release probability are more likely to be increased by an LTP-inducing stimulus. Presynapthic metaplasticity also occurs *in vivo*: at mossy fiber–CA3 synapses in the rat hippocampus, intense synaptic activity *in vivo* leads to increased presynaptic release probability *in vitro* (lasting several weeks), an increase in the pool of releasable glutamate available in the presynaptic terminal, and a corresponding reduction in the ability to induce LTP *in vitro*.

Another way in which presynaptic changes can mediate metaplasticity of excitatory synapses is through plasticity of inhibitory synapses. At hippocampal CA3–CA1 synapses *in vitro*, an HFS which is subthreshold for LTP induction can nonetheless produce an LTD of GABAergic inhibitory synaptic transmission via retrograde endocannabinoid signaling (see earlier, section titled 'Signal transduction pathways,' and Figure 6). This results in a persistent enhancement of subsequently induced LTP.

3,4-Methylenedioxymethamphetamine (MDMA, "Ecstasy")

A R Green, University of Nottingham, Nottingham, UK
M I Colado, Universidad Complutense, Madrid, Spain

© 2009 Published by Elsevier Ltd.

Ecstasy is the name given to 3,4-methylenedioxymethamphetamine (MDMA). However, ecstasy tablets obtained illicitly often contain impurities and even other psychoactive compounds in addition to MDMA. Ecstasy is widely used by young people as a recreational drug, particularly as part of the dance party or 'rave' scene. The major pharmacological effects of MDMA, both acute and long term, primarily involve the neurotransmitter serotonin (5-hydroxytryptamine; 5-HT), but other neurotransmitters are also involved in the action of MDMA, particularly dopamine. In addition to an acute effect on serotonin release from nerve endings in the brain, high or repeated doses of MDMA produce neurotoxic damage to serotonin nerve terminals in the brains of experimental animals. However, unequivocal evidence for similar long-term damage in the brain of human users remains lacking. Nevertheless, there is increasing evidence for both psychological and physiological abnormalities occurring in persons who have used the drug extensively.

History and Human Recreational Use

MDMA was originally synthesized and patented in Germany in 1912 as an intermediate for therapeutically active drugs being developed by E Merck. It is an amphetamine derivative and structurally related to several other amphetamine derivatives (Figure 1). Its pharmacological and toxicological effects were examined in the 1950s by the US military as part of a chemical warfare program examining psychoactive drugs related to mescaline, to which it also bears some structural similarity (Figure 1). By the 1980s, MDMA was being used as an adjunct to psychotherapy, but it was classed as a Schedule 1 drug in the United States in 1985, and this was closely followed by it being listed as an illegal Class A drug in the UK. Despite (or possibly in part because of) these restrictions, MDMA rapidly gained considerable popularity as a recreational drug, particularly as part of the dance scene.

Ecstasy tablets continue to be sold in an assortment of colors, sizes, and shapes, and recent studies have suggested that most now contain primarily MDMA and that each tablet is likely to contain between 70 and 90 mg of MDMA. While many users will only take one or two tablets in an evening, high doses (upward of eight tablets) are sometimes consumed in one session, and binge dosing (taking large numbers of tablets but divided over time) has also been reported to occur, in an apparent effort by the user to reduce adverse effects. Concurrent use of other psychoactive compounds, particularly alcohol and cannabis, is common. While acute fatalities do occur, they are relatively infrequent and are estimated to be approximately 12 per year in the UK despite upward of 500 000 young persons ingesting it weekly. However, concern continues at possible long-term damage to the brain, particularly as this could be occult and only become apparent at some time in the future.

Acute Effects in Animals

Brain Neurochemistry

A single acute dose of MDMA produces a rapid release of 5-HT from its nerve terminals in the rodent brain. This has been demonstrated *in vivo* using microdialysis (Figure 2) and also using brain slice preparations *in vitro*. The brain 5-HT concentration can be depleted by as much as 80% within the first few hours following a dose of MDMA (Figure 3). This rapid 5-HT release can be prevented by the administration of a 5-HT uptake inhibitor such as fluoxetine (Figure 2) or citalopram, which indicates that MDMA is being taken up into the nerve ending via the 5-HT transporter site. The drug also inhibits tryptophan hydroxylase activity, the rate-limiting step in serotonin biosynthesis. Inhibition of this enzyme will also increase 5-HT depletion in the brain. MDMA also enhances dopamine release and again this has been demonstrated *in vitro* using brain slice preparations and *in vivo* using microdialysis, but this has little overall effect on the dopamine concentration in the brain. MDMA also exerts a stimulatory effect on cholinergic neurons resulting in the release of acetylcholine in several brain areas as well as in striatal slices. This response seems to be secondary to the enhanced 5-HT release induced by the drug. MDMA has been shown to enhance norepinephrine release *in vitro* but evidence for this effect occurring *in vivo* is lacking. In contrast to the long-term effects, the acute changes induced by MDMA on brain 5-HT and dopamine release appear to be produced by the action of the parent compound since both are evident when the drug is administered peripherally or directly into the brain.

MDMA binds to 5-HT, dopamine, and norepinephrine transporters, having the highest affinity for the 5-HT transporter. It also has some affinity for

Figure 1 The structure of MDMA, MDA, some other amphetamine compounds, and mescaline.

Figure 2 The acute effect of MDMA (15 mg kg^{-1} given at time 0) on 5-HT release in the hippocampus and the effect of fluoxetine (10 mg kg^{-1}) given at –5 and +55 min. Results shown as mean ± SE of mean.

Figure 3 The concentration of 5-HT in frontal cortex of rats administered MDMA (5 mg kg^{-1} given at 3 h intervals to a total of three doses) at various times after administration of the final dose compared to saline-injected controls. Different from saline-injected rats: $^{**}P < 0.01$; $^{*}P < 0.05$.

several neurotransmitter receptors including 5-HT$_1$, 5-HT$_2$, α-adrenergic, and β-adrenergic receptors.

Administration of MDMA also results in a rapid increase in free radical production in the brain of both rats and mice together with subsequent lipid peroxidation. The free radicals are thought to result from the metabolism of MDMA and its principal metabolite 3,4-methylenedioxyamphetamine (MDA) to catechol and quinine compounds that then produce free radicals following further degradation. Dopamine has also been suggested to be involved, but this is controversial, and evidence has recently been presented which indicates that MDMA increases cerebral tyrosine which is converted to free radical-producing metabolites by nonenzymatic processes. Free radical production has been linked to the long-term neurotoxic action of MDMA (discussed later). Both oxygen-(hydroxyl) and nitrogen-based radicals have been implicated in the damage. MDMA also causes a decrease in superoxide dismutase and glutathione peroxidase activities in several regions of the brain.

An increase in the production of the proinflammatory cytokine interleukin 1-beta (IL-1β) is also detected shortly after MDMA. This effect is partially a consequence of the hyperthermic response subsequent to MDMA and it is reduced when rats are maintained at low ambient room temperature. In addition to increasing IL-1β release, MDMA also induces microglial activation, but, in contrast to the changes in IL-1β, the glial response is not significantly modified when the hyperthermia is abolished. These changes in neuroinflammatory parameters are probably involved in the long-term neurotoxic effects induced by MDMA.

Physiological and Psychological Effects

The major acute functional consequence of MDMA administration to rodents is a change in body temperature. Generally, the response is hyperthermia, which is seen if the animals are housed at normal or warm (>20 °C) ambient room temperatures. However, if rats are housed in cooler room conditions (<17 °C), a hypothermic response is observed. Increasing the room temperature results in rats displaying a greater hyperthermic response than that seen in animals housed at normal ambient temperature. The hyperthermia appears to result primarily from enhanced MDMA-induced dopamine release stimulating D1 dopamine receptors, while the hypothermia seen in rats housed in cool conditions is due to stimulation of D2 receptors. The rise in rectal temperature following MDMA involves thermogenesis. There is an increase in metabolic rate involving the hypothalamic–pituitary–thyroid axis, and β3-adrenergic stimulation in brown adipose tissue. Since the tail temperature does not increase in hyperthermic animals following MDMA, and the tail is a major heat loss organ in rodents, it can be proposed that MDMA also interferes with heat loss mechanisms. If sufficient MDMA is administered, the hyperthermic response can prove fatal. In common with other amphetamine compounds, the toxic action of MDMA can be enhanced by grouping animals together (so-called aggregation toxicity). High temperature and noise also worsen toxicity, which is a matter of concern given the use of MDMA by humans in hot, noisy, crowded dance floor conditions. A somewhat different pattern of temperature effect is seen in nonhuman primates following MDMA. While MDMA does produce a hyperthermic effect, the magnitude of the response is not altered by the ambient temperature conditions. Hyperthermia is seen in nonhuman primates housed in cool conditions and normal ambient temperature conditions and is not increased further by increasing the room temperature, which suggests that monkeys have a greater ability to lose heat even at elevated room temperature.

Rats given a high dose of MDMA display the so-called serotonin syndrome, a series of behavioral changes which include hind limb abduction, head weaving, reciprocal forepaw treading, and increased locomotor activity. This behavioral syndrome is indicative of increased 5-HT_{1A} receptor activity in the brain. In mice, the predominant behavioral consequence of MDMA administration is enhanced locomotor activity, due in part to 5-HT_{1B} receptor stimulation. While it has been suggested that the changes in body temperature observed after MDMA administration might be the result of the increased activity, this seems unlikely since studies have shown a dissociation between MDMA-induced hyperthermia and hyperlocomotion. Thus, at an elevated room temperature (30 °C), the same dose of MDMA produced a marked hyperthermia but similar locomotor response to that observed in rats given MDMA at standard room temperature.

Administration of MDMA to rats induces several neuroendocrinological changes. Serum corticosterone is increased as is prolactin, aldosterone, and renin. There have also been cardiovascular abnormalities observed, with increases in both mean arterial pressure and bradycardia.

Acute effects of MDMA in rats examined in models of anxiety remain somewhat conflicting. In rats, MDMA has been reported to have an anxiogenic-like effect when animals are tested on the elevated plus maze, while both an anxiogenic and an anxiolytic effect have been reported in the social interaction test. In mice all studies performed have indicated that MDMA has an anxiogenic-like effect. Several studies have found that the rewarding properties of the drug MDMA produces a rewarding effect in electrical and drug self-administration tests in both rats and baboons. This effect is probably associated with the increase in dopamine release from the nucleus accumbens produced by MDMA administration. Interestingly, the drug-induced dopamine release is enhanced by housing the rats in warm conditions, which suggests that the enthusiasm for taking the drug in warm dance-club conditions may not be coincidental.

It is also possible that previous exposure to MDMA may increase the reinforcing effects of other psychostimulants. Cocaine produces a higher increase in the extracellular levels of dopamine in the nucleus accumbens of animals pretreated with MDMA than that seen in control rats. These animals also show a significantly greater conditioned place preference (CPP) response to cocaine than the vehicle-treated group. Since CPP is believed to be a measure of appetitive behavior, these results provide direct evidence of an increase in the rewarding properties of cocaine in

rats preexposed to MDMA and suggest that MDMA abuse leads to increased vulnerability to cocaine addiction and dependence. Consequently, and taking into account the limitations involved in extrapolating results from animals to humans, it would seem reasonable to propose that MDMA users may be at risk of developing addiction to and dependence on other psychostimulants.

Acute Effects in Humans

While there is a considerable body of information on the acute effects of MDMA in human users, the value of many of the observations is somewhat compromised by the fact that the doses consumed and time of ingestion are often unknown, and other drugs, both known and unknown to the subject, will have been taken around the same time as the MDMA. A further complication includes the fact that MDMA metabolism appears to have saturable kinetics; that is, higher doses are metabolized relatively more slowly than lower doses. Furthermore, it is metabolized by the CYP450 enzymes, including the CYP2D6 enzyme, which means that not only will other drugs interfere with its rate of metabolism but also the rate of metabolism is influenced by whether the person is a poor or fast metabolizer.

The acute physiological effects of MDMA in humans are very similar to those reported in rodents. These include increased heart rate and increased systolic and diastolic blood pressure. These symptoms are blocked by the 5-HT uptake inhibitor citalopram. Crucially, hyperthermia is one of the major consequences of MDMA-induced toxicity, with body temperatures of over 43 °C being reported: such marked hyperthermia can prove fatal. Like rats, the hyperthermia is not blocked by a 5-HT uptake inhibitor, but, unlike rats, MDMA increases body temperature in humans regardless of the ambient temperature. Various other adverse effects have been reported in MDMA users including tachycardia, coagulopathy, rhabdomyolysis, thrombocytopenia, and pulmonary congestion, all of which are potentially fatal. Kidney failure, subarachnoid hemorrhage, and liver failure have also been seen, and many of these severe adverse effects are primarily the result of the severe hyperthermia.

Acute psychological changes following MDMA ingestion can include both desirable and undesirable effects. The presumed desirable effects of this recreational drug include elation, happiness, friendliness, calmness, and increased perception of color, sound, and touch, but confusion has also been reported. However, following the drug intake feelings of low mood, paranoia, insomnia, and irritability have been regularly reported by subjects. 'Low mood' can be experienced several days after the last ingestion of the drug. Many of the psychological effects of MDMA can be blocked with citalopram, but since MDMA is an amphetamine compound and also acutely releases dopamine, it is reasonable to propose that excitability and euphoria are associated with dopamine rather than serotonin release in the brain. Other undesirable effects reported by ecstasy users are nausea/vomiting, bruxism, muscle aches/headache, sweating, dry mouth, and dizziness.

Long-Term Neurotoxicity in Animals

There have been a substantial number of reports attesting to the fact that high or repeated doses of MDMA produce neurotoxic degeneration of 5-HT nerve terminals in the forebrain of rats. Most of these studies have used biochemical measures of 5-HT loss to indicate damage (Figure 3). It has been found that MDMA produces a loss of 5-HT in regions of rat brain lasting for many months. Similar reductions in the concentration of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) and 5-HT uptake into cerebral tissue preparations have also been shown to occur. The most relevant index of terminal loss is the 5-HT uptake site on the presynaptic terminal (measured by radioligand binding of [^{3}H]-paroxetine), and MDMA administration decreases the number of these sites in a dose-dependent manner (Figure 4). The long-term loss of 5-HT occurs in most forebrain regions, but is of somewhat shorter duration in the striatum. The concentration of other monoamine neurotransmitters is unaltered. This selective 5-HT neurotoxicity is seen not only in rat but also in guinea pig and primate brain following MDMA. In contrast, MDMA administration to mice produces no long-term toxic effect

Figure 4 Long-term effect of a single administration of MDMA (4, 10, and 15 mg kg^{-1}, i.p.) on the cortical [^{3}H]-paroxetine binding 7 days after injection. Different from saline $^*P < 0.01$. Results shown as mean ± SE of mean.

on cerebral serotonin, but does produce long-term toxicity to dopamine neurons as reflected in a major loss in cerebral dopamine content and dopamine transporter.

The biochemical evidence for MDMA-induced damage to 5-HT neurons in rat brain is supported by histological observations of damage. Techniques used include staining methods of cerebral tissue and immunocytochemical analysis of brain regions indicating reductions in serotonergic axonal density and morphological evidence of terminal damage in both rat and primate brain. Recovery is region dependent but loss is still detectable in rat frontal cortex after 2–3 months (Figure 3) and in some brain regions up to a year later, while it is still apparent in primate brain after 7 years. A positron emission tomography (PET) study in baboons, using a marker for the 5-HT transporter indicated significant terminal loss for more than 9 months.

In mice, the long-term dopamine loss following MDMA leads to an enhanced expression of glial fibrillary acidic protein (GFAP), which is indicative of astrocyte hypertrophy (reactive gliosis) and thus reflective of neurodegeneration. However, in rats studies have failed to observe a GFAP increase in brain following a neurotoxic dose of MDMA, and this has led to suggestions that MDMA is not producing a true neurotoxic degeneration even though it is clearly causing 5-HT neurochemical and functional deficits.

Interestingly, MDMA itself does not cause neurotoxicity when injected directly into the brain which suggests that a neurotoxic metabolite is probably formed peripherally, and it is this metabolite that produces free radical formation and neurotoxicity in the brain.

Various approaches have been made to prevent the MDMA-induced damage in rat brain. A most effective approach has been to administer the drug when the animals are housed at low ambient temperature. This prevents both the acute hyperthermia and the long-term toxicity, and it is generally acknowledged that preventing the acute hyperthermia by either the use of a cool room or giving drugs that decrease the hyperthermic action of MDMA has the effect of severely attenuating or even preventing neurotoxic damage. There is evidence that prevention of the hyperthermia also has the effect of inhibiting the formation of free radical species in the brain following MDMA, which suggests that free radicals are a key factor in inducing the damage. This interpretation is supported by studies that have shown that administration of the free radical trapping agent α-phenyl-*N*-tert-butyl nitrone (PBN) lessens the MDMA-induced neurotoxicity, and other free radical scavengers including cysteine and ascorbic acid can also provide neuroprotection. There are compounds that provide protection against MDMA-induced neurotoxicity in rats by a mechanism not related to changes in body temperature. The selective 5-HT uptake inhibitor fluoxetine, co-administered with MDMA or even injected up to 4 days before MDMA, prevented the long-term loss of 5-HT concentration without altering MDMA-induced hyperthermia. Fluvoxamine also totally prevents MDMA neuronal damage, although protection is only observed when it is given concurrently with MDMA. Both compounds inhibit 5-HT transporter and could be blocking the entry of a toxic metabolite of MDMA into the 5-HT nerve terminal.

Not surprisingly, given the many roles of 5-HT in the brain, the damage produced by MDMA results in a variety of functional deficits in animals given a neurotoxic dose of the drug. For example, rats given a prior toxic dose of MDMA show an impaired ability to thermoregulate when exposed to a high-temperature environment; this problem is not seen in normothermic conditions. This problem of thermoregulation becomes even more apparent if lesioned rats are placed in warm room conditions and given a further small dose of MDMA, since the acute hyperthemic response is substantially prolonged. Obviously, if this observation in rats has any clinical relevance, it means that heavy recreational users might be more at risk when further doses are taken in a hot environment.

Rats with a prior neurotoxic lesion also display abnormal responses when examined in various psychological tests. For example, most studies have found that lesioned rats display greater anxiety-like behavior in the elevated plus maze and social anxiety tests.

Studies in mice are far fewer than those in rats, presumably because the long-term dopamine loss seen is thought to have little relevance to the damage seen in both primates and humans. The dopamine loss is also probably the result of increased free radical production since transgenic mice with enhanced CuZn-superoxide dismutase are resistant to MDMA-induced damage. Furthermore, toxicity is enhanced in selenium-deficient mice.

Long-Term Effects in Humans

The problems in ascertaining the doses ingested, other drugs taken, and frequency of dosing by recreational users have already been alluded to. Not only is such information not generally available, but the veracity of the subjects studied is sometimes questionable. Furthermore, direct assay of cerebral tissue is impossible except occasionally postmortem.

Proton magnetic resonance spectroscopy has been used to measure *N*-acetylaspartate a neuronal marker and myoinositol as a possible marker of gliosis. Conflicting data were obtained with one study producing data suggestive of gliosis, the other not confirming this; it is possible that differences in drug exposure in the two studies were responsible for the discrepant data. Some evidence for neuronal loss was also obtained.

There have been several imaging studies performed on recreational users, using ligands to examine the 5-HT transporter with PET and single-photon computed tomography (SPECT). Data suggested a loss of transporter site number in the brain of ecstasy users though such studies cannot determine whether this is drug related or secondary to users having a preexisting difference in serotonergic function to control subjects. Exclusive ecstasy use does not appear to decrease the striatal dopamine transporter density; that is, it is not neurotoxic to dopamine neurons. However, the combined use of amphetamine and MDMA may be associated with a reduction in striatal dopamine transporter density. These data may have substantial clinical significance since ecstasy users are often polydrug users and many of the heavy ecstasy users also take amphetamine.

Serotonin function in the brain has also been examined by use of neuroendocrine challenge tests. There was some indication that the serum prolactin response to an infusion of L-tryptophan was blunted in MDMA users, and a challenge test using fenfluramine showed a similar effect and also a blunted cortisol effect. What was striking was the fact that these abnormal responses were seen a year after the subjects had stopped using MDMA. The 5-HIAA concentration in the cerebrospinal fluid (CSF) may also be lower in MDMA users, but this is a poor marker of central 5-HT function.

There have been many studies of long-term psychological effects in recreational users of MDMA, and generally where abnormalities have been observed these have been seen long after drug use has ceased. A range of psychiatric symptoms has been reported including anxiety and panic attacks, depression, paranoid delusions, and visual hallucinations. Chronic psychosis has also been reported in a small number of subjects. The problem, however, is that these symptoms are seen in many polydrug users, and heavy users of MDMA are likely to be taking other recreational drugs, so it is unclear whether MDMA is the specific culprit for the problems seen or indeed whether some of the problems are preexisting in the personality types attracted to heavy recreational drug use.

There is much evidence that ecstasy use can produce selective cognitive impairment, and this problem can continue in drug-free persons, being more pronounced in heavy drug users. The MDMA user group display impaired immediate verbal memory and delayed visual memory as well as longer reaction time to visual and auditory stimuli. Memory deficits of MDMA users seem to be the result not only of a temporal or hippocampal dysfunction but also of a dysfunction of regions within the frontal cortex.

General Conclusions

MDMA produces a complex series of acute neurochemical events in the brain of experimental animals, primarily involving monoamine neurotransmitter function, and these changes initiate a number of physiological and behavioral changes. Similar functional changes are also seen in recreational users of the drug. The drug also produces long-term neurotoxic damage in both rodent and primate brain which is dose dependent. A major problem in interpreting the neurotoxicity data in experimental animals in terms of its relevance to human pharmacology is the doses administered. Many preclinical experimental studies on MDMA have used high doses, and it is questionable whether the effects seen are clinically relevant. While it has been argued that it is relevant to use 'interspecies scaling' to interpret results, the fact remains that similar doses (in $mg\,kg^{-1}$ quantities) can produce many comparable acute physiological and psychological effects in rodents and humans. Unfortunately, few animal studies have measured plasma drug concentrations, and without this information interpretation remains difficult. It is to be hoped that future studies will correct this oversight.

Introduction

Conventional molecular biology techniques enable gene expression analysis in a wide variety of analytical approaches and paradigms. Experimental methods include Southern analysis (DNA detection), Northern analysis (RNA detection), polymerase chain reaction (PCR; DNA detection), reverse-transcriptase PCR (RT-PCR; RNA detection), ribonuclease (RNase) protection assay, and *in situ* hybridization, among others. The majority of these approaches typically quantitate the abundance of individual elements one at a time (or a few at a time). Recent developments in high-throughput genomic methodologies enable the assessment of dozens to hundreds to thousands of genes simultaneously in a coordinated manner. Recent advances in molecular genetics have led to sequencing of the entire human genome, as well as whole-genome sequencing of several relevant animal models. Furthermore, expression data are increasingly available for many diverse tissues throughout the body, allowing for exciting hypothesis testing of critical concepts such as development, differentiation, normative function, and, ultimately, disease pathogenesis.

Input Sources of RNA

Input sources of RNA can originate from a variety of *in vivo* and *in vitro* sources. Fresh, frozen, and fixed tissues are useful to varying degrees, depending on the paradigm and tissue quality. Many laboratories isolate genomic DNA and total RNA from paraffin-embedded fixed tissues as well as from fresh and frozen tissues. In addition, genetic material preserved by fixation is a significant resource because fresh and/or frozen tissues are not frequently available, whereas archived fixed human tissues exist in many brain banks and individual laboratories. With mRNA as a starting material, the importance of preservation of RNA integrity in tissues and cells for downstream genetic analyses cannot be emphasized enough. RNA species are particularly sensitive to RNase degradation. RNases are found in virtually every cell type and are quite stable over a broad pH range. Therefore, it is prudent to employ RNase-free precautions during all RNA extraction and analytical procedures. In addition, a laudable goal is to devise optimal methods to prepare brain tissues for downstream genetic analyses for consistency across laboratories and paradigms. A consensus protocol awaits further development and implementation. Salient variables for the accrual of postmortem human tissues include documentation of agonal state, antemortem characteristics, clinical diagnostic criteria, duration of fixation, length of storage, and postmortem interval. A useful method for assessing RNA quality in tissue sections prior to performing expression profiling studies is acridine orange (AO) histofluorescence. AO is a fluorescent dye that intercalates selectively into nucleic acids and has been used to detect RNA and DNA in brain tissues. Significantly, individual RNA species (including mRNA, rRNA, and tRNA) cannot be delineated by AO histofluorescence. Rather, this method provides a diagnostic test that is employed on adjacent tissue sections to ensure the likelihood that an individual case has abundant RNA prior to performing expensive expression profiling studies. A more thorough examination of RNA quality can be obtained via bioanalysis, which uses capillary gel electrophoresis to detect RNA quality and quantitate relative abundance.

Expression Profiling in the Central Nervous System

The central nervous system (CNS) is an exciting structure to evaluate relationships between functional genomics and expression data. Recent developments in functional genomic technologies, specifically microarray platforms, have enabled the coordinated assessment of a plethora of gene alterations that occur within the CNS. However, unlike an organ that comprises one principal cell type, the brain contains a multiplicity of both neuronal (principal neurons, interneurons, and others) and nonneuronal (glial cells, epithelial cells, inflammatory cells, vascular elements, and others) populations of cells. The intricate connectivity of synaptic-based circuits within the brain demands cognizance of rostrocaudal and mediolateral coordinates as well.

Microarray analysis has emerged as a useful and fairly cost-effective tool to assess transcript levels in a myriad of systems and paradigms. A disadvantage of these high-throughput technologies is a requirement for significant amounts of high-quality input sources of RNA for increased sensitivity and reproducibility. Whole-organism studies can generate significant input amounts of RNA species without any amplification procedures, but does not allow regional and/or

cellular specificity. Regional analysis of gene expression is a widely used paradigm due to the relatively large amounts of RNA that can be extracted from cultured cells, animal-model tissues, and postmortem human brain tissues. An advantage of regional gene expression analysis is that, in most cases, extracted RNA is sufficient to generate significant hybridization signal intensity for microarray analysis, enabling the analysis of hundreds to thousands of targets without requiring RNA amplification. However, expression profiles garnered from regional dissections cannot discriminate molecular signatures from admixed neuronal populations and nonneuronal populations within the region of interest.

Homogeneous Cell Gene Expression Analysis

An emerging goal of modern molecular neuroscience is to sample gene expression from similar cell types within a defined region without potential contamination by expression profiles of adjacent neuronal subtypes and noneuronal cells. For example, the development of a series of molecular and cellular criteria that differentiate selectively vulnerable neurons from relatively spared neurons is critical. An important factor that determines specificity of functional genomics methods is the identification and subsequent purity of captured cells for subsequent downstream genetic analyses. As such, single-cell and population-cell molecular fingerprinting requires accurate, nondestructive isolation of cells from optimally prepared tissue sections. This is a difficult task that demands a multidisciplinary approach (Figure 1). At present, an optimal methodology to assess gene expression is to evaluate single cells, either identified physiologically in living preparations or by immunocytochemical or histochemical procedures in fixed cells *in vitro* or *in vivo*. Unfortunately, the quantity of RNA harvested from a single cell, estimated to be approximately 0.1–1.0 pg, is not sufficient for standard RNA extraction. Therefore, exponential PCR-based analyses and linear RNA amplification including amplified antisense RNA (aRNA) amplification and terminal continuation (TC) RNA amplification have been used in combination with microdissection procedures to enable the use of microarray analysis. For example, specific neuronal populations can be identified by selective expression of relevant proteins, such as cholinergic basal forebrain neurons and midbrain dopaminergic neurons. Moreover, cells that lack a distinct or selective signature phenotype can be analyzed using a variety of Nissl stains (including cresyl violet and hematoxylin and eosin) for downstream genetic applications. For example, cresyl violet has been used in our laboratory to identify CA1 and CA3 pyramidal neurons in postmortem human tissue sections for subsequent single-cell microarray analysis and quantitative real-time PCR (qPCR) studies.

Microaspiration Procedures

Single-cell assessment and analysis of a homogeneous group of cells (termed population-cell analysis) requires precise nondestructive isolation from optimally prepared tissue sections. Provided that labeling procedures are performed on well-prepared tissue sections and RNase-free conditions are employed, both immunocytochemical and histochemical procedures can be used to identify specific cells of interest. Several techniques are used to aspirate individual cells or populations of cells, including single-cell microaspiration and laser capture microdissection (LCM). Single-cell microaspiration entails visualizing an individual cell (or cells) using an inverted microscope connected to a micromanipulator, a vacuum source, and an imaging workstation on an air table. Microaspiration results in the accurate dissection of the neurons of interest with minimal disruption of the surrounding neuropil and has been used on a variety of tissues and cell types, including normal samples and tissues undergoing various forms of neurodegeneration in animal models and human postmortem tissues.

Another high-throughput microaspiration device, LCM, enables rapid accession of single cells and populations for downstream molecular and cellular analyses. LCM is a popular and effective technique that was developed originally by investigators at the National Institutes of Health (NIH). Positive extraction entails pulsing an infrared laser onto thermoplastic film embedded in a specialized microfuge cap to form a thin protrusion that bridges the gap between the cap and a tissue section, effectively adhering to target cells. Lifting the thermoplastic cap separates targeted cells from surrounding undisturbed tissue. Negative extraction (or noncontact laser extraction) procedures employ a near-infrared laser source to cut around the area of interest within a tissue section, and the microdissected material is catapulted into a microfuge tube. Positive and negative extraction methods enable captured cells to be examined microscopically, confirming the identity and quality of isolated cell populations. Individual cells or dozens, hundreds, or thousands of cells can be collected rapidly by LCM. RNA, DNA, and protein extraction methods can be performed on microdissected cells. LCM is used conventionally to enable cellular isolation for RNA extraction and subsequent microarray analysis.

Microarray Platforms

Technical advances have enabled the development of a wide variety of microarray platforms that serve as the substrate for high-throughput analysis of dozens to hundreds to thousands of genes simultaneously. Microarrays represent miniaturized, high-density dot-blots that exploit the complementary hybridization between nucleic acids. Synthesis of cDNA microarrays entails adhering cDNAs or expressed sequence-tagged cDNAs (ESTs) to solid supports such as glass slides, plastic slides, or nylon membranes. A parallel technology uses photolithography to adhere oligonucleotides to array media. The anchored cDNA/EST/oligonucleotide is commonly called the microarray target. The target length varies from short oligonucleotides to chromosomal fragments. When the input RNA is not amplified (as in the case of regional assessments), probe generation is performed via reverse transcription, and a detection moiety is incorporated directly into the cDNA strand. If input RNA is amplified through an RNA amplification methodology, then the amplified material is labeled and used to probe the microarrays. Arrays are washed to remove nonspecific background hybridization and imaged using a laser scanner for biotinylated/fluorescently labeled probes and a phosphor imager for radioactively labeled probes. A target-labeled probe complex emits a quantifiable signal that is proportional to the abundance of the labeled probe in the sample. The specific signal intensity (minus background) is expressed as a ratio of the total hybridization signal intensity, reducing variation across array platforms due to differences in the specific activity of the probe and absolute quantity of probe present. Quantification of hybridization signal intensity is performed to evaluate relative expression levels of each cDNA, EST, or oligonucleotide feature on the array platform. Gene expression is then assessed using statistical and informatics modules that coordinate statistical analyses. Computational analysis is critical due to the large number of data points that are generated from a single assay.

RNA Amplification Strategies

An RNA amplification technique is often required to perform microarray analysis and related downstream genetic analyses when using small sample inputs as starting material. PCR-based amplification methods are not optimal because exponential amplification can skew the original quantitative relationships between genes from an initial population. Linear RNA amplification is another strategy that has been used successfully to generate input RNA for molecular-profiling studies. One method of linear amplification, termed aRNA amplification, uses a T7 RNA polymerase-based amplification procedure that allows quantitation of relative gene expression levels from microdissected cells and tissues (Figure 2). aRNA maintains a proportional representation of the size and complexity of the initial mRNAs. Relative mRNA expression levels can be quantified using cDNA or oligonucleotide arrays by probing with fluorescent-and/or biotin-tagged nucleotide triphosphates incorporated directly into aRNA products. Alternatively, radiolabeled nucleotide triphosphates can be incorporated into aRNA products and used for hybridization to membrane-based cDNA arrays via reverse Northern analysis to known cDNAs and/or ESTs. aRNA products are biased toward the 3′ end of the transcript because of the initial priming at the poly(A)+ RNA tail. This 3′ bias exists for all amplified aRNA products, and relative levels of gene expression can be compared. Although aRNA is often a technically involved procedure, successful results have been generated with micro-aspirated animal model and human tissues using a wide variety of microarray platforms. Modifications of the initial aRNA procedure have been used, and several aRNA-based kits are available commercially.

A variety of strategies have been developed by independent laboratories to improve RNA amplification, including combining PCR with aRNA and isothermal RNA amplification, among others. One obstacle is the problematic second-strand cDNA synthesis. This impediment is not specific to the aRNA protocol. Rather, this issue is endemic to all current RNA amplification methods. Key factors to improving RNA amplification include increasing the efficiency and/or obviating the second-strand cDNA synthesis and allowing for flexibility in the placement of bacteriophage transcription promoter sequences.

A new RNA amplification procedure has been developed in our laboratory that uses a method of TC (Figure 3). TC RNA amplification entails synthesizing first-strand cDNA complementary to the RNA template and generating second-strand cDNA complementary to the first-strand cDNA. RNA is amplified via an *in vitro* transcription procedure using the newly formed double-stranded cDNA as template. Synthesis of the first-strand cDNA complementary to template mRNA is performed by two oligonucleotide primers, a poly(dT) primer and a TC primer. The poly(dT) primer is similar to conventional primers that anneal to the poly(A)+ sequence present on most mRNAs. The TC primer consists of an oligonucleotide sequence at the 5′ terminus and a short span of three cytidine triphosphates or guanosine triphosphates at the 3′ terminus. TC RNA transcription can

Figure 2 aRNA amplification scheme. An aRNA primer {oligo-d(T)T7} primer is hybridized directly to poly(A)+ mRNAs. A double-stranded mRNA–cDNA hybrid is formed (first-strand synthesis) by reverse transcribing the primed mRNAs with reverse transcriptase. The double-stranded mRNA–cDNA hybrid is converted into double-stranded cDNA, forming a functional T7 RNA polymerase promoter. A first round of aRNA synthesis occurs via *in vitro* transcription using T7 RNA polymerase and nucleotide triphosphates. A second round of aRNA amplification begins by annealing random hexamers to the newly formed aRNA and performing first-strand synthesis. The aRNA primer is then reintroduced, which binds to the poly(A)+ sequence on the newly synthesized cDNA strand. A double-stranded cDNA template is formed by second-strand synthesis. A second round of aRNA products is produced by *in vitro* transcription using biotinylated, fluorescent, or radiolabeled nucleotide triphosphates. Labeled second-round aRNA products are used as probes to hybridize to cDNA microarrays, oligonucleotide arrays, or membrane-based cDNA arrays. IVT, *in vitro* transcription; NTPs, nucleotide triphosphate. Adapted from Ginsberg SD (2005) RNA amplification strategies for small sample populations. *Methods* 37: 229–237; Ginsberg SD and Mirnics K (2006) Functional genomic methodologies. *Progress in Brain Research* 158: 15–40.

be driven using a promoter sequence attached to either the 3′ or 5′ oligonucleotide primers (Figure 3). Therefore, transcript orientation can be in an antisense orientation (similar to conventional aRNA methods) when the bacteriophage promoter sequence is placed on the poly(dT) primer or in a sense orientation when the promoter sequence is attached to the TC primer, depending on the design of the experimental paradigm (Figure 3). TC RNA amplification enables the quantitative assessment of a large proportion of genes, as evidenced by bioanalysis and microarray analysis in animal model and human postmortem brain tissues, including single cells and populations of homogeneous neurons. Significantly, the increased sensitivity of the TC RNA amplification method appears greatest for genes with relatively low abundance. Moreover, background hybridization is significantly attenuated when using TC RNA amplification.

Validation of Microarray Results via Quantitative Polymerase Chain Reaction

Amplification of genetic signals can be performed at both the DNA and RNA levels, and final amplified-products are either DNA or RNA. A common method for DNA amplification is PCR. However, PCR is an exponential, nonlinear amplification, and variation can occur within individual mRNA species of different molecular mass and base-pair composition. PCR-based methods tend to amplify abundant genes over rare genes and may distort quantitative relationships among gene populations. Real-time qPCR can quantitate PCR product formation during each cycle of amplification and has lessened concerns that are associated with conventional PCR methods. Other advantages of real-time qPCR include high-throughput capabilities, the ability to simultaneously multiplex reactions, enhanced sensitivity, reduced interassay variation, and lack of post-PCR manipulations. A variety

Figure 3 Overview of the TC RNA amplification method: (a) sense orientation; (b) antisense orientation. As shown in (a), a TC primer (containing a bacteriophage promoter sequence for sense orientation) and a poly(dT) primer are added to the mRNA population to be amplified (green rippled line). First-strand synthesis (blue line) occurs as an mRNA–cDNA hybrid is formed following reverse transcription and TC of the oligonucleotide primers. After an RNase H digestion step to remove the original mRNA template strand, second-strand synthesis (red line) is performed using *Taq* polymerase. The resultant double-stranded product is used as a template for *in vitro* transcription, yielding high-fidelity linear RNA amplification of sense orientation (green rippled lines). The scheme in (b) is similar to (a), illustrating the TC RNA amplification procedure amplifying RNA in the antisense orientation (yellow rippled lines). TC, terminal continuation. Adapted from Che S and Ginsberg SD (2004) Amplification of transcripts using terminal continuation. *Laboratory Investigation* 84: 131–137; Ginsberg SD (2005) RNA amplification strategies for small sample populations. *Methods* 37: 229–237.

of dye chemistries are employed in qPCR assays, including hydrolysis probes, molecular beacons, and double-stranded DNA binding dyes.

The most well-known hydrolysis probes are the TaqMan assay. In this assay, the *Taq* polymerase enzyme cleaves the TaqMan probe during the PCR extension phase. The TaqMan probe is dual labeled, with a reporter dye and a quenching dye at two separate ends. When the probe is in its free form, fluorescence emission of the reporter dye is absorbed by the quenching dye by fluorescence resonance energy transfer. An increase of reporter fluorescence emission occurs when the separation of the reporter and quencher dyes takes place during nuclease degradation in the PCR reaction. This process takes place during each PCR cycle and does not interfere with the exponential accumulation of amplified product. Molecular beacons are probes that form a stem–loop structure from a single-stranded DNA molecule. Molecular beacons are particularly useful for identifying point mutations because these probes can detect targets that differ by only a single nucleotide. DNA-binding dyes such as SYBR green incorporate selectively into double-stranded DNA. SYBR green emits undetectable fluorescence levels when it is in its free form. Once bound to double-stranded DNA, an intense fluorescent signal is emitted. qPCR has emerged as an excellent companion technology to microarray analysis in that the differential regulation of individual transcripts observed via array platforms can be tested with relative ease and quickness via qPCR-based assays.

Caveats

The application of microarray technology in the neuroscience disciplines is still in its infancy. Most high-throughput transcriptome-profiling studies are moderately expensive, labor intensive, and somewhat time consuming. To generate meaningful data sets, an appropriate experimental design is imperative prior to initiating actual studies. A concern is that

significant variation exists between and across array platforms. For example, significant differences exist in microarray production (including target deposition vs. *in situ* synthesis), microarray target length (ranging from >20 to >50 bp oligonucleotides vs. partial ESTs to full-length cDNAs and chromosomal fragments), probe-labeling procedures (e.g., radioactive labeling, direct or indirect fluorochrome incorporation, and gold-particle deposition), amplification procedures (including PCR-based amplification, T7-based RNA amplification, isothermal amplification, and microRNA amplification), and a dizzying array of hybridization procedures. Each of these procedural and technical variables may have substantial effects on the subsequent data sets that emerge from the microarrays. As a result of these potential pitfalls, negative findings on any array platform must be interpreted cautiously. Significantly, independent validation methods of transcript analysis (Northern hybridization, RNase-protection assay, and *in situ* hybridization, among others) are not made obsolete by high-throughput transcription-profiling technologies. Rather, these traditional (relatively low-) throughput methods often have important advantages over the high-throughput assays, especially when a specific gene of interest is being hypothesis tested. Also, an important caveat about microarray analysis is that coordinate changes in proteins encoded by the genes of interest are common but not absolute.

Conclusion

Simply stated, when deciding whether to use a specific functional genomic methodology, the most crucial aspect to consider is the question the researcher is interested in answering; only then can the researcher determine the method(s) that are appropriate to perform the experiments. Advancements in functional genomics have led to the development of high-throughput gene-profiling techniques to quantify the expression levels of multiple transcripts simultaneously within discrete brain regions and specific cell types. Microarray-based paradigms are enabling the analysis of coordinate changes in gene expression that were not feasible prior to the development of these exciting technologies. However, the use of high-throughput analysis does not obviate the need for traditional methods of expression-level quantitation for validation purposes in a lower-throughput fashion. Thus, a combination of multidisciplinary approaches is ideal for verification of gene-expression-level alterations, with the explicit knowledge that the sum of the evaluations may be more informative and reflect the actual biology of the system better than an individual method.

Microcephaly Vera

G H Mochida, Beth Israel Deaconess Medical Center, Massachusetts General Hospital, and Harvard Medical School, Boston, MA, USA

What Is Microcephaly?

Microcephaly refers to a condition in which the human brain fails to achieve normal growth. Clinically, a diagnosis of microcephaly is made by measuring the occiptofrontal circumference (OFC) using a non-stretchable tape measure. When the OFC is below a certain cutoff for the person's age and sex, a diagnosis of microcephaly is made. In the clinical setting, a cutoff of −2 SD below the mean is often used, but in the research setting a stricter cutoff of −3 SD is more commonly used.

Microcephaly is a highly heterogeneous condition, and its etiology can be divided into environmental and genetic causes. The environmental causes are numerous and include intrauterine infections, intrauterine exposure to toxic substances, and hypoxic–ischemic injury before the early postnatal period. Many different types of environmental insults that affect the development of the brain while it is still growing in size can lead to microcephaly. The genetic causes of microcephaly are also diverse. In many cases, microcephaly is one of the clinical signs of a syndrome that also affects other organ systems or shows characteristic dysmorphic features. Examples include Rubinstein–Taybi syndrome, Seckel syndrome, and Smith–Lemli–Opitz syndrome. However, in some cases, the brain is the only affected organ, and no dysmorphic features are seen. Microcephaly vera is a condition that belongs to this latter group.

Historical Note and Nomenclature

The term microcephaly vera (literally, 'true' microcephaly) was first coined by Giacomini in the late nineteenth century. This term was used to describe a condition in which no anatomical abnormalities of the brain (except for its smallness) were identified. In contrast to microcephaly vera, the term 'microcephaly spuria' ('false' microcephaly) was used to describe a condition in which destructive lesions were in evidence. The essence of Giacomini's definition of microcephaly vera has not changed to date. Currently, in the narrow and strict definition of the term, it refers to a condition that is characterized by the constellation of clinical manifestations including severe congenital microcephaly, normal to mildly delayed motor development, mental retardation, and a lack of motor signs such as spasticity. The term 'primary autosomal recessive microcephaly' may also be used to describe this condition. In a broader sense, the term microcephaly vera is sometimes used to refer to various forms of genetic microcephaly without other organ involvement or dysmorphic features. However, this broader definition encompasses a highly heterogeneous group of brain malformations and can lead to confusion. Thus, the usage of the term microcephaly vera in the broader definition should be avoided, and in this article, microcephaly vera in the narrow sense is discussed.

Epidemiology

Microcephaly vera has been reported from different populations and ethnic groups. However, because it shows autosomal recessive inheritance, it appears to be much more common in the countries and regions where the rate of consanguineous marriage is high. Many genetic studies have been conducted in such populations, including northern Pakistan and the Arabic Middle East. Although population-based epidemiological data of microcephaly vera are not available, the prevalence may be as high as 1/10 000 in some populations with a high rate of consanguinity. It appears that the male:female ratio is 1:1, and this is consistent with its autosomal recessive mode of inheritance.

Clinical and Radiological Manifestations

Clinical Presentation

Patients with microcephaly vera present with microcephaly at birth (congenital microcephaly). Therefore, it is important to confirm the head circumference at birth when a patient presents after the neonatal period. It is also important to measure the parents' head circumferences because they are usually normal in microcephaly vera. If one of the parents has a small head circumference, the autosomal dominant form of microcephaly may be suspected. This is a separate entity from microcephaly vera and is often associated with normal intelligence. In patients with microcephaly vera, microcephaly may be detected by prenatal ultrasound during the third trimester. Complications during the perinatal period are not common, and weight and length at birth are generally normal. Early motor milestones, such as rolling over, sitting, and independent walking, are normal or mildly delayed. Delay in cognitive development and subsequent mental retardation are always present.

The severity of mental retardation is often of moderate degree. Some patients acquire language skills, often consisting of single words. The final head circumference generally is between −4 and −12 SD. Height and weight are generally within the normal range, and when significant short stature is noted, other syndromes such as Seckel syndrome (characterized by pre- and postnatal growth retardation and unique facial features) may need to be considered. There are usually no dysmorphic features, except for sloping forehead and relative prominence of the ears, both of which are due to severe decrease in the size of the cranium. Many patients with microcephaly vera acquire basic self-care skills. Social interaction is not severely impaired, and many patients have a friendly personality. Autistic symptoms and severe behavioral disturbances appear to be rather uncommon. Epilepsy is also uncommon. Although patients with microcephaly vera and epilepsy have been reported, it is not known if the incidence of epilepsy among patients with microcephaly vera is higher than that of the general population. Organs other than the brain are apparently not affected, and usually there are no associated signs or symptoms outside the central nervous system.

Neuroimaging

Detailed radiological studies of microcephaly vera have not been reported, but available data suggest that the basic structure of the brain is generally well preserved. In terms of the brain volume decrease, the cerebrum appears to be most severely affected, although the cerebellum and brain stem are also

Figure 1 Brain MRI of microcephaly vera. Axial T1-weighted MRI image of a 9-year-old boy with microcephaly vera and an *ASPM* mutation (a) reveals a mildly simplified gyral pattern and significantly decreased brain volume compared to an age-matched control (b). Sagittal T1-weighted MRI image of a 5-year-old boy with microcephaly vera and an *ASPM* mutation (c). shows essentially normal architecture of the midline structure, but severe craniofacial disproportion is evident compared to an age-matched control (d). Scale bars = 2 cm.

smaller (Figure 1). Sagittal brain magnetic resonance imaging (MRI) images are often striking for severe craniofacial disproportion (i.e., a small cranium compared to the size of the facial structure). The gyral pattern of the cerebral cortex may be normal or mildly simplified. At least one patient with microcephaly vera and a mutation in the *MCPH1* gene has been shown to have periventricular heterotopia, but it is not known how common this finding is among patients with microcephaly vera.

Treatment and Prognosis

There is no treatment for the underlying biological defects of microcephaly vera, and like other disorders with mental retardation, early intervention with special education and therapy is important to the functional outcome of the individual. It is not a progressive disorder, and many patients acquire some language (often single words) and basic self-care skills. Microcephaly vera is usually not associated with epilepsy, but rare patients are known to have epilepsy. In such instances, the treatment of seizure is essentially the same as in other cases of epilepsy. No data exist on the life expectancy of patients with microcephaly vera. However, it is believed that life expectancy is not significantly shorter than that of the general population.

Genetics and Biology

Genetic Loci and Causative Genes for Microcephaly Vera

Even before the era of modern human genetic research, it was known that many microcephaly syndromes showed autosomal recessive inheritance, and microcephaly vera was no exception. Microcephaly vera that fits the previously discussed clinical description is inherited in an autosomal recessive manner. In recent years, the genetics of microcephaly vera has been extensively investigated, and it has been found that it is genetically highly heterogeneous. Six genetic loci for microcephaly vera have been identified, and these loci are named MCPH1 through MCPH6 (Table 1). There is no clear genotype–phenotype correlation, and the clinical phenotype of a patient cannot predict the underlying causative locus. It appears that MCPH5 is the most common locus for microcephaly vera, and it may account for nearly half of all cases of microcephaly vera in the limited populations studies that have been performed. Still, up to 20–25% of the pedigrees with microcephaly vera do not map to any of the known six loci, and it is almost certain that there are other loci yet to be identified. Among these six loci, the causative genes have been identified in four (Table 1). MCPH1 is caused by the gene of the same name, *MCPH1* (also known as *microcephalin* and *BRIT1* (BRCT-repeat inhibitor of TERT expression)), MCPH3 by *CDK5RAP2* (cyclin-dependent kinase 5 regulatory subunit-associated protein 2), MCPH5 by *ASPM* (abnormal spindle-like, microcephaly associated), and MCPH6 by *CENPJ* (centromeric protein J). Only a few mutations have been reported for each of *MCPH1*, *CDK5RAP2*, and *CENPJ*, but more than 20 different nonsense or frameshift mutations have been reported for *ASPM*. There appear to be no particular 'hot spots' for mutations in *ASPM*. Although the head circumference of patients with *ASPM* mutations varies widely from approximately –4 to –12 SD, the location of a mutation within the gene does not predict the severity of reduction of the brain size. Thus, it is speculated that all the mutations that have been reported so far lead to complete loss of function of the protein.

Biological Functions of the Genes for Microcephaly Vera

The essentially identical phenotype caused by the different genes for microcephaly vera suggests that these genes may be involved in the same or related biological process. This speculation has largely proven correct. All the four known genes appear to be important to regulation of cell division of neuronal progenitor cells. Among these, ASPM, CDK5RAP2, and CENPJ are

Table 1 Genetic loci and causative genes for microcephaly vera

Locus	*Gene*	*Chromosome location*	*Gene function*
MCPH1	*MCPH1*	8p23.1	DNA damage response/cell cycle checkpoint regulation
MCPH2	Not known	19q13.1–13.2	Not known
MCPH3	*CDK5RAP2*	9q34	Mitotic centrosome regulation?
MCPH4	Not known	15q14–22.2	Not known
MCPH5	*ASPM*	1q31.3	Mitotic spindle/centrosome regulation
MCPH6	*CENPJ*	13q12.2	Mitotic centrosome regulation?
Others	Not known	?	Not known

shown to localize to the spindle pole/centrosome during mitosis.

ASPM ASPM is a large protein with 3477 amino acids. It consists of four distinguishable regions: a putative N-terminal microtubule-binding domain, a calponin homology domain, a domain consisting of IQ repeats, and a C-terminal region. Calponin homology domain is found in many actin-binding proteins, and IQ repeats (the name derives from isoleucine (I) and glutamine (Q), which are key amino acids that define the repeat structure) is shown to bind to calmodulin in some proteins, although the functions of these domains in ASPM are not known. The gene is the homolog of the *asp* (abnormal spindle) gene in *Drosophila melanogaster*. The Asp protein localizes to the spindle pole/centrosome during mitosis, and mutations in *asp* result in abnormal morphology of mitotic spindle and mitotic arrest. The human ASPM protein has also been shown to localize to the spindle pole/centrosome during mitosis. *Aspm* (the mouse homolog of *ASPM*) is highly expressed in the telencephalic ventricular zone during the period of active neurogenesis and rapidly downregulated once the period is over. Interestingly, *Aspm* is also expressed in other organs where there is active cell division, and this seems to be true in humans as well. It is not known why mutations in *ASPM* do not cause obvious defects in the development of the other organs.

CDK5RAP2 and CENPJ CDK5RAP2 and CENPJ comprise 1893 and 1338 amino acids, respectively. Their roles are not precisely understood, but the protein products of both genes have been shown to localize to the centrosome during mitosis. Studies of their mouse homologs showed that both genes are highly expressed during the period of neurogenesis in the neuroepithelium of the forebrain. The brain and spinal cord showed the highest expression, but, like *Aspm*, the expression was seen widely in other organs in the developing mouse embryo.

MCPH1 MCPH1 is an 835-amino-acid protein with three BRCT (BRCA1 C-terminal) domains. BRCT domains are often found in proteins involved in regulating cell cycle checkpoint in response to DNA damage, and MCPH1 is also thought to function in this capacity. A high level of *MCPH1* gene expression is observed in the neuroepithelium along the lateral ventricles of the developing mouse brain. Interestingly, MCPH1 seems to function, at least in part, in the same DNA damage response pathway as ATR (ataxia–telangiectasia and RAD3-related), which is one of the causative genes for Seckel syndrome. Seckel syndrome, like microcephaly vera, is characterized by severe congenital microcephaly but, in addition, shows severe pre- and postnatal growth retardation. Both *MCPH1* and *ATR* mutant cells show defective G_2–M checkpoint arrest and nuclear fragmentation after DNA damage, but *MCPH1* mutant cells show premature chromosome condensation, which is not seen in ATR mutant cells, suggesting an additional ATR-independent role of MCPH1.

Genes for Microcephaly Vera and Brain Evolution

One of the most striking characteristics of the human brain is its large size in relation to the body size. The molecular and genetic basis of this dramatic volume expansion during evolution is not well understood. However, insufficient growth of the brain without major disruption in the architecture in microcephaly vera raised a possibility that the genes for microcephaly vera may have played a role in the volume expansion of the human brain during evolution. Several studies have examined the evolution of the microcephaly vera genes to explore this possibility. These studies searched for evidence of positive selection of these genes by calculating the parameter called the K_a/K_s ratio of the genes. The K_a/K_s ratio of a gene is a ratio of nonsynonymous nucleotide changes (i.e., nucleotide changes that alter resulting amino acids) and synonymous nucleotide changes (i.e., nucleotide changes that do not alter resulting amino acids) during the course of evolution. When the ratio is low, the gene is under negative selection, meaning that any change in the protein sequence is likely deleterious, and it is unlikely that the gene has played important roles in evolutionary changes seen among organisms. On the other hand, if the gene has a high K_a/K_s ratio, the gene is under positive selection (i.e., rapidly evolving), and it is more likely that the gene has played a role for the organism to have acquired new characteristics during evolution. *MCPH1* was found to have evidence of positive selection during primate evolution, particularly prior to the ancestor of great apes. In contrast, *ASPM* was shown to have evidence of positive selection in the more recent history of primate evolution. The evidence for positive selection was the strongest in the human lineage and also seen to a lesser extent in the African hominoid clade (human, chimpanzee, and gorilla) or great apes (the African hominoid clade and orangutan). There are also data to suggest evidence of positive selection for *CDK5RAP2* and *CENPJ* in primates.

Experimental data to prove the relationship between the positive selection of these genes and the evolutionary volume expansion of the human brain

are difficult to obtain. However, it is remarkable that all four known genes for microcephaly vera show evidence of positive selection, and it appears very likely that these genes were key molecules for the volume expansion of the brain in humans and other primates.

Future Directions

Although significant progress in our understanding of microcephaly vera has been made during the past decade, there are still many unanswered questions. First, it appears that there are additional microcephaly vera loci yet to be identified. Second, the functions of the known causative genes are still not well understood. For example, we know that *ASPM*, *CDK5RAP2*, and *CENPJ* are associated with the spindle pole and centrosome, but how mutations in these proteins lead to human microcephaly is far from clear. Third, the potential role of these genes in human brain evolution is strongly suggested but has been difficult to prove experimentally. By addressing these questions, we will gain knowledge not only about microcephaly vera but also about general mechanisms of human brain development and evolution, and this will likely have a major impact on much broader fields of neuroscience and biology.

Microglia Identification Methods

E Raibon and T Möller, University of Washington, Seattle, WA, USA

Brief History of Microglial Identification

Utilizing the silver staining method developed by Golgi, Ramón y Cajal first described an uncharacterized 'third element' within the central nervous system in 1913. In his definition, this term applied to all cells morphologically different from either neurons (first element) or astrocytes (second element). As we know today, this term actually applies to two distinct cell groups, oligodendrocytes and microglia. Pio del Rio Hortega formally described 'microglia' as their own unique entity in 1921 and provided the first systematic investigation of microglial cells in 1932. He described microglia as cells that "possess liberal ramified expansions and display migratory and phagocytic activity." Both Ramón y Cajal and del Rio Hortega used silver staining and relied on cell morphology for their assessments. Their method reveals resting microglia as cells with characteristically elongated, almost bipolar, cell bodies with spine-like processes having many short branches. The nucleus of microglial cells is large in comparison with the small perikaryon. While this early morphological description of microglial cells still holds true today, the staining methods of Ramón y Cajal and del Rio Hortega were neither specific nor reproducible. Consequently, for an extended period of time there was little progress in our understanding of microglial cells. This quest was further hampered by the fact that microglia show a remarkable morphological plasticity, which ranges from highly ramified cells in normal central nervous system (CNS) tissue, over rod-shaped cells in inflamed cerebral cortex, to full-blown phagocytes in tissue with necrotic or apoptotic cells. This enormous hurdle was finally overcome by the development of 'specific' stains, including lectins and monoclonal antibodies against epitopes expressed by microglia. This rekindled interest in microglial cells in the 1980s and set the stage for our current understanding of microglial cells in health and disease. However, one major caveat, inherent to all currently available microglial markers, should be pointed out early on. Virtually all available markers to identify microglia also detect other myeloid cells, such as macrophages and monocytes. The so-called microglia-specific labeling, as used here and in virtually all literature, actually only indicates that these labels do not cross-react with other CNS resident cells, such as neurons, astrocytes, or oligodendrocytes.

Lectins

Lectins are carbohydrate-binding proteins ubiquitously found in species from plants to humans. They play an important role in cell adhesion and control of protein levels in the blood. Their ability to recognize specific terminal carbohydrates on glycoproteins or glycolipids makes them valuable markers. The α-D-galactosyl-specific isolectin B4 (IB4) of *Griffonia simplicifolia*, an African medicinal plant, is a lectin widely used to label microglial cells in the rat, guinea pig, sheep, salamander, and even leech. *Ricinus communis* (castor bean) agglutinin-1 (RCA-1), a β-D-galactosyl-preferring lectin, is frequently used to stain microglial cells in normal and pathological human tissue. The lectin from *Lycopersicon esculentum* (tomato) has a high affinity to poly-*N*-acetyllactosamine and is a good marker for mouse microglia. It has been used for fixed tissue but also for labeling of living microglia in brain slices. One common caveat for all lectins is their cross-reactivity with endothelial cells. While blood vessels are rarely mistaken for microglial cells, abundant staining of endothelial cells can hamper the identification of the smaller microglia. However, because of their ease of use, lectin stainings are frequently used in routine histology.

Antibodies

The advent of monoclonal antibodies directed against specific epitopes paved the way to improved and more specific ways of microglial cells staining. Due to the myeloid lineage of microglial cells, most of the markers frequently used and presented here are also found in macrophages and monocytes. These markers are linked to common tasks of myeloid cells, such as phagocytosis or other immune functions. Even though most of the antibodies were developed against peripheral myeloid cells, protocols were successfully adapted to stain microglia in the CNS. Antibodies can be used in a variety of methods in immunocytochemistry and immunohistochemistry, flow cytometry, immunopanning, and fluorescent and magnetic cell sorting. Many antibodies can be used on fixed and/or frozen tissue and on paraffin-embedded sections (an antigen retrieval step is sometimes required for the most sensitive antibodies). Furthermore, primary antibodies from different species or different primary antibody isotypes allow for multiple labeling in the same sample.

Among the most used antibodies to detect microglia are CD11b, CD68, and F4/80 antibodies, which recognize, respectively, antigens from the integrin family, a lysosomal glycoprotein, and the F4/80 antigens. CD11b is part of the complement receptor 3

and is also known, under the name of the antibody clones, as Mac-1 (antimouse) and OX-42 (antirat). CD68, also known as macrosialin, is a lysosomal protein also found on the cell surface. Interestingly, the antibody ED1, used for a long time to stain rat microglia, was found to recognize rat CD68. F4/80 antibody is mainly used in mouse tissue and the F4/80 protein was recently found to be involved in immune functions within the eye, which constitutes a CNS-like functional entity. Antibodies against all three epitopes have been extensively used and stain both resting and activated microglia, along with circulating monocytes and macrophages. Interestingly, differentiation between monocyte-derived macrophages invading the CNS and microglial cells was made possible by using anti-CD45 antibodies. CD45, also known as the leukocyte common antigen (LCA), is a member of the receptor protein tyrosine phosphatase family. Although expressed widely by microglia, monocytes, macrophages, and other hematopoietic cells, CD45 expression levels differ between microglia and macrophages. Microglia have a low level of expression, whereas circulating monocytes and peripheral tissue macrophages express high levels of CD45. This feature has been successfully exploited for the identification of microglial cells via *ex vivo* flow cytometry.

ED2 and ED3 antibodies, raised against macrophage-specific lysosomal markers with still unknown function, stain activated microglia and macrophages in rats. However, the ED2 antibody does not label resting parenchymal microglia, and ED3 staining of resting microglia is variable. Other antibodies recognize epitopes linked to immune functions of microglial cells and are upregulated when microglia become activated. For example, major histocompatibility complex class (MHC) II antigen is virtually not present on resting microglia, but is strongly upregulated in activated cells. However, MHC II upregulation varies depending on the type of CNS injury. MHC II is highly expressed during bacterial infection whereas its level is usually low in neurodegenerative diseases. Thus antibodies against the MHC II antigen, such as OX-6 (antirat), reveal activated microglial cells. However, they can also label other MHC II-expressing cells, such dendritic cells, which have been shown to be involved in the CNS immune response.

A recent addition to the microglial marker repertoire is ionized calcium-binding protein adaptor molecule 1(Iba1). Iba1 is a calcium-elongation factor (EF) hand protein, and is specific to the monocytic lineage, including microglia and macrophages. Iba1 protein function is still not completely understood; however, the Iba1 gene is highly conserved throughout evolution, suggesting an important role for this protein. Recent molecular studies pointed out a possible role in membrane ruffling and phagocytosis. The ubiquitous intracellular localization of Iba1 provides good staining, delineating whole microglial cells when used in immunohisto- and immunocytochemistry, as shown in Figure 1.

It is worth noting that there is yet no available single marker to reliably distinguish resting from activated microglia. The distinction between the two still mainly relies on morphological criteria. Another way to distinguish resting from activated microglia is to detect the expression of activation-associated cytokines. However, cytokine secretion is not restricted to activated microglia. For example, astrocytes can secrete some of the same cytokines secreted by microglia. In order to identify the source of cytokine secretion, it is necessary to combine the intracellular cytokine

Figure 1 Fluorescent microscopy images of microglia stained with Iba1 antibody. (a) In the microglial N9 cell line, Iba1 antibody stains cytoplasm and processes, and the nucleus is clearly distinguished. (b) Iba1 staining of microglial cells (arrows) in the healthy adult mouse brain. Cells present a ramified morphology, with a small cell body and highly branched processes. (c) In the spinal cord of amyotrophic lateral sclerosis model mice with end-stage disease, Iba1 staining reveals activated microglial cells (arrows), with larger cell bodies and shortened processes. Scale bars = 5 μm (a), 10 μm (b, c).

staining with a cell-selective (e.g., microglia) marker. Double labeling is a useful approach that can help to distinguish resting and activated microglia.

Many antibodies were developed and used before their corresponding antigen was actually known. Consequently, when used as cell markers, they are often referred to by the name of the antibody clone rather than the name of the antigen. This has inevitably led to some confusion. For example, the CD11b antigen, which together with CD18 forms the CR3 receptor, is also known as Mac-1 (mouse) and OX-42 (rat), the names of the respective antibody clones. The Table 1 gives an overview of the different categories of markers currently in use, with a focus on a classification by antigen names instead of clone names.

Genetic Labels

Specific labeling of microglia (and all other cells) depends on the restricted expression of certain molecules, which are inherent only to particular cells. For example, the expression of Iba1 in microglial cells, but not in neurons, macroglia, or endothelial cells, is what makes the antibody directed against it such a valuable marker. If the genetics of a cell-type-specific molecule are known and a promoter has been identified, this information can be used to devise transgenic animals which express a readily identifiable molecule – for example, green fluorescent protein (GFP) – under the control of the promoter. Such approaches have been used to make GFP-labeled neurons, astrocytes and oligodendrocytes. However, transgene expression in microglia and closely related macrophages has proved to be more challenging than expression in neuroectodermal cells. Early experiments using CD11b or CD14 promoters were disappointing. The first report of GFP-expressing microglia was a by-product of engineering a *CX3CR1* knockin/knockout mouse. The investigators sought to interrupt the functional expression of *CX3CR1* by inserting GFP into this gene. While originally constructed to investigate the role of *CX3CR1*, the engineered mice have been used by the microglial community to investigate microglial behavior *in vivo*. However, results from these animals have to be interpreted carefully. Even though these studies used heterozygous animals ($CX3CR1^{+/-}$), the disruption of one genomic copy of *CX3CR1* might reduce *CX3CR1* expression, and thereby influence microglial motility. Other animals with GFP-expressing microglia have been reported since, using

Table 1 Commonly used microglial markers

Marker	*Name*	*Other names*	*Antigen (function)*	*Staining pattern*
Lectins	*Griffonia simplicifolia* isolectin B4	IGSA-IB4 IB4	α-D-Galactosyl group (cell adhesion and control of immune function)	Resting and activated microglia (rat) Vascular endothelium Patchy staining
	Ricinus communis agglutinin-1 lectin	RCA-1	β-D-Galactosyl group (cell adhesion and control of immune function)	Resting and activated microglia (human) Vascular endothelium Patchy staining
	Lycopersicon esculentum lectin	Tomato lectin TL	Poly-*N*-acetyllactosamine group (cell adhesion and control of immune function)	Resting and activated microglia (mouse) Vascular endothelium Patchy staining
Antibodies	CD11b	Mac-1 OX-42 (rat)	Complement receptor CR3; integrin family (adhesion)	Resting and activated microglia Macrophages
	CD14	rmC5-3; Sa2-8 (mouse)	Coreceptor for lipopolysaccharide (endotoxin immune response)	Activated microglia Monocytes
	CD45	LCA OX-1 (rat)	Receptor protein tyrosine phosphatase family (T cell receptor/B cell receptor-mediated activation)	Resting and activated microglia (low) Monocytes/macrophages (high)
	CD68	ED1 (rat)	Lysosomal glycoprotein (phagocytosis)	Resting and activated microglia Macrophages
	ED2 ED3	ED2, ED3 (rat)	Macrophage-specific lysosomal marker (unknown function)	Resting and activated microglia; not parenchymal microglia Macrophages
	F4/80	F4/80; BM8 (mouse)	Glycoprotein (role in immune regulation)	Resting and activated microglia Macrophages
	MHC II	I-A; I-E (mouse) RT1B; OX-6 (rat)	MHC class II (antigen presentation)	Activated microglia
	Iba1	Ionized calcium-binding adaptor molecule 1	Calcium-EF hand protein (membrane ruffling; phagocytosis)	Resting and activated microglia Monocytes/macrophages

Iba1, CD68, and F4/80 as microglia-specific promoters. Again, one has to keep in mind that the term 'microglia-specific' only refers to 'not expressed in other CNS resident cells.' All these animals express GFP in other myeloid cells (e.g., macrophages and monocytes).

A variation in these transgenic approaches to drive expression of a marker gene is the use of microglia-specific promoters such as F4/80 or CD11b in a cyclization recombinase/locus of 'X-over' P (Cre/Lox) system. Expression of Cre recombinase in microglial cells allows the microglia-specific knockdown of a gene flanked by *loxP* sites.

PK11195

The isoquinoline PK11195 is a ligand for the peripheral benzodiazepine receptor expressed in myeloid cells. In the CNS it selectively labels microglial cells, and PK11195 binding strongly increases in activated microglia. Based on these observations, radiolabeled PK11195 was successfully used in positron emission tomography (PET) studies to investigate microglial cells in human disease. For example, in Alzheimer's disease (AD), hot spots with PK11195-labeled activated microglia can be readily identified, providing a prognostic tool for disease progression. In patients with multiple sclerosis (MS), activated microglial cells are found in active lesions identified in gadolinium-enhanced magnetic resonance images (MRIs). Similar results have been obtained for many other neurological diseases and have kindled the interest of neuroradiologists.

Other Labels

Before specific antibodies against microglial epitopes became widely available, enzymes such as nucleoside diphosphatase or thiamine pyrophosphatase were used to identify microglial cells in tissue sections. Ecto-5′-nucleotidase (CD73), another enzymatic marker used, is found on microglia cell membranes, and its expression is strongly upregulated in activated cells; however, it is not cell-type specific. The same is true for NADPH diaphorase, which has frequently been used to detect oxidative burst in activated microglial cells. Furthermore, due to the necessity of maintaining enzyme activity, such stainings cannot be used on paraffin-embedded tissue.

A less frequently used method to identify microglial cells exploits the increased pinocytosis of myeloid cells. Microglial cells incubated with a dye solution such as lucifer yellow will take up this dye into pinocytic vesicles, and therefore the cells become labeled over time. Another indirect labeling technique takes advantage of the phagocytic capability of fully activated microglia. Fluorescent carbocyanine dye (Di-I) injected into axons retrogradely labels neuronal cell bodies. When neuronal cell death is induced, Di-I is found in cells with microglial morphology. Although interesting for studies focusing on phagocytic functions of microglial cells, this type of indirect labeling will only mark cells which have differentiated into phagocytes.

Microglia as a Latent Central Nervous System Macrophage

Microglial cells represent the central nervous system (CNS) equivalent of a tissue macrophage. Major roles relate to the surveillance, support, protection, and, as much as possible, restoration of structural and functional tissue integrity. Microglial cells can rapidly respond to homoeostatic disturbances and potential threats by a transformation process (known as microglial activation) to mount a broad variety of reactive measures. Microglia can share or acquire many features known from macrophages of non-CNS origin, including the constitutive and inducible expression of receptors and surface structures for effector functions, cellular communication, and matrix interactions; the production of a plethora of releasable factors with signal or enzymatic activity; as well as abilities for chemotactic movement, phagocytosis, or antigen presentation. As immunocompetent cells, activated microglia can execute innate defense mechanisms and recruit the assistance of adaptive immunity. Yet resident microglia may differ from other macrophages by regulatory aspects and inducible reactive profiles because they are influenced by the specific biochemical and cellular milieu of the CNS in general and they are adapted to the structural vulnerability of neuronal networks. The anatomical restraints on tissue swelling are a feature that, besides the brain's extraordinary structural complexity and poor capacity for reconstruction, further compromises the ability of the CNS to fight defensive battles. Accordingly, there is a tight control on inflammatory and immune defense mechanisms in neural tissues to which microglia must obey.

Distribution and Morphological Features in CNS Tissues

The term microglia, introduced in the early twentieth century by del Rio-Hortega, refers to the parenchymal cell population, which is distinct from other macrophage-like cells with perivascular or meningeal localization. Estimated to account for up to 20% of glia, microglial cells are dispersed throughout the brain and spinal cord and also found in the retina. Although regional tissue densities vary, cells normally occupy and control discrete territories. The characteristic, macrophage-atypical appearance in the mature and healthy CNS is that of a small cell body with highly branched processes (Figure 1). This ramified morphology of the resting microglia is commonly revealed by specific immuno- or lectin histochemical staining methods in fixed tissue specimens. However, the dynamics of the highly motile processes have only recently been visualized by experimental *in vivo* imaging techniques. The scanning movement of the otherwise territorial microglia thereby seems to assist the environmental monitoring function. Upon activation, microglia can rapidly reorganize the processes. Cells reveal a granular appearance and turn into a more rounded, bushy or rod-like and ameboid shape. Local cell densities can increase at sites of an injury by chemotactic movement and congregation as well as proliferative expansion, building a pool of reactive cells which is assisted also by bone marrow-derived, invading monocytes. The postactivation principles that would reestablish normal microglia densities are less well understood. Apoptosis appears to be a mechanism to reduce local numbers. On the other hand, areas that donated cells to another location may be repopulated by migration or mitosis in order to guarantee sufficient microglial surveillance and protection capacity. The dramatic gradual transition in microglial morphology has been a sensitive and reliable hallmark to indicate neuropathological changes of most diverse etiology and to reveal primary or secondary engagement of these cells. Morphological appearance, however, is a poor surrogate of functional properties and may not reflect the actual functional consequences of activated microglia. The fact that isolated microglia *in vitro* present with a heterogeneous but essentially not ramified morphology (Figure 2) has been taken as sign of partial activation. Nevertheless, even though cells in culture are at a higher alert level due to the lack of certain tissue-related cues, many executive functions rapidly and tightly associated with reactive microglia, such as the synthesis and release of proteins (e.g., cytokines), are not yet effective. On the contrary, ramified appearance can be enforced without guaranteeing a fully resting, *in vivo*-like state. Moreover, due to a more complex response potential and a previously underestimated functional diversity of microglia, neither morphological signs of activation nor detection of a single marker molecule can provide reliable insight into the actual performance. As discussed later, the reactive phenotype of such a cell is defined by a molecular expression pattern and a related ensemble of cellular properties. Currently, there is also no

Figure 1 Microglial cells in the healthy adult CNS reveal a ramified morphology. The image represents an immunostaining for microglia-expressed Iba1 protein in adult rat cerebral cortex. Kindly provided by Dr. Shinichi Kohsaka, National Institute of Neuroscience, Tokyo, Japan.

Figure 2 Microglia in culture display heterogeneous cell shapes different from the typical appearance in the CNS. *In vitro* settings are widely used to study molecular and cellular properties as well as mechanisms of activation but lack the tissue complexity. The fluorescence micrograph shows mouse microglia stained by FITC-conjugated *Griffonia simplicifolia* isolectin B4 after phagocytotic incorporation of rhodamine-labeled myelin.

established marker available that could easily distinguish microglia from other macrophages by immunostaining or *in situ* hybridization, even though expression levels of certain surface molecules allow separation by quantitative analysis. Constitutive and inducible diversity among and exchange between cells of functional microglia/macrophage orientation may even render it unlikely that a single molecule could fulfill the criteria as a simple distinguishing marker. On the other hand, gene and protein arrays deliver increasingly more molecular patterns to identify individual subtypes within regional and situation-associated cell populations.

Developmental Origin and Population Replenishment

The predominant notion of origin views microglial cells as of monocyte/macrophage lineage and thus as descendents of mesoderm. Precursors of microglia colonize the developing CNS (probably in waves) during embryonic and early postnatal periods from mesodermal tissues and via routes of invasion involving the bloodstream or the ventricles and meninges. The early ameboid cells subsequently turn into resident microglia which undergo relatively little turnover by proliferation and exchange. Although the first precursors arrive within the CNS even before vascularization, early ontogenetic settlement and some further replenishment of parenchymal microglia seem to be based on circulating monocytes, probably also through the pool of perivascular cells. Conversion of blood-borne cells into microglia proper may occur to some extent under normal conditions, whereas pathological changes are associated with enhanced monocyte infiltration. Despite the use of modern techniques such as bone marrow chimeras, the source, heterogeneity, and plasticity of brain macrophages/microglia remain subjects of controversy.

Functions in Healthy and Diseased CNSs

As an ameboid phagocyte in the developing CNS, microglial cells participate in the shaping of neuronal circuitry by removal of aberrant cells and synaptic connections. Additional contributions to a maturation of neuronal properties are likely. However, there is little information regarding microglial participation and partnership in neuronal functioning and plasticity later on, as is documented for astrocytes. On the other hand, significant effects of surrounding microglia on spinal cord neuron signaling in chronic pain suggest that these cells have the communicative assets to exert marked influence on neuronal information processing. Major known functions of the resting microglia relate to the surveillance of tissue homeostasis – an active process that involves the constant monitoring of the ionic, molecular, and cellular milieu. For this purpose, microglial cells express a large number of cognate surface molecules to sense the unusual occurrence, changed concentration, or altered structure of biochemically most different compounds, ranging from nucleotides, (co)transmitters and small peptides, and large proteins and aggregates (Table 1). Regardless of their chemical nature, microglia-alerting factors may carry either on- or off-signal character, depending on whether their appearance or disappearance is the critical trigger. The stimulation of receptors for certain ligands with external and endogenous

origin can then lead to microglial responses that aim to protect neuronal and glial cell function and integrity. Microglia can, for example, synthesize trophic factors as well as unfold a repertoire of defense actions. Molecular cues associated with pathogens, such as bacterial or viral DNA/RNA and cell wall components, are sensed through pattern recognition molecules and alert microglia to fight off a CNS-threatening infection. Breakdown of the extracellular matrix (ECM) or factors released from endangered, degenerating, or damaged neurons, such as ATP and other purines or abnormally processed membrane lipids and proteins, could indicate neuronal impairment as a consequence of acute neurotoxicity, mechanical injury, stroke, or degenerative processes. Serum components that usually do not have access to parenchymal microglia can similarly inform about a potentially dangerous situation, such as due to trauma or disruption of the blood–brain barrier, which normally guarantees controlled exchange of molecules between the central compartment and the circulation. On the other hand, deviation from a normally constitutive signaling of certain ligand–receptor systems can lift a calming influence on microglia and thus initiate an autonomous response program. Known examples of such ligand–receptor systems reveal reciprocal expression by neurons and microglia. Activated microglia can migrate along chemotactic gradients (e.g., created by chemokines or complement) to concentrate at a site of need as well as release complex cocktails of chemoattractive molecules for highly organized recruitment and guidance of further microglia as well as immune cells (granulocytes, monocytes, and lymphocytes). Microglial phagocytosis is important for the removal of apoptotic cells, clearance of debris resulting from tissue damage, as well as the elimination of opsonized or immune-complexed material. Accordingly, microglia can express a repertoire of receptors for complement, immunoglobulins, and cell-associated structures (Table 2). Expressing the required surface structures (i.e., major histocompatibility complex and accessory molecules), microglia can also act as antigen presenting cells, a feature shared with both macrophages and dendritic cells. Effective production of an enormous variety of neuromodulatory, immunoregulatory, ECM modeling, and even cytotoxic factors further serves the interaction with and support of resident neural and infiltrating immune cells, the neutralization of harmful agents, as well as attempts at repair. Together, the molecular equipment and cellular mechanism organizing the sensory and

Other proteins and compounds	Albumin, ApoE, CD40L, MSH, endothelin, S100B, thrombin, VIP, cannabinoids, ceramide, gangliosides, lysophosphatidic acid, melatonine, opioids/endomorphines, PAF, PGE_2, steroids/steroid hormones, vitamin D_3

Table 2 Examples of molecules expressed and released by (activated) microglia

Receptors and cognate structures	B7.1 (CD80), B7.2 (CD86), C3bi receptor (CR3/CD11b/Mac1), CD14/TLR4 (LPS receptor/signaling complex), CD68, CD16, CD32, CD64 (FcR I, II, and III), CD54 (ICAM-1), CD45 (LCA), MHC II, several cyto- and chemokine receptors, TLR2
Ion channels	Kv1.3 outward K^+ channel
Cytokines and chemokines	CCL2 (MCP-1), CCL3, CCL4 (MIP-1α/1β), CCL5 (RANTES), CCL22 (MDC), CXCL1 (GROα/KC), CXCL2 (MIP-2), CXCL8 (IL-8), CXCL10 (IP-10), IL-1α/-1β, IL-1ra, IL-3, IL-6, IL-10, IL-12 ($p40_2$, p70), IL-15, IL-18, M-CSF, TGF-β, TNF-α
Intracellular proteins	Granule cell death-10 gene (*gcd-10*) product, Iba-1 Ca^{2+}-binding protein, microglia response factor (MRF-1)
Neurotransmitters, neuromodulators, toxins, and proteases	Glutamate, NO, reactive oxygen species (ROS), MMPs

effector functions of the resting and the activated states enable microglia to act primarily protective. In contrast, under certain conditions microglia may actively induce or facilitate neuronal death instead of trying to prevent it, especially when irreversible impairment is associated with improper function (e.g., incorrect and thus rather disturbing signaling). Furthermore, the cytotoxic weaponry and arsenal of neuro- as well as immunoregulatory messenger compounds and effector molecules can turn against the CNS when the microglial activation process is out of control. Then, microglia fuel or carry autodestructive cascades that employ a range of inflammatory mediators and can also involve recruited activities of immune cells.

Microglial Activation and Phenotypic Diversity

In order to activate the array of macrophage-like features and functions, microglial cells have to become activated (Figure 3). Traditionally, the transformation process has been considered as a stereo yped reaction. According to this view, cells would respond to different stimuli with a rather uniform profile of inducible functions. The reflex-like image was influenced by the typical transitions in cell shape as routinely found in histopathological analyses. It was also largely based on, and apparently confirmed by, experimental challenges of isolated microglia with single activating agents, such as bacterial lipopolysaccharide. In such restricted settings, complex integration of multiple signals cannot take place and the resulting reaction reflects an emergency program of defense. This view leaves little room for adjustments by the situational context or feedback regulation within a tissue. It also cannot provide a satisfying explanation of the dichotomy of protective versus destructive actions of microglia.

However, the concept is changing. Activation of microglia is probably an adaptive process with the cells committing to different phenotypes depending on the signaling context as given by more than a single factor and as subject to influences by other resident CNS or infiltrating immune cells. Much of the evidence for such diversity in the response behavior is provided by studies on extraneural macrophages. Treatment with certain cytokines, defined agonists of pattern recognition receptors or their combinations, confrontations with complex microbial agents, and exposure to tumor material or apoptotic or necrotic cells induce macrophages to acquire distinct reactive phenotypes. Reactive phenotypes are not simply characterized by a single release product or receptor expression but, rather, comprise coordinated sets of induced or selectively not induced gene products, adjustments in metabolic and signaling pathways, as well as defined functional (inter)actions. They reveal selective, partially overlapping, as well as partially reciprocal production of mediators for cellular communication and profiles of effector molecules (e.g., cytokines, metabolic or extracellular matrix modeling enzymes, and surface structures for phagocytosis or antigen presentation). These adaptations have physiological consequences, such as opposite effects on inflammation, skewing for types of immune responses, and orientation toward defense

Figure 3 The process of microglial activation causes the normally resting cells in healthy CNS tissue to enter alert and reactive states which are associated with characteristic changes in morphology, increased motility, directed migration and proliferation, as well as a range of macrophage-like functions. The activation is rapidly triggered by signals derived from exogenous or endogenous sources, including structural cues of infectious agents and factors released from damaged cells and tissues. Microglia can then synthesize a huge variety of neuro- and immunoregulatory mediators, toxic compounds, and effector molecules; express surface receptors for cellular and matrix interaction; clear material from the extracellular space by phagocytosis; and present antigen to T cells. As a consequence, microglia may exert mostly protective effects, but they also contribute to cell and tissue damage in certain neuropathological situations and processes. The traditional concept, however, considered microglia activation as a rather stereotyped response, offering little explanation for the variable outcome and impact. Moreover, based on *in vivo* imaging techniques, the resting microglial cells in normal tissue appear to be very motile for actively scanning their environment. The term 'resting,' implying 'nonactive,' may thus not properly apply to describe this functional state. Consequently, the term 'microglia activation' may also require reconsideration.

or repair. Conceivably, microglia can similarly choose from variable response options to adequately cope with an exogenous or endogenous threat or to organize the recruitment of adaptive immune support. Moreover, distinct reactive phenotypes may not only occur as alternative responses to different initial activation scenarios but also interchange in a stage-specific manner during an activation process (Figure 4). Highly organized, context-determined, situation-adapted switches in anti/inflammatory messenger production, timed recruitment versus decline of immune infiltrates, phagocytotic clearance, and tissue rebuilding attempts could be the elements in versatile, (usually) self-limiting, and (mostly) efficient programs for protection and (partial) restoration. Interregional and intrapopulational heterogeneity in constitutively expressed features could also determine the response potential of microglia. In this regard, discrete expression of, for example, neurotrophic factors indicates that microglia are not uniform in the beginning, and that specialized functions could be carried by individual cells. Microglial activation could thus prove to be a much more variable process than originally assumed. Although certain functional features may be part of an initial core program in emergency situations, some are downregulated or become effective when suitable.

Neuropathological Consequences of Microglial Dysfunction

Microglial activation is observed in the neurodegenerative processes of Alzheimer's disease (AD), Parkinson's disease, and amyotrophic lateral sclerosis; in the autoimmune-driven demyelination of multiple sclerosis (MS); in infectious CNS complications associated with, for example, AIDS, meningitis, cerebral malaria, or Creutzfeldt–Jakob disease; as well as with destructive cascades following stroke and trauma. Evidence from morphological examination and staining procedures often reveal locotemporal correlation with the occurrence and development of tissue lesions. It has been interpreted as contributing to an insult or disease process. Combined with the fact that experimental challenges of microglia can cause profound neuronal cell damage

Figure 4 Based on findings and conceptual development, microglial activation is viewed as a more adaptive process. Although some factors would have to appear or to increase in a signaling-relevant form or concentration in the vicinity of microglia in order to trigger a transformation to alerted, activated, or full-blown reactive states, other factors could induce microglial activation by a kind of 'off-signaling.' They usually maintain the resting status and probably keep an attenuating influence. Interruption of their calming input would then result in activation by unchaining an autonomous program for installing increased readiness to provide support or to prepare for an attack. The functional heterogeneity among microglial populations and the diversity in the executive profiles are still poorly understood. Granting microglial cells the ability to integrate the large number of molecular signals for which they can express cognate receptors, the prejudice of a stereotyped response with little adaptive capacity may no longer hold true. Consequently, the term 'activated microglia' would not adequately describe the actual involvement of individual cells or subpopulations in the complex context of an endangered or diseased tissue. Depending on the primary activating signals, as they indicate a threat to the functional and structural integrity of the tissue, microglia may choose an immediate response program which is influenced and adjusted according to further incoming information. Surrounding neurons and glial cells as well as infiltrating immune cells could exert an important control on the initial commitment and development of reactive phenotypes. During the course of activation, affected microglia could shift phenotypes in order to exchange the defense-dominated character of the response for repair orientation. Such changes could, for example, cover the profile of released chemoattractive messengers to support organized infiltration of different immune cell populations or relate to the production of enzymes and substrates for extracellular matrix breakdown versus restoration. Finally, the activation process has to resume. Local microglial distributions and features may return more or less to preactivation conditions. Alternatively, microglia may maintain some altered status, conditioning responses to a subsequent challenge. The concept of context-dependent phenotype diversity and dynamics suggests that not only excessive stimulation (quantitative aspect of a response) but also maladapted reactions (response quality) of microglia contribute to neuropathologies.

and death, activated microglia have earned the reputation of being destructive cells. Yet most of the transient, focally restricted, and successfully resolved episodes of microglia activation may never present with clinical symptoms, and the neuropathological records may be biased for the cases in which microglial attempts to protect, support, and restore were insufficient. Due to a dysregulated engagement, microglia may fail to fight off a threat and to rescue the CNS from further impairment. Collateral (bystander) damage can result when microglial activities exceed critical limits. Whereas in acute settings, such as a bacterial invasion, massive stimulation of microglia may simply result in excessive reaction, such as exaggerated production of potentially neurotoxic molecules (reactive oxygen and nitrogen species, cytokines, and proteases), it may also be the quality and duration of the response which are inappropriate. Granting microglia diversity and adjustment of reactive phenotypes, a misleading signal or signaling context may trigger unnecessarily aggressive cellular behavior. There is reason to assume that endogenously produced factors can be read by microglia (through respective receptor systems) as a signal which otherwise would trigger an antimicrobial and therefore toxic defense action. Detrimental consequences of an active microglia may arise when certain functions are inhibited or when adjustments of phenotypic features are prevented. Microglial activation may often resolve when a particular activating stimulus vanishes. These cells might even organize for its removal, for example, by phagocytosis. Impaired phagocytotic activity or resistance of the target material could then condemn microglia to remain in a certain activation state associated with secretion of proinflammatory and neurotoxic mediators. Vicious cycles of microglia-caused damage resulting in microglia recruitment could thereby cause the progressive neuronal impairment in aggregopathies such as AD. Phagocytosis is certainly also critical for the neutralization of infectious agents. For example, bacterial structures will trigger the release of proinflammatory and toxic substances, which resumes upon their removal from the extracellular space. Phagocytotic clearance of myelin debris in MS is a prerequisite for partial remyelination and probably affects the risk of additional autoimmune challenges. Further research efforts need to address the question of whether functional properties of microglia are strictly or unavoidably coupled. For example, physical contact with molecular or cellular structures for (potentially beneficial) phagocytotic elimination may concomitantly trigger certain (potentially harmful) release activities. During CNS development, phagocytosis is carried out in the absence of inflammatory reactions, whereas the situation may be different under pathological conditions. Finally, a shift from an initial emergency program to repair-promoting phenotypes could eventually be followed by the termination of the activation process. Disturbances along such conversions could hamper de-escalation or result in essential restoration capacities being skipped. The link between the regulated, selective, and sequential execution of functional contributions is likely key to understanding the actual impact of an activated microglia in a disease setting. It is important to note that the surveillance accuracy, support performance, protective capacity, as well as regulatory influences and control mechanisms of and on microglia could fade with aging. This aspect has major implications for the CNS's ability to withstand neurodegenerative processes.

Microglia as a Target of Diagnostic Tools and Therapeutic Intervention

Microglia activation and activities are associated with virtually all challenges of CNS homeostasis. This central role and the repertoire of inducible effector functions make these cells attractive for the development of clinical methods and strategies. Imaging techniques built on radioligands in positron emission tomography aim at visualizing anatomical regions with activated microglia during and even before cell and tissue damage occurs in certain CNS diseases. Silencing of undesired or excessive activities, such as overproduction of potentially harmful substances, may be combined with sparing or enhancing beneficial functions, such as phagocytotic removal of neurotoxic or autoimmunogenic material. Whereas selective molecular manipulation could be designed to attenuate receptor stimulation, alter intracellular signal processing, or intercept with released mediators, general suppression of microglia would deprive the CNS of its supportive functions. Enhanced recruitment of monocytic cells to the resident microglia at sites of lesions may offer access to Trojan horse drug delivery systems.

Approaches to Study Microglia

Models to study microglial behavior outside CNS tissue suffer from several restrictions. In homogenic culture, the isolated cells are deprived of their natural environment. Because soluble and insoluble cues normally surrounding the microglial cells are missing, the cells may not develop the standby mode commonly considered as the 'resting state'. Regarding the principle of off signals, the calming influence normally imposed on microglia by neighboring cells is absent. After the mechanical stress of isolation and culture preparation, cells may therefore remain in a kind of

subalerted mode. Nevertheless, this setting has been very useful for identifying basic mechanisms in the range of activation processes. Despite the respective limitations, *in vitro* approaches still allow for relatively easy and direct experimental manipulations and analyses. Compared to primary cultures, microglia-derived cell lines yield larger cell numbers and require less preparational effort, but they often have deviated features. Mixed and co-cultures offer additional cellular elements and interactions. Yet the intact tissue is more than a mixture of different cell types. Therefore, microglial properties have also been studied in CNS tissue slices. Nevertheless, the surface of a brain slice represents injured tissue. Any acute study thus runs the risk of observing microglia in a response to trauma. Although expression (or lack of expression) of a receptor or ion channel protein does not change within minutes, functional properties may do so. Rapid responses of microglia are thus very likely considering their physiological role as a sensor and effector in pathological situations. Phosphorylation cascades affecting the cytoskeleton, metabolic enzymes, or features of receptor signaling occur faster than the tissue handling prior to measurements. Accommodated slice preparations may instead allow the activated microglia to readjust and to return to a more resting state. Organotypic culture preparations avoid massive tissue disintegration immediately before an investigation and maintain, at least for some time in culture, the cells within the context of their natural environment, including other cell types and their relative orientation. However, organotypic tissue cultures cannot prevent some progressive degeneration of cellular, mainly neuronal, components, which will unavoidably influence microglia. *In vivo* studies guarantee the CNS tissue context and avoid potential artifacts of disintegrative models, but they have not been suitable for directly studying characteristics of a given cell population over a period of time. Developments in *in vivo* imaging of microglia in superficial cortical layers through the thinned skull bone make it possible to visualize the living cells while avoiding massive tissue disruption and leaving the organ untouched. Further technological improvements will provide access to deeper structures as well. Still, the systemic approach has the disadvantage of being very complex. Identifying molecular mechanisms and cellular principles will thus require a combination of *in vitro* and *in vivo* approaches based on wild-type as well as genetically modified systems. Concerning microglia, transgenic mouse models already exist in which the cells are rendered fluorescent. Constitutive and conditional knockout animals have been generated as well. Cell type specificity is achieved for cells of the monocyte/macrophage lineage only, due to the current lack of microglia-restricted gene targets, but is sufficient for many applications within the CNS. Moreover, use of bone marrow chimeras and reciprocal donor–recipient experiments allow the identification of the contributions of resident microglia versus invading monocytes. Approaches aimed at insertion of a reporter or deletion of a functional protein must yet take into account the involuntary impairment of critical molecules operating in the extremely sensitive activational control of microglia.

Microglial Response to Injury

K Ohsawa and S Kohsaka, National Institute of Neuroscience, Tokyo, Japan

© 2009 Elsevier Ltd. All rights reserved.

Microglia ubiquitously exist in the neural parenchyma and exhibit ramified morphology under the normal brain, and they are called 'resting microglia.' In neuronal injuries, microglia are activated to show a number of features, including morphological changes; cell migration and proliferation at lesion sites; induction of wide-ranging myeloid markers, cytokines, free radicals, and nitric oxide; and acquisition of phagocytic phenotype in extensive neuronal cell death (Figure 1). The activated microglia are recognized during neuronal degeneration and then revert to the resting phenotype in parallel with the neuronal regeneration. Therefore, the activated microglia are thought to participate in the degeneration and regeneration of neuronal cells and to play an important role in the repair of the injured nervous system.

Microglia in Normal Brain

In the normal adult central nervous system (CNS), microglia display ramified morphology, and they have a small body with long branched processes (Figure 2). The microglia show a slow turnover from either proliferation of resident microglia or recruitment of bone marrow-derived cells through the intact blood–brain barrier (BBB). Ramified microglia are thought to be in a resting state, but they appear to participate in the immune surveillance in defense of the CNS. Fine branches of the ramified microglia are highly mobile, providing extensive and continuous surveillance of their cellular environment. The resting microglia constitutively express a calcium-binding protein Iba1 and several surface molecules, including CD11b (Mac-1 in mice and complement receptor type 3 (CR3) in rats), F4/80 (in mice), and lectin-binding sugar molecules. Expression of phagocytic marker ED1 and antigen-presenting molecules major histocompatibility complex (MHC) class I and II is undetectable or very low in the ramified microglia under the normal brain.

Animal Models of Acute Neuronal Injury

Activation of microglia following acute neuronal injury has been studied in animal models of transection of nerve axons, injection of toxins, and ischemia. The neuronal injury by a stab or stroke breaks the BBB, leading to the influx of blood-derived monocytes and macrophages to the CNS parenchyma. It is impossible for the monocytes or macrophages to be distinguished from resident microglia. Transection of nerve axons, such as rodent facial, hypoglossal, or sciatic nerve and an entorhino-dentate perforant path projection, induces retrograde changes in the central nucleus of the axotomized neuron without BBB disruption and activates local microglia around the axotomized neurons. In axotomy of the facial nerve of adult rats, which includes transection of the facial nerve in the stylomastoid foramen distant from the facial nucleus in the brain stem, most of the facial motoneurons survive after nerve axotomy, and the activated microglia accumulate around the regenerating facial nucleus (Figure 3). On the contrary, neonatal axotomy induces massive degeneration and death of facial motoneurons to activate local microglia. The rat facial axotomy has been used as the most helpful model in research of the function of activated microglia in degeneration and regeneration of injured neurons.

Morphological Transformation

In the initial stage of activation ranging from minutes to a few hours following neuronal injury, microglia cause morphological changes with partial retraction and slight hypertrophy of the microglial processes, and they become bushy or rodlike cells. Clustering of the hyperramified microglia is recognized around the injured neuronal cell bodies 1–3 days following injury. In the case of extensive neuronal degeneration, especially in the later phase of the degenerative process, microglia may become large, round phagocytic cells called 'brain macrophages.'

Accumulation around Injured Neurons

One to three days following neuronal injury, activated microglia rapidly move and accumulate around the damaged structure like injured neurons or degenerating neurite terminals. These microglia directly contact with injured neuronal cell bodies, where they displace synaptic input, a phenomenon known as synaptic stripping. In the case of laser-induced focal tissue injury, processes of nearby microglia extend toward the lesion site. Within 30 min after laser ablation, the microglial processes reached the damaged site and appeared to accumulate and fuse together around the damaged area. Microglia establish a potential barrier between healthy and injured tissues, which may play a neuroprotective role for microglia.

Microglia activated by neuronal injury increase expression of the receptors for the microglial mitogens

Figure 1 A schematic summary of microglial response to neuronal injury. Neuronal injury induces a rapid transformation of resting (ramified) microglia to the activated form. Microglia change their morphology, migrate toward the injured sites, and proliferate and accumulate around the injured neurons. Activated microglia produce and release various molecules in response to several stimuli from surroundings. Cell death leads to a further transformation of microglia into phagocytic cells. Activated microglia also interact with the immune cells infiltrating through the blood–brain barrier. In parallel with the regeneration of neuronal cells, microglia gradually return to a resting state.

Figure 2 Ramified microglia in the adult rat cerebral cortex. A brain section was immunostained with an anti-Iba1 antibody.

macrophage colony-stimulating factor (M-CSF) and granulocyte macrophage colony-stimulating factor (GM-CSF), and they begin to proliferate. Mitotic activity in these cells reaches the maximum approximately 2–4 days after axotomy or during the anterograde degeneration.

Production of Bioactive Molecules

In parallel to their morphological transformation, microglia are also induced to upregulate constitutively expressed markers such as CD11b, F4/80, and Iba1, and they are stimulated to express MHC class I, CD45, CD4, and cell adhesion molecules such as intracellular adhesion molecule-1 (ICAM-1), very late antigen 4 (VLA-4), and the leukocyte function antigen-1 (LFA-1). The activated microglia also synthesize a number of cytokines, such as transforming growth factor (TGF-β1), interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α); growth factors, such as M-CSF, GM-CSF, and insulin-like growth factor (IGF-1); and chemokines, such as CCL2/MCP-1, CCL3/MIP-1α, CCL4/MIP-1β, CCL5/RANTES, CXCL10/IP-10, and CXCL1/fractalkine. Expression of the receptors for M-CSF, GM-CSF, and chemokines is upregulated in activated microglia, and they are involved in migration and proliferation of resident microglia. Molecules such as MHC class II and B7, which are involved in antigen presentation, are usually only expressed by subpopulations of the lesion-reactive microglia.

Phagocytosis

Neuronal cell death causes a further transformation of microglia into phagocytotic cells that remove neural debris. In neonatal rat facial nerve axotomy, microglia rapidly transform to phagocytes in parallel with the degeneration process of the axotomized motoneurons. Phagocytotic microglia express high levels of Fcγ receptors, B7, and MHC class I and II, which may serve as potent stimuli of T cell activation in the presence of specific antigen. The phagocytotic microglia can play a role in CNS antigen-presenting cells. On the other hand, microglia gradually decrease in number, lose activation markers, and revert to a resting state with ramified morphology in the absence of neuronal cell death. In adult rat facial nerve axotomy, microglia accumulate at the regenerating facial nucleus without turning into phagocytes.

(b) Low-magnification image of a brain stem section including the facial nucleus. A section from the brain stem 1 week after facial nerve axotomy of adult rats was immunostained with an anti-Iba1 antibody. (c) High-magnification image of the axotomized (left) and nonoperated side (right) of the facial nucleus.

Interaction with Immune Cells Recruited to the CNS

The entry of lymphocytes into the neural parenchyma is recognized 1 day after injury. In a mouse model of facial nerve axotomy, the response is limited to a small number of T lymphocytes and restricted to the reacting facial nerve nucleus. Invading lymphocytes produce interferon-γ and induce expression of MHC class II and inducible NO synthase in microglia. A direct mechanical injury with the BBB disruption leads to the massive influx of a variety of immune cell types, macrophages, neutrophils, and granulocytes, as well as T lymphocytes. They show numerous and rapid recruitment to the vasculature and parenchyma in the damaged brain. A disruption of the BBB gives the microglial access to the circulating proinflammatory molecules (TNF-α, IL-1, and lipopolysaccharide), which activates microglia. Various molecules produced by activated microglia, such as cytokines, chemokines, and cytotoxic factors, are likely to contribute to leukocyte recruitment and control of CNS inflammation.

Microtubule Associated Proteins in Neurons

L Cassimeris, Lehigh University, Bethlehem, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

From a cell biologist's perspective, a neuron represents an extreme cell shape with unique intracellular compartments. Neurons typically have a relatively small, round cell body with long projections of axons and dendrites extending from the cell body. These projections differ in structure; axons are of uniform caliber and do not have many branches, whereas dendrites have extensive branches. The axon and dendrite compartments are unique intracellular environments without membrane-based barriers to separate them from each other or the cell body. The ability of neurons to form projections and maintain their functions requires the cytoskeleton, with the microtubule cytoskeleton playing a critical role in both growth and maintenance of the neuronal cell.

Microtubules are polymers that are required for a number of functions relevant to terminally differentiated neurons, including vesicle and organelle motility, cell polarity, and cell motility. The hollow microtubule is assembled from 13 linear chains of alpha/beta tubulin heterodimers; each linear chain is termed a protofilament. Within each protofilament, the dimers bind to each other in a head-to-tail orientation. Protofilaments bind to each other around a central open lumen, forming a polarized tube structure having two structurally different ends. These two ends are referred to as plus (beta tubulins exposed at the end) and minus (alpha tubulins exposed at the end).

The organization of microtubules differs in axons and dendrites. In each compartment, microtubules do not extend for the entire length of the projection but instead are found as numerous overlapping polymers. In axons, the microtubules all face in the same direction, with the plus ends all facing the distal end of the projection. In contrast, dendrites are filled with microtubules of mixed polarity: some have their plus ends facing the distal end of the projection, and others have their minus ends facing this direction.

Microtubule Dynamic Turnover

Microtubules continually convert between a growing state, in which subunits add to the end of the microtubule, and a shortening state, in which the protofilaments peel away from each other and fall apart, releasing individual dimers into the cytoplasm. This process is called dynamic instability to reflect the unstable character of microtubules. Dynamic instability is a nonequilibrium process and requires energy input. The energy comes from assembly of tubulin dimers bound to guanosine triphosphate (GTP). Hydrolysis of GTP to guanosine diphosphate (GDP) follows assembly, making the bulk of the microtubule composed of tubulin-GDP. The microtubule plus end is the faster growing end, and it is also more dynamic, switching to shortening and back to growth more frequently than does the minus end. In most cells, the minus end is attached to the centrosome and is not dynamic. Neurons are unique in having large numbers of microtubules with free plus and minus ends in their axons and dendrites. Under some conditions, microtubules in cells can also show net assembly at one end and net disassembly at the other, a process termed treadmilling.

Microtubule-Associated Proteins Regulate Microtubule Dynamics

For many microtubule-based functions in the neuron, such as providing tracks for vesicle transport, it is important for microtubules to remain stable and not depolymerize. In other cases, such as extension of the growth cone, microtubules must be highly dynamic and able to remodel quickly. Cells use a number of associated proteins to modify microtubule assembly, making them more or less dynamic to fit these specific cell tasks. Several microtubule-associated proteins (MAPs) are expressed only in neurons, and these can be localized specifically to either axons or dendrites. This article will summarize general features of MAPs and outline how MAPs contribute to neuron function and how genetic defects in MAPs contribute to neuronal disease.

The definition used to classify a protein as a MAP has changed over the years. Originally, MAPs were defined as proteins that cofractionate with microtubules during purification or proteins that co-localize with microtubules in cells. For this article, the definition of MAPs is proteins that modify microtubule assembly by binding either to the microtubule lattice or to soluble tubulin subunits. Besides regulating microtubule assembly, MAPs also function to define the spacing between microtubules, to regulate organelle motility, and to serve as scaffold proteins to anchor kinases and phosphatases to the microtubules.

MAPs can be broadly divided into two classes of regulatory proteins depending on whether they stabilize or destabilize microtubules. Stabilization means that the MAP either promotes polymer assembly or prevents polymer disassembly. Stabilizing MAPs

include MAP1, MAP2, doublecortin, and tau. Microtubule destabilizing proteins favor loss of tubulin dimers from microtubules. They act either by preventing new dimers from adding to the polymer, by stimulating catastrophes at microtubule ends, or by severing microtubules into pieces. Examples of destabilizing proteins include stathmin and katanin. By shifting the balance between active stabilizers and destabilizers, cells can regulate the dynamic turnover of microtubules and the amount of tubulin subunits assembled into polymers. Mutations in genes encoding either microtubule stabilizers or destabilizers lead to neuronal diseases, indicating that regulation of the microtubule cytoskeleton's dynamic turnover is critically important for cell and tissue health. The stabilizing and destabilizing MAPs are described in more detail below.

Assays to Monitor MAP Functions

MAPs were first isolated from brain tissue, and their ability to regulate microtubule assembly was measured using *in vitro* assays combining purified tubulin with purified MAP fractions. Several relatively straightforward but low-resolution assays can be used to measure tubulin assembly into microtubules and determine whether a specific MAP promotes or inhibits microtubule polymerization. A common spectrophotometric assay measures light scattering by microtubules; the amount of light scattering is proportional to the amount of microtubule formation. Often microtubule assembly is 'seeded' by adding a tiny number of preassembled microtubules to serve as nucleation sites for polymerization. MAP fractions can be assayed for their ability to speed or inhibit polymerization over 30 min or less. Microtubule assembly has also been monitored by measuring the quantity of microtubules pelleted by centrifugation. Each of these assays measures the total quantity of microtubules formed but does not give any information on the function of the MAP at the resolution of an individual microtubule.

Higher-resolution assays use microscopy to examine microtubule assembly in fixed samples taken at time points or to follow the assembly of individual microtubules in real time. Samples of microtubules and MAPs can be fixed and pelleted onto coverslips, stained with antitubulin and/or anti-MAP antibodies, and examined by fluorescence microscopy. Alternatively, fixed samples can be applied to electron microscopy grids and examined after negative staining. In these assays, it is possible to differentiate between MAPs that stimulate polymerization of long microtubules from those that act by nucleating many short microtubules or those that bundle microtubules.

To understand how a MAP regulates dynamic instability, it is best to watch microtubule dynamics in real time. Individual microtubules can be viewed by high-resolution differential interference contrast (DIC) microscopy and their length changes followed over time. Microtubules also can be visualized by fluorescence microscopy in samples containing small amounts of fluorescently tagged tubulin. By following individual microtubules as they grow and shorten in the presence of a purified MAP, one can figure out how a MAP modifies dynamic instability. While assays with purified components are critical for determining mechanisms at the molecular level, it is also important to measure MAP function in the context of a cell or organ.

Cell-based assays of MAP function use either nonneuronal cell lines or explanted neurons grown in culture. To visualize microtubule assembly, cells are engineered to express green fluorescent protein (GFP)-alpha tubulin. Images of a small region of the cell are collected at time points to record the dynamic turnover of microtubules. Cells can be modified to overexpress a MAP (typically in nonneuronal cells) or to decrease expression of a MAP. In this way, the MAP's effects on microtubule assembly can be monitored.

Expression of neuronal MAPs in nonneuronal cells can give clues to MAP function simply through examination of the morphology of the cell or the organization of microtubules in the cell. For example, long, axonlike projections filled with microtubules form in fibroblast cells expressing tau. Likewise, blocking tau expression in neuronal cells results in loss of both axon formation and growth cone motility.

MAP functions are also assayed in the context of the organism, where a protein's function during neuronal development or aging can be determined. Vertebrate MAPs have been examined in mice by gene knockout. *Drosophila* is also used as a model organism for study of MAP function in neurogenesis.

Many Stabilizing MAPs Bind to the Sides of Microtubules

The best-characterized stabilizing MAPs, including MAP2 and tau, bind to the sides of microtubules through a conserved microtubule binding domain. MAP2 and tau have similar microtubule binding domains, including the conserved sequence KXGS. Tau protein isoforms, generated by alternative splicing, vary in the number of microtubule binding domains, having either three or four microtubule binding repeats. Not surprisingly, those isoforms with four binding domains are more potent microtubule stabilizers than those having only three repeats. In addition to the microtubule binding domain, stabilizing MAPs often have a projection domain that extends out from the microtubule surface (**Figure 1**). This projection domain can regulate the spacing between microtubules

Figure 1 Microtubule-associated proteins (MAPs) stabilize or destabilize microtubules. (a) Several classes of MAPs interact with the microtubule. Stabilizing MAPs (e.g., MAP2 or tau) bind to the side of the microtubule. +TIPs associate with growing microtubule ends. Severing proteins cut the polymer into pieces. Depolymerizing kinesins disrupt the structure of the microtubule end. Stathmin binds to tubulin dimers (shown as black and gray balls) to limit polymerization. (b) Hypothetical curves of microtubule (MT) dynamic instability in the presence of stabilizing or destabilizing MAPs. The lengths of the hypothetical microtubules are shown over a timescale of several minutes.

or between microtubules and either neurofilaments or actin filaments.

MAP2 and tau compete with the motor proteins kinesin and dynein for binding to microtubules. In this way, MAP binding to microtubules can inhibit the ability of these motor proteins to transport vesicle or organelle cargos by blocking motor access to the microtubule. In experiments involving overexpression of tau, motility in the direction of microtubule plus ends (anterograde movement in the axon) is more sensitive to excess tau than retrograde movement toward microtubule minus ends.

While MAP2 and tau share a similar microtubule binding domain, they differ at the cellular level by their localizations to different compartments in the neuron. MAP2 is found in dendrites, while tau is found in axons. Consistent with these unique localizations, mice deficient in MAP2 have defects in dendrites, and those deficient in tau have defects in small-caliber axons. Mice lacking tau show an increased expression of another wall-binding MAP, MAP1A, which may explain how their nervous system is able to develop normally, perhaps using MAP1A to compensate for the loss of tau.

MAP1A and 1B are large proteins encoded on two separate genes.These polypeptides associate with smaller polypeptides, the light chains LC1, LC2, and LC3. MAP1A and 1B also bind to the sides of microtubules and stabilize them, although they are not as potent microtubule stabilizers as MAP2 and tau are.

MAP1B is the first MAP detected during neurogenesis and is required for nervous system development in mice. MAP1B levels are low in the adult central nervous system but remain high in the peripheral nervous system. This MAP is found throughout the nerve cell, with the highest concentration at the distal end of the axon.

In localization and expression levels during development, MAP1A is opposite of MAP1B. MAP1A is present in adult neurons at a concentration tenfold that of its level during development. Like MAP1B, MAP1A is found throughout the nerve cell, but MAP1A is present at higher levels in dendrites.

The final wall-binding MAP considered here is doublecortin. Doublecortin is one of several proteins linked to lissencephaly, a severe disease resulting from loss of cortical neuron migration during brain development. Doublecortin associates with microtubules through a pair of binding domains and stimulates microtubule polymerization. Mutations that result in lissencephaly are located in the microtubule binding domains of doublecortin, suggesting that the disease results from a disruption of the microtubule cytoskeleton.

Several other gene mutations give rise to lissencephaly, including mutations in genes encoding LIS1, a regulator of the microtubule-based motor dynein and

alpha-1 tubulin, a subunit of microtubules. The ability of mutations in these genes to cause lissencephaly indicates that the microtubule cytoskeleton plays a critical role in neuronal migration. It should be noted that mutations in the gene encoding reelin, an extracellular matrix protein, also result in lissencephaly.

Regulation of Wall-Binding MAPs

In general, the wall-binding MAPs are regulated by phosphorylation. Phosphorylation adds negatively charged phosphate groups to the MAP and reduces MAP binding to the microtubule, reducing the microtubule stabilizing function of MAPs (Figure 1). Phosphorylation also changes the structure of tau from a flexible protein in the dephosphorylated state to a stiffer protein when phosphorylated. Whether other MAPs undergo structural changes with phosphorylation is not known.

A large number of kinases phosphorylate MAP1, 2, and tau. For example, MAP2 is phosphorylated by protein kinase A, calcium/calmodulin-dependent protein kinase II (CaMKII), protein kinase C, extracellular signal-regulated kinases, glycogen synthase kinases, cyclin-dependent kinases, and MAP/microtubule affinity regulating kinases (MARKs). MARKs recognize the KXGS sequence found in the microtubule binding domain of MAP2 and tau and thus disrupt MAP binding to microtubules. Tau is also phosphorylated by a number of kinases, including the c-Jun N-terminal kinase (JNK) family of stress kinases. Tau phosphorylation downstream of JNK is likely important during the hyperphosphorylation of tau in Alzheimer's disease.

Several factors determine the phosphorylation state of each MAP. First, some kinases and phosphatases have specific subcellular localizations within the neuron, which limits their MAP targets to those present in that part of the cell. For example, both MAP2 and tau are phosphorylated by CaMKII *in vitro*, but only MAP2 should be phosphorylated in cells because both MAP2 and this kinase are found in dendrites. Second, kinases and phosphatases bind to the microtubule cytoskeleton by associating with MAPs, which localizes enzyme activity near their MAP substrates.

MAP phosphorylation is also linked to disease. Tau is hyperphosphorylated, which causes it to aggregate and form filaments, in Alzheimer's disease, Pick's disease, frontotemporal dementia with parkinsonism linked to chromosome 17, and several other diseases. The cause of tau hyperphosphorylation and the pathological consequences of this hyperphosphorylation are presently under study. One model has recently suggested that tau is first expressed at higher than normal levels (for reasons unknown), which inhibits the ability of motor proteins to transport vesicles on microtubules. In this model, the cell responds by hyperphosphorylating tau to release it from the microtubules, but the loss of tau from the microtubule reduces microtubule stability and leads to neurodegeneration.

In addition to phosphorylation, the wall-binding MAPs can be regulated by a nonenzymatic protein termed mapmodulin. Mapmodulin binds MAPs 1B, 2, and tau and preferentially binds to soluble MAPs, compared with those bound to microtubules. It is interesting to note that mapmodulin may sequester MAPs and prevent them from binding to microtubules. One hypothesized function for mapmodulin is to displace MAPs from microtubules to enhance motor protein-driven transport of vesicles along microtubules.

MAP Binding to Microtubule Plus Ends

A growing number of MAPs have been identified that associate with growing ends of microtubules (as comets 1–2 μm in length at the microtubule end). Collectively, these MAPs are called +TIPs to denote their association with microtubule plus ends. Some +TIPs bind directly to the assembling microtubule end, perhaps in association with incoming tubulin dimers. Other +TIPs hitch a ride by binding those proteins interacting directly with the growing microtubule end. The +TIPs bind for a short time and then dissociate from the microtubule (Figure 1). In this way, individual proteins remain stationary as the microtubule end grows; these MAPs do not move with the growing microtubule.

In general, the +TIPs stabilize the growing microtubule plus end. For example, the +TIP CLIP170 stimulates microtubule rescues, promoting the transition from a shortening state back to a growing state. CLIP170-associated protein (CLASP) has a similar function, while adenomatous polyposis coli inhibits catastrophes. These +TIPs often bind to a subset of microtubules, allowing the cell to regulate the dynamics of this subset differently from other microtubules in the same cytoplasm.

By binding to growing microtubule plus ends, the +TIPs can also localize additional proteins to this domain. The minus end-directed motor dynein and its accessory complex dynactin bind to microtubule plus ends through their interaction with CLIP170. One current model suggests that binding of dynein/dynactin to the microtubule plus end transports this motor complex to the periphery of cells, where the motor complex can pick up vesicles for delivery back to the center of the cell.

Microtubule Destabilizing Proteins

By destabilizing microtubules, this broad group of proteins likely increases microtubule turnover in cells, allowing the microtubule cytoskeleton to reorganize quickly. As mentioned above, the destabilizing proteins can act by one of three general mechanisms: sequester tubulin dimers and prevent their polymerization, disrupt the structure at the microtubule end to favor disassembly, or cut microtubules into smaller pieces.

Stathmin (also known as Oncoprotein 18) is a small cytosolic protein that binds to tubulin dimers rather than to microtubules. Each stathmin binds two tubulin dimers, preventing those dimers from polymerizing, resulting in destabilization of microtubules (Figure 1). By an unknown mechanism, stathmin can also function as a catastrophe promoter and stimulate microtubules to shorten. Stathmin may interact with tubulin dimers at the end of the microtubule and favor the splaying conformation of shortening microtubules. This latter model is consistent with the structure of the stathmin/tubulin complex but has not been demonstrated experimentally.

Stathmin is expressed ubiquitously, but several proteins related to stathmin are expressed specifically in the nervous system. These neuronal stathmin family proteins, SCG10, SCLIP, and RB3, all contain a conserved region homologous to stathmin and additional extensions that target them to membranes (golgi apparatus or secretory vesicles). Each of the neuronal proteins binds tubulin dimers and destabilizes microtubules, although the affinity of each protein for tubulin is different.

Each stathmin family member is likely to have a unique function in the brain, a conclusion based on the phenotypes of mice lacking specific proteins or on cell-based assays of protein function. Experiments in cultured neurons have demonstrated that SCG10 and SCLIP are required to control growth cone expansion and axon branching, respectively. In contrast, mice lacking stathmin are viable, but their axons lose integrity as they age. It is interesting that stathmin –/– mice have revealed a role for this protein in controlling both learned and innate fear. How the microtubule cytoskeleton contributes to fear responses is not yet apparent.

Members of the kinesin-13 subfamily also cause microtubule depolymerization. Unlike other members of the kinesin family, the kinesin-13 proteins do not possess motor activity. Instead, they use adenosine 5′-triphosphate (ATP) hydrolysis to disrupt the structure of microtubule tips, stimulating microtubules to depolymerize (Figure 1).

Kif2a, a kinesin-13 protein, functions as a microtubule depolymerizing protein in neurons. Mice lacking Kif2a have brains with numerous defects and die within a day of birth. Microtubules are less dynamic in the growth cones of neurons from the Kif2a knockout mouse. Neurons also show defects in migration during development.

Two members of the large AAA ATPase family of proteins, katanin and spastin, destabilize microtubules by cutting them perpendicular to the microtubule's long axis. Without stabilizing MAPs bound to the sides of the microtubules, these cut fragments would rapidly depolymerize. To sever a microtubule, six kananin polypeptides form a ring surrounding it and then use ATP hydrolysis to somehow break tubulin–tubulin contacts within it (Figure 1).

Spastin also functions to sever microtubules. Spastin is so named because mutations in the spastin gene are associated with hereditary spastic paraplegia. Loss of spastin expression reduces the density of microtubules in axons and at synaptic boutons, opposite to what one might expect at first glance after loss of a severing protein. The phenotype of cells lacking spastin suggests that spastin contributes to microtubule density, perhaps by generating small microtubule fragments that serve as templates for formation of longer microtubules. Stabilizing MAPs must also protect the severed fragments from depolymerization.

Concluding Remarks

The term MAP describes a number of different proteins that function to regulate microtubule assembly. These proteins regulate the assembly dynamics of microtubules to either temper the dynamics and stabilize the microtubule or enhance the dynamics to speed microtubule turnover. Expression levels of MAPs and the regulation of their activities contribute to the stability and organization of the microtubule cytoskeleton in neurons. MAP activities can be regulated within subdomains of the cell, setting up unique microtubule populations in different areas of the cell.

The microtubule cytoskeleton does not function alone in providing support for neuronal cell processes. Neurofilaments and actin filaments also play critical roles in the neuron. MAPs likely also mediate some of the cross talk between cytoskeletal filaments. In particular, MAP2c and MAP1 are able to bind both microtubules and actin filaments.

Several recent studies have highlighted the role of MAP mutations in causing human disease, particularly diseases resulting in developmental defects in brain development. Further study of how MAPs contribute to neuron development and migration are needed to understand these processes.

Introduction

Neurons are one of the most remarkable cells in nature. They are the cell type whose exaggerated morphology is most intimately associated with its unique functions. A typical vertebrate neuron consists of a rounded cell body (located in the brain, spinal cord, or peripheral ganglion), several dendrites, and a single elongated axon. The axon is highly specialized to transmit information outward, while the dendrites form a receptive field for the uptake of information. The axon is effectively unlimited in its growth potential and can traverse great distances within the body, extending, for example, from the spinal cord to the fingertips. Dendrites, by contrast, are generally short, stout, and highly branched. In addition to these morphological differences, axons and dendrites also differ compositionally. Axons contain only a subset of the organelles found in the cell body, while dendrites generally contain all the same types of organelles as the cell body does. Most protein synthesis and organelle biogenesis occur within the cell body of the neuron, thus demanding highly sophisticated mechanisms for actively transporting specific proteins and organelles into each type of process. During development, there is a great deal of motility involved in the wiring of the nervous system, so that the cell bodies of the neurons arrive at their proper locations and so that the tips of axons reach their appropriate target tissues. Thus, a number of challenges must be met in order for neurons to establish and maintain their high degree of morphological, functional, and compositional polarity. Meeting these challenges depends on tightly regulated architectural elements within the neuron and sophisticated mechanisms of transport and motility.

The architectural elements of the neuron consist of three cytoskeletal filaments: microtubules, actin filaments, and intermediate filaments. Together, these three filaments are responsible for the generation of neuronal morphology and function. Microtubules are particularly important for the architecture of axons and dendrites and for the specific and directional transport of proteins and organelles within these processes. Over the past few decades, enormous progress has been made in understanding the central role of microtubules in serving these functions. Microtubules are classically known as 'spindle fibers' because they are the filaments that comprise the mitotic spindle during cell division. It is interesting that microtubules are extremely abundant in neurons, even though neurons are terminally postmitotic cells that no longer form mitotic spindles. Microtubules occupy axons and dendrites as paraxially aligned arrays. These microtubule arrays provide a structural backbone for axons and dendrites that allows them to acquire and maintain their specialized morphologies. In addition, microtubules are the major railways along which proteins and organelles are actively transported in both directions within axons and dendrites. Microtubules are also critically important for early developmental stages of the neuron, such as migration of the cell body and the cue-dependent pathfinding of the growth cone at the tip of the elongating axon. A vast array of accessory proteins regulate the properties and functions of microtubules during development and throughout the life of the neuron. Mutations and flaws in the regulation of some of these microtubule-related proteins give rise to major neuropathies that plague the human population.

Organization of Neuronal Microtubules

Microtubules are hollow polymers made up of tubulin subunits. Neurons, like other eukaryotic cells, contain a pool of free tubulin subunits and a pool of the microtubule polymers. These two pools dynamically exchange with one another such that microtubules undergo bouts of assembly and disassembly. Tubulin is a heterodimer consisting of an alpha subunit and a beta subunit. Because the two subunits are different, the microtubule is an intrinsically polar filament. One end, termed the plus end, is favored for the addition and subtraction of subunits, while the other end, termed the minus end, is less favored for these dynamics. The assembly properties of a microtubule are defined by a mechanism called dynamic instability, in which rapid bouts of assembly and disassembly are ultimately attenuated by molecules that selectively stabilize certain microtubules within the array. Neurons are rich in molecules that can stabilize microtubules, as well as other molecules that can destabilize microtubules and promote their disassembly. Tight control over microtubule assembly, disassembly, stabilization, and destabilization (i.e., 'microtubule dynamics') is one key means by which neurons change the configuration of microtubules during critical stages of development. Regulation of microtubule dynamics is particularly important for rapid changes in neuronal morphology and motility,

a good example of which is the turning of the growth cone in response to environmental cues that guide it to its target.

It is important to realize that the polarity of the microtubule is not manifest only at its two ends but also exists all along the length of the polymer. This structural polarity is recognized by a class of enzymes called molecular motor proteins that 'walk' along the surface of the microtubule. Cytoplasmic dynein walks toward the minus end of the microtubule, while most members of the kinesin superfamily walk toward the plus end of the microtubule. A few unusual kinesins walk toward the minus end (Figure 1(a)). Each molecular motor protein can potentially interact with different types of 'cargo' to be moved along the polymer. Thus, the organization of microtubules relative to their polarity is key to the directionality with which different cytoplasmic constituents are transported. In the axon, microtubules have a uniform polarity orientation, with their plus ends directed away from the cell body toward the axonal tip (Figure 1(b)). By contrast, dendritic microtubules have a mixed, or nonuniform, polarity orientation, with roughly equal numbers of microtubules directed each way (Figure 1(b)). These distinct microtubule polarity patterns are one of the most essential and earliest differences to arise between axons and dendrites and are almost certainly responsible for many of the compositional and morphological differences that distinguish the two types of processes. For example, dendrites contain Golgi stacks and axons do not, because Golgi elements are transported toward minus ends of microtubules by cytoplasmic dynein. Axons may become longer and more slender than dendrites because vesicular organelles that expand the membrane have a unidirectional vector to the tip of the growing axon via their plus-end-distal microtubules, while the same is not true of dendrites. It should be noted that, despite the enormous influence of microtubule polarity patterns on neuronal morphology and organelle distribution, the distinct polarity patterns of axonal and dendritic microtubules cannot explain all aspects of neuronal polarity. For example, some molecular motors transport cargo toward plus ends of microtubules into one type of process but not the other, even though both axons and dendrites contain microtubules with a plus-end-distal orientation.

Axonal and dendritic microtubules also differ compositionally, for example with regard to the complements of fibrous microtubule-associated proteins (MAPs) that decorate each type of microtubule. Fibrous MAPs are one category of microtubule-regulatory protein; these MAPs consist of a microtubule-binding domain as well as a domain the projects away from the microtubule. MAPs bind along the surface of the microtubule and can influence properties of the microtubule, such as its stability, stiffness, and interactions with other cytoskeletal elements, such as actin filaments. Axonal microtubules are particularly rich in the MAP termed tau, and dendritic microtubules are rich in MAP2. These different MAPs are known to space the microtubules more closely in axons and farther apart from one another in dendrites because

Figure 1 Neuronal microtubule organization. (a) By reading the polarity of the microtubule, molecular motor proteins are able to move along the microtubule surface toward either the plus end or the minus end. Cytoplasmic dynein moves toward the minus end, and most members of the kinesin superfamily move toward the plus end. (b) Microtubules in the axon are uniformly oriented with plus ends distal to the cell body, whereas microtubules in dendrites are nonuniformly oriented. At sites of branch formation, microtubules in the parent axon are severed into short pieces, some of which transit into the new branch with plus ends outward. In growth cones, short and long microtubules extend, plus ends outward, into filopodia.

MAP2 has a longer projection domain than tau does. In addition, the enrichment of tau in axons is relevant to a number of pathologies, termed 'tauophathies,' in which the tau molecules become hyperphosphorylated and lose their association with the microtubules. The dissociated tau often forms abnormal filaments that are detrimental to the health of the axon. For example, tau forms the 'neurofibrillary tangles' that are a hallmark feature of Alzheimer's disease.

There is great interest in understanding the mechanisms by which neurons organize microtubules into the distinct patterns that characterize axons and dendrites. In simple nonneuronal cells, microtubules are generally organized by structures such as the centrosome, which act as nucleation sites for the formation of the microtubules. The microtubules elongate, with the plus end growing away from the centrosome and the minus end associated with the centrosome. This generates an orderly array of uniformly oriented microtubules. In neurons, microtubules are also nucleated at the centrosome (located in the cell body of the neuron), but the microtubules are then severed from the centrosome so that they can be deployed into axons and dendrites. The microtubules are deployed by molecular motor proteins that move the microtubules specifically with either their plus end leading (into axons and dendrites) or with their minus end leading (into dendrites only). Thus, in neurons, the organization of microtubules relative to their polarity is determined, not by the attachment of the microtubules to their sites of nucleation, but instead by the forces that transport them into each type of neuronal process.

Another critically important feature of the neuronal microtubule arrays is that each array consists of individual microtubules that assume a variety of different lengths. The array of microtubules within an axon or dendrite extends from the cell body to the tip of the process, but individual microtubules generally do not traverse the entire length of the process. Some microtubules are extremely short, only a few micrometers in length, and other microtubules can achieve great lengths, exceeding a hundred micrometers or even hundreds of micrometers in longer axons. The longer microtubules are important for two reasons: they act as architectural struts that oppose the propensity of the axon or dendrite to retract, and they act as major long-distance railways for organelle transport. The short microtubules are important because they are highly mobile and provide the means by which tubulin is actively transported down the axon.

Axonal and Dendritic Transport

For decades, axons were considered to be incapable of sustaining local protein synthesis. Today we know that small amounts of certain proteins are synthesized in axons, at least during development. Local protein synthesis can be quite important for events such as growth cone navigation. Even so, most of the proteins destined for the axon are synthesized in the cell body and then actively transported down the length of the axon. In addition to this anterograde transport, retrograde transport moves substances from the axonal tip back toward the cell body. Retrograde transport includes endocytosed materials such as growth factors and also substances destined for degradation within the lysosomes of the cell body. Microtubules are the major railways for membrane-bound vesicular organelles (and the proteins associated with the vesicles) moving in either the anterograde or retrograde direction. Members of the kinesin superfamily provide the forces necessary for anterograde transport of these vesicular organelles, while cytoplasmic dynein is the motor for their retrograde transport. This type of transport is known as fast axonal transport and occurs at rates of about 50–400 mm per day, with larger organelles such as mitochondria moving more slowly and smaller organelles moving more quickly. Over shorter distances, similar transport can occur along actin filaments, but it is the microtubule array of the axon that serves as the major long-distance highways for fast axonal transport (**Figure 2(a)**).

The other type of axonal transport, termed slow axonal transport, has been far more controversial over the years and has proven more difficult to study mechanistically. Slow axonal transport is the transport of the cytoskeletal proteins themselves, together with their associated proteins (such as tau, for example) and a vast array of 'soluble' proteins such as cytosolic enzymes. This type of transport was originally termed 'slow' because the rate at which these proteins are conveyed down the axon was determined to be many times slower than fast transport. Transport rates were originally determined using a biochemical technique in which newly synthesized proteins are allowed to incorporate radiolabeled amino acids, after which the levels of the proteins that incorporate the label are assessed as they progress down the axon. On the basis of the slow rate, it was hypothesized that the cytoskeleton marches coherently down the axon in the form of polymers, together with their associated cytoskeletal proteins. Microtubules and neurofilaments move at roughly the same rate (0.2–1 mm per day), and actin moves a bit faster (2–8 mm per day). It was posited that the 'soluble' proteins somehow affiliate with the actin cytoskeleton and hence move at roughly the same rate as actin. This model for slow axonal transport, proposed in the early 1980s, met with numerous challenges over the ensuing decades because live-cell imaging studies failed to reveal the slow, coherent march of cytoskeletal polymers down the axon.

Figure 2 Axonal transport. (a) Fast axonal transport involves concerted movement of vesicular cargo by molecular motor proteins along microtubules. This type of transport occurs at rates of 50–400 mm per day, depending on the size of the particular cargo being moved. Kinesins are responsible for anterograde fast transport of organelles, which may contain proteins important for cell growth and/or growth cone navigation. Retrograde fast axonal transport is mediated by cytoplasmic dynein, which is responsible for moving structures destined for degradation, as well as packaged growth factors, to the cell body. (b) Slow axonal transport is the transport of the cytoskeletal elements and their associated proteins, as well as a variety of cytosolic proteins. The term 'slow axonal transport' was given to this type of motor-driven movement on the basis of early studies, in which microtubules and neurofilaments were documented to move at rates of 0.2–1 mm per day, much slower than rates of fast axonal transport. More-recent analyses have revealed that the movements of individual cytoskeletal elements are rapid, intermittent, and bidirectional, such that the average rate is slow although individual movements are actually quite fast. Under the current model for slow axonal transport, cytoplasmic dynein transports short microtubules (by generating forces against both long microtubules and the actin cytoskeleton) in the anterograde direction while also mediating the retrograde transport of neurofilaments against long microtubules. Kinesin motors transport neurofilaments anterogradely and short microtubules retrogradely (by generating forces against long microtubules). Little is known about the mechanisms of actin transport.

The past few years have seen a revolution in the mechanistic understanding of slow axonal transport, in large part owing to direct studies on microtubule behaviors in cultured neurons. More-sophisticated live-cell imaging approaches have revealed that microtubules and neurofilament polymers are indeed in transit down the axon. However, these studies showed that the polymers are not transported coherently or slowly but rather very asynchronously and quite rapidly. When they move, microtubules and

neurofilaments are transported at rates similar to those for fast axonal transport. However, most of the polymers are immobile for prolonged periods. Thus, slow axonal transport is an average of a small number of intermittent fast movements and a great deal of nonmovement, or 'pausing,' of the polymers. It is interesting that the microtubules that are transported are particularly short, usually on the order of 5–7 μm or shorter (Figure 2(b)). As noted earlier, microtubules in the axon assume a variety of lengths. Presumably, some of the short microtubules that are actively transported can disassemble to provide subunits for the elongation of other microtubules. Other short microtubules can elongate and thereby become immobile. In order for long microtubules to resume movement, they need to be cut into pieces that are shorter than the threshold for transport, which appears to be about 7 μm. The process of microtubule severing, therefore, is a critical determinant of where and when microtubules are most avidly transported. For example, when axonal branches form, microtubules are severed within the parent axon at the site of branch formation so that large numbers of short microtubules can transit into the new branch (Figure 1(b)). The major microtubule-severing proteins in the neuron are enzymes called katanin and spastin. Abnormalities to spastin can lead to the neuropathy known as spastic paraplegia.

Of course, there is also dendritic transport, but transport of organelles and proteins within dendrites is far less studied than their transport in axons. The abundant presence of ribosomes and Golgi elements within dendrites introduces the possibility for more local protein synthesis and processing than in the axon. Even so, only certain proteins are locally synthesized in dendrites (e.g., tubulin is not), and typical organelles are simply too large to diffuse. Dendritic transport probably utilizes machinery to similar to that of axonal transport, but the traffic would presumably be more complex because the microtubules are nonuniformly oriented in dendrites. As noted earlier, the lack of a unidirectionally polarized microtubule array may explain why dendrites remain short whereas axons appear to be effectively unlimited in their growth potential. In the dendrite, for example, certain organelles may tend to move back and forth rather than unidirectionally to the tip of the process, as is the case with the axon. Slow axonal transport is certainly also more complex in dendrites, given that microtubules would have to move into the dendrites with two different polarity orientations.

Motors Organize and Generate the Neuronal Microtubule Arrays

The profound importance of neuronal microtubules raises the question of how the microtubule arrays of axons and dendrites are established during the development of the nervous system and how they are regulated throughout the lifetime of the neuron. Studies on these mechanisms have been an active topic of research over the past two decades. As noted earlier, the machinery that establishes the microtubule polarity patterns of axons and dendrites is essentially the same as the machinery that continuously supplies microtubules to these processes throughout the life of the neuron. Microtubules originate at the centrosome and are oriented by molecular motors that convey them specifically with one or the other end of the microtubule leading. The transport of the microtubules occurs via motors that generate forces against structures with more resistance to movement in the opposite direction than the direction in which the microtubule is able to move. Microtubules are thought to move via motors pushing against either actin filaments or longer, immobile microtubules.

Ongoing studies are aimed at identifying precisely which motors are responsible for transporting microtubules in various compartments of the neuron. Cytoplasmic dynein appears to be the primary motor responsible for transporting microtubules with their plus ends leading. Because all motion is relative, a short microtubule will move with its plus end leading when cytoplasmic dynein pushes against a cargo with greater resistance to movement than the short microtubule. The microtubules within axons and the plus-end-distal microtubules in dendrites are thought to be transported in this fashion. The minus-end-distal microtubules are conveyed into dendrites by a kinesin motor called CHO1/MKLP1, which transports microtubules with their minus ends leading by pushing against microtubules of the opposite orientation. It is interesting that this motor was originally believed to be specific to the mitotic spindle, where it localizes to a region of overlap between oppositely oriented microtubules. More recently, at least two other kinesin motors (namely, Eg5 and Kif15) originally identified in the mitotic spindle have now been found to be components of the neuronal microtubule arrays. These kinesins have microtubule binding motifs outside the motor domain and are specialized for generating forces between two microtubules rather than between a microtubule and a vesicular organelle. The use of these motors in neurons suggests that the same type of motor-driven forces that organize and transport microtubules during the formation and functioning of the mitotic spindle are also important for the transport, organization, and regulation of the postmitotic microtubule arrays in axons and dendrites.

A variation on this theme occurs during the process of neuronal migration. During development, many types of neurons undergo significant movement

from their sites of birth to their ultimate destinations; this movement involves translocation of the cell body, not just process outgrowth. The migration of the neuron requires force generation within the cytoskeleton, and these forces may be a variation of the same forces that fuel slow axonal transport. Most microtubules apparently remain attached to the centrosome during neuronal migration and are far more cross-linked with each other than in a neuron with a stationary cell body and growing axon. The cell body extends a 'leading process' containing microtubules, many of which remain attached to the centrosome. Instead of individual microtubules moving independently, the same motor-driven forces that would otherwise transport the microtubules during axonal outgrowth are utilized to tow the centrosome and nucleus along, thus causing the cell body of the neuron to move along with the microtubule array. Such movements also require a cage of microtubules around the nucleus to ensure that the nucleus moves in unison with the leading process, as well as actomyosin-driven forces within the leading process.

More Proteins That Regulate Neuronal Microtubules

As noted earlier, fibrous MAPs are another major factor in the organization and regulation of the neuronal microtubule arrays. MAPs are important for microtubule transport for many reasons; they can influence how motor proteins interact with microtubules; they can stabilize microtubules so that they do not simply depolymerize once released from the centrosome; and they can regulate the access of severing proteins to the microtubule lattice. In particular, tau has been identified as an important determinant of microtubule severing in the axon because microtubules rich in tau are far less accessible to the severing proteins. This may relate to why the axonal microtubule array degenerates in tauopathies such as Alzheimer's disease, given that the microtubules would fall victim to uncontrolled severing once the tau has been dissociated from the microtubule. In addition, because tau's association with microtubules can be tightly regulated by phosphorylation and dephosphorylation, it is appealing to speculate that microtubule severing might be regulated locally, for example at axonal branch sites, by signaling cascades that determine whether tau is bound to the microtubules. MAP1b is another important MAP that is particularly important for regulating the plasticity of the microtubule array during axonal growth and has some functions that overlap with those of tau. These ideas are useful to contemplate because they demonstrate how a variety of different microtubule-related proteins can work cooperatively to regulate the neuronal microtubule arrays and because they also illustrate how flaws in any of the microtubule-related proteins can give rise to severe pathological problems.

Motors, MAPs, and severing proteins only scratch the surface of the enormous array of molecules that interact with the microtubule arrays of the neuron. For example, there are microtubule stabilizing proteins that are generally not considered to be traditional fibrous MAPs, and these include stable tubule only protein, doublecortin, and a family of cross-linker proteins called plakins. There are proteins such as stathmin, SCG10, and even some members of the kinesin superfamily that promote microtubule dynamics and disassembly. Any protein that influences the actin cytoskeleton is likely to influence microtubules indirectly because the distribution of microtubules in developing neurons and particularly within the growth cone is strongly influenced by the organization and distribution of actin filaments. Proteins such as Lis1 and members of the dynactin complex are important for regulating the functions of cytoplasmic dynein and other molecular motors. It is interesting that both Lis1 and doublecortin appear to be quite important for regulating microtubules during neuronal migration and appear to interact with one another. In addition, there is a recently discovered family of proteins, called +TIPs, that associate mainly with the plus end of the microtubule as it undergoes bouts of assembly. The +TIPs can influence the assembly properties of the microtubule but can also influence the interactions of the microtubule tip with molecular motors and with cortical structures within the leading edge of the cell. Finally, a great deal of recent evidence has shown that microtubule behaviors are influenced by a wide array of small G-proteins and kinases that can affect many of the other microtubule regulatory proteins. As already mentioned for tau and spastin, abnormalities to some of these microtubule-related proteins can give rise to neuropathies and/or developmental abnormalities. For example, abnormalities in the dynein/dynactin motor system can give rise to amyotrophic lateral sclerosis, and mutations in doublecortin can give rise to defects in the lamination of the brain during embryogenesis. Table 1 summarizes some of the microtubule-related proteins and their proposed functions but is not meant to be all-inclusive.

Concluding Remarks

Microtubules are one of the most prominent cytological structures in the neuron. They appear as dense arrays of aligned filaments in both axons and dendrites. When first observed by electron microscopy,

Table 1 Partial list of microtubule-related proteins in neurons and other cell types

Microtubule (MT)-related proteins			*Mainly in neurons*	*Putative functions*	*Related disease(s)*
MT-associated proteins (MAPs)	Fibrous MAPs	MAP1A	Yes	Promote MT assembly and stabilization; determine spacing between MTs; influence MT stiffness; regulate interactions between MTs and other structures such as actin filaments; tau and MAP2 can also protect MTs from severing and promote MT bundling	Giant axonal neuropathy
		MAP1B	Yes		Unknown
		MAP2	Yes		Unknown
		Tau	Yes		Alzheimer's disease; FTDP-17
	Novel MAPs	Doublecortin	Yes	Promotes MT assembly and stabilization; interacts with Lis1	Lissencephaly; double cortex syndrome
		STOP	No	Promotes MT assembly and stabilization, especially stability against cold	Unknown
Molecular motors	Cytoplasmic dynein		No	Transports organelles and vesicles (cargo) toward minus end of MTs; transports MTs with plus end leading; generates forces on MTs and sometimes between MTs and actin filaments relevant to several events, such as mitosis, cellular migration, axonal growth, and growth cone guidance	ALS; distal spinal and bulbar muscular atrophy
	Kinesin superfamily		No	Most family members transport cargo toward plus end of MTs; some transport cargo toward minus end; some are involved in generating forces on MTs during mitosis; one type suppresses MT assembly (see below)	Hereditary spastic paraplegia; Charcot–Marie–Tooth disease type 2; neurofibromatosis; fragile X syndrome; neurotropic viral disease
Cytoplasmic dynein-interacting proteins	Lis1		Yes	Modifies MT dynamics and dynein activity; interacts with doublecortin; plays roles in neuronal migration, neurogenesis	Lissencephaly
	Dynactin complex		No	Mediates interactions between cytoplasmic dynein and other structures; modify functions of cytoplasmic dynein; may also influence MT dynamics and interact with other proteins, such as some kinesins	ALS, Huntington's disease
MT-destabilizing proteins	SCG10		Yes	Suppress MT assembly; promote MT disassembly	Unknown
	Stathmin		No		
	Kinesin 13 superfamily	KIF2a	No		
		KIF2b	No		
		KIF2c	No		
MT-severing proteins	Katanin		No	Release MTs from the centrosome; regulate MT length; fragment MTs in discrete locales to increase MT number	Unknown
	Spastin		Yes		Hereditary spastic paraplegia
Cross-linking proteins	MT actin cross-linking factors		No	Cross-link cytoskeletal elements; anchor them to the plasma memberane	Unknown
	Plakins		No		
MT plus-end tracking proteins	End-binding proteins		No	Modify MT dynamics and regulate interaction of plus ends of MTs with other proteins and structures	Unknown
	Cytoplasmic linker proteins (CLIPs)		No		
	CLIP-associating proteins		No		

ALS, amyotrophic lateral sclerosis; FTDP, frontotemporal dementia with parkinsonism; STOP, stable tubule only protein.

microtubules were thought to be mainly structural. Today we know that microtubules are indeed structural in the neuron, but they are also highly dynamic and can interact with a vast array of regulatory proteins. They participate in a number of important functions, such as the transduction of forces necessary for neuronal migration and for the guidance of the growth cone toward its target. Microtubules are also essential for carrying out axonal and dendritic transport and for establishing many important features of neuronal polarity. Elucidating the mechanisms that regulate neuronal microtubules is essential for understanding the normal development of the nervous system, flaws in its development, and an array of debilitating neuropathies that affect the adult nervous system.

Midbrain Patterning

The midbrain, or mesencephalon, is defined by embryology. It is the middle of the three primary cerebral vesicles of the vertebrate neural tube, lying between the forebrain and hindbrain vesicles. The neural tube constriction formed at the junction of the midbrain and hindbrain vesicles is called the isthmus. This tissue harbors a major signaling center that patterns the adjoining midbrain and hindbrain. No comparable anterior signaling center has yet been identified at the junction between the midbrain and forebrain vesicles. By gene expression, however, the transition between dorsal midbrain and caudal forebrain is very abrupt, suggesting the presence of an important developmental boundary. Studies of cell lineage have provided evidence that both the isthmus and the dorsal midbrain–forebrain junction form barriers to cell mixing. Whether the midbrain vesicle constitutes a true developmental compartment, however, remains unresolved.

Pattern of the Adult Midbrain

The adult midbrain comprises a dorsal tectum (Latin for 'roof') and a ventral tegmentum (from 'tegmen,' which is Latin for 'cover'). In mammals, the cerebral peduncle, a fiber bundle of descending neocortical axons, is found beneath the tegmentum at the base of the midbrain. The tectum is dominated by a single structure, the optic tectum, or, in mammals, the superior colliculus. The optic tectum is a sensorimotor structure whose roles include a 'sentinel' function of orienting the head and eyes toward salient stimuli. It is organized into layers, with superficial layers receiving sensory input and deep layers containing premotor cells controlling eye and head movements. These sensory and motor layers contain sensory and motor maps that are in register across the layers and can be viewed as forming a coordinated representation of eye-centered external space when projected onto the tectal surface. The dominant sensory input to the optic tectum is from the retina. Retinal terminations form a coherent retinotopic map across the contralateral optic tectum, with the retinal temporal–nasal axis aligned with the tectal anterior–posterior axis and the retinal ventral–dorsal axis corresponding to the tectal medial–lateral axis. In addition to its intrinsic role in sensorimotor processing, the optic tectum serves as a relay for visual information traveling to the forebrain. The dorsal midbrain also contains an ascending relay for auditory and lateral line sensory information. This posterior midbrain structure is called the inferior colliculus in mammals, the mesencephalicus lateralis dorsalis nucleus in birds, and the torus semicicularis in other vertebrates ('torus' is Latin for 'bulge').

The ventral midbrain contains a complex constellation of nuclei, many of which are involved with motor system function. Among these are the red nucleus, which is part of the cerebellar motor system, and the nigral complex, a basal ganglia component that includes the dopamine neurons of the nigrostriatal and mesolimbic systems. The ventral midbrain also contains the most anterior motor neurons of the vertebrate nervous system. These are the somatic motor neurons of the oculomotor nucleus, which innervate extraocular muscles, and the visceral motor neurons of the Edinger–Westphal nucleus, which supply the ciliary parasympathetic ganglion. The oculomotor nucleus and the Edinger–Westphal nucleus are together called the oculomotor complex. Their motor axons travel to the eye's orbit in the third cranial nerve.

Early Midbrain Patterning: Boundaries and Signals

The regionalization of the brain into forebrain, midbrain, and hindbrain occurs early in gastrulation through the action of axial signals that organize the embryonic body plan. Once regionalized, the brain vesicles are patterned largely independently by local organizing centers. In the midbrain, the presence of two such organizing centers, the isthmic organizer (IsO) at the midbrain–hindbrain boundary and the rostral floor plate (rFP) of the ventral midbrain midline, is well established. The roof plate (RP), which runs along the dorsal midline of the midbrain, is also enriched in known developmental signaling molecules and is likely to serve as a midbrain signaling center.

Establishment of the Isthmic Organizer

Midbrain patterning depends critically on the establishment of the IsO. The IsO is initially formed anterior to the physical constriction of the midbrain–hindbrain junction. By gene expression, the IsO falls precisely at the posterior expression boundary of *OTX2*, a vertebrate homolog of the *Drosophila orthodenticle* gene, and the anterior limit of a second homeobox gene, *GBX2*, a vertebrate homolog of the *Drosophila* gene *unplugged* (Figure 1(a)). Gain- and loss-of-function

Figure 1 Identification of the major regional boundaries of the embryonic midbrain by gene expression for transcription factors and signaling molecules. (a) Plane of apposition of *Otx2* and *Gbx2* homeobox gene expression identifies the midbrain–hindbrain junction and the location of the isthmic organizer. Side view of an embryonic day 9 mouse prepared for whole mount *in situ* hybridization. Anterior is to the right. *Otx2* (blue) is expressed throughout midbrain and into forebrain, whereas *Gbx2* (brown) labeling is in hindbrain. (b) Polygon formed by gene expression markers of midbrain boundaries outlines the right midbrain of a chick embryo. Whole mount *in situ* hybridization of dissected stage 17 chick brain oriented with anterior to the right and probed for *WNT1*, *SHH*, and *PAX6* gene expression. The diencephalon–midbrain boundary is identified by *PAX6* expression in the diencephalon, the ventral midbrain midline is marked *SHH* labeling, and the isthmic organizer and the roof plate are demonstrated with *WNT1* gene expression. Di, diencephalons; Hb, hindbrain; Mb, midbrain.

experiments suggest that mutual repression between *OTX2* and *GBX2* is critical for the positioning and maintenance of the IsO.

A number of transcription factors are expressed within the midbrain and at the IsO and are required for the specification of the IsO and the midbrain. These include the paired box genes *PAX2/5/8*, the engrailed homeobox genes *EN1/2*, and the LIM homeobox gene *LMX1B*. In addition, WNT and FGF8 signaling molecules (WNT1 and FGF8/17/18) are expressed by the IsO (Figure 1(b)). The initial induction of these IsO genes is thought to depend on the mesendodermal tissues lying subjacent to the neural tube. Subsequently, within the neural tube, cross-regulation among *EN1/2*, *PAX2/5/8*, *WNT1*, and *FGF8* is required to establish and maintain IsO identity. Many of these genes are at first broadly expressed and progressively become restricted to partially overlapping but distinct domains of the isthmus, the posterior midbrain, and rhombomere 1 of the hindbrain. In mice, the loss of *Pax2/5/8*, *En1/2*, *Wnt1*, or *Lmx1b* function results in variable phenotypes depending on the genetic background. The most severe of these phenotypes is a partial to complete deletion of the IsO and the adjacent midbrain and anterior hindbrain.

Midbrain Patterning by FGF8

FGF8 at the IsO is expressed in a band around the anteriormost hindbrain immediately behind a ring of WNT1 expression. Transgenic mouse analyses, quail–chick chimeras, and FGF8 delivery by plasmid electroporation or ligand-soaked bead have demonstrated that FGF8 signaling is critical to midbrain patterning. In midbrain, FGF8 delivery shifts the isthmus forward and converts midbrain into hindbrain. In caudal diencephalon, FGF8 delivery induces an ectopic IsO (*EN1/2+*, *WNT1+*, and *FGF8+*) and the ectopic IsO converts the surrounding diencephalon into midbrain tissue (Figure 2(b)). This transformation can be quite dramatic, producing a full midbrain duplication in extreme cases. Unlike the native midbrain, the duplicated midbrain has its IsO at its anterior end, resulting in anterior–posterior patterning that is mirror image to that of the native midbrain. This induction of an ectopic midbrain cannot be produced throughout forebrain; it can only be elicited caudal to the zona limitans intrathalamica (zli), a signaling center that bisects the diencephalon. Evidence suggests that the transition from permissive (post-zli) to nonpermissive (pre-zli) tissue may be controlled by the expression domains of the iroquois homeobox gene *IRX3*, expressed posterior to the zli, and the sine oculis homeobox gene *SIX3*, expressed anterior to the zli.

The Forebrain–Midbrain Junction

Genetic fate mapping studies have shown that a lineage restriction boundary preventing the mixing of midbrain and forebrain cells is established at the diencephalon–midbrain boundary (DMB) by embryonic day (E) 9.5 in the mouse. Interestingly, this boundary may fall precisely along the midbrain–forebrain junction only dorsally. Ventrally it is shifted anteriorly into the subthalamic region. Interactions between the midbrain–hindbrain junction genes *EN/PAX2/FGF8* and the paired box homeobox gene

Figure 2 Regulation of midbrain pattern formation by FGF8 and Shh. (a) Chick brain at embryonic day 6, illustrating FGF8 expression at the midbrain–hindbrain boundary (blue) and Shh expression at the ventral midline and extending up the zona limitans intrathalamica (zli) in diencephalon (green). The anterior–posterior polarity of the midbrain is illustrated for ventral midbrain by a midbrain arcs schematic (red). (b) Exogenous FGF8 delivered to the diencephalon induces an ectopic isthmic organizer and a duplicate midbrain with a polarity mirror image to that of the native midbrain. (c) Ectopic Shh can ventralize dorsal midbrain and induce a duplicate set of midbrain arcs. Mb, midbrain; Tel, telencephalon.

PAX6, which is expressed in the diencephalon, have been shown to regulate DMB positioning in birds and fish. Thus, the establishment of the DMB critically depends on the prior specification of the IsO.

Induction of the Midbrain Floor Plate

The rFP and the underlying axial mesoderm (notochord and prechordal plate) express the signaling molecule Sonic hedgehog (Shh), a principal architect of ventral midbrain patterning. The origin of the floor plate and its mode of induction have long been a matter of controversy. A dual origin for spinal cord floor plate is indicated by zebra fish mutant analyses and quail–chick chimera experiments which show that the medial floor plate is derived from the node, expresses Shh, and helps induce lateral floor plate in adjoining neural tube. In the zebra fish, the specification of the medial floor plate depends on nodal signaling. Shh signaling is required for the maintenance but not the induction of the medial floor plate.

The rFP of the midbrain eventually forms a complex, wedge-shaped structure – one much broader than the floor plate of spinal cord and hindbrain. The rFP is likely to be induced by nodal and Shh signaling derived from a transient contact between the prechordal plate and the midbrain anlage. Subsequently, the notochord is briefly apposed to the ventral midbrain, but its rapid retraction strongly suggests that, unlike the arrangement in spinal cord in which notochord and floor plate collaborate on cell type specification, the rFP alone provides patterning signals for rFP expansion and the specification of ventral midbrain cell types. Fate mapping studies have shown that the rFP contains a mixed population of cells that at least in the chick incorporates a unique set of cells from a region anterior to the node called area a.

Roof Plate

The midbrain RP expresses the rich collections of WNT and BMP signaling molecules and ZIC and LMX transcription factors that are found in roof plate at other axial levels of the nervous system and that are thought to contribute to dorsal neural tube patterning. In midbrain, loss-of-function experiments for these molecules have only presented extreme phenotypes, either midbrain deletions or exencephaly, or no apparent patterning effects, possibly reflecting signaling redundancy. Consequently, the contributions of the midbrain RP to midbrain patterning remain obscure.

Interactions among Midbrain Organizers

Despite the complete orthogonality of the IsO and the rFP signaling centers, there is clear evidence for cross-regulation in their construction and maintenance. When Shh signaling is perturbed, the midbrain–hindbrain junction is disrupted, allowing mixing of midbrain and hindbrain cells. Moreover, in the mouse, loss of Shh

leads by E12.5 to a severe loss of *Wnt1* and a complete loss of *Fgf8* in the IsO. Interactions between the IsO and the RP include a direct contribution of midbrain–hindbrain boundary cells to the developing midbrain roof plate.

Ventral Midbrain Patterning

Medial Longitudinal Fasciculus

The first neurons to be born in ventral midbrain are part of a cohort of cells that straddle the midbrain–forebrain junction and contribute to the interstitial nucleus of Cajal and the nucleus of Darkschewitsch of the adult. The axons of these early born neurons travel posteriorly in a paramedian position and pioneer a major fiber tract that corresponds to the medial longitudinal fasciculus of the mature brain stem.

Midbrain Arcs

The embryonic midbrain is organized into a series of longitudinal territories arrayed bilateral to the ventral midline. These territories were first identified in the mantle layer of the chick embryonic midbrain with acetylcholinesterase histochemistry, which identifies postmitotic neurons in embryonic brain. Because these longitudinal territories constitute acetylcholinesterase-rich columns and have arcuate shapes, which are accentuated by the cephalic flexure, they are called midbrain arcs. The acetylcholinesterase-poor columns between the arcs also contain neurons and are referred to as interarcs. The arcs are numbered 1–5, from medial to lateral, and the interarcs are identified by their flanking arcs. Each arc and interarc expresses a unique signature of transcription factors and neurotransmitter-specific genes. For example, arcs 2 and 3 are enriched in the GABA synthetic enzyme *GAD2* and the zinc finger transcription factor *GATA2*, whereas the two-thirds interarcs expresses the transcription factor gene *PAX6* (Figure 3). Combined molecular and tract-tracing studies have shown a clear relationship between the first arc and nuclei of the adult midbrain. The first arc contains primordia for the oculomotor complex and the red nucleus. These primordia are separated within the first arc along the ventricular–pial axis, with the primordium of the oculomotor complex next to the ventricular layer and that of the red nucleus more pial. The possible nuclear fates of the lateral arcs and interarcs are not clear, in part because of the absence of selective markers for many adult ventral midbrain structures. Resolution of this important question will likely require genetic fate-mapping experiments.

The ventricular zone of ventral midbrain progenitor cells also contains arcuate territories. These territories are readily demonstrated as arcuate periodicities in the expression patterns of signaling molecules, including

Figure 3 Arcuate organization of the embryonic midbrain tegmentum demonstrated by transcription factor gene expression. Illustrated are dissected flat mounts of embryonic day 5 chick brain stem prepared for *in situ* hybridization. The tissue documentation is arranged with the ventral midline oriented vertically, the midbrain arcs 1–3 identified on the left side only, and the isthmus (is) and hindbrain (hb) shown at the bottom of the panel. (a) *PHOX2A* labeling (brown) identifies the oculomotor complex of the most medial, or first, arc, whereas *GATA2* message enrichment (blue) distinguishes arcs 2 and 3. (b) Panel of three homeobox genes indicates regularly spaced arcuate territories (blue) corresponding to arc 1 (*PHOX2A*), interarc 2/3 (*PAX6*), and interarc 3/4 and arc 4 (*EVX1*). Gene expression for *SHH* (brown) illustrates the balloon-like expansion of the *SHH*-rich floor plate during midbrain development. rFP, rostral floor plate.

the WNT ligands WNT5A and WNT7A and ligands of the NOTCH receptor. The ventricular zone periodicities and the mantle layer arcs lie in radial registration, suggesting that midbrain arc patterning is set up in the ventricular zone and that arcs are populated by direct radial migration. Intracellular dye labeling studies demonstrating that radial clusters of coupled cells extend into the ventral midbrain mantle layer support this model.

Shh misexpression experiments have shown that the entire midbrain arc pattern, including the ventricular zone periodicities, can be generated by an ectopic source of Shh (Figure 2(c)). These ectopic arcs have precisely the same relative spatial positioning and the same molecular identity as the native arcs. The size

and shape of the ectopic arcs, however, are controlled by the size and shape of the ectopic Shh source. This type of pattern regulation is predicted by morphogen-based positional signaling and provides support for an 'action-at-a-distance' mode of Shh signaling in midbrain development. A specific requirement for Shh in the generation of the midbrain arcs and the specification of their constituent cell types has been demonstrated in loss-of-function experiments in chick and mouse.

At a morphological level, the midbrain arcs are the midbrain continuation of an embryonic columnar organization that runs from the spinal cord through brain stem to the subthalamic region of the caudal diencephalon. At a molecular level, however, the midbrain arc patterning mechanism shares only some features with those of the caudal central nervous system, and there is no coherent mapping that carries the molecular signature of the spinal cord domains V0–V1–V2–MN–V3 forward to the arc and interarc organization of the midbrain.

Oculomotor Complex

The midbrain oculomotor complex (OMC) is a derivative of the first arc. The earliest specific marker for these cells is the paired-like homeobox gene *PHOX2A*, which can be detected in still dividing ventricular zone precursor cells. In mice null for *Phox2a* function and in the zebra fish *phox2a* mutant *soulless*, the oculomotor nucleus and the nearby trochlear nucleus of anterior hindbrain are not generated. OMC neurons also express PHOX2B, which shares an identical homeodomain with PHOX2A, and the LIM homeobox gene *ISL1*, a pan-motor neuron marker, but they do not express the homeobox gene *HLXB9*, which is found apparently in all somatic motor neurons posterior to the trochlear nucleus. In this regard, the midbrain OMC is more akin to the branchial and visceral motor neurons of hindbrain than the somatic oculomotor neurons of the hindbrain abducens nucleus. Phox2b is required for the development of the hindbrain branchiovisceral motor neurons but not for the generation of OMC. Experiments in mouse in which *Phox2a* coding sequence is replaced by that of *Phox2b* demonstrate only a partial rescue, suggesting that the nonhomeodomain sequence differences between *Phox2a* and *Phox2b* are important for OMC development.

The human midbrain oculomotor system and its peripheral targeting are affected in many congenital cranial dysinnervation disorders. In one of these, CFEOM2 (congenital fibrosis of the extraocular muscle 2), patients present a bilateral ptosis (drooping eyelids) with eyes primarily in an exotropic (outward-looking) position. This presentation indicates that third cranial nerve motor function, which in humans includes innervation of the levator palpebrae superioris (upper eyelid muscle), is lost. Gene mapping studies have identified three distinct *PHOX2A* mutations in CFEOM2 patient families, at least one of which appears to be a null.

Red Nucleus

The red nucleus primordium is identified in the first arc by its specific expression of the POU homeobox gene *POU4F1/BRN3A*. Gene targeting studies have demonstrated that the absence of *Pou4f1* gene function leads to loss of the red nucleus by birth. In mice mutant for the homeobox gene *Emx2*, the *Pou4f1*-positive neurons of the red nucleus are also generated, but they are lost earlier – by midgestation.

Midbrain Dopamine Neurons

Midbrain dopamine neurons are born in ventromedial midbrain within the Shh-expressing ventricular zone of the rFP. Specific sites of origin likely include the ventral midline and the ventricular zone overlying the first arc. Some dopamine neurons remain medially to form the A10 complex of the ventral tegmental area. The A9 and A8 dopamine cell groups of the substantia nigra and retrorubral area are populated by a reelin-dependent lateral migration. Studies of transcription factors involved in midbrain dopamine development have identified a large number of genes that regulate distinct aspects of dopamine neuron production, differentiation, and survival. These factors include a suite of homeodomain transcription factors, En1/2 and Lmx1a/b, that are also expressed in the IsO or rFP, and the nuclear receptor Nr4a2/Nurr1, which is required for expression of the dopamine synthetic enzyme tyrosine hydroxylase. Particularly notable among these factors is the paired-like homeobox gene *PITX3*, which is a uniquely specific marker of apparently all midbrain dopamine neurons. In mice lacking *Pitx3* gene function, there is a severe reduction in midbrain dopamine cell generation that particularly affects the A9 dopamine cell group.

Nuclei Not of Midbrain Origin

Classical and modern embryology have shown that some nuclei found at the midbrain–hindbrain junction in the adult brain are clearly of hindbrain origin. These include the trochlear nucleus of the fourth cranial nerve and the serotonin cells of the raphe system. The cholinergic isthmic nucleus of birds, which maintains reciprocal connections with the optic tectum, is also generated in hindbrain. A hindbrain origin is therefore possible for its predicted mammalian homolog, the parabigeminal nucleus.

Dorsal Midbrain Patterning

The tectal–tegmental boundary is readily demonstrated by many developmental control genes that mark dorsal midbrain selectively, including the paired box homeobox genes *PAX3/7*, the homeobox gene *DBX1*, and the nuclear receptor *NR2E1*. The possibility that this sharp tectal–tegmental boundary may form a cell lineage boundary has not been addressed, but tissue culture experiments have shown that ventral cells progressively lose their capacity to intermix with dorsal cells. As is true for the dorsal spinal cord, dorsal midbrain identity can be switched to a ventral character by ectopic expression of Shh. Unlike the dorsal spinal cord, however, dorsal midbrain growth and specification are dependent on ventral midbrain Shh signaling. In mice lacking *Shh* or the Shh effector *Smo*, the dorsal midbrain is severely reduced in size and an early molecular marker of dorsal midbrain identity, *Dbx1* gene expression, is lost. The molecular mechanism for this Shh-dependent effect is unknown, but because of the distances involved, it seems likely to involve intermediary signals. One candidate intermediary is *Fgf15*, which is expressed in embryonic dorsal midbrain and is largely lost from this tissue in the *Shh* mutant mouse.

Figure 4 Cellular organization of the chick optic tectum. Cytoarchitects distinguish up to 16 tectal layers between the pial surface (top) and the midbrain ventricle (V). The layering of the optic tectum serves to organize the cell bodies, the dendritic arborizations, and the inputs of the tectal neurons. Illustrated in red are three examples of retinotectal axons that target specific lamina within the retinorecipient layers a–f. Illustrated in blue are two examples of tectal projection cells – one in stratum griseum centrale (SGC) that has 'bottlebrush' dendritic endings in layer d and issues ascending projections to the thalamus, and a second in layer i that projects to the isthmic nuclear complex. PE, the periventricular and ependymal layers; SAC, stratum album centrale; SGFS, stratum griseum and fibrosum superficialis; SO, stratum opticum.

Mesencephalic Trigeminal Nucleus

The mesencephalic trigeminal nucleus is found in all jawed vertebrates and contains primary sensory neurons for jaw muscle proprioception. Its constituent neurons are the first to differentiate in the midbrain and issue descending axons that on leaving midbrain pioneer the lateral longitudinal fasciculus of the hindbrain. Whether these primary sensory neurons are generated directly in brain or are returnees of neural crest origin has been difficult to resolve with experimental embryological methods. Molecular studies using neural crest markers and genetic fate mapping support a central origin for these cells.

Optic Tectum

Proper tectal histogenesis entails the generation of a layered structure that shares many features with cortex, including layer-specific cell types with apically oriented dendrites and topographically organized inputs that target particular layers (Figure 4). The cellular mechanisms for constructing the optic tectum, however, parallel only in part those found in cortex. The deepest layers of the optic tectum, including the output neurons of the stratum griseum centrale, are generated first. The next born neurons, however, do not follow the simple neocortical 'inside-out' pattern but, rather, are produced in a much more complex manner. The cells of the prospective stratum griseum and fibrosum superficialis layers, which are designated the tectal plate in development, are born in two major waves, with superficial layers a–g produced first and the deeper layers h–j born later. In addition, within both waves, there are further temporal gradients, with layers a–g following an inside-out pattern of birthing and layers h–j observing an 'outside-in' sequence. Retroviral lineage analysis has shown that the tectal plate is principally populated by clonally related cells traveling from the ventricular zone along radial glia. However, there are also early and late tangential migrations. Some of these tangential migrations give rise to both neurons and glia.

One role of tectal lamination is to segregate inputs to particular dendritic territories. Focusing on the retinal input layers a–f, anatomical mapping studies have identified a large number of potential cell surface cues that are expressed in specific retinorecipient laminae and could contribute to retinal axon layer targeting. These include adhesion molecules of the cadherin family and the extracellular matrix molecule versican, a member of the aggrecan family of chondroitin sulfate proteoglycans. Function-blocking experiments employing an antibody to N-cadherin or a lectin that binds to versican have demonstrated lamina-specific defects in retinal axon arborization. Inappropriate laminar targeting by incoming retinal

fibers has also been found following misexpression of the Groucho family corepressor TLE4 in the embryonic chick tectum. The TLE4 defect is likely secondary to a disruption of tectal cell-type specification which also causes lamina formation defects.

The most studied of the tectal input topographies is that of the retina. It now appears almost certain that retinotectal topography is set up by multiple independent batteries of guidance molecules acting along orthogonal axes. These guidance ligands are found in increasing gradients across the ventral-to-dorsal and anterior-to-posterior axes of the tectum, and their receptors are found in gradients across the retina. Current models of map formation are that each ligand has attractive and repulsive actions and that retinal axons distribute themselves across the tectal axes based on the attractive–repulsive set point conferred by their retinal position-dependent receptor status. The retinotectal ligand–receptor combinations identified to date are: (1) ephrin-As and EphA receptor tyrosine kinases, (2) RGM and neogenin receptors for the tectal anterior–posterior axis, (3) ephrin-Bs and EphB receptors, and (4) Wnt3 and the WNT receptors Ryk and Frizzled-5 for the tectal dorsal–ventral axis. In addition to these specific guidance molecules, direct axon competition for tectal target space is thought to regulate retinotopic map development, although the specific molecular mechanisms involved in this process remain obscure. Finally, neuronal spiking activity is needed for refinement of the retinal topographic map. Activity-dependent mechanisms are also likely to mediate sensory map registration across the tectal layers, integrating input from the isthmic nuclear complex and from nonvisual sensory structures.

The axon guidance gradients found in the tectal anterior–posterior axis are set up by the IsO. The 'naive' model is that the IsO releases FGF8, which forms an instructive, posterior high concentration gradient that is converted into a cellularized expression gradient of transcription factors (such as En1/2) and target ligands (such as eprhin-A2 and ephrin-A5). A striking modification of this model derives from the finding that soluble En2 homeodomain protein can act directly to guide retinal axons, repelling temporal axons and attracting nasal ones, which accords precisely with the posterior high gradient in EN2 expression. For the tectal dorsal–ventral gradients, it is anticipated that the RP plays a major instructive role, and there is direct evidence that rFP contributes to retinotectal dorsal–ventral patterning as well.

Midbrain Patterning and Invertebrates

Midbrain is a feature of vertebrates, and its possible status in invertebrates is uncertain. In the cephalochordate *Branchiostoma*, for example, even the presence of a tectum-like structure is disputed and the best guide for a possible midbrain is the positioning of the anteriormost motor neurons. Modern molecular developmental biology, however, has identified regional markers of anterior–posterior identity that allow informative comparisons to be made within and across phyla. For assessing the origins of midbrain, a potentially informative marker is the paired-like homeobox gene *DMBX1* (diencephalons/mesencephalon homeobox gene). *DMBX1* expression onset precedes the establishment of the IsO. It is first detected during gastrulation as a crescent in the anterior neural plate and then accumulates at the level of the prospective midbrain and, with the appearance of definitive brain vesicles, is strongly expressed in the embryonic midbrain and adjoining posterior diencephalon. Unfortunately, the functional importance of DMBX1 to midbrain development is unclear; whereas *dmbx1* zebra fish morphants show reduced tectal growth, *Dmbx1*-deficient mice present no gross abnormalities in brain development. Moreover, as development proceeds, *DMBX1* is found in other central nervous system sites including the hindbrain. Despite these handicaps, DMBX1 is the single best molecular marker of embryonic midbrain tissue.

A *DMBX1* ortholog has not been described in protostomes. However, comparative genomics has readily identified *DMBX* orthologs throughout invertebrate deuterostomes, including cephalochordates, urochordates, echinoderms, and hemichordates. The finding of one *Hydra* and six *Nematostella* DMBX sequences indicates that this gene was present in the cnidarian–bilateralian ancestor. Studies of *dmbx* gene expression in the hemichordate acorn worm *Saccoglossus* provide strong support for the conclusion that midbrain-like regional gene expression and isthmus-like organizer activity were present in at least the deuterostome ancestor. The midlevel structures of the acorn worm, the mesosome and the anterior metasome to the level of the first gill slit, express makers characteristic of midbrain and caudal forebrain, including *dmbx*, *dbx*, *otx*, *engrailed*, and *pax2*. In addition, the posterior end of this region is marked by a *fgf8*- and *wnt1*-rich signaling center. By contrast, transcription factor markers characteristic of anterior and ventral forebrain are found anteriorly, in the prosome, and *hox* genes are expressed only posterior to the first gill slit. This finding of a conserved core of midbrain patterning circuitry does not mean that the shared ancestor of vertebrates and hemichordates had a midbrain. The predicted nervous system of the deuterostome ancestor, like that of the acorn worm, is an epidermal nerve net.

Mitochondrial Dysfunction in Nervous System Injury

Mitochondria Structure

Mitochondria are organelles that evolved from a symbiotic relationship between aerobic bacteria and primordial eukaryotic cells. Despite being in eukaryotic organisms, mitochondria still carry a functional relic of their original genome. They are intracellular tubular organelles delimited by two membranes. The outer mitochondrial membrane is permeable to ions and small proteins of molecular weights <10 kDa, whereas the inner mitochondrial membrane houses the multimeric enzyme complexes of the electron transport chain (ETC). Human mitochondria DNA is a circular double-stranded molecule of approximately 16.6 kb in length with the genome containing 37 genes. Of these, 13 genes encode protein subunits of respiratory chain complexes, with a significant amount of mitochondrial proteins being encoded by the nuclear genome and transported into the mitochondria. For example, complex II is solely composed of proteins encoded by nuclear genes. The varying mitochondrial density in various tissues is usually dictated by the need for oxidative phosphorylation and energy production. Cardiac and skeletal muscles and neurons have the highest density of mitochondria, hence their sensitivity to energy-dependent defects resulting from mitochondrial dysfunctions following injury.

Mitochondria Electron Transport Chain, Membrane Potential, and Energy Metabolism

Central to the role of mitochondria is energy metabolism through the production of ATP. This energy production is usually carried out at the level of the inner mitochondrial membrane through oxidative phosphorylation involving the reduction of oxygen to water by multimeric enzyme complexes. The ETC is composed of NADH–ubiquinone oxidoreductase (complex I), succinate dehydrogenase–CoQ oxidoreductase (complex II), cytochrome reductase (complex III), cytochrome oxidase (complex IV), and ATP synthase, which is sometimes referred to as complex V. These multimeric complexes are arranged in the inner mitochondrial membrane according to their reduction potentials. During oxidative phosphorylation, ETC complexes are usually involved in the reduction and oxidation reactions through reducing equivalents such as NADH or succinate, which are transported into the mitochondria from the cytosol. In the process, protons are pumped from the matrix into the intermembrane space, terminating with the reduction of O_2 to H_2O. The transfer of protons from the matrix to the inner mitochondrial membrane leads to the generation of a mitochondrial membrane potential ($\Delta\Psi_m$) of 150–180 mV, which usually determines the energetic status of the mitochondria. This reserve of potential energy through the electrochemical gradient is then coupled to the generation of ATP from ADP and inorganic phosphate P_i through the ATP synthase complex (complex V).

Ca^{2+} Regulation and Excitotoxicity

Mitochondria under normal conditions usually act as high-capacity Ca^{2+} sinks through a highly complex system for the regulation and the transportation of Ca^{2+}. Through these processes, mitochondria sense and respond to changes in cytosolic Ca^{2+} loads to maintain cellular Ca^{2+} homeostasis that is required for normal neuronal function. Disruptions in Ca^{2+} homeostasis are one of the major factors that contribute to the neuropathology following central nervous system (CNS) injury. It has been shown that following CNS injury, mitochondrial dysfunction is primarily involved in glutamate neurotoxicity. Glutamate excitotoxicity is usually triggered by the excessive influx of calcium following activation and overstimulation of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors. The resulting increase in intracellular calcium has been shown to lead to impaired function of the mitochondrial ETC and formation of reactive oxygen species/reactive nitrogen species (ROS/RNS), particularly superoxide anion and hydrogen peroxide. In addition, as mentioned previously, extreme loads of Ca^{2+} have been shown to lead to the opening of the mitochondrial permeability transition pore (mPTP) and induction of the apoptotic pathways, eventually leading to neuronal cell death following CNS trauma.

Mitochondria and Oxidative Stress

Oxidative stress can be defined as an imbalance in the antioxidant defense mechanisms and the amount of ROS/RNS produced. The mitochondria are a key source of ROS. Through the generation of ATP via the oxidative phosphorylation by the ETC components, there is always some leakage of electrons (1% or 2%) from the mitochondria resulting in the-partial reduction of O_2 to form superoxide anion O_2^-, a majority of which is generated from complex I

Figure 1 A summary of the production of reactive oxygen and nitrogen species (ROS/RNS) following CNS injury. In addition, the figure displays the antioxidant systems that provide protection against increased oxidative stress as seen in nervous system injury.

and complex III of the ETC. The production of superoxide anion can occur when the ETC is impeded following mitochondrial injury. Note that the production of ROS by the mitochondria is tightly linked to the mitochondrial membrane potential since hyperpolarization or high mitochondrial membrane potential promotes the production of ROS. With a high mitochondrial membrane potential, the ETC cannot transfer protons against the electrochemical proton gradient from the matrix. This, in essence, leads to a reduced state of electron carriers and an increase in the half-life of semiquinone. The intermediates thus remain in a prolonged reduced state, thereby increasing the chances of electron leakage and partial reduction of O_2 to superoxide anion O_2^-. As discussed later, it is on this basis that mitochondrial protein uncouplers are gaining importance as possible therapeutics for CNS injuries.

As noted previously, one major pathway predominantly involved in the production of ROS/RNS is the secondary activation of glutamate receptors and excitotoxicity following injury to the nervous system. Following CNS injury, the cytosolic levels of Ca^{2+} increase and are sequestered into the mitochondrial matrix through various transporters, as stated previously. However, excessive calcium loads result in the dysregulation of mitochondrial Ca^{2+} homeostasis, leading to the activation of nitric oxide synthase (iNOS) and the production of nitric oxide radical ($NO^{\cdot}$). The presence of nitric oxide NO and superoxide anion O_2^-, as seen in Figure 1(g), leads to the formation of peroxynitrite $ONOO^-$, another significant RNS, which can lead to the oxidative modification of proteins through nitration. Elevated intracellular Ca^{2+} levels also activate phospholipase A_2; this enzyme liberates the unsaturated fatty acid arachidonic acid, initiating the formation of free radicals via the cyclooxygenase-2 and lipoxygenase pathways. Arachidonic acid can also be oxidized, leading to the formation of lipid peroxidation products such as 4-hydroxynonenal (HNE), malodialdehyde (MDA), and acrolein. The activation of inflammatory response following CNS injury also leads to the production of substances such as cytokines, tumor necrosis factor-α, and interleukin-1β that can damage neurons. In addition, activation of microglia and astrocytes can also lead to the generation of more ROS. For example, NADPH and xanthine oxidase significantly contribute to O_2^- production upon activation of microglia. If the significant increase in ROS and RNS following CNS injury is not controlled, damage to DNA, proteins, or lipids would result, eventually leading to loss of function and possibly neuronal cell death.

Mitochondria Permeability Transition Pore

The mitochondrial permeability transition (mPT) is defined as an increase in the permeability of the inner mitochondrial membrane to solutes that have molecular masses lower than 1.5 kDa. The induction of this transition has since been demonstrated to involve the opening of a 2- or 3-mm inner membrane megachannel referred to as the mPTP. This pore is a voltage-dependent channel that is activated by the elevation of Ca^{2+} levels, oxidative stress, and low inner mitochondrial membrane potentials as observed in most nervous system injuries. The exact identity of this megachannel is still under investigation. However, progress has been made in trying to provide a logical model for its composition. The minimum configuration of the mPTP requires the adenine nucleotide translocator (ANT), which is located in the inner mitochondrial membrane, in association with outer mitochondrial membrane proteins such as the voltage-dependent anion channel and cyclophilin D (a peptidyl–prolyl *cis–trans* isomerase whose activity is usually inhibited by immunosuppressant cyclosporine A (CsA)). In addition, other proteins, such as Bcl-2 and Bax, have been shown to interact with ANT, providing a regulatory role for mPTP. The exact physiological function of mPTP has not been established; however, there seems to be a clear consensus on its involvement in the induction of permeability transition in the neuropathology of various CNS injuries, such as traumatic brain injury (TBI) and spinal cord injury (SCI). This is particularly evident since it has been established that CNS injury triggers the opening of mPTP, resulting in a collapse of the electrochemical gradient, the swelling of mitochondria, the inhibition of ATP synthesis, the release of apoptotic factors, and the eventual initiation of cell death pathways that are blocked by the use of the cyclophilin D binding immunosuppressant drug CsA.

Mitochondria Apoptosis and Necrosis

Mitochondria also play a central role in the regulation of both programmed cell death (also known as apoptosis) and uncontrolled cell death (i.e., necrosis). Evidence of apoptosis following CNS trauma (discussed later) has been well established. As mentioned previously, events leading toward CNS injury usually occur in a biphasic manner – that is, through a primary necrotic process that results in rapid and significant decline in the levels of ATP and in the ensuing hours, days, and weeks, a secondary injury that exacerbates the primary insult occurs through apoptosis. These two mechanisms of neurodegeneration differ in their morphological features of general cell structure. Apoptosis is marked by cell shrinkage and DNA fragmentation, whereas necrosis is marked by cellular swelling and uncontrolled cell lysis.

As noted previously, following CNS injury, there is an increase in oxidative stress and excitotoxicity leading to Ca^{2+} overload, which in turn triggers the induction of the permeability transition. This usually leads to excessive mitochondrial swelling and depolarization of the mitochondria and uncoupling of the oxidative phosphorylation, eventually leading to a rapid decline in ATP reserves which if not restrained, as seen in severe CNS injuries, would more often than not lead to necrotic cell death. However, it has been shown that transient opening of the mPTP is associated with the induction of apoptosis through the release of cytochrome c and other pro-apoptotic proteins. Released cytochrome c usually complexes with apoptosis protease-activating factor 1 (Apaf-1), dATP, and procaspase-9 to form the high-molecular-weight complex, the apoptosome. The apoptosome then activates downstream effector caspases, which then initiate the apoptotic cascade. However, apoptotic events can still occur without the opening of the permeability transition pore. Pro-apoptotic proteins, such as Bax and Bad, also have been thought to be capable of forming pores in the outer mitochondrial membrane, thereby influencing the release of other pro-apoptotic proteins such as cytochrome c, apoptosis inducing factor, endonuclease G, and Smac/Diablo, thereby activating the apoptotic cascade. However, their role in CNS injury is still not well established. These various pathways have been summarized in Figure 2.

Mitochondria and Antioxidant Defense System

Cells are equipped with efficient strategies to control and maintain the intracellular levels of ROS/RNS and antioxidants. As mentioned previously, following CNS injury there is extensive production of ROS/RNS through a wide range of mechanisms. If these levels are not controlled, these ROS/RNS could lead to oxidative damage to key mitochondrial proteins or enzymes, DNA, and lipids, leading to a loss in function of the mitochondria, decline in ATP production, and possibly eventual cell death as observed in most events following CNS injuries. As a result, mitochondria have developed a defense system to protect themselves and the cell from the possible deleterious effects of these ROS/RNS through the use of key enzymes and proteins (discussed later). The key antioxidant found in the mitochondria is manganese superoxide dismutase (MnSOD), with the glutathione and thioredoxin antioxidant systems playing key roles in the

Figure 2 A summary of the molecular pathways and downstream cascades of apoptosis and necrosis following injury to the CNS. Adapted from Green DR and Reed JC (1998) Mitochondria and apoptosis. *Science* 281(5381): 1309–1312.

regulation of ROS/RNS. Figure 1 provides a summary of the key pathways of antioxidant systems which are discussed here with emphasis on CNS injury.

As a first line of defense following CNS injury and against production of ROS, the mitochondria use the MnSOD (Figure 1(a)). There are two classes of SOD; manganese SOD (Mn-SOD), which is predominately located in the mitochondrial matrix, and copper/zinc SOD (Cu/Zn SOD), which is predominately found in the cytosol, although studies have shown that Cu/Zn SOD can also be located in the intermembrane space of the mitochondria. The SOD enzymes catalyze the disproportionation of O_2^- to H_2O_2 and H_2O, thus eliminating the cytotoxic superoxide anions from the cell. However, the disproportionation of O_2^- generates H_2O_2, another ROS. H_2O_2 also can lead to oxidative damage through various mechanisms. In the presence of transition metal ions such as Fe^{2+} or Cu^+, H_2O_2 can undergo a Fenton reaction resulting in the generation of hydroxyl radicals $OH^{\cdot}$, a much more toxic ROS that can exact excessive damage at distant sites from where H_2O_2 was generated. As a result, there is need for the cell to regulate intracellular levels of H_2O_2. One immediate mechanism through which the intracellular levels of H_2O_2 are regulated is via the enzyme catalase (Figure 1(b)), which catalyzes the conversion of H_2O_2 to H_2O and dioxygen. However, catalase is not found in brain mitochondria; as a result, CNS mitochondria predominately depend on other peroxidases to regulate the levels of H_2O_2. One mechanism involves the glutathione (GSH) system in conjunction with glutathione peroxidase (GPx) and glutathione reductase (GR), as shown in Figures 1(c) and 1(d). GSH is usually synthesized in the cytosol but is then transported into the mitochondria through various mechanisms. H_2O_2 can be converted to water by GPx (Figure 1(c)) using GSH as the hydrogen donor. The oxidized glutathione (GSSG) is then recycled back to GSH by the-enzyme GR (Figure 1(d)), which uses NADPH as a cofactor. Another antioxidant system associated with glutathione is through the enzyme glutathione-*S*-transferase (GST). As mentioned previously, following CNS injury, there is a significant production of reactive aldehydes such as HNE or MDA which, if not eliminated from the cell, could lead to additional damage. The levels of these reactive aldehydes are usually regulated by the enzyme GST, which catalyzes their conjugation to GSH as shown in Figure 1(e). With the aid of multidrug-resistant protein-1 (MRP1), this GS–alkenal conjugate is exported out of the cell, removing toxic reactive aldehydes (Figure 1(f)). Peroxiredoxins are another important H_2O_2-removal antioxidant system. Peroxiredoxins belong to a family of enzymes that are homodimers and require no prosthetic groups. They use thioredoxin-2 to reduce H_2O_2

and are dependent on cysteine at the active sites. These antioxidant defense mechanisms within the mitochondria, if maintained well, are sufficient to protect against ROS/RNS. However, when they are perturbed, as in the case with most CNS injuries, the excess levels of ROS can lead to mitochondrial dysfunction, a decline in ATP levels, and eventual activation of necrotic and/or apoptotic pathways, as discussed previously. As a result, modulation and maintenance of antioxidant levels through the use of exogenous antioxidant compounds has been considered as a potential therapeutic intervention following CNS injury.

Mitochondria and Traumatic Brain Injury

TBI is a serious health care problem in the United States, with more than 400 000 individuals hospitalized each year and an estimated annual cost of $25 billion. As noted previously, for most CNS injuries the pathophysiological events in TBI occur in a biphasic manner. Following TBI, the primary insult results in a rapid and significant necrosis of cortical tissue at the site of injury, and in the ensuing period (days and weeks) a secondary injury occurs that exacerbates the primary damage. One underlying feature of this secondary injury in both experimental and clinical TBI is the loss in mitochondrial bioenergetics. This loss is usually characterized by mitochondrial dysfunction that includes exposure of neurons to excitotoxic levels of excitatory neurotransmitters with excessive uptake of Ca^{2+} and eventual overload, generation of reactive oxygen species, induction of the opening of mPTP, release of cytochrome c, inhibition of ATP production, and ultimately neuronal cell death. Following TBI, ROS/RNS can also be generated through other cellular pathways, such as calcium activation of phospholipases, iNOS xanthine oxidase, the Fenton and Haber–Weiss reactions, and by inflammatory cells, as previously discussed. It has been shown that following TBI there is a significant loss in mitochondria bioenergetics, possibly through the loss of activity of key enzymes. It has also been shown that following experimental TBI, there is increased oxidative damage in mitochondria. Using proteomics, it has since been shown that key mitochondrial-related proteins are oxidatively modified, contributing to the loss in mitochondrial-related bioenergetics. There is currently no particularly effective therapeutic intervention for TBI; thus, TBI still presents clinicians and researchers with a major challenge.

Mitochondria and Spinal Cord Injury

Spinal cord injuries are the leading causes of disability and mortality in the United States, with the estimated incidence rate of 43–55 per million annually. The primary cause of SCI is automobile collisions, followed by violence, falls, and injuries in sporting events. Like TBI, SCI also undergoes multiple secondary injuries following the initial or primary impact. SCI results in hemorrhage, edema, axonal demyelination, increased glial activity, and the eventual compromise and loss of neurological function. The pathophysiology of SCI is characterized by an immediate and irreversible primary insult that is composed of physical and mechanical trauma. The generation of sharp bone fragments, contusions, compression, and eventual concussion are often observed. This damage is more manifested as ischemia through continuous compression after injury. The secondary injury, which is also considered as the more severe, involves a highly complex cascade of molecular downstream events that range from early neuronal apoptosis at the site of injury to the degeneration of white matter tracts weeks after injury among many other pathologies. Although there are a significant number of factors that contribute to the events seen in the secondary injury during SCI, such as ischemia, edema, ionic imbalances, compromised energy metabolism, and biochemical changes, mitochondria play a significant role in the neuropathology of SCI. Following SCI, there is a sustained activation of glutamate receptors, which leads to the intracellular accumulation of high levels of Ca^{2+} and a rapid impairment of mitochondrial function. This glutamate-mediated excitotoxicity, the formation of ROS, and lipid peroxidation are prominent events thought to contribute to neuronal dysfunction and cell loss following traumatic damage and ischemic injury to the CNS. Evidence for the involvement of mitochondria in these mechanisms stems from the fact that there is impaired mitochondrial function and lipid peroxidation within 1 h following experimental SCI, with an increase in ROS or evidence of oxidative damage occurring at 4 h and 24 h and as long as 4 weeks following injury. In addition, there were changes in the levels of ROS scavenger molecules 24 h following injury, as characterized by an increase in catalase activity and GSH levels. There is no known highly effective therapeutic remedy for SCI; however, there is a time window through which therapeutic interventions would be protective, as discussed in the next section. A summary of the pathophysiology of the secondary injury following SCI is given in Figure 3.

Stroke (Cerebral Ischemia)

Stroke (cerebral ischemia) is a major cause of death and the primary cause of adult disability in most

Figure 3 A summary of the pathophysiological events in SCI following the initiation of the secondary injury pathways. Following SCI, there is neuronal depolarization that leads to glutamate release and activation of NMDA and AMPA receptors. This then leads to excessive influx of calcium, resulting in an overload. Ca^{2+} as a second messenger leads to mitochondrial dysfunction and activation of iNOS, arachidonic acid (AA), and calpain. These calcium-activated events lead to production of ROS/RNS, cytoskeleton degradation, axonal and myelin damage, activation of apoptosis, and eventual neuronal cell death. AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazols propionic acid. Adapted from Hall ED and Springer JE (2004) Neuroprotection and acute spinal cord injury: A reappraisal. *NeuroRx* 1(1): 80–100. industrialized countries, accounting for the largest number of hospitalizations among neurological disorders. Thrombolytic stroke occurs as a consequence of irreversible brain injury resulting from cerebral ischemia provoked by interruption of cerebral blood flow through the occlusion of cerebral arteries. As in SCI and TBI, the mitochondria also play a critical role in the pathological mechanisms leading to tissue damage and infarction following stoke. Reduction or interruption of regional blood flow in the brain produces ischemic injury when delivery of metabolic substrates (i.e., glucose and oxygen) fails to meet the energy demand of the affected tissue. As in SCI and TBI, glutamate also plays a significant role in the pathogenesis of ischemic brain injury through mechanisms already discussed. Briefly, glutamate is released at high concentrations within the core of the cerebral infarction and in the penumbral tissue, overactivating its receptors and leading to excessive influx of calcium that activates a myriad of pathways, leading to mitochondrial dysfunction and to neuronal cell death (excitotoxicity), as previously discussed.

Therapeutic Interventions for Mitochondrial Involvement in CNS Disorders

The mechanisms that follow TBI, SCI, and stroke, among other CNS injuries, are similar, consisting of a primary injury that is further compounded with a secondary injury. Since the secondary injury evolves over time, this has provided a possible window of opportunity through which therapeutic interventions can be developed. Most therapeutic strategies have successfully concentrated on facilitating the actions of antioxidant enzymes, maintaining mitochondrial function, or inhibiting the formation of ROS/RNS following CNS injury. One key therapeutic strategy following

CNS injury has been the use of CsA. As noted previously, CsA is a potent immunosuppressive drug that transiently inhibits the opening of mPTP by unbinding mitochondrial matrix cyclophilin D from the pore. In experimental TBI, CsA dramatically reduces Ca^{2+}-induced cytoskeleton changes, improves mitochondrial function, and significantly ameliorates the volume of cortical damage in rodents. However, CsA does not offer the same neuroprotective effects in SCI as seen in TBI due the intrinsic differences. These intrinsic differences have further complicated the search for therapeutic interventions for SCI. Moreover, CsA may have its own damaging effects with regard to ROS generation under certain conditions. However, there are ongoing studies that show that NIM811, a nonimmunosuppressive CsA derivative, is able to provide neuroprotective effects in both TBI and SCI models. Preliminary results indicate that NIM811 increases cortical tissue sparing, improves mitochondrial function, and reduces mitochondrial oxidative stress after TBI in adult rats. This agent could provide a promising approach in the development of a therapeutic intervention for both SCI and TBI.

Since there is an increase in oxidative stress following CNS injury, the use of antioxidants and antioxidant-related compounds has also been shown to provide neuroprotective effects following CNS injury. For example, it has been demonstrated that posttraumatic administration of the N-type calcium channel blocker SNX-111 (S) and a novel blood–brain barrier penetrating antioxidant U-101033E (U) significantly ameliorates mitochondrial dysfunction induced by TBI in rats. However, caution should be exercised since U-101033E was shown to induce protein oxidation even though it is an inhibitor of lipid peroxidation. In addition, the use of *N*-acetylcysteine (NAC) has also resulted in improvement of mitochondrial function following TBI. Moreover, NAC protected striatum in injury from the lesions modulated by the complex II inhibitor 3-nitopropionic acid. A creatine-supplemented diet significantly attenuates cortical damage after TBI in rodents and induces tissue sparing and possibly provides neuroprotection following SCI.

Mitochondrial uncoupling has also been used as an effective neuroprotective strategy following CNS injury. As noted previously, the production of ROS by the mitochondria is tightly dependent on the mitochondrial membrane potential. As a result, it has been suggested that a reduction in the membrane potential through transient uncoupling would decrease the membrane potential and reduce ROS production and Ca^{2+} uptake. Mitochondrial uncoupling *in vitro* reportedly reduces neuronal mitochondrial Ca^{2+} loading and can inhibit excitotoxic cell death. The use of the uncoupler 2,4-dinitrophenol (2,4-DNP) following stroke/cerebral ischemia has been shown to result in early stabilization of mitochondrial homeostasis and a reduction in the release of cytochrome c into the cytoplasm. Also, administration of uncouplers DNP and carbonylcyanide-*p*-trifluoromethoxyphenylhydrazone following TBI and SCI has been shown to lead to less tissue loss, improved behavioral outcomes, a reduction in mitochondrial oxidative damage, Ca^{2+} loading, and dysfunction, and significantly reduces mitochondrial dysfunction associated with injury. As a result, mitochondria uncoupling could potentially be another therapeutic intervention strategy for TBI.

Since glutamate-related excitotoxicity is one of the mechanisms involved in the secondary mechanism following SCI, it has been hypothesized that antagonists against non-NMDA receptors would provide protection following SCI. Fifteen-minute post-SCI treatment with one non-NMDA receptor antagonist, 2,3,4-tetrahydro-6-nitro-2,3-dioxo-benzol[f] quinoxaline-7-sulfonamide disodium (NBQX), resulted in improvements in mitochondrial function and a reduction in the levels of ROS and lipid peroxidation products. The therapeutic interventions are not limited to those discussed in this article. There is much ongoing promising research for the development of therapeutic interventions against nervous system injuries.

Conclusions

CNS injuries such as TBI, SCI, and stroke are among the leading causes of disabilities in the population. An urgent program for the development of therapeutic interventions is needed. There are several pathological events that occur following CNS injury/trauma that lead to neuronal cell death. These events occur in a biphasic manner, consisting of an initial or primary insult followed by a prolonged and more deleterious secondary injury. Central to these pathologies are the mitochondria involving postinjury pathological events, such as glutamate-induced excitotoxicity, Ca^{2+} dysregulation, production of ROS/RNS, increased oxidative stress, loss of mitochondrial membrane potential, induction of mPT, release of pro-apoptotic bodies, and activation of downstream caspases leading to eventual cell death. The increased Ca^{2+} levels also lead to reduced mitochondrial bioenergetics and compromised ETC capacity demonstrated by altered oxygen consumption in TBI and SCI. Promising therapeutic strategies are being developed to provide neuroprotection against nervous system injuries. The use of antioxidants and antioxidant-related compounds, dietary intervention using creatine supplementation, the use of mPTP blockers such as cyclosporin

A, mitochondria uncouplers, the use of NMDA antagonists, among many others, are potential approaches to therapeutic treatment of TBI and SCI. 'Omic' methods, such as genomics, proteomics, lipidomics, and metabolomics, may offer means of better understanding the molecular mechanisms of TBI, SCI, and stroke, as well as monitoring the efficacy of therapeutic interventions.

Mitochondrial Encephalomyopathies

S DiMauro, E Bonilla, and E A Schon, Columbia University Medical Center, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Mitochondrial myopathies were described in the early 1960s, when systematic ultrastructural and histochemical studies revealed excessive proliferation of normal- or abnormal-looking mitochondria in muscle of patients with weakness or exercise intolerance. Because, with the modified Gomori trichrome stain, the areas of mitochondrial accumulation looked purplish (Figure 1), the abnormal fibers were dubbed 'ragged-red fibers' (RRFs) and came to be considered the pathological hallmark of mitochondrial disease. However, it soon became apparent that in many patients with RRFs, the myopathy is associated with symptoms and signs of brain involvement, and the term 'mitochondrial encephalomyopathies' was introduced. It also became clear that lack of RRFs in the biopsy does not exclude a mitochondrial etiology, as exemplified by Leigh syndrome (LS), an encephalopathy of infancy or childhood invariably due to mitochondrial dysfunction but never accompanied by RRFs.

According to the widely accepted 'endosymbiotic hypothesis,' mitochondria are the remnants of protobacteria that populated anaerobic nucleated cells and endowed them with the precious gift of oxidative metabolism. Thus, mitochondria are the main source of energy for all human tissues and contain many metabolic pathways, only some of which (e.g., the pyruvate dehydrogenase complex (PDHC), the carnitine cycle, the ß-oxidation 'spirals,' and the tricarboxylic acid (TCA) cycle) are shown in Figure 2.

Respiratory Chain

Although defects in all of the aforementioned metabolic pathways are by definition mitochondrial diseases, the term 'mitochondrial encephalomyopathy' has come to indicate disorders due to defects in the respiratory chain. This is the 'business end' of oxidative metabolism, where adenosine triphosphate (ATP) is generated. Reducing equivalents produced in the TCA cycle (also known as the Krebs cycle) and in the ß-oxidation spirals are passed along a series of protein complexes embedded in the inner mitochondrial membrane (the electron transport chain). The electron transport chain consists of four multimeric complexes (I to IV) plus two small electron carriers, coenzyme Q (or ubiquinone) and cytochrome *c*. The energy generated by these reactions is used to pump protons from the mitochondrial matrix into the space between the inner and outer mitochondrial membranes. This creates an electrochemical proton gradient, which is utilized by complex V (or ATP synthase) to produce ATP in a process known as oxidation/phosphorylation coupling.

A unique feature of the respiratory chain is that it is controlled by two distinct genomes, the nuclear DNA (nDNA) and the mitochondrial DNA (mtDNA). Of the approximately 80 proteins that make up the respiratory chain, 13 are encoded by mtDNA and all others are encoded by nDNA. As indicated by the different shadings in Figure 2, complex II, coenzyme Q, and cytochrome *c* are exclusively encoded by nDNA. In contrast, complexes I, III, IV, and V contain some subunits encoded by mtDNA: seven for complex I, one for complex III, three for complex IV, and two for complex V.

Human Mitochondrial DNA

Human mtDNA (Figure 3) is a 16 569-kb circular, double-stranded molecule, which contains 37 genes: 2 rRNA genes, 22 tRNA genes, and 13 structural genes encoding the aforementioned respiratory chain subunits. In the course of evolution, mtDNA has lost much of its original autonomy and now depends heavily on the nuclear genome for the production of factors needed for mtDNA transcription, translation, and replication. Since 1988 (when mutations in mtDNA were first associated with human disease), the circle of mtDNA has become crowded with pathogenic mutations, and the principles of mitochondrial genetics should, therefore, be familiar to the practicing physician.

Heteroplasmy and Threshold Effect

Each cell contains hundreds or thousands of mtDNA copies, which, at cell division, distribute randomly among daughter cells. In normal tissues, all mtDNA molecules are identical (homoplasmy). Deleterious mutations of mtDNA usually affect some but not all mtDNAs within a cell, a tissue, and an individual (heteroplasmy), and the clinical expression of a pathogenic mtDNA mutation is largely determined by the relative proportion of normal and mutant genomes in different tissues. A minimum critical number of mutant mtDNAs is required to cause mitochondrial dysfunction in a particular organ or tissue and mitochondrial disease in an individual (threshold effect).

Figure 1 Illustration of ragged-red fibers (RRFs). (a) RRFs revealed by the modified Gomori trichrome stain. Abnormal accumulations of mitochondria appear as reddish blotches, mostly at the periphery of muscle fibers. (b, c) Serial cross-sections from the muscle biopsy of a patient with Kearns–Sayre syndrome. In (b), an RRF (white asterisk) is highlighted by the histochemical stain for succinate dehydrogenase (SDH), which is entirely encoded by nuclear DNA. In (c), the same RRF (black asterisk) shows no activity for cytochrome *c* oxidase, an enzyme that contains three subunits encoded by mitochondrial DNA.

Mitotic Segregation

At cell division, the proportion of mutant mtDNAs in daughter cells may shift and the phenotype may change accordingly. This phenomenon, called mitotic segregation, explains how certain patients with mtDNA-related disorders may actually shift from one clinical phenotype to another as they grow older.

Maternal Inheritance

At fertilization, all mtDNA derives from the oocyte (Figure 4). Therefore, the mode of transmission of mtDNA and of mtDNA point mutations (single deletions of mtDNA are usually sporadic events) differs from that of Mendelian inheritance. A mother carrying a mtDNA point mutation will pass it on to all of her children (males as well as females), but only her daughters will transmit it to their progeny. A disease expressed in both sexes but with no evidence of paternal transmission is strongly suggestive of an mtDNA point mutation. The best way for the clinician to chart a course toward a diagnosis in the jungle of mitochondrial encephalomyopathies is to use a classification that combines genetic and biochemical criteria (Table 1). From the genetic point of view, there are two major categories, disorders due to defects of mtDNA and disorders due to defects of nDNA.

Disorders Due to Defects of mtDNA

Disorders due to defects of mtDNA include rearrangements (single deletions or duplications) and point mutations.

mtDNA Rearrangements

Single deletions of mtDNA have been associated with three sporadic conditions:

1. Pearson syndrome, a usually fatal disorder of infancy characterized by sideroblastic anemia and exocrine pancreas dysfunction.
2. Kearns–Sayre syndrome (KSS), a multisystem disorder with onset before age 20 of impaired eye movements (progressive external ophthalmoplegia; PEO), pigmentary retinopathy, and heart block. Frequent additional signs include ataxia, dementia, and endocrine problems (diabetes mellitus, short stature, hypoparathyroidism). Lactic acidosis, elevated cerebrospinal fluid (CSF) protein (over 100 mg dl^{-1}), and RRFs in the muscle biopsy are typical laboratory abnormalities.
3. PEO with or without proximal limb weakness, often compatible with a normal life span. Deletions vary in size and location, but a 'common' deletion of 5 kb is frequently seen in patients and in aged individuals (Figure 3).

Duplications of mtDNA can occur in isolation or together with single deletions and have been seen in patients with KSS or with diabetes mellitus and deafness. Duplications and duplications/deletions (as well as the associated phenotypes) are transmitted by maternal inheritance.

Point Mutations

Over 150 pathogenic point mutations have been identified in mtDNA from patients with a variety of disorders, most of which are maternally inherited and multisystemic, but some are sporadic and tissue specific (Figure 3). Among the maternally inherited encephalomyopathies, four syndromes are more common. The first is MELAS (mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes), which usually presents in children or young adults after normal early development. Symptoms include recurrent vomiting, migrainelike headache, and strokelike episodes causing cortical blindness, hemiparesis, or hemianopia. Magnetic resonance imaging (MRI) of the brain shows 'infarcts' that do not correspond to the distribution of major vessels, raising the question of whether the strokes are vascular or metabolic in nature. The most common mtDNA mutation is A3243G in the $tRNA^{Leu(UUR)}$ (*MT-TL1*) gene, but about a dozen other mutations have been associated with MELAS, most notably a mutation (G13513A) in the *MT-ND5* gene, which encodes subunit 5 of complex I.

The second syndrome is MERRF (myoclonus epilepsy with ragged red fibers), characterized by

Figure 2 Schematic representation of mitochondrial metabolism. ADP, adenosine diphosphate; ATP, adenosine triphosphate; CPT, carnitine palmitoyltransferase; CoA, coenzyme A; TCA, tricarboxylic acid; FADH2, flavin adenine dinucleotide, reduced form; NADH, nicotinamide adenine dinucleotide, reduced form; I, II, III, IV, V, complexes of the respiratory chain (stippled, complexes containing both subunits encoded by nuclear DNA and subunits encoded by mitochondrial DNA; solid, complexes encoded entirely by nuclear DNA); CoQ, coenzyme Q; Cyt c, cytochrome *c*; PDHC, pyruvate dehydrogenase complex.

myoclonus, seizures, mitochondrial myopathy, and cerebellar ataxia. Less common signs include dementia, hearing loss, peripheral neuropathy, and multiple lipomas. Three mtDNA mutations (A8344G, T8356C, and G8363A) have been associated with MERRF and all are in the $tRNA^{Lys}$ (*MT-TK*) gene.

The third syndrome comes in two forms: (1) NARP (neuropathy, ataxia, retinitis pigmentosa) usually affects young adults and causes retinitis pigmentosa, dementia, seizures, ataxia, proximal weakness, and sensory neuropathy; (2) maternally inherited Leigh syndrome (MILS) is a more severe infantile encephalopathy with characteristic symmetrical lesions in the basal ganglia and the brain stem.

The fourth syndrome, LHON (Leber hereditary optic neuropathy), is characterized by acute or subacute loss of vision in young adults, more frequently males, due to bilateral optic atrophy. Three mtDNA point mutations in NADH dehydrogenase (ND) genes (encoding subunits of complex I) have been associated with LHON. These are G11778A in *MT-ND4*, G3460A in *MT-ND1*, and T14484C in *MT-ND6*.

mtDNA Mutation Effects

Not surprisingly, syndromes associated with mtDNA mutations can affect every system in the body, including the visual (optic atrophy, retinitis pigmentosa, cataracts), auditory (neurosensory deafness), and endocrine (short stature, diabetes mellitus, hypoparathyroidism) systems, and the heart (familial cardiomyopathies, conduction blocks), the gastrointestinal tract (exocrine pancreas dysfunction, intestinal pseudoobstruction, gastroesophageal reflux), and the kidney (renal tubular acidosis). Any combination of the aforementioned

Figure 3 Morbidity map of the human mitochondrial genome as of 1 January 2003. The map of the 16 569-kb mitochondrial DNA (mtDNA) shows differently shaded areas representing the protein-coding genes for the seven subunits of complex I (NADH dehydrogenase, ND), the three subunits of cytochrome *c* oxidase (COX), cytochrome *b* (Cyt *b*), and the two subunits of ATP synthetase (A8/6), the 12S and 16S ribosomal RNAs (12S, 16S), and the 22 transfer RNAs (tRNA) identified by one-letter codes for the corresponding amino acids. FBSN, familial bilateral striatal necrosis; KSS, Kearns–Sayre syndrome; LHON, Leber hereditary optic neuropathy; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes; MERRF, myoclonic epilepsy with ragged-red fibers; MILS, maternally inherited Leigh syndrome; NARP, neuropathy, ataxia, retinitis pigmentosa; PEO, progressive external ophthalmoplegia.

symptoms and signs should raise the suspicion of a mitochondrial disorder, especially if there is evidence of maternal transmission. On the other hand, point mutations in mtDNA protein-coding genes often escape the rules of mitochondrial genetics in that they affect single individuals and single tissues, most commonly skeletal muscle. Thus, patients with exercise intolerance, myalgia, and, sometimes, recurrent myoglobinuria may have isolated defects of complex I, complex III, or complex IV, due to pathogenic mutations in genes encoding ND subunits, cytochrome *b*, or cytochrome *c* oxidase (COX) subunits. The lack of maternal inheritance and the involvement of muscle alone suggest that mutations arose *de novo* in myogenic stem cells after germ-layer differentiation ('somatic mutations').

Disorders Due to Defects of Nuclear DNA

Disorders due to defects of nDNA are all transmitted by Mendelian inheritance and include three major subgroups.

Mutations in Genes Encoding Subunits or Ancillary Proteins of the Respiratory Chain

As noted in the preceding discussions, mtDNA encodes only 13 subunits of the respiratory chain, while nDNA encodes all subunits of complex II, most subunits of the other four complexes, as well as coenzyme Q_{10} (CoQ_{10}) and cytochrome *c*. Nuclear DNA mutations can affect respiratory chain complexes directly or indirectly.

Figure 4 Schematic representation of the mitochondrial respiratory chain, showing nuclear DNA (nDNA)-encoded (unlabeled) and mitochondrial DNA (mtDNA)-encoded (labeled) subunits. Electrons (e^-) flow along the electron-transport chain, and protons (H^+) are pumped, first from the matrix into the intermembrane space through complexes I, III, and IV, then back into the matrix through complex V to generate ATP. Disorders due to mutations in nuclear genes are listed below the defective respiratory chain complexes. LHON, Leber hereditary optic neuropathy; NARP, neuropathy, ataxia, retinitis pigmentosa; MILS, maternally inherited Leigh syndrome; FBSN, familial bilateral striatal necrosis; ND, NADH dehydrogenase; CoQ, coenzyme Q; Cyt *b*/Cyt *c*, cytochromes *b*/*c*; COX, cytochrome *c* oxidase.

Direct 'hits' – that is, mutations in genes encoding respiratory chain subunits – are known only for complex I and complex II. These have been associated with autosomal recessive forms of Leigh syndrome. Primary or secondary CoQ_{10} deficiency can cause four major syndromes: (1) a predominantly myopathic disorder with recurrent myoglobinuria but also central nervous system involvement (seizures, ataxia, mental retardation), (2) a predominantly encephalopathic disorder with ataxia and cerebellar atrophy, (3) an isolated myopathy, with RRFs and lipid storage, and (4) a generalized mitochondrial encephalomyopathy, usually with onset in infancy. An example of secondary CoQ_{10} deficiency is that associated with aprataxin (*APTX*) gene mutations, which cause ataxia oculomotor apraxia type 1 (AOA1). Examples of primary CoQ_{10} deficiency include mutations in two of the eight biosynthetic genes, *COQ1* and *COQ2*. Irrespective of etiology, diagnosis is important because most patients with CoQ_{10} deficiency respond to high-dose CoQ_{10} supplementation.

Indirect 'hits' are mutations in genes encoding proteins that are not components of the respiratory chain, but are needed for the proper assembly and function of respiratory chain complexes. This 'murder by proxy' mechanism has been identified in disorders due to defects in complexes I, III, IV, and V, but is best illustrated by Mendelian defects of complex IV (cytochrome *c* oxidase). Mutations in six ancillary proteins (SURF1, SCO2, SCO1, COX10, COX15, and LRPPRC) have been associated with COX-deficient Leigh syndrome or other multisystemic fatal infantile disorders in which encephalopathy is accompanied by cardiomyopathy (SCO2, COX15), nephropathy (COX10), or hepatopathy (SCO1).

This is a burgeoning field of research with important theoretical and practical implications. From an investigative point of view, these disorders teach us a lot about the structural and functional complexity of the respiratory chain. At a more practical level, identification of mutations in the related genes renders prenatal diagnosis available and suggests approaches to therapy, such as copper administration to infants with mutations in SCO2, a copper-carrying protein.

Defects of Intergenomic Signaling

As noted previously, the mtDNA is highly dependent for its proper function and replication on numerous factors encoded by nuclear genes. Mutations in these

Table 1 Genetic classification

Defects of mitochondrial DNA	*Defects of nuclear DNA*
Mutations in protein synthesis genes	Mutations in respiratory chain subunits
tRNA, rRNA, rearrangements	Complex I, complex II, CoQ_{10}
Mutations in protein-coding genes	Mutations in ancillary proteins
Multisystemic (LHON, NARP/MILS)	Complex III, complex IV, complex V
Tissue specific	Defects of intergenomic signaling
	AR-PEO with multiple Δ-mtDNA
	mtDNA depletion
	Defective mtDNA translation
	Defects of protein transport
	Mohr–Tranebjaerg syndrome
	Defects of the lipid milieu
	Barth syndrome

tRNA/rRNA, transfer/ribosomal ribonucleic acid; LHON, Leber hereditary optic neuropathy; NARP, neuropathy, ataxia, retinitis pigmentosa; MILS, maternally inherited Leigh syndrome; CoQ_{10}, coenzyme Q_{10}; AR-PEO, autosomal recessive progressive external ophthalmoplegia; Δ-mtDNA, mutated mitochondrial DNA.

genes cause Mendelian disorders characterized by qualitative or quantitative alterations of mtDNA. Examples of qualitative alterations include autosomal dominant or autosomal recessive multiple deletions of mtDNA, usually accompanied clinically by progressive external ophthalmoplegia plus a variety of other symptoms and signs. Four of these conditions have been characterized at the molecular level. Mutations in the gene for thymidine phosphorylase (*TP*) are responsible for an autosomal recessive multisystemic syndrome called MNGIE (mitochondrial neurogastrointestinal encephalomyopathy). Mutations in the gene for one isoform of the adenine nucleotide translocator (*ANT1*) have been identified in some, but not all, patients with autosomal dominant PEO. Mutations in the *PEO1* gene, encoding Twinkle, a helicase, are associated with autosomal dominant PEO, whereas mutations in the gene encoding polymerase γ (*POLG*) may cause either autosomal dominant or autosomal recessive PEO. Autosomal recessive mutations in *POLG* also cause an mtDNA depletion syndrome (see later) involving liver and brain, known as Alpers or Alpers–Huttenlocher syndrome. Interestingly, all of these mutations affect genes involved in the homeostasis of the mitochondrial nucleotide pool and probably have similar pathogenic mechanisms.

Examples of quantitative alterations of mtDNA include severe or partial mtDNA depletion, usually characterized clinically by congenital or childhood forms of autosomal recessively inherited myopathy or hepatopathy. Mutations in five genes, four of them involved in mitochondrial nucleotide homeostasis, have been associated with mtDNA depletion syndromes, although they still do not explain all cases. Mutations in the gene encoding thymidine kinase 2 (*TK2*) are often seen in patients with myopathic mtDNA depletion syndromes, whereas mutations in the gene (*SUCLA2*), encoding the β subunit of the mitochondrial matrix enzyme succinyl-CoA synthetase, cause both myopathy and encephalopathy. Mutations in *DGUOK*, encoding deoxyguanosine kinase, predominate in patients with hepatic or hepatocerebral mtDNA depletion syndromes, but, as mentioned previously, mutations in *POLG* are the major causes of Alpers–Huttenlocher syndrome, a severe hepatocerebral syndrome with vulnerability to valproic acid. Mutations in a gene (*MPV17*) not involved in nucleotide pool homeostasis have been associated with hepatocerebral syndrome and with the Navajo neurohepatopathy (NNH) syndrome, prevalent in the Navajo population of Southwestern Unites States. An iatrogenic form of mtDNA depletion may follow treatment with nucleoside analogs such as zidovudine (AZT).

A new group of defects of intergenomic communication is due to mutations in genes encoding factors necessary for the faithful translation of mtDNA-encoded proteins, including *EFG1* (encoding elongation factor 1), *MRPS16* (encoding small subunit protein), *EFTu* (encoding elongation factor Tu), *TSFM* (controlling the expression of both EFTs and EFTu), and *PUS1* (encoding pseudouridine synthase 1). The resulting disorders usually affect infants and cause severe encephalomyopathy, cardiomyopathy, and sideroblastic anemia. Typically, both quality and quantity of mtDNA are normal in these patients, but there are – not surprisingly – multiple respiratory chain defects involving all complexes containing mtDNA-encoded subunits.

Defects of Mitochondria as Causes of Neurodegenerative Disorders

Although they do not affect the respiratory chain directly, defects of mitochondrial motility, fusion, and fission are taking center stage as causes of neurodegenerative disorders. Mitochondria travel on microtubular rails, propelled by motor proteins, usually GTPases, called kinesins or dyneins. The first defect of mitochondrial motility was identified in a family with autosomal dominant hereditary spastic paraplegia and mutations in a gene (*KIF5A*) encoding one of the kinesins. Interestingly, the mutation affects a region of the protein involved in microtubule binding.

Mutations in *OPA1* cause autosomal dominant optic atrophy, the Mendelian counterpart of LHON. Mutations in *MFN2* cause an autosomal dominant axonal variant of Charcot–Marie–Tooth (CMT) disease. Also, mutations in *GDAP1*, the gene encoding ganglioside-induced differentiation protein 1, which is located in the mitochondrial outer membrane and regulates the mitochondrial network, cause CMT type 4A, an autosomal recessive, severe, early-onset form of either demyelinating or axonal neuropathy.

Indirect Causes of Respiratory Chain Dysfunction

We include here mutations in nuclear genes that affect neither respiratory chain subunits or ancillary proteins, nor mtDNA structure or copy number. For example, the function of the respiratory chain can be impaired by alterations in the lipid composition of the inner mitochondrial membrane or by defective importation of one or more subunits. The first situation is exemplified by Barth syndrome, an X-linked recessive disorder characterized by mitochondrial myopathy, cardiopathy, and leukopenia. The gene responsible for this disorder (*TAZ*) encodes a family of proteins ('tafazzins') involved in the synthesis of phospholipids, and biochemical analysis has shown altered amounts and composition of cardiolipin, the main phospholipid component of the inner mitochondrial membrane.

An example of defective protein importation is the X-linked deafness–dystonia syndrome (Mohr–Tranebjaerg syndrome), characterized by progressive sensorineural deafness, dystonia, cortical blindness, and psychiatric symptoms. This disorder is due to mutations in *TIMM8A*, which encodes the deafness–dystonia protein (DDP1), a component of the mitochondrial protein import machinery located in the intermembrane space.

Mitochondrial Organization in Neurons

The Need for Mitochondrial Organization and Motility in Neurons

The ability of mitochondria to move and establish a characteristic distribution within a given cell type is a general cell biological process. In dividing yeast, for example, the transport of mitochondria determines the inheritance of the proper quotient of mitochondria by the two daughter cells, and this phenomenon has been studied extensively. In neurons, however, mitochondrial transport and localization are particularly vital because of the extraordinary lengths of axons and dendrites and the complex anatomy of each cell. Neurons depend on mitochondria for adenosine 5′-triphosphate (ATP) production and for Ca^{2+} buffering. Because the demand for energy and the need for Ca^{2+} buffering differ from one neuron to another and indeed from one part of the neuron to another part, the density of mitochondria differs between neurons and within a single neuron. Though much remains to be determined about how mitochondrial number and distribution are regulated in neurons, it is apparent that mitochondria are dynamic organelles that move long and short distances and stop and start often. These movements presumably allow them to alter their distribution and thereby adapt to changes in the neuron's local energy requirements. In this regard, their movements may be more complex and more tightly regulated than those of other neuronal cargoes, such as synaptic vesicle precursors or receptors undergoing transport to dendrites. The mechanisms of mitochondrial motility, the motors employed, and the adaptor proteins and regulatory proteins that control these motors in neurons are beginning to be understood.

Complex Distribution of Mitochondria

Mitochondria accumulate in subcellular regions that have high energy demands, such as in axonal growth cones and nodes of Ranvier. The latter, for example, have more mitochondria than internodal regions of myelinated nerve, and this is likely to reflect the need for ATP to drive the extrusion of the ions that enter during action potentials at the node. Mitochondria are enriched both pre- and postsynaptically at synapses and also at areas of high metabolic demand as a consequence of the need to pump out ions that have entered through voltage- and ligand-gated channels. An example of this phenomenon occurs in the clustering of mitochondria at the presynapse of the neuromuscular junction during differentiation in frog spinal neuron–muscle cultures (Figure 1). The distribution of mitochondria in dendrites may be a limiting factor in the development and maintenance of synapses in cultures of hippocampal neurons.

The correlation of mitochondrial activity with neuronal activity has proven to be useful as a reporter of regional brain function. Dramatic examples of this correlation have been found in somatosensory and visual cortices that were stained for the activity of the mitochondrial enzyme cytochrome oxidase. When these cortices are deprived of sensory input, the corresponding regions of the cortices have decreased cytochrome oxidase staining (Figure 2). The decrease in cytochrome oxidase activity can result either from a decrease in the number of mitochondria at inactive synapses or from a decrease in the activity of mitochondrial enzymes, and in fact a combination of both these phenomena is the most likely explanation. This correlation has been examined in some detail in crustacean motor neurons that were subjected to sustained increases in activity. Mitochondrial vital dyes and counts of mitochondrial cross-sectional areas by electron microscopy have indicated that both the number and functional state of mitochondria were enhanced. Similarly, a comparison of tonic and phasic synapses in the crayfish demonstrated that tonic synapses, which are thought to be the more active class, have a higher mitochondrial density as measured by electron microscopy. Activity-dependent changes are likely to result in changes in number of mitochondria in nonsynaptic compartments of the neuron as well. For example, when the activity in the axonal growth cone of a chick sympathetic neuron is decreased by inhibiting axonal growth, the density of mitochondria in the growth cone also decreases.

Mitochondrial Functions in Neurons

Production of ATP At the synapse and throughout the neuron, mitochondria are thought to play three important roles: producing ATP, buffering Ca^{2+}, and sequestering apoptotic factors. ATP supports many essential neuronal functions. Some, such as protein synthesis and regulatory phosphorylations, are common to all cells, but others are either unique to or more significant in neurons. Thus, either directly or indirectly, ATP fuels the sodium pump for maintaining the membrane resting potential, clearing Ca^{2+} from the cytosol via membrane pumps, packaging

Figure 1 Mitochondria are enriched at synapses. (a) At the frog neuromuscular junction (NMJ), mitochondria labeled with a mitochondrion-selective dye (mitotracker) are found at the nerve terminal, as indicated by their presence near nicotinic acetylcholine receptors labeled with α-bungarotoxin. (b) Stimulation of the nerve terminal increases mitochondrial staining at the NMJ. Belair EL, Vallee J, and Robitaille R (2005) Long-term *in vivo* modulation of synaptic efficacy at the neuromuscular junction of Rana pipiens frogs. *Journal of Physiology* 569: 163–178.

Figure 2 Neuronal activity affects distribution of active mitochondria. The mitochondrial enzyme cytochrome oxidase (CO) serves as a marker for active mitochondria in layer 4 of macaque visual cortex. Removal of one eye severely reduces the activity of neurons in the lateral geniculate nucleus that receive input from that eye. As a consequence, the regions of primary visual cortex that are innervated by those neurons also have reduced activity. This is reflected in the pattern of stripes of high and low cytochrome oxidase activity, which corresponds to regions devoted to input from the active eye and those receiving input from the silenced pathway. Horton JC and Adams DL (2005) The cortical column: A structure without a function. *Philosophical Transactions of the Royal Society of London, Series B: Biological Sciences* 360: 837–862.

neurotransmitter into vesicles, and recovering neurotransmitter from the synaptic cleft. Indeed, maintaining ionic homeostasis through pumps is the most important energetic demand on a nerve cell.

Ca^{2+} buffering In addition to producing ATP, mitochondria play a key role in buffering local Ca^{2+} concentrations in nerve terminals. Ca^{2+} enters the mitochondrial matrix through the Ca^{2+}-permeable uniporter (presumably a channel) in the mitochondrial inner membrane. The rapid mitochondrial uptake of cytoplasmic Ca^{2+} dissipates microdomains of high Ca^{2+} and prevents diffusion of Ca^{2+} in the cell. In addition to Ca^{2+} influx into the mitochondria, the exit of Ca^{2+} from the mitochondria also affects cytoplasmic Ca^{2+}. After accumulating Ca^{2+}, mitochondria release it slowly through a sodium–Ca^{2+} exchanger. Thus, if Ca^{2+} channels in the plasma membrane open to create a large, sudden rise in cytoplasmic Ca^{2+}, Ca^{2+} will first accumulate in the mitochondrial matrix, which can decrease the amplitude and duration of the large change in cytosolic Ca^{2+}. When Ca^{2+} slowly exits the mitochondria, the effect will be to keep the cytoplasmic level of Ca^{2+} somewhat elevated, long after the original stimulation for the Ca^{2+} increase has stopped. Ultimately, this Ca^{2+} will be extruded across the plasma membrane to restore the initial resting conditions of the cell.

Apoptosis In addition to producing ATP and buffering Ca^{2+}, mitochondria are important for apoptosis, or programmed cell death. Many different factors, such as DNA damage, oncogene activation, or withdrawal of growth factors, can activate mitochondrial-dependent apoptosis. On activation of apoptosis, two proteins, Bax and Bak, oligomerize on the

mitochondrial outer membrane, and this leads to mitochondrial outer membrane permeabilization and release of cytochrome C, which in turn activates caspases, proteolysis, and cell death. It remains uncertain to what extent changing the distribution of mitochondria in a cell will alter the cell's susceptibility to localized proapoptotic signals.

Mitochondria and the Function of the Nerve Terminal

Because the availability of ATP and the regulation of cytosolic Ca^{2+} are so important to nerve terminals, and because mitochondria are abundant at synapses, it is not surprising that the particular role of mitochondria in shaping synaptic transmission has received a lot of attention. For many years this has been addressed pharmacologically, through the application of compounds that poison the electron transport chain in mitochondria. Some drugs will collapse the potential across the mitochondrial membrane (e.g., the protonophore FCCP) and thereby prevent both oxidative phosphorylation for the production of ATP and mitochondrial uptake of Ca^{2+}. Other compounds (e.g., ruthenium red) can be employed that selectively block the Ca^{2+} uptake pathway. More recently, it has been possible to examine synapses in *Drosophila* mutants that lack mitochondria because of defects in mitochondrial fission or transport. This approach can bring about the complete absence of mitochondria from the nerve terminal, but unlike the pharmacological approach, it is a chronic manipulation. In principle, genetic approaches may also be able to distinguish among types of mitochondrial function, but this has not yet been reported.

Ca^{2+} buffering by mitochondria can influence transmitter release One manner in which mitochondria can influence transmitter release is via their ability to sequester and then release Ca^{2+}. Cytosolic proteins are likely to be the major buffers of Ca^{2+} in neurons, but mitochondria can also contribute to the buffering. As discussed above, if mitochondria take up Ca^{2+} rapidly when the cytosolic concentration is high and then release it slowly as the concentration falls, a prolonged phase of somewhat elevated cytosolic Ca^{2+} arises in consequence. After a train of action potentials, this sustaining of cytoplasmic Ca^{2+} is thought to be important for synaptic plasticity. For example, it has been shown that posttetanic potentiation (PTP), the enhancement of synaptic transmission for several minutes that often occurs after high-frequency stimulation, is in part due to mitochondrial Ca^{2+} sequestration. The underlying mechanism is likely to be that cytoplasmic Ca^{2+} levels remain elevated after stimulation and thereby increase the amount of neurotransmitter release. Inhibition of mitochondrial Ca^{2+} uptake and release both blocked PTP and reduced cytoplasmic Ca^{2+} levels. Mitochondrial sequestration has also been shown to be important for terminating transmitter release after a stimulus and preventing asynchronous neurotransmitter release.

The endoplasmic reticulum (ER) may also play an important role in buffering synaptic Ca^{2+}, although this point is very controversial, and the relative importance of the ER and mitochondria for buffering Ca^{2+} may vary between synapses. At some, one compartment or the other may dominate, or both may contribute to Ca^{2+} sequestration. At other synapses, neither the ER nor mitochondria have a substantial influence on the shape of the Ca^{2+} signal. Regardless of how actively they sequester Ca^{2+}, release induced from either store can influence transmitter release. Thus multiple Ca^{2+} buffering mechanisms may allow different synapses to tailor their buffering capacity to the needs of the synapse.

Synaptic transmission in mutants lacking synaptic mitochondria The importance of mitochondria for synaptic function has been highlighted by three different *Drosophila* mutants that lack mitochondria in their axons and terminals (Figure 3). These mutants, *milton*, *miro*, and *drp1*, all have defects in synaptic transmission and indeed were identified in screens for impaired synaptic transmission at photoreceptor synapses. Transmission in the *miro* mutant has been examined closely at the neuromuscular junction, where it causes a decrease in vesicle release (decreased amplitudes of excitatory junctional potentials) during high-frequency stimulation protocols and an increase in asynchronous release after prolonged stimulation. *Drp1* mutants have a similar neuromuscular phenotype. The *drp1* phenotype was interpreted as arising from a requirement for mitochondrial ATP in the mobilization of the reserve pool of synaptic vesicles. Drp1 is the fly homolog of dynamin-related protein and plays a role in mitochondrial fission, whereas milton and miro proteins are required for axonal transport of mitochondria (see below).

These phenotypes notwithstanding, the three *Drosophila* mutants (*milton*, *miro*, and *drp1*) that lack synaptic mitochondria are not as severely compromised at their synapses as might have been anticipated. The axons develop normally and reach their targets with no gross abnormalities. Moreover, these mutants have normal synaptic transmission at the neuromuscular junction unless challenged with high-frequency stimulation. The mutations are lethal, but the homozygotes for *miro* and *drp* survive to the third instar stage. The explanation for this persistence of normal function is not yet clear but

Figure 3 Mitochondria are absent from axons of flies lacking the protein milton. (a–f) Images of peripheral nerves that extend from the posterior of the nerve cord to the body wall muscles. (a) In control larvae, mitochondria labeled with green fluorescent protein (mitoGFP) are abundant in axons. (b) In mutant larvae lacking the protein milton, mitochondria are absent from axons. The defect is specific for mitochondria. Antisynaptotagmin immunolabeling of synaptic vesicles (c, d) or antikinesin heavy chain immunolabeling (e, f) is indistinguishable between *milton* mutant and control larvae. (g–j) Confocal images through the middle of the ventral nerve cord. (g) In control larvae, on either side of the midline, the synapse-rich neuropil is enriched for mitochondria (mitoGFP) relative to the surrounding cell-body region. (h) In mutant nerve cords lacking milton, the mitoGFP is primarily in cell bodies. (i, j) Synaptotagmin is concentrated in the neuropil of both control and mutant larvae. Khc, kinesin heavy chain; syt, synaptotagmin. Glater EE, Megeath LJ, Stowers RS, and Schwarz TL (2006) Axonal transport of mitochondria requires milton to recruit kinesin heavy chain and is light chain independent. *Journal of Cell Biology* 173: 545–557.

may indicate a relatively minor role for the mitochondria in Ca^{2+} buffering at these terminals and the presence of alternative sources of ATP.

Mechanisms of Mitochondrial Motility

Mitochondrial Movement

Imaging of mitochondria in neurons reveals that their neurites contain many discrete mitochondria and that a number of these mitochondria are in motion at any given moment. Thus, whereas mitochondria may exist in a continuous, interconnected reticulum in many cell types – and indeed may form such a reticulum in neuronal cell bodies and in primary dendrites – in many neuronal processes they are encountered as discrete organelles that appear to travel independently of one another. The visualization of mitochondrial motility depends on live imaging, which has been accomplished with a variety of vital dyes and, more recently, with transgenes that express green fluorescent protein to which a mitochondrial import signal has been attached.

Why do neurons contain moving mitochondria? One likely explanation is that mitochondria must move from the cell body, the site of the majority of organelle biogenesis, to the axons and their terminals. It is also possible that some replication of mitochondria occurs in the periphery of the cell. Mitochondrial movement is bidirectional; some of the mitochondria are moving from the soma to the periphery and some from the periphery back to the soma. This may represent older mitochondria that are returning to the soma for degradation or to be resupplied with newly synthesized proteins. Equally important as an explanation of mitochondrial motility may be the capacity of the cell to monitor local energy supplies and redistribute the mitochondria accordingly. If mitochondria become mobile where ATP is high and are immobilized where it is low, they will shift in such a

way as to preserve an adequate energy supply throughout the cell. In contrast, the stationary mitochondria may guarantee that a subset of mitochondria is devoted to the energetic demands of a given region.

The pattern of mitochondrial movement has been described in several systems, including hippocampal neurons and *Drosophila* nerves. Their movement is often described as saltatory, meaning they stop and start, change speed, and often reverse direction. In hippocampal axons, approximately one-third of mitochondria move at any one time, and in the same preparation, they can behave in a variety of manners: some move exclusively in one direction, others shift directions, some change their speed between fast and slow rates, and others exhibit only a single speed. Thus the complex movements of mitochondria are somewhat different from those of other axonal cargoes, such as small vesicles and endosomes, which consistently move in a single direction.

Mechanisms of Axonal Transport of Mitochondria

Mitochondria move by both microtubule and actin-dependent mechanisms. The majority of mitochondrial movements are microtubule-based and can be arrested by the pharmacological depolymerization of the microtubules. Actin depolymerization also decreases mitochondrial movement, though to a lesser extent, which has led to suggestions that only 20% of mitochondrial movement in axons is actin-based, with the remainder driven by microtubule-based motors. The actin-based movements are likely to drive only short-range movement, with long-distance transport of mitochondria transpiring via microtubules. In most neurons, the axon is a highly polarized structure, with the minus ends of the microtubules located in the cell bodies and the plus ends at axon terminals. Dendrites, in contrast, contain microtubules of both polarities. In consequence, transport can be simpler to analyze in axons than in dendrites, but in both types of neurite, the behavior of the mitochondria will be governed by the interplay of plus end-directed microtubule motors, the kinesins, with dynein, the minus end-directed motor, as well as with actin and myosin-based motors and the poorly understood machinery that is likely to tether mitochondria in place.

A kinesin-containing complex for mitochondrial transport Two kinesin motors have been implicated in axonal transport of mitochondria: conventional kinesin-1 and kinesin-3. Kinesin-1 is a tetramer made up of two kinesin heavy chains (KHCs) and two kinesin light chains (KLCs). In *Drosophila,* KHC is crucial role in mitochondrial transport. In *khc* mutants, axonal transport is severely impaired and in the segmental nerves, gives rise to large swellings of axons at irregular intervals (Figure 4). These swellings, sometimes called traffic jams, are filled with a variety of immobilized organelles, including mitochondria. In photoreceptor axons that are homozygous for *khc* null alleles, the axons are devoid of mitochondria. In live imaging of *khc* mutants, mitochondrial anterograde movement is greatly decreased. Thus the *khc* phenotype provides strong evidence for the importance of this conventional kinesin-1 in anterograde axonal transport of mitochondria.

However, the conventional kinesin may be acting in an unconventional state. The structure of a kinesin-1 motor is typically tetrameric, consisting of two heavy chains and two light chains. The heavy chains form the motor and stalk domains, and the light chains often serve as regulators and cargo-attachment areas. In *Drosophila*, however, mitochondria are transported into axons even in neurons that are homozygous for null alleles of the single KLC, and the light chain is not present in the mitochondrial motor-adaptor complex that includes the heavy chain.

The importance of the kinesin-1 motors for anterograde movement of mitochondria appears to be evolutionarily conserved. In mammals, a homolog of KHC, called KIF5B, has similarly been implicated in mitochondrial transport. In *kif5B-/*-mouse extraembryonic cells, the mitochondria were clustered in the perinuclear region of the cell and absent from the periphery, where they are normally found in wild-type cells. In subcellular fractionation studies, KIF5B was associated with the mitochondrial fraction. It is not known if this mammalian kinesin-1 heavy chain is coupled to mitochondria without a light chain, as in *Drosophila*, but two isoforms of the mammalian light chains, KLC-B and KLC-3, have been reported to associate with mitochondria in nonneuronal cells. Whether they are involved in axonal transport is unknown.

Kinesin-1 may not be the sole anterograde motor for mitochondria. A kinesin-3 family member, mammalian KIF1B, was shown to transport purified mitochondria along microtubules *in vitro*, to colocalize with mitochondria, and to be enriched in a mitochondrial fraction. It is interesting that mutants in the *Drosophila* homolog of KIF1B, *Imac*, do not have defects in axonal transport of mitochondria but do have defects in transport of synaptic vesicles. Thus there may be some variation from species to species and from cell type to cell type as to which motors are involved in the anterograde movement, although the case for the involvement of the conventional kinesin-1 is presently very strong.

How then is the kinesin attached to the mitochondrion and how is its activity regulated? Recent studies have identified a protein complex that couples the KHC

Figure 4 Axonal pathology caused by defects in kinesin. Axonal swellings include accumulations of organelles, including mitochondria. *Drosophila* segmental nerves from control larvae (left) and from larvae mutant in the heavy chain of kinesin-1 (right). Though most axons retain their normal appearance, with diameters of less than 1 μm, some axons have massive swellings within which a variety of organelles are encountered, including mitochondria (M), multivesicular bodies (MV), likely prelysosomal vacuoles (PLV), and a variety of smaller vesicles. Hurd DD and Saxton WM (1996) Kinesin mutations cause motor neuron disease phenotypes by disrupting fast axonal transport in Drosophila. *Genetics* 144: 1075–1085.

to the outer surface of the mitochondrion, and this complex is likely to be a focal point for the regulation of plus end-directed mitochondrial movement. The complex consists of at least three proteins: conventional KHC, milton, and miro. Milton is a protein of approximately 1100 amino acids that is conserved between *Drosophila* and mammals, though in mammals it has also been named *O*-linked *N*-acetylglucosamine-Interacting Protein 106, OIP98/$GABA_A$ Receptor Interacting Factor-1, and Trafficking Protein, Kinesin Binding. The importance of the protein for axonal and dendritic transport was revealed by the isolation of null mutants in *Drosophila* in a screen for mutations with defective synaptic transmission. In these mutants, neuronal mitochondria were found to be restricted to the cell bodies. Within photoreceptor cell bodies, they were broadly distributed, much as in wild-type photoreceptors, but they were never encountered beyond the axon hillock. Milton contains a coiled-coil domain through which it binds to the KHC. This association is inhibited by the presence of the KLC, which is consistent with the persistence of mitochondrial transport in light chain mutants. Milton in turn binds to the mitochondrial membrane, at least in part, via its interactions

with the third protein, miro. Miro is anchored in the mitochondrial membrane by a C-terminus transmembrane domain, but the protein is chiefly exposed on the cytoplasmic surface. It contains two guanosine triphosphatase (GTPase) domains with some similarity to the rho family and also contains a pair of EF hands. The *miro* mutants, like *milton* alleles, lack axonal mitochondria but retain functional mitochondria in their cell bodies. Thus the present model for mitochondrial transport has milton serving as an adaptor between the mitochondrial surface protein, miro, and the KHC.

An additional protein that may be important for determining the distribution of mitochondria in mammalian neurons is syntabulin, a protein without a clear homolog in the *Drosophila* genome. Syntabulin localizes to the mitochondrial outer membrane and also interacts with microtubules. Syntabulin may serve as an adapter between KHC and mitochondria or may play a role in tethering stationary mitochondria to the cytoskeleton.

Dynein and mitochondrial transport Dynein has been implicated as the major motor for microtubule-based retrograde axonal transport, and dynein has been shown to be associated with mitochondria. The most direct evidence for a role of dynein in retrograde transport of mitochondria is impairment of this process in *Drosophila* dynein heavy chain mutants. Dynein is part of a complex including dynein heavy, intermediate, and light chains as well as many associated adapter and regulatory proteins. To date, no specific dynein complex components or adapters have been shown to be specifically associated with mitochondria.

It is interesting to note that dynein seems to depend on kinesin-1 for transport and that these two motors are interconnected. Indeed, a direct interaction has been shown between dynein intermediate chain and KLCs. The interaction of these proteins may reflect a requirement for kinesin to bring dynein to the periphery so that dynein is available for returning cargoes to the soma, but it may also indicate an ongoing connection and functional interdependence. An indication of this interdependence may be the observation that *Drosophila khc* mutants are impaired in both anterograde and retrograde movements of mitochondria. A regulatory interplay between the motors would seem to be required when mitochondria switch directions in the axon.

Actin, myosin, and mitochondrial transport Actin-based transport of mitochondria is well established in nonneuronal cells and, as mentioned above, may be responsible for short-range movements of mitochondria in axons as well, though less is known about these mechanisms in neurons. In yeast, actin-based mechanisms drive mitochondrial motility. One important pathway is myosin independent and is driven instead by the polymerization of actin. In contrast, in neurons and other animal cells, the evidence presently points to unconventional myosin motors as the basis of actin-dependent mitochondrial movements. In locust photoreceptor cell bodies, mitochondrial transport has been shown to be actin-dependent, and a putative, myosin, has been implicated as the motor. This myosin was shown to localize to mitochondria in photoreceptor cells, and *in vitro* the protein shows an ATP-dependent binding to actin filaments.

Regulation of Mitochondrial Movement

Recently, several intracellular signals have been shown to play a role in specifically controlling the movement of mitochondria. Some pathways seem to affect global mitochondrial movement and some local mitochondrial movement. In general, sensitivity to local cytoplasmic Ca^{2+} concentration may be a crucial regulatory mechanism for neuronal mitochondria. High local influxes of Ca^{2+} will correlate with regions of high metabolic demand, such as nerve terminals and postsynaptic specializations. Thus a tendency for mitochondria to arrest where Ca^{2+} is elevated will cause them to cluster near synapses. In addition, a sustained elevation of cytosolic Ca^{2+} may be a symptom of insufficient local ATP to power the ATPase that extrudes the ion across the plasma membrane. In this case, it would again be advantageous for mitochondria to be attracted to areas of high Ca^{2+} or to stop in their vicinity as a means of balancing ATP production throughout the cell. One manifestation of the ability of elevated Ca^{2+} to arrest mitochondrial transport is seen in the application of glutamate to cultured hippocampal neurons and the consequent Ca^{2+} influx through *N*-methyl-D-aspartate receptors. How Ca^{2+} regulates mitochondrial motility is unknown, but the EF hands of miro are candidates for the Ca^{2+}-binding sites that mediate this effect. As part of the complex that couples kinesin to the mitochondrial surface, Ca^{2+} binding to miro potentially could regulate either the activity of kinesin or its association with the mitochondrion.

Ca^{2+} is not the only signal to regulate mitochondria. Local mitochondria respond, for example, to the application of nerve growth factor (NGF). Mitochondria, via an actin-dependent mechanism, accumulate near beads coated with NGF. In addition, zinc has been shown to inhibit mitochondrial movement. It is interesting that both the zinc and NGF effects were shown to be mediated by phosphatidylinositol 3-kinase activity (**Figure 5**).

Other sites of mechanisms of potential regulation are suggested by studies of milton and miro. Miro contains

Figure 5 Model of mitochondrial transport. At least three motors are involved in the movement of neuronal mitochondria. Kinesin-1 moves mitochondria in the anterograde direction toward the plus ends of microtubules. Kinesin-1 is attached to the organelle by an adaptor complex of miro and milton. Dynein/dynactin moves mitochondria in the retrograde direction and is attached to the mitochondrion by unknown adaptors. Myosin moves mitochondria in short-range movements along F-actin. Stationary mitochondria may be anchored to F-actin by myosin or unknown anchor proteins. Phosphatidylinositol 3-kinase (PI3 kinase) has been shown to play a role in regulating mitochondrial movement. Modified from Hollenbeck PJ and Saxton WM (2005) The axonal transport of mitochondria. *Journal of Cell Science* 118: 5411–5419.

rho-like GTPase domains, and the GTP or guanosine diphosphate-bound state of these domains may therefore function as a regulator switch. Milton binds to the cytoplasmic glycosylating enzyme O-GlcNAc transferase and is glycosylated by that enzyme, though the significance of this posttranslational mechanism for mitochondrial movement is unknown. Finally, at least four isoforms of *Drosophila* milton exist as a consequence of alternative splicing of the N-terminus, and alternative splicing arises in the mammalian homologs as well. At least one of the *Drosophila* isoforms does not bind KHC when expressed in COS cells, which raises the possibility that this alternatively spliced region can regulate the association of the motor with the organelle.

Mitochondria and Neurodegenerative Disease

With the essential functions of mitochondria in ATP production, Ca^{2+} buffering, and apoptosis, it is not surprising that defects in mitochondrial function lead to disease. Moreover, recently it has been shown that defects specifically in the axonal transport of mitochondria are correlated with disease. The most well-characterized example is Huntington's disease, and several studies have shown that mitochondrial transport is disrupted in mouse and *Drosophila* models of the disorder. In transgenic mice expressing mutant huntingtin with polyglutamine repeats, mitochondria move more slowly and stop more frequently, and this occurs prior to overt neurological symptoms. The transport defect seems to be specific for mitochondria because the movement of other organelles, such as endocytic vesicles, appears to remain unaffected.

Several other neurodegenerative disorders have been shown to involve defects in axonal transport, though the extent to which mitochondrial movements are responsible for the pathology is less clear. These diseases include mutations in motor proteins implicated in hereditary spastic paraplegia, Charcot-Marie-Tooth disease Type 2A, congenital fibrosis of the extraocular muscles Type I, and motor neuron disease. In addition, axonal transport has been shown to be disrupted in Alzheimer's disease and implicated in subsequent neuronal death. Although these are complex disorders in which many cellular processes may be compromised, it seems likely that defects in the distribution of mitochondria will contribute to the manifestations of the disorders.

Introduction

Given the heterogeneity of the brain, the large numbers of genes encoded in the genomes of higher mammals, and the complexity of processes such as behavior, learning, and memory, how is it possible to identify the genes that regulate these phenotypes? How can we use genetic and genomic information to discover targets for therapeutic intervention for brain diseases? As genomic technologies such as DNA microarrays and high-throughput *in situ* hybridizations have become more commonplace, they have led to significant advances in the study of the molecular anatomy of the mouse, human, and primate brain. Researchers have utilized these data to identify genes associated with specific brain functions, behaviors, and disease-related phenotypes. Technologies, experimental design, and data analysis methods have improved so that it is now possible to reproducibly measure gene expression levels in different regions, nuclei, and even single cells of the brain, and to reliably detect very subtle expression differences under specific conditions.

An important goal in neuroscience is the development of a combined high-resolution map of the molecular, genetic, and physical anatomy of the brain, and this goal, although challenging, is now technically feasible. The purpose of obtaining such a map and of developing the tools to navigate is to provide a more complete context for neurobiological studies in much the same way that the genome sequence provides a genetic context for the study of biology. But like sequence information, such a map is more than just a reference text and a trail guide; it is also a discovery tool which will help neuroscientists to formulate and test hypotheses about the brain, speeding the identification of genes important for brain function and helping to understand the molecular bases of brain processes such as learning and memory and the sources of central nervous system (CNS) diseases.

Integrating Genomic Technologies with Neuroanatomy

The most widely used techniques for studying gene expression levels are *in situ* hybridization, DNA microarrays, quantitative real-time polymerase chain reaction (PCR), and Northern blots. In this article we discuss the use of *in situ* hybridization and microarrays, as these have been the methods of choice in the construction of molecular brain atlases. Both of these methods have their advantages and disadvantages. *In situ* hybridization provides an anatomical context for the gene expression, as it is based on hybridization of a probe complementary to the mRNA of interest on a section of the brain. The disadvantages of *in situ* hybridization are that the method is not very sensitive to small differences in expression levels when two samples are compared with each other, and that the anatomical signal is usually restricted to the nucleus of the cell. This latter problem has been solved in the case of bacterial artificial chromosome (BAC) transgenic mice (see later). Another problem with *in situ* hybridization is that usually only one gene is studied at a time and therefore analysis of large numbers of genes is time consuming, although the method can be automated to a certain extent, as in the case of the Allen Brain Atlas (ABA). The major advantage of microarrays is that expression levels of virtually the whole transcriptome can be studied at the same time. However, the anatomical resolution is dependent on the size of the tissue from which the studied RNA is extracted. Even though microarrays provide better sensitivity than *in situ* hybridization does, very small differences (<20%) in expression levels of the two samples are difficult to distinguish, which might be a problem in the brain, where even subtle changes may have dramatic effects on the phenotype.

Microarrays

Despite a great deal of initial skepticism, it is now clear that genomic approaches, such as parallel expression profiling with DNA microarrays, can be used to help elucidate the workings of the brain at the molecular level. Some of the early skepticism concerning the application of genomic techniques to neuroscience was not wholly unwarranted, however, as the study of the brain brings a variety of somewhat unique and formidable technical challenges. Studies of the nervous system are complicated by the fact that the brain is very heterogeneous, the cells of greatest interest might comprise only a small fraction of the entire tissue, high-quality material can be hard to obtain, the appropriate anatomical divisions between regions are not always clear, dissections may be inconsistent, some anatomical and functional regions are extremely small, cell bodies and processes (axons and dendrites) are often located in different parts of the brain, biologically important expression changes

may be very subtle, and the expression profiles are dynamic and subject to change in response to even minimal perturbations. Nevertheless, there have been great strides made in performing genome-wide gene expression studies in the brain, as detailed in the following sections.

In situ Hybridization

An important step in the process of developing a molecular map of the mammalian brain is also the acquisition of high-quality *in situ* hybridization patterns of genes expressed in the brain. *In situ* hybridization provides an in-depth picture of the neuroanatomical gene expression patterns for brain specific genes. These key brain-specific genes can be used to anchor large-scale microarray gene expression studies in an anatomical context. *In situ* hybridization provides information about the distribution of cells expressing a given gene in a given region (scattered vs. coherent; small population expressing at high levels vs. large population expressing at lower levels), as well as the relationship between gene expression boundaries and neuroanatomical boundaries that cannot be extracted easily from microarray data. By integrating microarray data with *in situ* hybridization data, a fuller picture of the molecular anatomy of the brain is developed. Cross-correlation of *in situ* hybridization patterns with microarray data for a relatively small number of genes makes it possible to identify combinations of microarray parameters that usefully predict whether a given gene is likely to be (1) detectable by *in situ* hybridization and (2) specifically expressed in one or more brain regions.

Brain Tissue Collection Methods

Dissection

Key to the molecular mapping effort in the brain are high-quality dissections that preserve mRNA intact. There are distinct advantages to working with mice as model organisms for the molecular mapping of the mammalian brain, as opposed to humans or other mammals. For example, the handling of the animals and the tissue dissections can be performed systematically and consistently. This is extremely important in order to minimize sample-to-sample variations. In our laboratory, all mice are singly housed for 7 days prior to sacrifice, and the dissections are carried out at specified hours of the day. Dissections are performed on the surface of petri dishes filled with wet ice. Samples are dissected as fast as possible and frozen on dry ice. For microarray studies, pooling of tissue from several animals is to be avoided whenever possible because dissection artifacts from one sample in a pool will invalidate the results of the entire pool. If dissecting small brain regions, such as the amygdala or cortical subregions, we either pool samples from two to five animals and collect them in RNAlater buffer (Ambion) or we use methods for small-sample amplification that do not require pooling.

For microarray studies, we perform many brain dissections by hand using a sophisticated dissection microscope and very fine dissection tools. It is important to dissect the exact anatomical structure of interest. Inclusion of too much additional material might 'dilute' a weak expression difference seen between two regions, and failure of including all small subnuclei might lead to missing important differences. Laser-capture microdissection (LCM) is a method for producing reasonably pure populations of targeted cells from small regions of tissue sections that cannot be obtained otherwise. LCM uses a specially designed microscope and an integrated laser to select and collect cells onto a special transfer film. It has been shown that the detailed morphology of the captured cells is maintained and that DNA and RNA of high quality can be extracted from laser-captured cells and used for a range of different analyses, including gene expression monitoring on DNA microarrays. It is important to use stringent quality control of extracted total RNA. This can be achieved by checking RNA quality on an agarose gel and by an absorption measurement or by using a bioanalyzer. It is clear that gene expression profiling of brain tissue from humans or model organisms is feasible if the special nature of the brain tissue is taken into account and rigorous quality control is performed.

Voxelation

With the advent of sophisticated imaging techniques, such as functional magnetic resonance imaging (fMRI), it is now possible to start to integrate brain imaging technologies with molecular and genetic data. To complement the aforementioned dissection strategies, a voxelation approach has been implemented which allows for microarray analysis of spatially registered voxels, or cubes, taken from the brain. Voxelation creates volumetric maps of gene expression similar to imaging techniques such as fMRI, computed tomography (CT), or positron emission tomography (PET). Voxelation has been performed in both human and mouse studies on Alzheimer's and Parkinson's disease brains. The voxelation approach can lead to volumetric resolution in the human brain from 1 cm^3 to as low as 87 μl and in the mouse brain from 7.5 μl to as low as 1 μl. As the mammalian brain is composed of greater than 700 anatomically distinct major regions and an even larger number of named subregions, hand dissection and LCM currently

remains an impractical high-throughput approach for mapping of the entire mammalian brain. The voxelation approach allows for high-throughput analysis of specific brain areas without dissection biases through the use of mathematical analysis techniques such as singular value decomposition. However, voxelation suffers information loss from what is known as 'voxel inhomogeneity,' which is the dilution or averaging of gene expression signals in any one voxel from various brain regions and cell types. Combining gene expression data from brain regions collected by voxelation, hand dissection, and LCM with *in situ* hybridization data will advance the coverage and resolution of the mammalian molecular brain maps.

Current Large-Scale Projects

Gene Expression Nervous System Atlas

The Gene Expression Nervous System Atlas (GENSAT) BAC transgenic project is a National Institute of Neurological Disorders and Stroke (NINDS)-supported two-stage approach that combines high-throughput *in situ* hybridization screening and the use of BAC transgenic reporter gene analysis. The principal investigators of the study are Nathaniel Heintz and Mary E Hatten, professors at the Rockefeller University. The project is designed to use enhanced green fluorescent protein (EGFP) reporter genes both to map gene expression in the developing and adult brain and to provide experimental access to CNS cell populations. The aim is to identify and map the expression of ~5000 of the most important CNS-expressed genes throughout development. First, a prescreen is done by *in situ* hybridization to identify the most interesting genes, and second, the chosen genes are analyzed at high resolution using BAC transgenic mice. This two-stage approach takes advantage of the sensitivity, dynamic range, and efficiency of *in situ* hybridization methodology to allow parallel analysis of large numbers of CNS-expressed genes, while exploiting BAC reporter gene technology to allow systematic analysis and high-resolution visualization of each cell type expressing a gene of interest. The data generated by the project are available in the GENSAT database, which contains a gene expression atlas of the CNS of the mouse based on BACs (see Figure 1). The technology is based on gene replacement, whereby endogenous protein-coding sequences of the studied genes have been replaced by sequences encoding the EGFP reporter gene. Thus, all the cells that would normally express the gene of interest now express the EGFP reporter gene, which can be easily visualized directly or indirectly by immunohistochemistry. This allows the visualization of gene expression patterns in the CNS (and other tissues). The GENSAT database contains histological data from given BAC transgenic mouse lines at three developmental stages: embryonic day 15.5, postnatal day 7, and adult. EGFP is visualized by staining with an anti-EGFP antibody using the diaminobenzidine (DAB) method, or by confocal microscopy of unstained tissue sections. Discoveries in several categories of developmental neurobiology can be made with the dataset, including (1) identifica-

Figure 1 *In situ* hybridization darkfield images of a sagittal section close to the midline and coronal sections of a C57BL/6J postnatal day 7 mouse brain, showing mRNA distribution of the ataxia telangiectasia mutated homolog (*ATM*) gene from GENSAT.

tion of genes that mark specific regions of the brain, (2) identification of genes that mark specific cell types, and (3) identification of genes that reveal patterns of axonal connections in the emerging neural circuitry of the immature CNS.

Brain Gene Expression Map

The Brain Gene Expression Map is focused on the mouse brain and is housed at St. Jude Children's Research Hospital in Memphis, Tennessee and is associated with GENSAT. This database contains gene expression patterns from mouse nervous system tissues at four time points throughout brain development, including embryonic day 11.5, embryonic day 15.5, postnatal day 7, and adult day 42. Using high-throughput *in situ* hybridization, there are gene expression patterns from approximately 2850 genes, available in a searchable database. The database includes darkfield images from radioactive probes, reference cresyl violet-stained sections, the complete nucleotide sequence of the probes used to generate the data, and all the information required to allow users to repeat and extend the analyses. The database is linked to PubMed, LocusLink, Unigene, and the Gene Ontology Consortium housed at the National Center for Biotechnology Information (NCBI) in the National Library of Medicine in Bethesda, Maryland.

Allen Brain Atlas

The ABA is an interactive, genome-wide image database of gene expression in the mouse brain. It is based on automated high-throughput *in situ* hybridization of adult 8-week-old male C57BL/6J mouse brains. The platform used for the ABA utilizes a nonisotopic approach, with digoxigenin-labeled nucleotides incorporated into a riboprobe produced by *in vitro* transcription. Colorimetric detection of bound probe is generated by the alkaline phosphatase substrates nitroblue tetrazolium (NBT) and bromochloroindolyl phosphate (BCIP), which produce a blue/purple particulate reaction product that allows cellular localization of the signal. In addition to the *in situ* hybridization data, the project is generating reference atlases of the mouse brain that include both coronal and sagittal planes. This Nissl-stained reference facilitates annotation of the *in situ* hybridization data in the anatomical context. In order to view the *in situ* hybridization data, the project has created a web-based tool that allows searching by gene name and visualizing the corresponding *in situ* hybridization data.

Brain Gene Expression Database

The Brain Gene Expression Database contains gene expression data for various physiological and pathological processes in the mouse brain. All of the data were obtained by adaptor-tagged competitive PCR, an advanced version of quantitative PCR. Assayed genes were selected from the Brain Expressed Sequence Tag (EST) Database containing 3656 genes. RNA samples were taken under unique biological conditions using the C57BL/6J inbred strain. The datasets include postnatal cerebellar and dentate gyrus development at postnatal days 2, 4, 8, 12, and 21, and week 6. The following hippocampal regions are also available at 6 weeks: CA1, CA2, and CA3. The database also analyzes several physiological and pathological processes, such as the effects of ischemia on gene expression in the hippocampus, aging in the whole brain, and antipsychotic drugs (haloperidol and chlozapine) in the frontal lobe.

Microarray-Based Brain Gene Expression Databases

TeraGenomics This database contains microarray gene expression patterns for 24 neural tissues covering the mouse CNS measured in three inbred mouse strains (C57BL/6J, 129S6/SvEvTac, and DBA/2J) using the Affymetrix U74Av2 array. The complete collection of extensively annotated gene expression data along with data mining, visualization, and filtering tools has been made available on a publicly accessible website. A large-scale database, called TeraGenomics, was built to house and provide access to all of the quantitative, brain region-specific gene expression data, along with quality control measures and metadata in accordance with the Minimal Information About a Microarray Experiment (MIAME) standard. The body of metadata contains 75 different sample annotation fields, which include information on sample origin, dissection protocols, sample preparation, and array hybridization parameters. In addition, the anatomical hierarchy of the Neuronames taxonomy has been included as a user-friendly query tool within the database. A reference document for each dissection was created, consisting of photographs, atlas figures, and bregma coordinates of each collected brain region along with step-by-step instructions to illustrate the exact methods used in tissue collection.

SymAtlas The Genomics Institute of the Novartis Research Foundation (GNF) has a publicly available microarray database composed of expression profiles for 79 human tissues (20 brain regions), 61 mouse tissues (10 brain regions), and approximately 15 rat brain structures in as many as four different rat strains. These human, mouse, and rat gene expression atlases are available online and can be accessed through the SymAtlas web application. The web application provides searching and visualization by

Molecular Relationships within the Mammalian Brain

Using the aforementioned resources and tools, we and other neuroscientists have set out to understand how regional gene expression patterns in the brain are related to anatomical brain architecture and organization, and to identify relationships between brain regions based on both shared and restricted gene expression patterns. The existing framework to organize the mammalian nervous system is based on studies of anatomy, embryology, and evolution. It is now possible to begin to understand the mammalian brain from a molecular viewpoint.

In developmental biology, gene expression patterns for small groups of genes have been used to identify particular brain regions during embryogenesis. Dynamic changes in expression patterns have also been used to understand functional relationships between brain regions during development. Distinct neural cell precursors form at different positions along the anteroposterior (AP) and dorsoventral (DV) axes of the developing neural epithelium, which is critical for the establishment of a structured pattern of differentiated neurons. The concept of an established genetic pattern during embryogenesis has been strengthened by the expression of genes that mark morphogenetic fields during brain development, such as homeobox transcription factor genes. Spatially restricted expression of transcription factors specifies regional identity in the developing nervous system. The expression of these transcription factors underlies a crucial stage in neuronal patterning: the partitioning of the neural epithelium into domains with distinct identities that later form different groups of neural cell types.

The role of transcription factors in the developing mouse CNS has been studied using *in situ* hybridization. As mentioned previously, transcription factors are known to play a critical role in brain development by directing the formation of neurons and glia from progenitor cells. The aim of a recent study was to identify transcription factor gene expression patterns that are spatially and temporally restricted within the brain. Gene expression of 1174 transcription factors was visualized at embryonic days 10.5 and 13.5 and postnatal day 0, as well as on sections through the postnatal cerebellum at days 7, 15, and 21. The *in situ* hybridization data showed that gross anatomical diversity based on seven general areas within the CNS could be described by the expression of specific transcription factors in specific brain areas. These seven areas included the cortex, striatum, thalamus, hypothalamus, midbrain, hindbrain, and spinal cord. This study focused on embryogenesis and found that transcription factors known to play a role in developmental patterning, such as homeobox and forkhead genes, had the most restricted expression and were the most informative about anatomical diversity within the brain.

Whole-genome microarray expression data now suggest that the imprinted genetic program established during embryogenesis is still evident in the mature brain. Using gene expression patterns measured from 24 spatially registered (based on bregma coordinates) neural tissues covering the mouse CNS, it was shown that the adult brain demonstrates a transcriptional pattern consistent with where those tissues were derived embryologically. In addition to this imprinted genetic program, significant numbers of embryonic patterning and homeobox genes with region-specific expression in the adult nervous system were observed (see Figure 2). Several studies of the developing brain have demonstrated that similar sets of embryonic patterning and homeobox genes are used to establish a particular anatomical region and to maintain the cell–cell relationships of the differentiated region. The global gene expression pattern relationships between different anatomical regions and the nature of the observed region-specific genes suggest that the adult brain retains a degree of overall gene expression

Figure 2 Genes with region-specific expression patterns function in development, pattern specification, and morphogenesis. (a) Reference brain atlas displayed in the three orthogonal planes. This atlas of Nissl-stained C57BL/6N mouse brain comprises 462 coronal sections at 30 μm thickness, digitized at a resolution of 1.3 μm per pixel. The sagittal and horizontal planes are 'virtual' sections dynamically constructed from the coronal sections. (b) Three-dimensional atlas of brain regions. Specific brain regions along the rostrocaudal neuraxis are color coded. OB, olfactory bulb; Ctx, cerebral cortex; Str, striatum; Bnst, bed nucleus of stria terminalis; Hy hypothalamus; Hi, hippocampus; SC, superior colliculus; IC, inferior colliculus; Pag, periaqueductal gray matter; Cb, cerebellum; Med, medulla; Sp Crd, spinal cord. (c) The expression levels of some of the homeobox and other embryonic patterning genes expressed in the adult mouse brain are digitally represented for each region. Adapted from Zapala MA, Hovatta I, Ellison JA, et al. (2005) Adult mouse brain gene expression patterns bear an embryologic imprint. *Proceedings of the National Academy of Sciences of the United States of America* 19: 10357–10362, with permission.

patterning, established during embryogenesis, that is important for regional specificity and for the functional relationships between brain regions in the adult.

There have also been smaller scale studies to investigate the molecular architecture of specific brain nuclei in the mouse. In a previous regional analysis of the amygdala, *in situ* hybridization had revealed that the majority of the genes specifically expressed in the amygdala displayed intra-amygdaloid expression boundaries corresponding to neuroanatomically defined subnuclei. Microarray data further confirmed these findings in that the gene expression patterns of specific amygdaloid nuclei were found to respect the ontogenetic origins of the subnuclei which derive embryologically from both pallial and subpallial structures. Similarly, the study of specific hippocampal subregions (CA1, CA2, and dentate gyrus) found that the relative enrichment and absence of genes in the hippocampal subregions support the conclusion that there is a molecular basis for the previously defined subregions, and these genes could define unique functions of these hippocampal subregions.

It has also become possible to examine anatomically distinct regional brain gene expression patterns in humans. For example, gene expression differences in the cerebellum and in the cortical areas in humans have been studied. Functional classification using gene ontology tools identified functional gene families enriched in the cerebellum and cerebral cortex. Genes with an enriched cortical gene expression pattern belong to categories such as 'calmodulin binding,' 'brain development,' 'receptor protein kinase,' and 'peptide hormones.' Several genes identified as being specifically enriched in the cortical areas have been previously implicated in psychiatric disorders, such as regulator of G-protein signaling 4 in schizophrenia; neuropeptide Y in bipolar disorder; cholecystokinin in depression; somatostatin in mania, schizophrenia,

and Alzheimer's disease; and 5-hydroxytryptamine receptor 2A in major depression and suicide.

Conclusions

There are several ongoing projects which have generated high-quality, spatially specific brain gene expression datasets. These molecular mapping efforts have provided invaluable information about specific gene expression patterns in anatomically distinct brain nuclei. They form a basis for other studies that aim to discover previously unknown functional elements in the brain, such as circuits involved in clinically important phenotypes. It is now possible to begin integrating and leveraging these unique data repositories to gain new insights into the molecular underpinnings of complex brain functions. Thus, it appears that not only are we closer to understanding the molecular anatomy of the mammalian brain, but we are also poised to begin to comprehend how it regulates complex behaviors or how disturbances in brain function manifest directly as specific neuropathologies.

Monoamine Transporters: Focus on the Regulation of Serotonin Transporter by Cytokines

J Masson and M Hamon, INSERM – Université Pierre et Marie Curie, Paris, France

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Monoamines are released at the synapse to exert their actions by activating specific receptors. The termination of synaptic transmission occurs through different mechanisms: degradation of the released monoamine, desensitization of the target receptors, and reuptake of monoamine by specific neuronal transporters. Monoamine transporters share several common features, particularly their dependence on Na^+ and Cl^- ions. Their encoding genes were cloned in several species (rat, human, bovine, ovine, and mouse) in the 1990s. They all belong to the same superfamily of genes (the SLC6 family), which give rise to proteins of ~600–620 residues termed DAT, NET, and SERT for dopamine, norepinephrine, and serotonin transporters, respectively. Due to the absence of a signal sequence, the N-terminus and C-terminus of these proteins are proposed to reside within the cytoplasm. To date, all experimental data have confirmed this inference, and further major progress in the knowledge of the molecular organization of Na^+/Cl^-dependent transporters of the SLC6 family has been made with the crystallization of the bacterial (from *Aquifex aeolicus*) leucine transporter. Thus, all monoamine transporters share the same topology with 12 transmembrane domains, the N-terminal and C-terminal regions located within the cytoplasm, and a large second extracellular loop endowed with N-glycosylation sites. Conservation of amino acid sequences among the three monoamine transporters seems to be highest within the putative transmembrane domains, whereas the least conserved regions are at the N-terminus and the C-terminus.

Amino acid sequence analysis of SERT, DAT, and NET proteins has revealed the presence of numerous serine (S), threonine (T), and tyrosine (Y) residues that could serve as phosphorylation sites, and many of these residues are present within consensus sequences for protein kinase C (PKC), protein kinase A (PKA), and calcium/calmodulin-dependent protein kinase (Figure 1), suggesting that second messengers play a role in posttranslational regulation of monoamine transporters. Extensive investigations aimed at identifying residues involved in the binding of monoamine to its specific pocket within the respective transporter identified residues within the first two transmembrane domains in the case of 5-HT binding into SERT. However, site-directed mutagenesis showed that substitution of amino acids at various locations within SERT (Y95, D98, I172, F335, F341, S438, and G442) affected the transporter affinity for 5-HT, indicating that the monoamine binding pocket involves several transmembrane domains.

The substrate specificity of monoamine transporters and their respective sensitivity to selective inhibitors have been examined in brain preparations and in heterologous systems with recombinant transporters. Although each monoamine is a substrate for its cognate transporter, it has been shown that both DAT and NET can transport dopamine as well as norepinephrine, whereas SERT transports only 5-HT.

This article focuses on SERT, with the aim of showing how cytokines regulating its expression and/or activity can provoke depressive symptoms. In brain, SERT is expressed only in serotonergic neurons, and immunolabeling has shown that it is targeted all over the neuronal plasmic membrane, from the somatodendritic compartment to the axonal varicosities and terminals. It is important to note that, in humans, SERT expressed in neurons, platelets, and placenta correspond to the same protein encoded by a single gene. In the following sections, we present and discuss results obtained in brain, platelets, as well as cell lines derived from placental choriocarcinoma.

SERT Is a Target for Antidepressant Drugs

Soon after radioligands became available for the quantitative labeling of SERT, it was established that uptake sites for 5-HT are generally downregulated in platelets from patients suffering from depression and in postmortem brain samples from depressed patients and suicide victims. On the other hand, the blockade of 5-HT transport by antidepressants appeared as a key pharmacological action to relieve depression, and selective serotonin reuptake inhibitors (SSRIs) are currently the most frequently used antidepressant drugs worldwide.

The cloning of the SERT encoding cDNA by Blakely et al. in 1991 allowed a more precise characterization of this protein at the molecular level and opened a new field of investigation into the identification of the binding pocket of specific inhibitors, such as fluoxetine, paroxetine, sertraline, fluvoxamine, and citalopram, within the SERT protein.

Blocking the SERT activity by SSRIs results in an immediate increase in extracellular 5-HT levels, and this is actually the first step, but not the only one, for the antidepressant effect of SSRIs.

Recent studies on the binding of citalopram to human SERT have revealed the presence of two binding sites, the first one involving the N-terminal transmembrane (TM) domains and the second one transmembrane domains (TM10 and TM11) close to the C-terminus portion of the transporter protein. There is evidence that the first site is directly involved in 5-HT uptake inhibition, whereas the second one exerts an allosteric influence, accounting for a reduced efficacy of escitalopram (the S enantiomer of citalopram) or paroxetine to inhibit 5-HT uptake when this site is occupied by R-citalopram. These findings suggest that in addition to SSRIs, it should be possible to develop drugs that produce fine-tuning of SERT activity through binding at this second allosteric site. Furthermore, positive allosteric influence on the first SSRI binding site can be expected to enhance the efficacy and accelerate the therapeutic action of SSRI antidepressants. Relevant research toward this goal is under way.

Consequences of the Genetic Deletion of SERT in Mice

The knockout gene strategy has been used to explore the consequences of the absence of SERT (during development and adulthood). As a model for whole life treatment with SSRIs, SERT knockout has been generated by homologous recombination involving the replacement of the second exon of the SERT gene by a neomycine cassette. This SERT–neomycine allele gives a mutant transcript coding for a mutant (truncated) protein unable to achieve its reuptake function in neurons. The loss of 5-HT reuptake function in SERT null mutants causes reduced clearance of extracellular 5-HT, leading to an increase (four- to sixfold) in basal levels of forebrain extracellular 5-HT. Furthermore, SERT knockout is associated with alterations in 5-HT neuronal firing and receptor function. In particular, the somatodendritic 5-HT_{1A} autoreceptor expressed in serotonergic dorsal raphe neurons is desensitized and downregulated, and the density of 5-HT_{1A} heteroreceptors expressed in forebrain regions also exhibits significant changes in SERT−/− mutants compared to paired wild-type mice.

General health, neurologic, and sensory functions were evaluated, and relevant data suggested that these SERT mutants are especially suitable for investigating physiopathological mechanisms underlying behavioral alterations related to 'emotion.'

It has been reported that null SERT mutants express exacerbated anxiety-like behavior in validated paradigms. This altered phenotype has notably been confirmed in relevant tests such as the elevated plus-maze, with its aversive open arms, and the dark/light box, with its 'anxiogenic' light compartment. It is important to note that this increase in anxiety-related behavior in SERT knockout mice has been observed only in SERT mutants with a C57B1/6J background. Indeed, behavioral alterations observed in knockout mice could be attributed not only to the deletion of the SERT gene but also to the background genes present in this mouse strain, indicating the complexity of gene interactions possibly associated with psychiatric diseases. Nevertheless, the key relationship between 5-HT and anxiety was further supported by the observation that SERT-overexpressing transgenic mice were much less anxious than paired wild-type animals, and that SERT blockade by the SSRI paroxetine reversed the low-anxiety phenotype of the mutants.

In addition, null SERT mutants were also investigated using validated depression-related paradigms. Results obtained with inescapable stress-related tests, such as the tail suspension test and the forced swim test, were contradictory depending on the genetic background of SERT−/− mutants. Nevertheless, as a whole, the reported data suggest that SERT−/− mutants have an exaggerated stress response, in line with the growing literature linking genetic variations in SERT function with emotional abnormalities.

On the other hand, null SERT mutants have also been described as less aggressive using the resident–intruder test. These behavioral traits are not completely similar to those observed after chronic systemic SSRI treatment or intracerebroventricular infusion of siRNA to knockdown SERT activity/expression in adult mice because the latter two treatments were regularly reported to induce clear-cut antidepressant-like effects in all validated tests. Subsequent studies that inhibited SERT selectively during the early postnatal period provided an explanation of the differences between constitutive SERT knockout and SERT inactivation in adults. Indeed, transient SERT blockade during early brain development was shown to produce paradoxical depression-related effects, which could then be subsequently reversed by SSRI antidepressants administered at the adult stage. These data highlighted the critical neurotrophic role of 5-HT for brain development, which was demonstrated more than 30 years ago by experiments showing that pharmacological alterations of 5-HT synthesis or inactivation at early stages provoke marked anatomofunctional alterations in brain. These data also illustrate that a constitutive

knockout is generally not homologous to long-term blockade of the corresponding gene product, enzyme/receptor/transporter, at the adult stage, notably because of the long-term consequences of the absence of the gene product during development.

SERT Gene Polymorphisms: Characteristics and Functional Consequences

The human SERT gene (SLC6A4; Figure 2) has been localized to chromosome 17q11.1–12, and its transcriptional activity is modulated by polymorphic repetitive elements located upstream of the transcription site, in the promoter region, and in the 5′ and 3′ untranslated regions. The SERT gene polymorphisms which have been most studied in depressed patients are (1) 5-HTTLPR in the 5′ untranslated region, described as L (long) and S (small) forms, which are associated with variable levels of SERT expression (in Caucasians, the 44-base pair insertion, which corresponds to the L variant of this polymorphism, is associated with higher expression of brain SERT compared to the S variant); and (2) STin2 variants in intron 2 (variable number of a 16- or 17-base pair tandem repeat).

In 1996, the first study of STin2 variants showed that STin2.9 allele (nine copies of the variable number tandem repeat (VNTR)) was more frequent in the unipolar depressive patient group. However, in other studies, unipolar affective disorder appeared to be associated with the STin2.12 allele (12 copies of VNTR). In fact, subsequent studies on unipolar and bipolar depressive disorder patients did not support any association with STin2.12. Interestingly, SERT gene transcription has been proposed to be determined by the combinatorial action of different promoter domains in intron 2, with the number of copies of VNTR markedly influencing the effects of specific transcription factors such as Y box binding protein 1 and CCTC-binding factor.

Much more data have been obtained on the polymorphism in the promoter region (5-HTTLPR), which indicate that this polymorphism is related to the tissue/cell levels of SERT mRNA. Evidence indicates that the distinctive structure of 5-HTTLPR gives rise to a specific DNA secondary structure that directly influences the transcriptional activity of the SERT gene promoter. When fused to a luciferase reporter gene and transfected into human SERT expressing cell lines, the short and long 5-HTTLPR variants differentially modulate transcriptional activity of the SERT gene promoter. The L allele confers a higher level of SERT mRNA expression than the S allele. The latter short allele was initially suggested to be associated with affective disorder risk, but subsequent results were contradictory. Thus, a few studies emphasized that the S allele was significantly more frequent in patients with unipolar depression. In particular, subjects with the biallelic SS promoter were found to more frequently suffer severe depression episodes in response to stressful life events than those with the biallelic LL promoter. However, no association between the L/S polymorphism and mood disorders was found in other studies. Indeed, marked heterogeneity between studies was evident, possibly reflecting differences in diagnosis, different control populations, and different ethnic origin. These factors unavoidably interfered with any reliable interpretation of the associations found in these studies.

On the other hand, the L allele of the 5-HTTLPR polymorphism was also found to be associated with a better and faster response to SSRIs in depressed patients in some but not all studies. Further investigation is needed to clarify the relationships between the SERT genotype, the susceptibility to affective disorders, and the response to serotonergic agents.

SERT Regulation

The regulation of any protein activity in cells mainly involves two types of molecular mechanisms. The first occurs after the protein has been translated from mRNA. It consists of phosphorylation/dephosphorylation of Ser, Thr, and Tyr residues by specific kinases and phosphatases. The second one concerns transcriptional regulation. Major improvements in methods for the quantification of specific mRNAs led to the characterization of gene promoter, transcriptional factors (activator and repressor), and their binding sites on genomic DNA and contributed to the current knowledge of SERT regulatory mechanisms.

Figure 2 Organization of the human SERT gene and its 5′ flanking region on chromosome 17q11.2. The white box represents the SERT promoter containing the 5-HTTLPR polymorphism, with the short (S) or long (L) allele. Boxes depict exons (1–14). Black and gray boxes are coding and noncoding regions, respectively. Introns are represented by dashed lines. STin2 polymorphism is localized in the second intron between exons 2 and 3.

Posttranscriptional Regulation

SERT regulation by signaling pathways involving PKC, cyclic guanosine monophosphate (cGMP), and calmodulin has been the subject of numerous studies. It is well established that PKC or activators of PKC reduce 5-HT transport capacity (V_{max}), suggesting it may silence membrane-bound SERT or change its cell surface expression. Indeed, SERT is phosphorylated following PKC and PKA activation and protein phosphatase 2A inhibition (by okadaic acid). PKC-dependent phosphorylation of SERT shows a close temporal correlation with a reduction in SERT transport capacity. On the other hand, SERT substrates and antagonists can influence PKC-dependent SERT phosphorylation and surface redistribution.

Transcriptional Regulation

Transcriptional regulation of SERT was first studied in human placental choriocarcinoma, a cell line that endogenously expresses the transporter. In these cells, cholera toxin has been used to determine the role of cAMP as a molecule upregulating SERT. On the other hand, steroids are also involved in the regulation of SERT gene transcription. In particular, SERT mRNA is significantly downregulated by estrogen treatment, through the activation of nuclear estrogen receptor-beta, which acts as an inhibitory transcription factor on SERT gene promoter in serotonergic neurons. In contrast, treatment of immortalized human B-lymphoblastoid cells, which express the human SERT, with dexamethasone, a synthetic glucocorticoid receptor (GR) agonist, results in increased SERT expression. Transcriptional activation by GR depends on the repetitive GC-rich sequence located approximately 1.4 kilobases upstream of the SERT gene transcription site. In particular, the steroid effect is no longer observed in cells transfected with a deleted mutant reporter gene construct, which lacks the repetitive promoter sequence.

In addition, studies on transcriptional regulation of SERT gave rise to a number of reports concerning the effects of cytokines. The mechanisms involved and the functional/clinical relevance of the effects of cytokines on SERT are presented in the following sections.

Cytokines and Depression

Cytokines are regulatory proteins secreted by lymphocytes and other cell types. They play key roles in immune responses to inflammatory processes, but they also regulate growth, differentiation, and function of many cells. Cytokines are classified as proinflammatory (interleukin (IL)-1, IL-6, tumor necrosis factor-α (TNF-α), and interferon (IFN)) when they stimulate immune cells and as anti-inflammatory (IL-4 and IL-10) when they silence the immune system to decrease the production of further cytokines. Historically, the existence of relationships between cytokines and depression has been postulated from convergent clinical reports indicating that patients treated with some cytokines (IFN-α) can develop symptoms resembling depression.

Cytokine Levels in Depressed Patients

Numerous reports have noted that the plasma concentrations of proinflammatory cytokines (IL-1β, IL-6, IFN-γ, and TNF-α) and the density of soluble cytokine receptors (IL-2 and IL-6) in peripheral blood mononuclear cells are increased in depressed patients. However, a few studies did not confirm these results. Discrepancies among studies are possibly due to the evaluation of various subtypes of depression, differences in severity of the disease, limited sample sizes, and treatment with or without antidepressant medication. In addition, rhythmic changes in cytokine levels may also account for the variable data from one study to another. Nevertheless, immune activation has been proposed to be a marker for susceptibility to depression. This hypothesis is based on numerous clinical observations, such as marked increases in serum levels of soluble IL-2 receptor, IL-6, and IL-10 in patients suffering from chronic hepatitis C (CHC) infection who developed major depressive disorder in response to treatment with IFN-α.

Depressive Symptoms Occurring during Cytokine Treatment

In line with the clinical observations summarized in the previous section, a large body of evidence indicates that a major proportion of patients treated for infections or malignancies with proinflammatory reactions display 'sickness behavior' including neuropsychiatric symptoms, some of which are typical of depression. Depression usually occurs within the first 4 weeks of antiviral therapy, but its incidence is variable, depending on the disease being treated, the cytokine molecule and dose, and the patient's psychiatric history.

IFN is a proinflammatory cytokine with antiviral and anticancer effects. IFN treatment has been shown to increase the risk of major depressive disorder by 23–45%. Interestingly, of all the pathologies cured by IFN treatment – myelogenous leukemia, melanoma, renal carcinoma, and CHC – patients suffering from the latter are more prone to develop IFN-induced depression.

The development of clinically significant neuropsychiatric changes is also common during treatment

with IL-2 and may be difficult to manage. However, usually psychoaffective alterations occur with a rather long latency after starting the treatment and disappear once patients have been cured.

Reversal by Antidepressants of Depression Caused by Cytokine Treatment

The emergence of depressive symptoms in cytokine-treated patients may possibly lead to discontinuation of treatment. Fortunately, antidepressant drugs, notably SSRIs, are generally effective in treating this unbearable side effect.

An interesting example concerns a study that was performed on a group of CHC-suffering patients who had to be re-treated with IFN after a first therapy failure because of IFN-induced depression. These patients were psychometrically monitored during re-therapy for CHC and SSRI prophylaxis. The SSRI medication started 3 weeks before initiation of the antiviral treatment. This antidepressant therapy protected patients from the IFN-induced depression observed during the IFN therapy-naive treatment. This strategy has also been used and validated for efficacy in patients with malignant melanoma treated with high doses of IFN-α.

Immune stimulation produced during proinflammatory cytokine therapy has been shown to induce a decrease in brain 5-HT tone. This deficit in 5-HT appeared to be secondary to the stimulation of indeolamine-2,3-dioxygenase and GTP-cyclohydrolase which results in tryptophan degradation to kynurenine and neopterin production, thereby reducing the concentration of the precursor aromatic L amino acid for 5-HT synthesis (Figure 3).

These data suggest that the mechanism responsible for cytokine-induced depression involves 5-HT, and that the pharmacological blockade of SERT is sufficient to cure the depression (and even prevent the occurrence of the disease) through facilitation of 5-HT neurotransmission compensating for the cytokine-evoked deficit.

Effects of Cytokines in Animal Behavioral Models of Depression

To study the influence of cytokine treatment on depression, several groups examined the effects of cytokines on rodent behavior in validated experimental paradigms. In behavioral tests developed to evaluate depression-like behavior in rodents, such as the tail suspension test, sucrose consumption, and the force swimming test, acute as well as chronic administration of IFN-α induced depression-like responses. Thus, anhedonia, a depressive-like symptom assessed through a decreased free consumption of sucrose in rats, is observed following acute administration of IFN-α, and this behavioral deficit can be reversed by a 2-week antidepressant (desipramine or fluoxetine) treatment. In contrast, IFN-β and IFN-γ do not trigger such depression-like behaviors. However, contradictory results have also been reported suggesting that the effects of cytokines, especially IFN-α, critically depend on the experimental conditions of each laboratory.

Further studies demonstrated that IFN-α-induced depression-like symptoms could be attributed, at least in part, to a decrease in brain 5-HT neurotransmission. Indeed, as detailed in the following section, *in vitro* data indicated direct effects of cytokine on SERT expression and/or activity.

Cytokines Regulate SERT Expression and Activity

The first report on the identification of a physiologically occurring cytokine which regulates expression of the SERT gene was published in 1995. This study opened a new field of investigation on the roles of cytokines in the control of brain 5-HT neurotransmission through SERT modulations. It was found that IL-1β stimulated SERT transcription in human JAR choriocarcinoma cells and yielded up to a three- or fourfold increase in SERT mRNA levels, a 2.5-fold increase in membrane-bound SERT protein, and a 1.8-fold increase in 5-HT uptake. A minimal 4 h exposure to the cytokine was required to produce significant effects. Interestingly, IL-1β-mediated SERT upregulation did not involve cAMP, cGMP, nitric oxide, or ceramide signaling. Upregulation of SERT by IL-1β appeared to be associated with the activation of mitogen-activated protein (MAP) kinases and nuclear factor-kappa B (NF-κB p65 homodimer) in response to the stimulation of IL-1 receptor type I. Indeed, the following sequence was established: (1) IL-1β activates its specific receptor, which in turn (2) activates MAP kinase with a maximal effect after a 15 min exposure to the cytokine; then (3) NF-κB is activated (maximal effect after a 30 min treatment); and, finally, (4) SERT is upregulated (after a 4 h treatment). In these IL-1 receptor type 1-expressing JAR cells, NF-κB activation follows the classical pathway: NF-κB is present in the cytoplasm as an inactive complex with an inhibitory protein IκB. The complex dissociates after IκB ubiquitination, and free NF-κB enters the nucleus to activate transcription. In JAR cells, the inhibitory protein involved in IL-1β-induced SERT upregulation is IκBε. Interestingly, IL-1 receptor type 1 encoding mRNA is expressed over the entire midline raphe in the rat, so the sequence established in JAR cells probably occurs in brain serotonergic neurons.

Figure 3 How cytokine binding onto 5-HT neurons influences serotonergic transmission. In basal condition, the released 5-HT activates 5-HT receptors, and receptor signaling proceeds until 5-HT is removed from the extracellular space by uptake through SERT localized on 5-HT neurons. During cytokine treatment, 5-HT synthesis is reduced because of the decrease in tryptophan, the 5-HT precursor (kynurenine and neopterin synthesis pathways are activated). Furthermore, SERT is upregulated (increase of mRNA and posttranscriptional activation of SERT protein), leading to an increase in 5-HT removal from the extracellular space and a decrease in serotonergic transmission. This hyposerotonergic activity can cause depressive symptoms in human and in animal models. Cytokine-induced 'depressive behavior' is reversed by SSRIs, which block 5-HT uptake, thereby restoring high levels of 5-HT in the extracellular space.

TNF-α was also found to enhance 5-HT uptake in JAR cells through an increase in maximal velocity (but no change of 5-HT affinity for SERT), which reached its maximum after a 48 h exposure to the cytokine. The presence of a TNF-α-responsive NF-κB element 62 base pairs upstream of the start of repetitive elements in the human SERT promoter strongly supports the idea that TNF-α-induced upregulation of SERT results from increased transcription of the SERT gene.

The interferons IFN-α and IFN-γ have also been described as SERT mRNA-regulating cytokines in another cell line, the human placental choriocarcinoma BeWo cells. Indeed, SERT expression increased after a minimal 3 h exposure to either interferon, and the maximal effect was observed after a 6 h

cytokine treatment. BeWo cells express receptors for both interferons and their signaling pathways through Janus kinase-STAT, and consensus binding sites of STAT family member were detected in the 5′-flanking region of the mouse SERT gene. It can therefore be inferred that the Janus kinase-STAT pathway is probably implicated in interferon-induced SERT upregulation in the mouse. Thorough analysis of the promoter of the murine SERT gene has resulted in the identification of several binding sites for transcription factors: cAMP-responsive element binding protein 1 (CREBP1) or its heterodimer with c-Jun (CREBP1CJUN), interferon regulatory factors 1 and 2 (IRF1 and IRF2), and transducers and activators of transcription (STAT), which mediate signal transduction triggered by interferon receptors. Accordingly, the various mechanisms underlying IFN-α and/or IFN-γ upregulation in BeWo cells probably also occur in rodents.

Direct evidence showing that cytokines increase SERT activity in serotonergic neurons has been reported by Zhu et al., who noted that IL-1β and TNF-α stimulate 5-HT uptake in the rat embryonic raphe cell line RN46A and in mouse midbrain and striatal synaptosomes. The effect of IL-1β is completely prevented by pharmacological blockade of p38 MAP kinase, indicating that IL-1β-induced p38 MAP kinase activation mediates the stimulatory effect of this cytokine on SERT. In contrast, only partial inhibition was noted with TNF-α, suggesting that additional non-p38 MAPK-mediated mechanisms participate in the stimulatory effect of this cytokine on neuronal 5-HT uptake. Unlike that found in cell lines, only short treatment (10–20 min) with IL-1β and TNF-α was needed to maximally increase 5-HT uptake in brain synaptosomes, indicating that this effect does not involve gene transcription but, rather, posttranslational regulatory steps. Indeed, this effect is short lasting, resolving within 20–60 min.

Interestingly, all cytokines with the capacity to upregulate SERT expression and/or activity are proinflammatory cytokines (IL-1β, TNF-α, and INF-γ). Conversely, the anti-inflammatory cytokine IL-4 has been found to induce a reduction of 5-HT uptake in immortalized B lymphocytes, which endogenously express SERT. Additional investigations demonstrated that IL-4-induced SERT downregulation is more pronounced in cell lines homozygous for the 5-HTTLPR long allele, corresponding to the high SERT activity. Because IL-4 is a potent inhibitor of IL-1β and TNF-α production *in vivo,* this anti-inflammatory cytokine might reduce 5-HT uptake through both its direct inhibitory effect on SERT expression and the blockade of any potential SERT upregulation by the proinflammatory cytokines.

Conclusion

Among monoamine transporters of the SLC6 family, the serotonin transporter, SERT, has been described for decades as a key protein for the physiopathology and treatment of depression. Antidepressant drugs target SERT; they act by blocking 5-HT transport activity, thereby increasing extracellular 5-HT and compensating for the deficit in serotonin release associated with the pathology. The effect of SSRI antidepressants proceeds in two key phases: First, 5-HT is increased in the extracellular space and, second, after a delay of 2 or 3 weeks, the sustained high level of extracellular 5-HT causes the desensitization of 5-HT_{1A} autoreceptors that are responsible for the negative feedback control of serotonergic neuron firing. The resulting suppression of this inhibitory control, combined with 5-HT reuptake blockade, produces a marked elevation of extracellular 5-HT concentration, which probably accounts for the antidepressant action of SSRIs. Interestingly, cytokines are able to differentially regulate SERT expression depending on their pro- or anti-inflammatory profile. Proinflammatory cytokines, which have the capacity to provoke depressive symptoms, enhance SERT activity, thereby causing a reduction in 5-HT extracellular levels and 5-HT neurotransmission (Figure 3). Cytokine-induced depression is reversed by SSRIs, confirming that the psychiatric pathology is causally related to a deficit in serotonergic transmission due to enhanced 5-HT reuptake.

Thus, the state of an immune response may be communicated to the central nervous system and lead to various adaptive changes in the plethora of brain functions that are under the influence of the 5-HT system, such as mood control.

Overview

Progressive increases in the elderly population worldwide, and the expected greater population increases in this age group in the developing countries in the next decades, create a sense of urgency to study the mechanisms of aging. Both at systemic and brain levels, it is of great importance to understand the neurochemical changes that take place, and the relationship of these changes with the clinical manifestations that limit physical and mental performance in late life. Among the age-associated changes, those involving brain monoamines, particularly dopamine, may represent strategic targets for interventions aimed at sustaining normal mood, motor, and cognitive functions.

Studies on brain neurotransmitter changes during aging trace back into the late 1960s. The not always consistent descriptions of age-associated alterations of monoamine content, synthesis, and receptors in various areas of the aging brain were actively pursued up to the late 1980s. Since then, the interest has shifted toward the investigation of age-associated neurodegenerative diseases and protein–protein interactions, rather than neurotransmitter dynamics. What is still valid at more than 15 years of distance from early research, and what deserves our continuous attention? What are the lessons learned from the first studies? Early studies on monoamines changes during aging were motivated by the seminal observations by Arvid Carlson and Olef Hornykiewcz, who focused on the role of dopaminergic transmission in motor function and its derangement in Parkinson's disease, an age-associated pathological condition. This led to the concept that it was possible to define the neurochemical fingerprints of neurological and psychiatric diseases and also of the functional motor and cognitive decline of the elderly, and to treat them by normalizing the function of the involved neurotransmitters, either by replacement therapy or by antagonizing their receptors in case of overfunction. This view, although obviously not complete, provided the rationale for the development of several drugs useful for neuropsychiatric conditions and promoted further studies on the aging brain. Both animal and human brains were subsequently investigated.

All of the data published on the age-associated changes of neurotransmitters in humans (in part summarized in Table 1) are potentially biased by the selection of and the variability of the investigated individuals and by the presence of age-associated pathologies of presymptomatic conditions. Indeed, neurotransmitter studies in humans have been performed on tissues obtained at autopsy. Investigations using postmortem material are limited by many factors, including age, sex, disease state, drug history, postmortem delay, stability of the neurotransmitter's indices, and many others. Some studies were done measuring monoamines and their metabolites in the cerebrospinal fluid (CSF) or in plasma. However CSF analyses, in addition to being invasive, present several problems, including cervical to lumbar concentration gradients of the species measured, and the fact that it is not possible to attribute the observed changes to a specific brain area. Plasma levels of monoamine and their metabolite are, in general, a poor index of events occurring at brain level and may rather reflect changes in peripheral monoaminergic nerve terminals or in platelets, in the case of serotonin. In turn, animal studies, mostly, but not exclusively, on rodents, present not only species-but also strain-dependent variability and are biased by the rather artificial conditions of laboratory animal life. All of this has to be kept in mind when taking into consideration the published data and in particular when extrapolating from laboratory conditions to human aging.

Dopaminergic Neurotransmission

In the elderly, the decline in memory and cognitive abilities is of great concern, as is motor weakening, which increases with age. The dopaminergic system mediates motor abilities as well as cognition and emotion and may be especially vulnerable to aging. Consequently, the aging of this system has both clinical and vocational aspects. The reason for the selective vulnerability of dopaminergic transmission to the aging process is only partially understood. The phenomenon in the past has been attributed to an excess of oxidative stress in dopaminergic areas linked to the metabolism of dopamine (DA) itself. Interestingly, it has been shown that dopamine-induced toxicity is age dependent. Rats of various ages receiving dopamine infusion in the substantia nigra show behavioral and histological correlates of dopamine toxicity, as indicated by motor behavioral deficits and by a loss of tyrosine hydroxylase; the effects are more severe in middle-aged rats (15 months) than in young ones. More recently the attention has been shifted to the interaction between dopamine and parkin, a key

Table 1 Synopsis of changes in some monoamine neurotransmitter systems during brain aging[a]

Parameter	*Change in humans*	*Change in laboratory animals*
Dopaminergic neurotransmission		
Presynaptic parameters		
Dopaminergic cells in substantia nigra	−	
Tyrosine hydroxylase	−	
DOPA decarboxylase	−	
Homovanillic acid	−	−
Dopamine	−	−

Serotonin transporter	−/=	

[a]Key to changes: −, decrease; +, increase; =, no change. The table provides an overview of several age-associated changes in monoamine neurotransmission. Besides dopaminergic transmission, displaying a rather consistent view, the results on noradrenergic and serotonergic transmission are more complex, brain area specific, and in line with the concept that normal brain aging is associated with subtle morphological and functional alterations rather than large-scale neuronal loss. If not indicated, laboratory animals include various strains of rats and mice.
[b]Impaired increased release of noradrenaline following immobilization stress in aged rats.

protein for the survival of neurons in the substantia nigra and locus coeruleus. In particular, it has been shown that parkin is a direct target of dopamine quinone *in vitro*, leading to a loss of parkin activity. Since dopamine oxidation occurs in aging brains, as indicated by an age-associated accumulation of neuromelanin, it is possible that this mechanism contributes to the degeneration of substantia nigra neurons over time. Also, age-associated changes in the activity of growth factors acting on nerve cells may have a role. Experiments on transgenic mice show that the age-related changes in nigrostriatal dopaminergic function are enhanced when one allele for brain-derived neurotrophic factor (BDNF) is deleted, thus supporting the view that changes in growth factor expression may alter the susceptibility of selected neuronal populations to the aging process (somewhat similar results were obtained for glial-derived growth factor and noradrenergic neurons; see later). Gender differences may also play a role. Data on aged Fisher 344 rats indicate that there are both age and sex differences in the brain's response to chemical lesioning using 6-hydroxydopamine, and that the compensatory or neuroprotective mechanisms are more efficient in the aged female brain.

A deficit in dopaminergic tone is present in the brain areas most densely innervated by dopaminergic neurons, and classical experiments in aged rodents made by Cotzias in the late 1970s suggested that fostering dopaminergic transmission by a prolonged treatment with 3,4-dihydroxy-L-phenylalanine (L-DOPA) was able to improve physical aspect, sexual behavior,

and longevity of treated animals. Characterization of the aging dopaminergic system in laboratory rodents (in decreasing order of frequency of use in aging studies: rats, mice, guinea pigs, rabbits) is based on detailed studies considering dopamine terminal synthesis, release, and uptake of dopamine, and of the ability of postsynaptic dopamine receptors to recognize dopamine and to trigger a correct signal transduction. Aging affects the number of dopamine receptors and their ability to stimulate adenylate cyclase and to promote cyclic adenosine monophosphate (cAMP)-stimulated protein phosphorylation through cAMP-dependent protein kinase A (PKA). In particular it has been shown that the dopamine-stimulated adenylate cyclase activity, which is functionally linked to dopamine D1 receptors, is significantly reduced in dopamine-rich areas. Most of the data have been obtained working with extrapyramidal dopaminergic areas such as the neostriatum, while less systematic data are available on other brain regions where dopamine terminals are present, such as nucleus accumbens, prefrontal cortex, hippocampus, and hypothalamus. The nigrostriatal system has been more intensively studied compared to other brain areas because several diseases that affect it have strong age-related incidences, particularly Parkinson's disease, the onset of which peaks after 50 years of age. The changes at receptor level are complex, depending upon the animal species or strain used and the ligand adopted. There are two families of dopamine receptors: D1 sites, which stimulate adenylate cyclase, and D2 sites, which inhibit adenylate cyclase or are independent of a cAMP-generating system. The number of binding sites for D1 receptor ligands has been reported to be unmodified in some rodent species (Sprague–Dawley rats, C57 mice) and reduced in other (Wistar and Fisher 344 rats). Selective D2 ligands, such as substituted benzamides, and the dopamine-inhibited adenylate cyclase (a dopamine D2 receptor-associated event) are unmodified. In contrast, the labeling of dopamine receptors using butyrophenones (the most popular ligand being spiroperidol) as ligands shows a reduced receptor density, suggesting that in the experimental conditions and animal species/strain used, butyrophenones label subsets of nondopaminergic receptors that are not labeled by benzamides and that show an age-associated decline.

Not only the binding sites for dopamine receptor ligands show age-associated changes, but also their ability to adapt to a challenge. As an example, it has been shown that in old rats the supersensitivity response (seen as an increased number of receptors) to chronic receptor blockade by the dopamine antagonist haloperidol is impaired. A reduced adaptive capacity of dopamine receptors in response to a chronic reduction in receptor activation has also been reported in mice. Since similar changes also take place in humans (see later), it may be predicted that failure of the compensatory receptor response, together with reduced presynaptic transmitter availability, may contribute to the greater sensitivity of the elderly to the extrapyramidal side effects of antipsychotic drugs.

In addition to the nigrostriatal system, also the limbic and hypothalamic dopaminergic systems are sensitive to aging. In particular, tuberoinfundibular dopamine (DA) transmission shows the greatest age-associated changes. In the animal model, dopamine concentrations decrease with age in the medial basal hypothalamus and in the median eminence. The increased secretion in senescent animals of prolactin represents the consequence of impaired hypothalamic dopaminergic transmission, which is under inhibitory dopaminergic control. Indeed, age-associated changes are commonly observed in the control of prolactin in laboratory rats and similarly in other species. In male and female rats of some strains, circulating prolactin levels become elevated in middle age. This observation supports the concept that hypothalamic dopaminergic mechanisms are impaired in aging due to a diminished dopamine release at the median eminence, in turn leading to an increased prolactin secretion. Increased serum prolactin levels have been observed also in humans, although the changes appear to be small. These data open, from a theoretical point of view, another perspective – that changes concerning hypothalamic monoamines may have long-range consequences due to the role that these neurotransmitters play in regulating hypothalamic neuroendocrine functions.

It should be remembered that some age-related changes might be modulated by gender and hormonal status. For example, it has been shown that long-term estrogen therapy may enhance dopaminergic response in postmenopausal women. Finally, it should be noted that most of the studies on dopamine transmission in aged rodents were performed at a time (late 1970s, early 1980s) in which the very definition of 'aged rodents' was somewhat ill defined, and the ages of the animals labeled as aged were somewhat variable (18, 21, 24, or 28 months) among the various laboratories worldwide, accounting for at least part of the variability of the published data.

In many studies on the human senescent brain, all biochemical indices of presynaptic nigrostriatal and mesolimbic dopamine neurons have been found substantially reduced. These changes include concentration of dopamine and its main metabolite, homovanillic acid; activity of tyrosine hydroxylase (TH) and DOPA decarboxylase; and dopamine uptake

sites. In extensive studies of dopamine and other presynaptic dopaminergic markers in human striatum, dopamine levels showed a pronounced postnatal increase during adolescence, followed by a decrease during aging. The levels of tyrosine hydroxylase and of aromatic amino acid decarboxylase show a similar postnatal increase, then decline by 30 years of age. Also, the vesicular monoamine transporter and the dopamine transporter show a similar pattern. The levels of the latter slightly, but significantly, decline in the caudate during aging. Consistent with the view of a reduced monoaminergic tone during aging, the activity of the monoamine-catabolizing enzyme, monoamine oxidase – in particular, the dopamine-degrading monoamine oxidase B – seems to be increased in several regions of the senescent human brain. On the whole, the data indicate a discrepancy between the loss of dopamine and the relative preservation of proteins involved in the biosynthesis and transport, suggesting that the decreased DA function in senescence may be explained by loss of DA *per se*, rather than by, or in addition to, a loss of dopaminergic neuropil. Notably, of the two dopamine-synthesizing enzymes, tyrosine hydroxylase and DOPA decarboxylase, the age-associated changes of the latter are more widespread, making it a better neurotransmitter index to monitor during aging.

The age-related loss of spiperone binding to dopamine D2 receptors has been shown to occur also in humans, and decreased concentrations are seen in the neostriatum long before old age, being significant by age 30 years. Notably, the selective loss of dopaminergic receptor subpopulations points to the possibility that their decreased number might be the consequence of a selective loss of postsynaptic elements, an observation that may distinguish between the context of the dopaminergic innervation loss in Parkinson's disease, which is much more pronounced and concerns predominantly presynaptic dopaminergic terminals, and nonpathological aging, in which the changes are more subtle and also involve postsynaptic elements. In relation to the presynaptic component, accurate positron emission tomography (PET) imaging studies using [^{18}F]fluorodopa indicate that the storage capacity for dopamine, both in the caudate and putamen, is reduced in the healthy elderly relative to young control individuals, and much more so, up to 85%, in parkinsonian patients. The observed changes have been attributed to a loss of vesicular storage capacity. On the other hand, the loss of dopamine D2 receptors in the senescent human striatum may be due to the loss of intrinsic striatal neurons as well as to the loss of nigrostriatal dopamine terminals and corticostriatal glutamatergic terminals bearing D2 dopamine receptors, even if animal data do suggest the possibility of a reduced receptor synthesis.

At partial variance with the preceding findings describing a reduced postsynaptic receptor number, observations showing that elderly patients develop spontaneous orobuccal–lingual dyskinesias suggest development of functional denervation supersensitivity of dopamine receptors, possibly due to the loss of presynaptic dopamine terminals. This view is also supported by data indicating that the ratio of homovanillic acid to dopamine (HVA/DA) is increased in elderly individuals, suggesting an increased DA turnover, a possible compensatory mechanism to the reduction of DA terminal number. Animal studies support this hypothesis; in fact the responsiveness of aged rats to apomorphine and amphetamine is increased.

On the whole, the data (summarized in Table 1) suggest that the age-related loss of dopamine D2 receptors represents the most generally observed change in the brain, both in laboratory animals and in humans. In turn, this observation suggests that the ratio between D1 and D2 receptors also changes with age, leading to a prevalence of the former. Even if the studies on dopamine metabolism are less consistent, the observed decline in the rate of HVA delivery from the brain to the CSF in elderly individuals is consistent with other evidence that brain dopaminergic neurotransmission declines with age.

The functional significance of these changes in normal human brain has also been investigated. From a general point of view it has been observed that the reduction in brain dopamine activity occurring as a part of aging is associated with changes in motor as well as cognitive functions. Interestingly, imaging studies have shown an association between dopamine D2 measures and metabolic activity in the frontal lobe. Together, these observations corroborate an involvement of the dopamine system in the cognitive deficits of the elderly. Moreover, these results, as well as observations in parkinsonian patients, indicate the possibility to identify strategies to improve motor and cognitive functions in the elderly based on the improvement of dopamine function. This view is further supported by data showing that diminished motor memory encoding in elderly humans is enhanced by L-DOPA intake. This goal may also be attained by nonpharmacological interventions. Notably, it has been repeatedly shown that dietary restriction in rats may prevent the loss of striatal dopamine receptors; as well, exercise training may affect brain catecholamine concentrations and receptor densities. Interestingly, new research also suggests the possibility to use compounds that mimic caloric restriction (CR) effects by targeting metabolic and stress

responses that are affected by CR, without actually restricting caloric intake. Also, drugs inhibiting glycolysis or enhancing insulin activity have provided some promising results showing enhanced dopamine action and upregulated brain-derived neurotrophic factor.

Noradrenergic Neurotransmission

Several studies report reduced noradrenaline concentrations at the level of the hypothalamus and hippocampus, and a similar trend also in other brain areas. Decreased levels of the neurotransmitter might be due to loss of noradrenergic neurons in the locus coeruleus. Compared to the age-associated loss of substantia nigra cells, the locus coeruleus cell loss is less pronounced. TH levels show little changes, even in regions of significant reduction of noradrenaline levels. Noradrenergic receptors appear to be intact in several brain areas, except in the cerebellum, where they are reduced. Studies in laboratory rats suggest that β-adrenergic receptors may become less able to express supersensitivity under reduced neurotransmitter concentrations and thus develop a reduced ability to efficiently couple to postreceptor transduction mechanisms.

From a more general point of view, in relation to postreceptor transduction mechanisms, it should be noted that data published on age-associated alterations of the coupling of receptors to G-proteins and to effector systems, in addition to data in published reports on changes in activities of several protein kinases, such as protein kinase A, calcium/calmodulin-dependent protein kinase, and, prominently, protein kinase C, do suggest that the age-associated changes of the response to monoamine transmitters acting on receptors using these transduction mechanisms might be more widespread than generally thought; this raises the possibility of a synergic combination of a reduced transmitter availability and a defective postreceptor machinery. Accordingly, age-associated alterations in the functional response may be more relevant than are changes in the number of receptors. Within this context, it has been shown that β-adrenergic receptors and the related cAMP signaling pathway play an important role in learning and memory, and change in aging in the hippocampus. In experiments using slices of the hippocampus of Fisher 344 rats of different ages, and a particular stimulation protocol involving the application of the β-adrenergic agonist isoproterenol, it was observed that the magnitude of long-term potentiation (LTP), an electrophysiological correlate of memory trace formation, was attenuated in old rats. Such changes may contribute to the compromised performance on memory tasks often observed with normal aging. It has also been shown in Fisher 344 rats that impaired acquisition and retention of the water maze task in aged rats were primarily associated with decreased norepinephrine (NE) activity in the cingulate cortex. No changes in the α1-, α2-, β1-, or β2-adrenergic receptor number were observed in any region sampled.

Within the brain, not only neuronally located β-adrenergic receptors but also those present on brain capillaries show selected age-associated changes. In fact, the locus coeruleus is the site of adrenergic nerve supply to parenchymal capillaries, and stimulation of this nucleus increases capillary permeability to small molecules and water. Abnormalities in the response of microvascular β-adrenergic receptors in aged rats in response to ischemic challenge have been observed, although it is not known whether these changes depend upon altered noradrenergic innervation of the vessels or upon altered intrinsic properties of the receptors. Such alterations may be relevant to microvascular dysfunctions known to occur with aging, including changes of control of the blood–brain barrier (BBB) permeation. On the other hand, it should be noted that in rodent models, no gross changes of the BBB permeability to proteins have been observed, as shown using horseradish peroxidase.

As in the case of dopamine, changes taking place at hypothalamic level influence the neuroendocrine status. The age-related decline of noradrenergic function in the hypothalamus influences the secretion of luteinizing hormone, growth hormone, and thyroid-stimulating hormone; drugs increasing catecholamines, administered to old rats, are shown to reverse this decline. Moreover, age-associated changes of noradrenergic transmission may influence the ability of an organism to cope with stress. In particular, the effects of acute stress on indices of the hypothalamic–pituitary–adrenal axis have been examined in aged Fisher 344 rats by evaluating the extracellular fluid content of noradrenaline and its metabolites, and of 3,4-dihydroxyphenylacetic acid (DOPAC), the metabolite of dopamine, by means of the brain microdialysis technique. In young animals, the stress produced by immobilization induces increased levels of NE in the paraventricular nucleus. The extent of the stress-induced NE increase is smaller in aged rats. The decreased responsiveness of the central catecholaminergic system is paralleled by a similar defect in the peripheral catecholaminergic system and is accompanied by a progressive hypothalamic corticotropin-releasing hormone deficiency. At the pineal level, the melatonin response to isoproterenol is age dependent, and in pineals from old Wistar rats the response is approximately half of that found in young rats.

The age-associated changes of noradrenergic brain neurotransmission may in part be due to the failure of trophic factors, such as glia-derived neurotrophic factor (GDNF), for noradrenergic neurons in the locus coeruleus. Old (18 months) mice heterozygous for the GDNF gene (*Gdnf*+/−), compared to +/+ mice, present a reduced locomotor activity and a reduction in NE transporter activity in the cerebellum and brain stem, as well as reduced noradrenaline tissue content in the locus coeruleus. The data suggest that GDNF may contribute to maintain the noradrenergic system throughout life. Together with the previously mentioned data showing that BDNF helps to maintain adequate dopaminergic neuron survival, these additional data support the concept that at least some of the age-associated changes in catecholaminergic innervation may depend upon defects in the synthesis of adequate amounts of growth factors.

Serotonergic Neurotransmission

The effect of age on serotonergic transmitter parameters has been less studied than the effect on catecholamines. From a general point of view the vulnerability of the catecholaminergic systems, in particular dopamine, to aging contrasts with the relative resistance of the serotonergic system. At a glance, it appears that aging affects the serotonergic system rather heterogeneously. The published reports are frequently contradictory and reflect strong differences according to the brain area investigated. In the case of serotonergic transmission, the data on presynaptic markers of activity are inconsistent, with increase, decrease, and no changes having been reported in the literature. As a whole, serotonin and its metabolite 5-hydroxyindoleacetic acid (5-HIAA), as well as the imipramine binding site, do not seem to show age-associated alterations. Also, the deaminating enzyme monoaminoxidase A appears to be stable with age. More consistent data have been reported in the case of serotonin 5-HT_1 and 5-HT_2 receptors, showing a decreased density at the level of the frontal cerebral cortex and hippocampus. Using a selective 5-HT_{2A} receptor ligand, a decrease in the binding index of a neuroreceptor radioligand has been observed in the frontocortical area in canine brain. PET studies investigating *in vivo* in conscious monkeys the effect of aging on 5-HT_{1A} receptors, and their functional response to agonists, revealed a significant age-associated decrease of 5-HT_{1A} binding in frontal and temporal cortices, but not in cingulate gyrus, hippocampus, occipital cortex, striatum, thalamus, or raphe nucleus. Moreover, the degree of displacement of the tracer from its binding sites following systemic administration of 8-hydroxy-2-(di-*n*-propylamino) tetralin (8-OH-DPAT), a 5-HT_{1A} agonist, was smaller in aged compared to young monkeys.

The reported loss of serotonin receptors with age may be attributed to loss of neurons or cell components that receive serotonergic inputs. At the cortical level, loss of serotonin receptors may be associated with cortical cell loss, rather than to a specific impairment of serotonin receptor synthesis. Such serotonin receptor loss, as well the decreased noradrenergic tone, may contribute to the increased risk to develop depression in the elderly, even if changes in other systems, such as control of growth factors and corticosteroid activity, may be more important in this respect.

Changes in the activity of serotonin may alter neuroendocrine function. The decline in circadian activity of the suprachiasmatic nucleus serotonergic neurons may account for the blunting of circadian rhythms in the secretion of several anterior pituitary hormones in old animals. Moreover, inasmuch as catecholamine levels decrease with aging, the ratios of serotonin to noradrenaline and of serotonin to dopamine rise. At hypothalamic level, catecholamines and serotonin modulate endocrine function through action on hypothalamic neurosecretory products, thus an imbalance between these systems may underlie some of the neuroendocrine changes associated with aging (see **Figure 1** for a scheme integrating these concepts). Serotonin transmission is also affected at the level of the pineal gland. In old Wistar rats, pineal 5-HT and 5-HIAA concentrations were 41–47% of those found in young rats. These observations and those on the melatonin response to noradrenergic stimulation suggest the existence of both a noradrenergic and a serotonergic deficit at the pineal level. Due to the putative roles attributed to melatonin in immunosenescence and in light/dark adaptation, these changes may participate in determining the complex pattern of monoamine-related neuroendocrine aging.

In humans, a reduced density of serotonin 5-HT_{2A} receptors has been observed using PET tracers in various brain regions, including the anterior cingulate, posterior medial prefrontal cortex, hippocampus, and occipital cortex. Most of the decrease in receptor binding occurred up through midlife and there was less decrease in late life. In the past, postmortem studies have provided limited and conflicting data regarding aging effects on the central serotonin transporter (SERT). However, data from autopsy studies are limited by the difficulties of assessment of the acute clinical picture before death and by postmortem artifacts. On the other hand, data based on *in vivo* studies using PET techniques have also

Figure 1 Illustration of the key role of monoamines in controlling several activities in the brain and in the neuroendocrine axis. Age-associated changes in synthesis, transporters, and receptors, coupling with effector systems involving any of the monoamines or in their ratios (DA, dopamine; NE, norepinephrine; 5-HT, 5-hydroxytryptamine), may profoundly affect brain function as well as peripheral organ function. Pineal and hypothalamic function should also comply with internal and external timing (consider the pulsatile secretion of several hormones); the age-associated changes may therefore occur not only in terms of absolute amount of transmitter or response, but also in terms of incorrect timing of secretion. See text for further details.

provided conflicting data. Single-photon emission tomography analyses of presynaptic SERT suggest an age-related decline in the thalamic/hypothalamic and midbrain/upper brain stem SERT density. However, it appears that when the appropriate control measures are taken, the changes of central SERT, if present, are much smaller than those of dopamine transporters. As a whole, the results of postmortem and *in vivo* imaging studies on the influence of age on serotonergic transmission are scanty and controversial, in spite of the major role that the central neurotransmitter serotonin plays in a number of neuropsychiatric human conditions.

Monoamines and Monoaminergic Neurotransmission

Monoamines are neuromodulators that arise from the decarboxylation of large neutral and aromatic amino acids in brain tissue. Depending on the specific precursor, they fall into two categories, the catecholamines that ultimately are derived from phenylalanine but in brain only come from tyrosine, and the indoleamines that are derived from tryptophan. The most important catecholamines are dopamine and noradrenaline, and the most important indoleamine is serotonin.

Neuromodulation is a special kind of neurotransmission. Neurotransmission, in turn, is the term applied to the exchange among brain cells of specific information encoded in chemicals known as transmitters. The conventional description of neurotransmission includes, at the very least, the steps of synthesis, vesicular storage, release, reuptake, and removal or breakdown. This is a simple view of the molecular interactions involving neurotransmitters, but it is the basis on which the molecular imaging of neurotransmission rests. The individual steps are implemented in extra- or intracellular proteins that act as enzymes, receptors, or transporters. Molecules that interact with the proteins are known as ligands, because the first step of the interaction is binding, regardless of the additional functions of the protein. By necessity, all neurotransmitter molecules are ligands, but not all ligands work as neurotransmitters.

Binding is the first step in the processing of the ligands, the ultimate fates of which differ, according to the proteins with which they interact. Receptors release ligands to the original pool of unbound molecules after a delay that depends on the affinity of the receptors toward the ligands and possible internalization. Transporters relocate ligands to different pools of unbound ligands. Enzymes release ligands to the same pools but in a new chemical form. Exogenous or artificial ligands may differ so much from native ligands that transporters or enzymes fail to carry out their primary function, and instead act as receptors by simply returning ligands unchanged to their original pool. Intentionally or unintentionally, this interaction with a protein may interfere with the access of any endogenous ligand. Depending on the degree of interference, exogenous or artificial ligands may thus be classified as antagonists or partial agonists of the action of the native neurotransmitters.

As neuromodulators, monoamines are not classical neurotransmitters. Classical neurotransmitters confine their action between cells to receptors located in or near synapses, or 'kissing points,' that are also the sites of release. This type of neurotransmission is 'wired'; in wired transmission, release, binding, and reuptake are linked by the very short distances, so as to prevent wide dissemination of the transmitter. In contrast, 'volume' transmission is a paracrine process, in which the transmitter molecules diffuse widely and their concentrations depend less on the moment-to-moment fluctuations of release. Instead, it is the density and location of transporters in relation to sites of release that determine the specificity of action. Thus, in volume transmission, the transporters are located far from the site of release and their location determines the nature of the transmission. Hence transmitters engaged in volume transmission carry no specific information about the sites of release. In keeping with the mechanism of neuromodulatory volume transmission, the monoamine transporters primarily are extrasynaptic, although the monoamines may serve both wired and volume transmissions, such as in the case of dopamine.

As neuromodulators, monoamines tend to reduce the excitability of target neurons, although this action does depend on the specific receptor subtypes that are expressed locally. Because the specificity of the proteins toward exogenous or artificial ligands varies, it is now possible to image presynaptic and intracellular as well as postsynaptic sites of transmitter interaction by selecting or designing exogenous or artificial ligands that match the specificities of the proteins. The main extra- and intracellular sites of binding, reuptake, and metabolism are listed in Table 1.

The expression of receptors and enzymes is highly variable and depends on the intra- and extracellular environments, making all results of positron emission tomography (PET) and single-photon emission computed tomography (SPECT) contingent upon the specific circumstances at the time of study. This is also true of the transporters, but when the first tropane-based PET probes for the dopamine transporters were used in baboons and humans, it was generally assumed that the number of transporters remained constant. However, it is now known that the number of dopamine transporters is subject to regulation by intrinsic mechanisms as well as pharmacological manipulation.

Table 1 Variables of monoaminergic neurotransmission

Location	*Variable*	*Example*
Presynaptic	Transporter availability (binding potential)	Dopamine transporters, vesicular monoamine transporter 2
	Enzyme activity	Dopa decarboxylase
	Precursor concentration	DOPA
Postsynaptic	Receptor availability, density, and affinity	Dopamine D_2-like receptors
	Receptor subtype selectivity	Dopamine D_1- or D_2-like receptors
Intrasynaptic	Endogenous neurotransmitter occupancy	Dopamine
	Endogenous neurotransmitter release	Dopamine
	Enzyme activity	Monoamine oxidase A or B

Table 2 Properties of radionuclides used in PET or SPECT imaging

Isotope	*Modality*	*Decay mode (%)*[a]	*Half-life (min)*	*Production type*[b]
^{11}C	PET	β^+ (100)	20.1	C
^{13}N	PET	β^+ (100)	9.996	C
^{15}O	PET	β^+ (100)	2.04	C
^{18}F	PET	β^+ (97), EC (3)	109.8	C/R
^{62}Cu	PET	β^+ (97), EC (3)	9.7	G[^{62}Zn]
^{68}Ga	PET	β^+ (89), EC (11)	68	G[^{68}Ge]
^{82}Rb	PET	β^+ (95), EC (5)	1.3	G[^{82}Sn]
^{99m}Tc	SPECT	IT (100)	360	G[^{99}Mo]
^{123}I	SPECT	EC (100)	780	C
^{131}I	SPECT	β^- (100)	8 (days)	C/R

[a]Decay modes: β^+, positron emission; β^-, electron emission; EC, electron capture; IT, isomeric transition.
[b]Production types: C, cyclotron; R, reactor; G, generator.

Methods of Molecular Imaging with PET and SPECT

Molecular imaging of neurotransmission *in vivo* is an extension of the principles of *in vitro* and *ex vivo* autoradiography to the living brain. Historically, much of the imaging has focused on the dopaminergic innervations of the basal ganglia by the nigrostriatal fibers, but the serotonergic, noradrenergic, and dopaminergic innervations of the limbic and cerebral cortices have since become important targets. The first reports on the use of PET and SPECT to image aspects of neurotransmission in the basal ganglia with radiolabeled drugs appeared as early as 1983. By labeling specific drug molecules of known action, the investigators confirmed the fates of these molecules in time and space in the brain and thus recorded events that could be ascribed to the known effects of these drugs on dopaminergic neurotransmission.

Although both PET and SPECT are used in these efforts, it is important to note their different characteristics, as listed in Table 2. PET tracers emit positrons, and PET detects the gamma radiation that arises from the annihilation of positrons when they collide with electrons. The most common radiolabels used with PET are the positron-emitting isotope of carbon (^{11}C) that replaces a stable carbon atom (^{12}C), and the positron-emitting isotope of fluorine (^{18}F) that either is added to some molecules or replaces stable fluorine (^{19}F) in other molecules, in most cases without significantly affecting the original kinetic properties of the molecules. PET has the advantage that the half-lives of these isotopes are very short (20 min for ^{11}C and 110 min for ^{18}F), but the disadvantage is that the nuclides must be produced in a local cyclotron.

SPECT tracers emit gamma radiation directly, arising from photon-emitting nuclides such as technetium-99m (^{99m}Tc) and iodine-123 (^{123}I). These nuclides have much longer half-lives, as listed in **Table 2.** Some SPECT tracers therefore have the advantage of being available in most nuclear medicine departments, and the relatively long half-life of ^{123}I (13 h) permits tomography to take place as late as 24 h after administration of the tracer, but it is a disadvantage that this nuclide currently is available primarily in North America only from a cyclotron facility in Vancouver, Canada (Tri-University Meson Facility, or TRIUMF).

Multiple brain images in the form of dynamic series of tomographic frames are acquired in PET studies of monoaminergic neurotransmission. Typically, 30–50 frames are obtained as two- or three-dimensional images in 60–120 min. Because of the short half-lives, this duration is the limit of most studies with ^{11}C or ^{18}F. In contrast, SPECT studies with ^{123}I may be continued for 6 or more h, as evident from Table 2. In two-dimensional imaging, the tomographic record consists of 15–64 or more sections of the brain, depending on the tomograph.

In many studies, both of animals and humans, investigators insert a catheter in a suitable artery to determine the tracer concentration in arterial blood. The blood samples are assayed for radioactivity and six to eight discrete samples of arterial plasma undergo additional high-performance liquid chromatography (HPLC), or thin-layer chromatography

(TLC), to determine the chemical nature of all labeled products in plasma, to account for metabolism in the course of circulation and to reconstruct the concentration of the parent compound as a function of time. The arterial samples and brain images establish the concentrations of the tracer in blood and brain as functions of time. The records then form the basis for the subsequent kinetic analysis that yields the specifics of the monoaminergic neurotransmission, as listed in Table 1.

The availability of the right tracers is the key to successful imaging of monoaminergic neurotransmission in animals or humans. With PET, the imaging is limited by the half-life of the tracers, which means in the case of ^{11}C-labeled tracers that all information must be extracted during the first hour of recording. The usefulness of this information in turn is dictated by the pharmacology and binding properties of the tracer in relation to the relevant proteins and not solely by the properties of the ligand.

An important challenge to PET imaging is the necessary anesthesia of animals used in research. It has been possible in very few places to train nonhuman primates to remain awake while seated comfortably under a horizontally suspended tomograph (e.g., Hamamatsu, Japan). In other places, it is necessary to use a within-subject design of drug studies to reduce the variability of the PET measures. Other factors, such as the size of brain, genotype, age, latent disease states, personality, and adaptation to stress and drugs, have not routinely been sorted out in most preclinical or clinical studies. A few studies addressed elements of psychology and personality, including introversion and social reclusiveness, and the effects of social anxiety. Nonetheless, it is clear that interpretation of these effects is difficult, as a single variable may reflect opposite changes of monoaminergic neurotransmission.

In one study of social isolation in monkeys, the availability of dopamine D_2 receptors in basal ganglia, measured by PET, was shown to rise in dominant monkeys when they moved from individual to social housing. Receptor 'availability' is the controversial term applied to the estimate of the ratio between bound and unbound ligand quantities in a tissue. This ratio is also known as the 'binding potential.' It declines when the receptors approach saturation and hence can be said to be an index of the relative number of unoccupied receptor sites. The number rises either because the total number of receptors rises, or because the concentrations of relevant ligands fall, or both. In the social isolation study, the result was interpreted, somewhat vaguely, as a 'rise' of dopaminergic neurotransmission when dominant monkeys met other monkeys that they could dominate, but the effect could just as well arise from a decline of dopamine, when dominant monkeys escape from the social isolation.

An important problem is sample size. Typical numbers in PET studies of humans range from 10 to 20 participants, and a study population of 30 individuals is rare. Adequate numbers are necessary to counteract the confounding influence of the tomograph's finite power of resolution of the recorded radioactivity, known as the 'partial volume' effect. The effect is most prominent in small structures that typically fuse below a diameter of 2–3 mm. The effect persists for diameters as large as two to three times the full-width-at-half-maximum (FWHM) property of a point source for any imaging agent. Thus, the human cerebellum usually loses about 5 or 10% of its total activity when the entire structure is imaged. The resolution of PET originally was no less than 8 mm FWHM. Current tomographs enjoy resolutions as low as 2–3 mm FWHM for the high-resolution research tomograph (HRRT), which allows visual separation of two points with distances as small as 0.5 cm. The partial volume effect is an even greater problem with SPECT, because the attenuation correction is much greater with this method.

Tracers of Monoaminergic Neurotransmission

PET and SPECT both use marker molecules (tracers) that bind to the proteins of monoamine synthesis, binding, and metabolism with sufficiently high affinity and selectivity, but ordinarily with such low concentration that pharmacodynamic effects are absent. The marker molecules are tracers because the radiation that they emit can be detected externally by the tomographs.

The typical investigation of monoaminergic neurotransmission begins with identification of an appropriate precursor of a tracer that targets a specific step in the pathway from the aromatic amino acid parent to final metabolite. Both the choice of precursor and the synthesis of the tracer from the precursor are based on evidence obtained *in vitro* or *ex vivo* in animals or humans. When a potential tracer is labeled, its usefulness must be examined carefully, first in animals and then in humans; at any time in this process, unexpected species differences may interfere with the imaging – for example, by blocking the transfer of the tracer across the blood–brain barrier, or by altering the metabolism of the tracer in the brain tissue. The necessary safety profile in the form of toxicology and radiation dosimetry must also be established. Validation in animals may involve

initial studies *in vitro* to confirm the saturability of the binding, or the competition with chemically or pharmacologically related drugs. Once the binding and metabolism characteristics are known, the tracer may finally be deemed appropriate for use *in vivo* in nonprimate mammals or nonhuman or human primates.

Table 3 lists the large number of monoaminergic tracers that have been tested with variable success since 1983. Unfortunately, of the hundreds of

thousands of compounds developed by pharmaceutical industry, university, or government institutions, only a tiny fraction can be used successfully in labeling. Radioligands are useful only when they meet specific requirements of selectivity, affinity, and kinetics of binding, transport, or metabolism. Only when these requirements are met can reliable estimates of receptor density or neurotransmitter synthesis, release, or metabolism, be obtained noninvasively.

Three tracers illustrate the historical advance of tracer development from 1983 till today, and the problems associated with the use of the tracers. In 1983, the experimental neuroleptic spiroperidol (spiperone; 8-[4-(4-fluorophenyl)-4-oxo-butyl]-1-phenyl-1,3,-8-triazaspiro[4.5]decan-4-one) was the precursor by methylation of the radioligand 3-*N*-[^{11}C]methylspiperone (NMSP), for which the dopamine D_2-like (D_2, D_3, and D_4) receptors have high affinity. Spiperone is a piperazine, originally so named because of the chemical relation to piperidine, a constituent of piperine in the black pepper plant (*Piper nigrum*), but the radioligand is known also as a butyrophenone. The radioligand yielded the first D_2-like receptor PET images in humans. However, the selectivity was not exclusive for this receptor subtype, as the serotonin $5HT_{2A}$ receptors also have significant affinity. Kinetic analysis of the binding was complicated by this high affinity; the relative influences of transport across the blood–brain barrier and binding to the receptors cannot be fully resolved when a secular equilibrium of bound and unbound ligand is not approached during the period of uptake. Therefore, ligands that bind irreversibly often have delivery-dependent, rather than affinity-dependent, uptake. In contrast, useful ligands frequently have binding characteristics that include high selectivity but only moderate affinity, commensurate with binding potentials between 1 and 6. In the case of NMSP, the binding potential exceeds 6 in humans, although partial volume effects may reduce this value in the smaller brains of experimental animals. Interestingly, NMSP has been of use in cerebral cortex, where the lower affinity of the serotonin receptors renders the binding reversible in the period available for PET, without serious interference from the lower density dopamine receptors in cortex.

The currently most common monoamine receptor ligand used with PET is [^{11}C]raclopride (3,5-dichloro-*N*-[(1-ethylpyrrolidin-2-yl)methyl]-2-hydroxy-6-metho xy-benzamide), which derives from another class of chemical, the benzamides. Benzamides are derivatives of benzoic acid, and substituted benzamides often serve as neuroleptics or antipsychotics in psychiatric practice. Two active substances from the group of benzamides are in clinical use, sulpiride and amisulpride. Raclopride binds reversibly and selectively to the dopamine D_2 and D_3 receptors, with a binding potential of 3 in human brain, and as such is an ideal tracer of these dopamine binding sites in high-density locations such as the striatum. In cerebral cortex, the lower density renders the binding potential too low to be useful. Several alternatives with higher affinity are available for this purpose. The tracer [^{18}F]fallypride ([5-(3-fluoropropyl)-2,3-dimethoxy-*N*-[(2*S*)-1-(2-propenyl)-2-pyrrolidinyl]-methyl]-benzamide) is a radioligand with binding potentials of 0.5–1.5 in cerebral cortex. The higher affinity elevates the retention in striatum, where the binding potential is so high that binding is delivery dependent. Benzamide tracers are also available for SPECT. They include [^{123}I]iodobenzamide (IBZM) and [^{123}I]- and [^{125}I]epidepride.

In the case of metabolic substrates, it is necessary that the product be retained in brain as an index of the activity of the enzyme, provided the transport across the blood–brain barrier is not rate limiting for the uptake. The first study with PET of the metabolism of the dopamine precursor [^{18}F]fluorodopa (FDOPA) was also published in 1983. The tracer is one of several substrates of the aromatic amino acid decarboxylase, which produces both dopamine and serotonin from appropriate amino acid precursors in respective terminals. The uptake appears to be irreversible but the appearance may be deceiving, as the retention may reflect only a fraction of the tracer.

For FDOPA, a host of different kinetic analyses have been attempted to solve the issue of the specificity of the signal. Increasingly, it is clear that the retention primarily reflects the transport of the labeled product fluorodopamine (FDA) into vesicles, and the retention depends on the irreversibility of this transport. Two processes interfere with the retention: First, FDA is subject to oxidation by monoamine oxidases, and second, release of FDA from the vesicles exposes the released FDA to renewed metabolism after reuptake into the terminals. Therefore, low retention can reflect both reduced vesicular incorporation due to loss of terminals or loss of dopa decarboxylase activity, or loss or inhibition of vesicular transporters, or increased release of FDA in response to increased dopaminergic neurotransmission. As indicators of neuronal function, these interpretations have completely opposite implications for the health of the patient, yet the PET signals may look exactly the same. It should be noted that FDOPA is not specific for dopaminergic terminals, as both serotonergic and noradrenergic terminals use this enzyme in the synthesis of their transmitters. However, only in dopaminergic terminals is the product FDA retained.

As markers of dopaminergic activity in presynaptic terminals, the only alternatives to FDOPA are

the tracers of the monoamine reuptake sites, which are based on the tropane structure known as nortropane (8-azabicyclo[3.2.1]octane). Tropane is a nitrogenous bicyclic organic compound, mainly famous for the large group of alkaloids that are derived from it (called tropane alkaloids). The derivatives include, among others, atropine and cocaine. These two alkaloids both contain tropinone, from which tropane is derived. Tropane alkaloids occur in plants of the family Solanaceae (mandrake, henbane, deadly nightshade, potato, and tomato) and in the coca plant.

Several potentially irreversible ligands for the cocaine receptor site on the dopamine transporter are derived from cocaine or 3β-phenyltropane. The cocaine analog CFT (2β-carboxymethoxy-3β-(4-fluorophenyl) tropane, or WIN 35,428) was first recommended as a radiolabeled probe for PET and SPECT by Madras and co-workers and was later developed as the PET tracer [^{11}C]WIN 35,428 by Kuhar and co-workers. The tracer binds irreversibly to the cocaine site on the dopamine transporter (DAT) but lesser to the serotonin transporter (5HTT, or SERT) and the norepinephrine transporter (NET). In attempts to overcome the low selectivity, the basic structure has been modified repeatedly with substitutions of fluorine or small carbon chains that may reduce affinity and raise selectivity. Versions suitable for SPECT include β-[^{123}I]CIT (β-carbomethoxy-3β-(4-iodophenyl)tropane) for the dopamine and serotonin transporters, and [^{99m}Tc] TRODAT-1 selective for the dopamine transporter (technetium(V)-oxo-3β-(4-chlorophenyl)-8-methyl-8-azabicyclo[3.2.1]oct-2-yl[*N*-(2-mercaptoethyl), *N*-(*N*′-(2-mercaptoethyl)-2-aminoethyl)]-aminomethyl).

The evidence for regulation of monoamine transporters has intensified the search for additional probes of events in monoaminergic terminals. The vesicular monoamine transporter (VMAT2) is located in the membranes of terminal vesicles and can be imaged with the radioligand D-[^{11}C]tetrabenazine (DTBZ). However, not even the imaging of the VMAT2 transporter may settle the 'transporter regulation issue,' as VMAT2 also appears to be regulated.

Pharmacokinetics of Monoaminergic Imaging

Generally, the characteristics of binding of radiotracers to the proteins of monoaminergic neurotransmission *in vivo* are consistent with insights from studies *in vitro*, particularly with respect to binding. In Figure 1, the binding of a number of compounds is expressed as the 50% inhibitory concentration (IC_{50}) of the tracer, which takes into account both the receptor's affinity toward the tracer and the concentrations of competitors.

Figure 1 Relationship between 50% inhibitory concentration (IC_{50}) values at dopamine receptors and therapeutic dose of neuroleptics in treatment of schizophrenia. The IC_{50} values are the concentrations of the antipsychotic drugs that reduce the stereospecific component of [^{3}H]haloperidol binding by 50%. The abscissa indicates the average values of doses used in schizophrenic patients. Redrawn from Seeman P, Lee T, Chau-Wong M, et al. (1976) Antipsychotic drug doses and neuroleptic/dopamine receptor. *Nature* 262: 717–719.

The most commonly reported variable obtained with imaging of monoaminergic neurotransmission is the ratio between the density of receptors and the affinity constant, known as the binding potential. Both terms are part of the Michaelis and Menten steady-state solution to the binding equations,

$$B = \frac{B_{\max} C}{K_m + C}$$

where B is the bound quantity of ligand, C is the unbound ligand's concentration, and K_m is the Michaelis constant or half-saturation concentration. The binding potential is the ratio between the bound and unbound ('free') quantities of an endogenous ligand, modified by the ratio of the affinities of the receptor toward the endogenous ligand and the tracer,

$$p_B = \frac{B^*}{C^*} = \frac{B_{\max}}{C^* + K_m^*\left(1 + \frac{C_i}{K_i}\right)} = \frac{K_i B_{\max}}{K_m^*(K_i + C_i)} = \left(\frac{K_i}{K_m^*}\right)\left(\frac{B_i}{C_i}\right)$$

where p_B is the binding potential and the remaining symbols represent bound tracer (B^*), unbound tracer (C^*), maximum number of binding sites ($B_{\max}$), affinity toward the tracer (K_m^*), affinity toward an endogenous ligand (K_i), concentration in brain tissue

of endogenous ligand (C_i), and bound endogenous ligand (B_i).

Sokoloff and co-workers first presented the now standard three-compartment model of tracer kinetics *in vivo* that typically is used to obtain the estimates of binding potential or other variables of tracer binding or metabolism. When kinetic modeling was first proposed for studies of neurotransmission *in vivo* in 1983 and 1984, its use in pharmacology was novel because the Michaelis–Menten solution requires equilibrium of binding, which in principle is not achieved with PET. The Michaelis–Menten equation is the solution to the differential equations of the exchange of tracer between the circulation compartment, the pool of unchanged and unbound tracer in brain tissue, and the pool of bound or metabolized tracer in the tissue. The model assumes that the tracer or its metabolite is retained in this latter pool to such an extent that the tracer exchange with the circulation is delayed significantly.

The model shown in Figure 2 includes the coefficient of clearance (K_1) of the tracer from the circulation to the brain, and the rate constant of fractional clearance (k_2) of the tracer from the exchangeable pool of unbound tracer in the brain back to the circulation. The exchange distribution volume is simply the ratio of these two terms. The rate constants k_3 and k_4 refer to the interaction with the specific proteins, indicative of the retention associated with binding, transport, or metabolism. The specific definitions depend on the process, but generally k_3 is related to the quantity of protein and the concentration of the tracer while k_4 is simply the decay constant of the pool of retained substance. In the case of binding, the definitions are

$$k_3 = K_{\text{on}}(B_{\max} - B_i)$$

and

$$k_4 = K_{\text{off}}$$

where k_3 and k_4 define the respective association and dissociation rate constants. The ratio k_3/k_4 is a function of the amount of protein (such as density of receptors) and the affinity for the tracer, and the ratio is therefore an index of the tissue's potential for retention, a real 'retention potential.' In the case of binding, the definitions show that this ratio is also the binding potential defined earlier.

The exact solutions can be obtained from any standard text. The receptor density $B_{\max}$ is calculated from multiple estimates of the binding potential when the quantity of bound ligand is known for each estimate. The bound quantity includes the endogenous as well as exogenous ligands, such as a drug given to reduce the binding potential of the tracer by competition for binding.

Figure 2 (a) Alternative 1: Three-compartment model (M) of receptor binding, with additional compartment for nonspecific binding of ligand. For definition of rate constants, see text. (b) Alternative 2: Three-compartment model (M) of receptor binding of radioligands. For definition of rate constants, see text. (a) From Wong DF, Gjedde A, and Wagner HN Jr. (1986) Quantification of neuroreceptors in living human brain. I. Irreversible binding of ligands. *Journal of Cerebral Blood Flow & Metabolism* 6: 137–146. (b) From Gjedde A (2003) Modeling metabolite and tracer kinetics. In: Feinendegen LE, Shreeve, WW, Eckelman WC, et al. (eds.) *Molecular Nuclear Medicine*, ch. 7, pp. 121–169. Berlin-Heidelberg: Springer.

It is preferable to obtain the records at steady state, but the exact requirements are dictated by the pharmacology of the ligand. Ideally, the uptake would approach steady state or pseudoequilibrium very closely. If the tracer is given as a bolus administration, true steady state, of course, is never reached. If the tracer is continuously infused, it is possible to get very close to true equilibrium, depending on the tracer's half-life. Equilibrium conditions are ideal, both because comparative binding *in vitro* in principle is at equilibrium, and because the binding transients decline to zero. Unfortunately, some of the most selective ligands have the highest affinity and do not approach secular equilibrium during the 90–120 min available for PET.

An important question is the number of frames necessary to optimize the kinetic analysis. The higher the

number of frames, the lower the radioactivity recorded in each frame and the higher the random variability. The image variance exceeds the Poisson distribution and thus increases with the number of frames and lower counts per frame. If multiple short frames are recorded, there is a trade-off between the number of frames and the accuracy of the kinetic analysis, expressed in terms of parameter 'identifiability.' The information content can be shown to decline as a function of the number of parameters as the variability of the radioactivity measurements increases. There is another trade-off between too many and too few parameters. Many researchers believe that the maximum number of parameters that can safely be derived from PET and SPECT is four, possibly as many as five, consistent with the existence of three compartments.

Estimates of the receptor density are not routine, because they require significant occupation of the receptors with a ligand, which in principle must then have a pharmacodynamic effect. The procedure consists of giving a pharmacologically active dose of a ligand together with the tracer (e.g., haloperidol with [^{11}C]NMSP, or raclopride with [^{11}C]raclopride). As many as five different estimates of the binding potential have been made to complete Scatchard or Eadie–Hofstee plots of the binding, as shown in Figure 3.

In the past and rather unrealistically, it was believed that the binding of radioligands to neurotransmitter receptors would not be affected by the endogenous ligand, but this appears not to be the case. Although the interference could be considered a hindrance to the proper quantification of the receptor density, it has instead permitted indirect and noninvasive investigations of the fluctuations of transmitter release, particularly with respect to the dopaminergic neurotransmission. The promise and excitement of this approach notwithstanding, the reality of the interpretations is the subject of considerable current controversy, as not only transmitter concentration but also receptor number and affinity affect the estimates of binding potentials that may change as a simple consequence of an affinity change.

Altered Monoaminergic Neurotransmission *In Vivo*

Binding potentials have been determined for a number of monoaminergic tracers in many parts of the brain in both health and disease. Figure 4 shows the coincident maps of average dopa decarboxylase activity, dopamine transporter binding potentials, and dopamine receptor binding potentials in normal human beings. The maps are mutually confirmatory, but the individual numbers are not particularly informative in the absence of related evidence of biology or pathology. The noninvasive probing of monoaminergic

Figure 3 Scatchard plots of dopamine receptor density and affinity, determined with [^{11}C]raclopride in monkeys rendered parkinsonian by means of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and methamphetamine (AMPH) administration, in comparison with control monkeys (B, bound; F, free; P_B, binding potential; K_d is special case of K_m for receptor binding; see text for discussion). From Holden JE, Jivan S, Ruth TJ, et al. (2002) *In vivo* receptor assay with multiple ligand concentrations: An equilibrium approach. *Journal of Cerebral Blood Flow & Metabolism* 22: 1132–1141.

neurotransmission in living human brain also promises to clarify the pharmacokinetic and pharmacodynamic mechanisms of expectation, reward, and drug effects in healthy human beings. It is now possible to map the increase of dopamine occupancy that follows when humans become aware of and assign meaning to meaningful stimuli in the environment (Figure 5).

It is well known that the pathological changes occurring in any of the three monoaminergic systems precede the presentation of overt clinical symptoms, and changes of dopaminergic, serotonergic, and noradrenergic neurotransmission are therefore actively monitored in major neurological and neuropsychiatric disorders such as Parkinson's disease, schizophrenia, stroke, depression, and dementia. Not only are such studies of great diagnostic value but they also help avoid over- or underdosing of human patients with the relevant medications.

Figure 4 Images of dopaminergic neurotransmission in human striatum, with [^{18}F]FDOPA (fluoro-l-dopa), for dopamine synthesis capacity; [^{11}C]raclopride, for dopamine receptor availability; and [^{11}C]WIN 35,428 (CFT; 2β-carbomethoxy-3β-4-(fluorophenyl) tropane) and [^{18}F]FP-CIT (fluoropropyl β-carbomethoxy-3β-(4-iodophenyl)tropane), for dopamine transporter availability.

Dopaminergic Disorders

The myriad number of sites that can now be imaged are relevant to multiple disorders, as exemplified for the dopamine systems in Table 4. The imaging of dopamine's receptors has shown that they are lost as a function of normal aging. Striking clinical examples of change include abnormalities at multiple steps in the neurotransmission of dopamine in disorders as diverse as Parkinson's disease, schizophrenia, and addiction, including cocaine and methamphetamine abuse.

Parkinson's disease and schizophrenia in many ways represent opposite ends of a spectrum of perturbed dopaminergic neurotransmission in striatum and midbrain. In schizophrenia, PET and SPECT reveal increased capacity of dopamine synthesis from DOPA, increased tonic and phasic dopamine release, elevated density of dopamine D_2-like receptors, and increased extracellular dopamine. These findings explain how antagonists of dopaminergic neurotransmission can mitigate the worst effects of the disease, at least for some subtypes with positive symptoms, but complete reversal has not been achieved, probably because the primary disorder is cortical. For antipsychotics as well as a number of antidepressants it has been shown that occupancy of 60–80% of the dopamine receptors yields the best therapeutic effect. The receptor occupancy plotted against the plasma level of the drug essentially is a Michaelis–Menten graph of the therapeutic 'window of opportunity' for a neuroleptic. This appears also to be true for partial agonists as well as antagonists of the dopamine receptors.

Figure 5 Reduction of dopamine receptor availability ([^{11}C]raclopride binding potential) in cognitive awareness. Left panel, control state; right panel, meditation state. Note that decline of raclopride binding is indicative of increased dopamine binding. From Kjaer TW, Bertelsen C, Piccini P, et al. (2002) Increased dopamine tone during meditation-induced change of consciousness. *Brain Research – Cognitive Brain Research* 13: 255–259.

Table 4 Changes of dopaminergic neurotransmission *in vivo*

Condition	*Variable*[a]				
	D_2-like receptor availability or density	*DDC enzyme activity*	*DA 'release' or DA occupancy*	*Extracellular or baseline DA concentration*	*DAT availability or density*
Cognitive awareness	–	–	Increase (1)	–	–
Normal aging	Decrease 7–10% per decade (2)	Decrease (3)	–	–	–
Schizophrenia	Two- to three-fold increase (some studies: 4, 5); no change (6, others)	Increase (multiple studies: e.g., 7, 8)	Increase (9, 10)	Increase (11, 12)	–
Bipolar disease/ psychosis	Two-fold increase (13)	–	–	Increase (12)	–
Gilles de la Tourette's syndrome	Increase (14)	–	Increase (15a,15b)	–	–
Attention-deficit/ hyperactivity disorder	Increase (16)	–	Increase (17)	–	Decrease (18)
Temporal lobe epilepsy w/psychosis	–	Increase (19)	–	–	–
Cocaine abuse	Decrease (20)	–	Decrease (i.e., attenuation of normal increase) (21)	–	Decrease (22)
Alcoholism	Decrease?	–	Decrease?	–	–
Parkinson's disease	Increase in untreated patients (23)	Decrease (multiple studies (24, 25)			Decrease (26, 27)

Remarkable changes of dopamine synthetic capacity and dopamine transporter availability have been shown in Parkinson's disease. The cause of the disease is not known, but two different forms could exist in theory, one in which the initial insult is a decline of vesicular incorporation of dopamine, leading to neurotoxic levels of dopamine in the dopaminergic terminals, and one in which the initial insult is a loss of dopamine synthesis capacity. Dopamine will be low in both cases, but the processes of synthesis and metabolism of dopamine will express opposite changes.

Attention-deficit/hyperactivity disorder (ADHD) is suspected of being a dopamine deficiency disorder related to a class of disturbances known as reward deficiency syndrome. PET reveals increased dopamine receptor availability (higher than normal binding potential) in ADHD, consistent with lower than normal extracellular dopamine level, which can be rectified by blocking the dopamine reuptake sites with methylphenidate, as shown in Figure 6. The reason for the deficiency may be abnormally high activity of the dopamine transporters.

Dopaminergic neuroimaging is particularly important to the investigation of substance abuse: the challenge is to understand the interactions of receptors and enzymes with the substances abused. PET has revealed that the main effect of blockade of dopamine transporters by cocaine, amphetamine, or methamphetamine is an increase in dopamine's occupancy of its receptors because of increased extracellular dopamine, as evidenced by decline of the binding potential of a dopamine receptor ligand. Other monoamine transporters are also affected because of the comparatively low selectivity of the transporters toward the blockers.

Many studies reveal decreased extracellular dopamine concentrations and reduced dopamine D_2 receptor availability and density in abstinent abusers, which would tend to exacerbate the dopamine deficiency. Indeed, the monoamine receptors tend to be the direct or indirect, intended or accidental, targets of a wide range of illicit drugs enjoyed recreationally by humans. The drugs that are abused most frequently (opiates, ethanol, nicotine, amphetamine, and cocaine) acutely increase extracellular dopamine concentrations in striatum and nucleus accumbens. In contrast, drugs that are not abused by humans do not appear to affect the dopamine occupancy, while drugs with aversive properties that are actively avoided tend to lower dopamine occupancy, indirectly proving that activation of dopaminergic neurotransmission is a fundamental property of drugs of abuse.

Continued abuse of cocaine or other blockers of monoamine transporters attenuates the increase of occupancy elicited by amphetamine and lowers the density of the transporters in the striatum, measured shortly after the onset of abstinence. The transporter availability rises again after longer periods of abstinence, but cue-induced craving for cocaine in abstinent abusers can raise dopamine's occupancy of its receptors without the aid of cocaine, probably because of cue-induced release of dopamine. Table 5 summarizes findings of dopamine transporter availability in three groups of study participants, as measured with the dopamine transporter ligand [^{11}C]WIN 35,428.

Figure 6 Reduction of dopamine receptor availability ([^{11}C] raclopride binding potential) by treatment with methylphenidate in patients with attention-deficit/hyperactivity disorder. (2005) Methylphenidate-evoked changes in striatal dopamine correlate with inattention and impulsivity in adolescents with attention deficit. *NeuroImage* 25: 868–876.

Serotonergic Disorders

Serotonin receptors are most abundant in cerebral cortex, particularly in the hippocampal region and the ventromedial prefrontal cortex, where PET also shows that binding potentials at $5HT_{1A}$ receptors decline with age and in depression, with return to normal after antidepressant treatment. The changes are somewhat equivocal because it is uncertain

Table 5 Dopamine transporter binding potentials in striatum

Group	*Number of participants*	*Binding potentials (k_3/k_4)*	
		Caudate nucleus	*Putamen*
Healthy volunteers	10	7.5 ± 1.7	7.3 ± 1.4
Methamphetamine abuse	6	5.8 ± 1.0	5.5 ± 0.9
Parkinson's disease	3	4.0 ± 0.9	2.3 ± 0.4

whether the changes are due to change of receptor density or change of serotonin level. Abnormalities of occupancy at these receptors have been difficult to show with the available radioligands because serotonin reuptake inhibitors have little effect on the binding potential. The decline of $5HT_{1A}$ binding potentials in aging is shown in Figure 7. Changes attributable to loss of serotonin have been observed after stroke in patients who develop pathological crying, which is relieved instantly by administration of selective serotonin reuptake inhibitors.

Figure 7 Reduction of serotonin ($5HT_{1A}$) receptor availability ([^{11}C]WAY binding potential) in aging. From Moller M, Jakobsen S, and Gjedde A (2007) Parametric and regional maps of free serotonin 5HT(1A) receptor sites in human brain as function of age in healthy humans. *Neuropsychopharmacology* 32(8):1707–1714.

The drug MDMA (3,4-methylenedioxy-*N*-methylamphetamine), commonly known by the street name Ecstasy, is a semisynthetic entactogen of the phenethylamine family, which affects the serotonin system by interaction with serotonergic and dopaminergic terminals. The acute effect of MDMA appears to result from the drug's interference with dopamine and serotonin reuptake. PET results obtained with the radioligands McN5652 and 3-amino-4-(2-dimethylaminomethylphenylsulfanyl)-benzonitrile (DASB) in humans and shown in Figure 8 suggest that MDMA abusers suffer a measurable reduction of serotonin transporter availability in multiple brain regions, which is relieved after abstinence, although the evidence is still equivocal.

Design of Drugs for the Monoaminergic Systems

PET and SPECT imaging techniques play an important role in the development of drugs that specifically target abnormalities that PET and SPECT have identified in disease. The applications typically involve imaging of the biodistribution of candidate drugs labeled with ^{11}C or ^{18}F for PET, or ^{123}I or ^{99m}Tc for SPECT. The areas of application include (1) therapeutic rationale, (2) justification for the study of specific biological systems, (3) mechanisms of drug action, and (4) rational drug dosing. Much of this work can be carried out in neuroreceptor imaging laboratories of universities

Figure 8 Effect of methylenedioxymethylamphetamine (MDMA; 'Ecstasy') on serotonin transporter availability – [^{11}C]McN5652 and [^{11}C]DASB (3-amino-4-(2-dimethylaminomethyl-phenylsulfanyl)-benzonitrile) binding potentials. From McCann UD, Szabo Z, Seckin E, et al. (2005) Quantitative PET studies of the serotonin transporter in MDMA users and controls using [^{11}C]McN5652 and [^{11}C]DASB. *Neuropsychopharmacology* 30: 1741–1750.

that negotiate master agreements with pharmaceutical companies for evaluations of ligands that will be used in the early stages of drug development.

Conclusions

In summary, imaging approaches to the study of monoaminergic neurotransmission have relevance to both neurological and psychiatric diseases. Historically, neuroreceptor imaging focused on the pathophysiology of major neuropsychiatric disorders such as schizophrenia, Parkinson's disease, and depression, but it is now also being used to study and diagnose dementia, stroke, and drug abuse, and to assist in the development of new drugs. The method of imaged neurochemistry is emerging as an effective means of clarifying the mechanisms and neuroadaptive properties of brain disease related to monoaminergic neurotransmission. Currently, a wealth of radiotracers of the monoaminergic systems can be brought to bear on the unraveling of these disorders. The efforts help provide rational drug dosing and examine mechanisms of action of drugs that are relevant to cognitive research. This will improve objectivity in research and clarify drug mechanisms and treatment pathways in the future.

Monoamines: Release Studies

A D Smith, A C Michael, B J Lopresti, R Narendran, and M J Zigmond, University of Pittsburgh, Pittsburgh, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Neurons in the brain act on their targets via the release of chemical transmitters, a process that is generally assumed to occur across a synapse. In the case of monoamines, there is reason to believe that the field of influence can be considerably larger and often involves nonsynaptic or 'volume transmission.' Even this larger space between a given monoaminergic neuron and its target is likely to defy direct chemical monitoring, and there is a long history of attempts to overcome this hurdle through a wide variety of indirect approaches. Many of these approaches have been reviewed in the past. This article reexamines the issue from the standpoint of current technology and understanding.

Monoamine neurotransmitters, by virtue of their easily oxidized catechol or indole functional groups, can be detected by means of electrochemistry. This has spurred the development of two technologies for monoamine analysis: one comprises electrochemical detectors coupled to chromatography and electrophoresis systems; the other comprises microelectrodes implanted directly into brain tissue for *in vivo* measurements, so-called *in vivo* voltammetry. A third approach, the use of positron emission tomography (PET), is based on an entirely different principle, which is that once released, an endogenous monoamine can displace a radioligand that also binds to a receptor on which the monoamine acts. This article reviews each of these three approaches to monitoring monoamine release in the intact brain.

Voltammetry

Electrochemistry has revolutionized the capacity to detect monoamine release. Electrochemical detection and voltammetry both use electrochemistry but are otherwise fundamentally different techniques. In the former, the electrode is intended to be nonselective, giving a signal for all oxidizable components of the sample after their separation on a column. It is of great value in studies of fluid samples that can be collected and then analyzed via high-performance liquid chromatography (HPLC). It will be considered at some length in the next section. In contrast, in voltammetry, various strategies, including customized potential waveforms and tailored electrode surfaces, are used to render the electrode as selective as practicable for a target monoamine. Absolute selectivity between the monoamines is not possible by electrochemical means alone, so experimental conditions are often chosen carefully in light of this point. For example, *in vivo* voltammetry is often applied in regions of the brain where a single monoamine is predominant, as in the case of DA within the striatum, to measurements of monoamine release during selective stimulation of pathways; or to measurements of an exogenously applied monoamine. Rather than selectivity, the forte of *in vivo* voltammetric techniques is their sensitivity, speed of response, and spatial resolution. Indeed, the technology has steadily improved over the course of the last three decades to the point that voltammetry provides access to information not available by other means.

Electrode Design

Although a variety of microelectrode designs are described in the literature, the majority of recent *in vivo* measurements of monoamines have relied on carbon fiber microelectrodes (Figure 1). Carbon fibers, which are available with diameters as small as 5 μm, are usually sealed into a pulled glass capillary with epoxy or sometimes just by virtue of the glass–carbon junction. The fiber protruding from the glass tip can be cut to a desired length, or the tip can be beveled on a polishing wheel so that only the cross section of the fiber is exposed. Although these beveled electrodes are usually called microdisk electrodes, they are actually elliptical in shape. The microdisk geometry is useful when high spatial resolution is needed, such as during the recording of individual exocytotic events, whereas the longer electrodes are suitable when spatial averaging is preferred.

The tiny dimensions of carbon fiber microelectrodes offer several benefits to *in vivo* voltammetry. The electrodes, for example, do very little damage to brain tissue during implantation. Electron microscopy of striatal tissue from anesthetized rats following acute carbon fiber implantation showed that the majority of tissue damage was confined to within approximately 3 μm of the electrode track. This short distance permits faithful recording of *in vivo* chemical events with minimal diffusional distortion because small molecules need only about 10 ms to diffuse 3 μm through the brain extracellular space. Thus, the minimization of tissue trauma contributes to the rapid speed of response available with *in vivo* voltammetry.

Figure 1 Scanning electron micrographs illustrate the features and dimensions of the carbon fiber microelectrodes used in the majority of *in vivo* voltammetry studies. The fibers in the image have a diameter of 7 μm. The fibers are sealed into a pulled glass pipet with epoxy. The microcylinder electrode protrudes from the pipet, whereas the microdisk is prepared by polishing the tip on a microelectrode beveller.

Fast-Scan Cyclic Voltammetry

Another benefit of the small dimensions of the microelectrodes is the small capacitance of the electrode surface. The small capacitance allows for rapid changes in the potential applied to the electrode, which has enabled the technique called fast-scan cyclic voltammetry. In this technique, the electrode is subjected to linear potential sweeps at rates of 300 V s^{-1} or more. Since monoamines can be detected with potential sweeps spanning about 3 V, individual voltammetric scans are completed in 10 ms or less. The ability to rapidly scan the potential, therefore, is another contributor to the rapid speed of response. Furthermore, as the potential sweep rate increases, voltammetry becomes selective for monoamine neurotransmitters over their acid metabolites and other oxidizable substances, including ascorbate and urate, encountered in brain tissue. This is due to a quirk of the kinetics of the oxidation and reduction reactions of the monoamines, which are substantially faster than those of the potential interfering substances.

The fast-scan cyclic technique generates a voltammogram, a plot of the electrode current versus the applied potential, which provides a fingerprint of the detected substance. Recently, as discussed further in the section titled 'Recording naturally occurring DA release on a subsecond timescale,' statistical analysis of these fingerprints by means of principal components analysis has greatly advanced the analytical capabilities of in voltammetric recording techniques.

While the rapid potential scanning approach has several advantages, they come at a price. Rapidly scanning the potential induces a flow of current called the electrode charging current. Even though the electrode capacitance is small in an absolute sense, the charging current is massive in comparison to the currents associated with the detection of monoamines. Consequently, the monoamine-associated current appears as a tiny signal component superimposed on a much, much (1000 times) larger background current. For this reason, voltammetry is well suited only to differential measurements, that is, voltammetry can be used to track changes in monoamine concentrations from a starting condition. On the other hand, voltammetry is not able to tell us 'absolute' or basal monoamine concentrations. Fortunately, much useful insight into the functional aspects of brain monoamine systems has been derived from differential voltammetric measurements.

Constant Potential Amperometry

As an alternative to fast-scan voltammetry, constant potential amperometry has proved a highly useful recording technique. Here, the electrode potential is simply poised at a value appropriate to the oxidation of monoamines, usually near 0.6 V versus Ag/AgCl. This approach provides no selectivity and thus is suitable only in those specialized experimental conditions in which there is no doubt about the identity of the substance being detected. However, several such conditions exist. One example is the use of the clearance of exogenously applied monoamine to evaluate transporter kinetics. Another example is electrical stimulation of the medial forebrain bundle to selectively release DA in the striatum and accumbens. In these experiments, the speed of the recording tends to be of the utmost concern, over and above the selectivity of the response. In the case of constant potential amperometry, the speed of the recording is determined by the data acquisition hardware rather than the features of an applied potential waveform.

Characterizing Monoamine Transporter Kinetics

One recent and extensive application of *in vivo* voltammetry has been to characterize the kinetics of the DA transporter (DAT) in several dopaminergic regions of the rat brain. DAT is responsible for clearing DA from the extracellular space to terminate the actions of DA on pre- and postsynaptic receptors. Two main strategies for evaluating DAT kinetics are described in the literature. One involves recording the clearance of extracellular DA following the electrical stimulation of DA axons in the medial forebrain. Detailed analysis of the descending phase of the stimulus response leads to values of the V_{max} and K_M of the clearance process. The ability to determine these kinetic parameters has engendered detailed study of

the factors that regulate them, include drugs and autoreceptor mechanisms. Much attention has also been focused on regional differences in DAT kinetics, a topic of long-standing interest in the field of substance abuse.

A second approach to evaluating transporter kinetics is to use *in vivo* voltammetry to monitor the clearance of exogenously applied substrate. Applications by both pressure ejection and iontophoresis have been described. A point that remains incompletely resolved is that these methods produce substantially smaller kinetic constants than those obtained by monitoring DA clearance after electrical stimulation. There has been speculation that this may be due to the voltage dependency of the transporter that might be affected by stimulation of an as yet unspecified diffusional process during the application of substrate. Nevertheless, the technique reveals modulation of clearance rates by drugs and anesthetics and reveals regional variations in transporter activity. Daws and co-workers have extended this procedure to 5-HT, reporting recently, for example, that the effect of ethanol on 5-HT clearance is enhanced in mice lacking the 5-HT transporter, a finding that sheds new light on the role of 5-HT in alcoholism. At present, however, voltammetry has not been extensively used to monitor endogenous 5-HT release.

Autoreceptor Control of DA Release

Considerable use has been made of voltammetry to examine the control of DA release by receptors present on the DA terminal itself, the so-called autoreceptors. In one such experiment by François Gonon and co-workers, amperometric recording was used to examine the time course of the control of evoked DA release by autoreceptors. Their data indicate that the D2 subtype of DA receptors can modulate DA release on a msec timescale and that the duration of the autoreceptor-mediated control of DA release is far longer than the stimulus-evoked elevation in DA itself, suggesting a role for downstream intracellular second messengers. Such studies both illustrate the power of high-speed recordings cases in which the identity of the monoamine is not in question and provide a task to which voltammetry is uniquely suited.

Recording Naturally Occurring DA Release on a Subsecond Timescale

Recently, R. Mark Wightman and his colleagues have described the voltammetric recording of naturally occurring DA release on the subsecond timescale. This represents a significant advance in the capabilities of *in vivo* voltammetry, which previously had been used mainly to monitor electrically evoked DA release. A key technical development that enabled this advance was the introduction of the principal components regression analysis of individual voltammograms recorded in the brain of conscious, freely moving rats. The regression algorithm separates the voltammetric signals arising from DA from those arising from pH fluctuations in the brain extracellular space. Fluctuations in pH trigger voltammetric signals at carbon fiber microelectrodes. However, the fingerprint voltammograms associated with pH changes are different from those associated with DA changes, which enables the regression analysis to distinguish pH and DA contributions to the signals. By separating these signal components, which statistically account for the entire signal, voltammetry achieves DA detection limits near 20 nmol l^{-1} and subsecond temporal resolution.

According to this voltammetric system, naturally occurring DA release comprises a series of subsecond transients in the nanomolar concentration range. It appears likely, although it remains to be definitively established, that the DA transients are associated with the burst firing of DA neurons. The amplitude, frequency, and duration of the transients are increased by DAT inhibitors, including cocaine and nomifensine, suggesting that the transients may play a key role in the psychostimulant properties of these drugs.

Microdialysis

Basis of Approach

Measurement of transmitter release via intracerebral dialysis is based on the combination of three separate techniques: (1) a dialysis membrane to collect sample by mass diffusion of small solutes across that membrane, (2) HPLC to separate out the several molecules that are collected in this manner, and (3) a detector to quantify the molecules of interest. In the case of monoamines, that detector is typically an electrochemical detector.

Microdialysis has a much slower timescale and provides much less anatomical resolution than voltammetry. On the other hand, microdialysis offers an unambiguous identification of a great many compounds, including the monoamines and their metabolites; provides absolute values; can be used to monitor the substances over many hours; and provides a means for delivering compounds as well as collecting them.

Diffusion is initiated when the inner surface and the outer surface of the dialysis membrane are in contact with two aqueous solutions, one containing a higher concentration of a substance of interest than the other. If the aqueous solution in contact with the inner surface of the membrane is continuously flowing and has a significantly lower concentration

Figure 2 Schematic diagram of the dialysis process using a concentric tube microdialysis probe. A drug in the perfusate (squares) can dialyze outward into tissue, while small molecules in the tissue (circles) diffuse inward and are collected with the dialysate for subsequent assay. From Kissinger PT (1996) Electrochemical detection in bioanalysis. *Journal of Pharmaceutical and Biomedical Analysis* 14: 871–880.

of the substance of interest, a concentration gradient is created resulting in continuous diffusion of the substance from the external medium into the membrane. If the dialysis membrane is attached to an inflow and outflow line, the continuous flow of solution carries the substance to the end of the outflow, line where it can be collected for later analysis (Figure 2).

Early Development of Monitoring Techniques

Several sampling procedures preceded intracerebral dialysis as a means of measuring the chemical environment within the brain. The earlier technique of ventricular perfusion did not allow sampling of distinct brain regions, and cortical cup perfusion allowed sampling of only the cortical surface in anesthetized animals. Push–pull cannula perfusion, introduced by John Gaddum in 1961, was the first technique in which extracellular fluid from distinct subcortical

Figure 3 Temporal effect of local perfusion of KCl (100 mmol l^{-1}) on extracellular DA in the striatum.

regions could be measured. Two concentric tubes were implanted into the brain, with the tip being within the region of interest. The inner tube was used to deliver the perfusion solution and the outer tube to collect the perfusate for subsequent analysis. Because the perfusion fluid was in direct contact with brain tissue, significant tissue damage was incurred from the fluid flow.

By placing a semipermeable bag over the tip of the push–pull cannula to circumvent this problem, Jose Delgado and colleagues introduced the first intracerebral dialysis probe, called the dialytrode. With the advent of highly sensitive methods of detection, such as HPLC coupled with electrochemical detection, Urban Ungerstedt extended this approach, pioneering its use to measure endogenous DA in extracellular fluid in response to drugs such as amphetamine. Soon this was further extended to include stimuli such as KCl (Figure 3) and electrical stimulation and to monitor various transmitter releases during exogenous stimuli and behavior. *In vivo* microdialysis quickly became the most common means by which *in vivo* transmitter efflux was monitored, resulting in more than 5000 publications by 2007.

Advantages of Microdialysis

Microdialysis has several advantages over earlier *in vivo* sampling methods. The damage incurred by the surrounding extracellular environment is minimized not only by the presence of the dialysis membrane but also by a decrease in the overall size of the probe. Another advantage of the dialysis membrane is that it acts as a filter against large molecules, such as enzymes, that may act to degrade the substance of interest, and it also purifies the sample for subsequent analysis. Furthermore, because intracerebral dialysis is merely a sampling technique, in conjunction with a

suitable assay, it can be used to study a broad range of compounds. However, the most studied class of compounds has been the monoamines, DA in particular.

Although modern dialysis probes minimize the damage to the surrounding tissue, studies have shown that immediately after implantation of the probe, not all transmitter 'release' is either tetrodotoxin (TTX) sensitive or calcium dependent and thus may represent a response to damage. On the other hand, by the next day, release is both TTX sensitive and calcium sensitive, at least in the case of DA, and thus is generally considered to reflect a physiological process.

The release of DA is known to occur largely if not entirely via exocytosis, and its actions are terminated by removal from the synapse by a combination of diffusion and high-affinity uptake via DAT. These processes can be exploited to determine the functional state of the DA system in response to various treatments. For example, in a normal intact DA system, addition of a high concentration of K^+ ions to the perfusate increases the concentration of DA sampled by the probe via an increase in exocytotic release of DA. However, infusion of 6-hydroxydopamine, a catecholaminergic toxin, into the nigrostriatal DA pathway decreases potassium-evoked DA release, indicating that the system is not functioning at full capacity.

Amphetamine increases extracellular levels of DA by reversal of the DAT, a calcium-independent process. In a normal nigrostriatal DA system, amphetamine induces an approximate 50-fold increase of DA in dialysate. However, in the denervated striatum, amphetamine-induced DA release is attenuated. Monitoring extracellular monoamine levels under basal conditions or during stimulation may provide information about the functional integrity of a given projection. However, care must be taken to extrapolate from extracellular levels to release. Extracellular transmitter concentration is a net result of release and removal of transmitter, and removal in turn is a consequence of diffusion and high-affinity uptake. Likewise, care must be taken before an assumption that extracellular transmitter levels are a simple reflection of the number of nerve terminals. For example, extensive damage to a catecholaminergic system is required to reduce basal extracellular levels of either norepinephrine or DA. In addition, some trophic factors, particularly glial-derived neuronal factor, have been shown to increase the synthesis and release of DA without affecting the apparent number of DA terminals.

Problems with Microdialysis

A major disadvantage of microdialysis, because of the need for large amounts of material for detection, has been temporal resolution. For example, even in the case of extracellular DA, which is present in high concentration compared with other monoamines or even DA in other brain regions, a sampling interval of at least 10 min has typically been required. However, separation techniques such as capillary electrophoresis and microbore columns for HPLC, requiring smaller sample volumes, coupled with more sensitive detection methods ($\leq 1\,\mu l$) have allowed the temporal resolution to be decreased to 1 min. Of course, this resolution still lags far behind that of synaptic events and *in vivo* voltammetry, which are on the millisecond scale.

Another drawback of intracerebral dialysis has been an inability to measure the actual concentration of endogenous substances. At the crux of this problem is a description of the relationship between the dialysate concentration and the actual concentration of substance within the extracellular fluid, or the recovery. However, here again, techniques have been developed which allow relatively quantitative measurement of the extracellular concentration of neurotransmitters independent of the recovery. One method uses a very slow rate, at which the *in vivo* recovery approaches 100%. However, this method requires long sampling intervals, which dramatically reduces temporal resolution and also introduces problems of sample stability. A second approach to the problem is the difference method (or method of no net flux) developed by Peter Lönnroth. In this technique, concentrations of the compound of interest above and below what is expected to be present in the extracellular fluid are perfused through the probe and the resulting dialysate concentration measured. When the differences between the inflow and outflow concentrations are plotted versus the inflow concentration, the resulting regression yields the extracellular concentration (zero point) and the *in vivo* recovery. Again, a disadvantage of this technique is the time required for its execution.

A third problem with microdialysis is that the probe size, typically 250 μm, precludes fine spatial resolution and also is associated with considerable local tissue damage characterized by acute and chronic histological, physiological, and biochemical changes in adjacent tissue. An area of altered release and uptake exists within the trauma layer, which could effectively result in discrepancies between the extraction fraction and the relative recovery, rendering an extracellular concentration that is over- or underestimated.

Imaging Dopaminergic Transmission

The reduction in the availability of D2 receptors as measured with benzamide radioligands (such as ^{123}I-iodobenzamide (IBZM) and ^{11}C-raclopride) following the administration of psychostimulants known

Figure 4 Effect of amphetamine on ^{11}C-raclopride and ^{11}C-(−)-*N*-propyl-norapomorphine (NPA) in a nonhuman primate (baboon). Magnetic resonance images (MRIs) and corresponding parametric binding potential (BP) maps shown in the same baboon under four conditions: ^{11}C-raclopride baseline study, ^{11}C-raclopride postamphetamine study (0.5 mg kg^{-1}), ^{11}C-NPA baseline study, and ^{11}C-NPA postamphetamine study (0.5 mg kg^{-1}). Following the same dose of amphetamine, 0.5 mg kg^{-1}, a greater decrease in BP is observed with the agonist radioligand ^{11}C-NPA (−46%) than with the antagonist ^{11}C-raclopride (−26%). From Narendran R, Hwang DR, Slifstein M, et al. (2004) *In vivo* vulnerability to competition by endogenous dopamine: Comparison of the D2 receptor agonist radiotracer (−)-*N*-[^{11}C]propyl-norapomorphine ([^{11}C]NPA) with the D2 receptor antagonist radiotracer [^{11}C]-raclopride. *Synapse* 52: 188–208.

to release DA (e.g., amphetamine or methylphenidate) is a clear example of an interaction between endogenous neurotransmitter and radioligand that has been extensively validated in both nonhuman primates and humans. In baboons, the increase in synaptic DA elicited by amphetamine is associated with a displacement of the binding of the single photon emission computed tomography (SPECT) D2 receptor radiotracer ^{123}I-IBZM and of the PET radiotracer ^{11}C-raclopride (Figure 4). By combining SPECT and microdialysis in baboons, Marc Laruelle and colleagues established that the magnitude of the ^{123}I-IBZM displacement after administration of amphetamine was related to the magnitude of DA release, and that a linear correlation existed between microdialysis measurements of DA release and radioligand displacement. Over the years, this technique of measuring the reduction in radiotracer binding following DA release via a stimulant challenge has been successfully used to study dopaminergic transmission in the living human brain in both healthy and diseased states such as schizophrenia and addiction.

Limitations of Imaging

The capacity to monitor neurotransmitter release in humans as well as experimental animals is a great advantage of *in vivo* imaging techniques employing radioligands. However, there are several limitations to these approaches. Some are similar to those of voltammetry: Both methods are applicable to a relatively small number of compounds. Indeed, only a few radioligands have been shown to have *in vivo* binding characteristics sensitive to fluctuations in endogenous neurotransmitter release. Other limitations are similar to those of microdialysis: limited spatial and temporal resolution. Although modern PET scanners can now provide images of the entire human brain with 2 mm spatial resolution, assessments of neurotransmitter release via these techniques are limited to the tissue level.

Other limitations are unique to imaging in general or to the specific radioligand employed. One example is the relatively low sensitivity of measuring endogenous transmitter by imaging its displacement of radiolabeled ligand. A 1% decrement in radiotracer binding corresponds to a 50% increase in extracellular DA as measured by microdialysis. Another limitation is the 'ceiling effect' seen when any of the available benzamide radiotracers are used: Only about half of the radiotracer's specific binding is vulnerable to changes in extracellular DA concentration.

Both the low sensitivity and the ceiling effect may be related at least in part to the fact that D2 receptors are configured in interconvertible states of high or low affinity for agonists. This is because benzamide radiotracers such as ^{123}I-IBZM and ^{11}C-raclopride are antagonists that bind with equal affinity to both states, but DA is not expected to compete efficiently with the fraction of the ^{123}I-IBZM or ^{11}C-raclopride binding to the low-affinity state. Thus, in contrast to the antagonist, a large fraction of the *in vivo* binding of an agonist radiotracer to D2 high sites will be available for endogenous competition by DA, thereby making it a more sensitive probe to study stimulant-induced DA release. Recent preclinical PET studies comparing novel agonist radioligands (in anesthetized nonhuman primates and cats) such as [^{11}C](−)-*N*-propyl-norapomorphine (NPA) and ^{11}C-PHNO with the reference antagonist radiotracer ^{11}C-raclopride tend to support this hypothesis. If the

increased sensitivity of these agonist radioligands extends to humans, they may provide researchers with a superior probe with which to report on acute changes in synaptic DA concentration. Such probes might also allow researchers to control for baseline affinity states (availability of receptors configured in D2 high) that may differ between clinical populations.

One limitation of the SPECT and PET radiotracers ^{123}I-IBZM and ^{11}C-raclopride is that the affinity of these ligands provides a quantifiable signal only in the striatum where receptors are abundant. However, a major advancement in availability of higher-resolution PET cameras has allowed the study of amphetamine-induced DA release in the functional subdivisions of the striatum with ^{11}C-raclopride, and further advances in instrumentation may provide even higher resolution.

Demonstration That Imaging Can Monitor Monoamine Release, Though with Relatively Low Sensitivity

In spite of methodological limitations and limited sample sizes, several reports indicate that imaging can detect DA release in response to cognitive challenges such as yoga, psychosocial stress tasks, and video games, as well as motor challenges such as finger tapping and foot movement.

Nonetheless, such stimuli, like psychostimulants, lead to decreases in 11C-raclopride binding that are on the order of 10%, rather than the 50–1, 500% increases in extracellular DA observed with microdialysis. Recent studies that combined PET with microdialysis highlighted the discord between microdialysis and PET as applied to measurement of DA release. For example, one such study showed that a dose of amphetamine that elicited the same degree of inhibition of 11C-raclopride binding as a given dose of methylphenidate resulted in a fourfold greater increase in DA release as measured by microdialysis. To reconcile such differences, it has been hypothesized that the DA release measured with PET radiotracers using endogenous competition techniques may be reflective of fluctuations in intrasynaptic DA, whereas the DA release measured using microdialysis techniques may be reflective of extrasynaptic DA concentrations.

Imaging Serotonergic Transmission

Defects in other monoamine systems, particularly serotonin (5-HT), have been implicated in various psychiatric disorders, including major depression, anxiety disorders, and schizophrenia. Efforts to measure endogenous release of 5-HT with PET have been modeled after similar experiments designed to measure DA release *in vivo*, whereby a pharmacologic stimulus is used to enhance or deplete extracellular 5-HT and thereby elicit a reproducible change in radioligand binding that correlates with the degree of endogenous neurotransmitter release.

It has been demonstrated, for example, that acute administration of the psychostimulant fenfluramine resulted in a two- to 15-fold increase in extracellular 5-HT concentrations in the rat hippocampus and that this endogenous release resulted in dose-dependent decreases in the binding of the 5-HT_{1A} radioligand 18F-MPPF. Other studies conducted in rodents have reported little or no effect of fenfluramine administration on the binding of another 5-HT_{1A} PET radioligand, ^{11}C-WAY-100635 or the 5-HT_{2A} radioligand 11C-MDL-100907. In nonhuman primate brain, acute administration of fenfluramine failed to elicit significant decreases in the binding of 18F-MPPF. Although one study reported modest decreases in the binding of the 5-HT_{2A} radioligand 18F-altanserin in whole human cortex (14–23%) after acute administration of the selective serotonin reuptake inhibitor clomipramine (25 mg), it is unclear whether this effect can be attributed to endogenous competition by 5-HT or to direct competition with clomipramine itself, which has been shown to have a 50–60 $\mathrm{nmol\,l^{-1}}$ affinity for the 5-HT_{2A} receptor.

Unfortunately, for reasons that are unclear, attempts to measure endogenous competition by serotonin using PET have been unsuccessful. This may have to do with the fraction of receptors configured *in vivo* in the high-affinity state for the agonist, cellular localization (intracellular versus extracellular), and their distance from the synaptic cleft.

Conclusions

Using such methods as immunohistochemistry, electrophysiology, and genomics, it is now possible to examine the characteristics of single cells in the brain, either *in vivo* or at least immediately after brain removal. Although the direct monitoring of transmitter release from a single neuron has now been achieved in culture, it is not yet possible within an intact brain. Nonetheless, the judicious application of voltammetry, capillary electrophoresis, microdialysis, and *in vivo* imaging is allowing us to draw important conclusions about the release of monoaminergic transmitters from groups of neurons, and important observations made with these approaches continue to provide enlightenment about both normal and abnormal brain function. Moreover, the sensitivity and specificity of these methods have improved significantly over the past decade, and these improvements should continue until biochemistry takes its place

alongside histology, electrophysiology, and molecular biology as a route to the monitoring of a single cell within the living brain.

Monocarboxylate Transporters

K Pierre and L Pellerin, Université de Lausanne, Lausanne, Switzerland

© 2009 Elsevier Ltd. All rights reserved.

Glucose has long been considered the only valuable energy source for brain cells. In the past few years, however, monocarboxylates such as lactate, pyruvate, and ketone bodies have attracted much attention and appear to play an important role in brain energy metabolism. Thus, it was demonstrated that monocarboxylates can be taken up by the brain from the systemic circulation in a number of circumstances. In the first few hours after birth, lactate present in the blood at high concentration provides a critical energy source for the brain during this early life period. Then, during the entire lactating period, ketone bodies become substantial brain energy substrates. Interestingly, monocarboxylates can also represent significant energy substrates for the adult central nervous system under specific conditions. It was shown, for example, that a rise in circulating lactate as observed following moderate exercise is sufficient to reduce brain glucose utilization and thus significantly contribute to satisfying brain energy needs. Similarly, in situations leading to increased production of ketone bodies (e.g., diabetes or prolonged starvation), these monocarboxylates are taken up and used by the adult brain. In addition to blood-borne monocarboxylates, some parenchymal cells also produce and release large amounts of lactate (from blood-borne glucose) within the adult brain that can be consumed in parallel by others. Because monocarboxylates are hydrophilic substances and do not cross membranes easily, specific transport systems must exist to carry them across the blood–brain barrier and within each cell type or transfer them from one cell type to the other when monocarboxylates are produced locally. Several monocarboxylate transporter subtypes have been identified and rapid progress has been made on their distribution in the brain. However, regulation of their expression has just started to be explored.

The monocarboxylate transportern (MCT) family (also termed the SLC16 gene family) is composed of 14 members based on sequence homologies, identified as MCT1–9, MCT11–14, and TAT1. MCT1–MCT4 were shown to transport several monocarboxylates that can be produced endogenously, such as lactate, pyruvate, and ketone bodies, as well as other monocarboxylates from exogenous sources, such as acetate, propionate, and butyrate. The mechanism of monocarboxylate transport is a cotransport with H^+ following a 1:1 stoichiometry. In the brain, three MCTs have been identified: MCT1, MCT2, and MCT4. Their affinity for each substrate differs substantially. For example, the K_m for L-lactate is 3.5, 0.7, and 34 mM for MCT1, MCT2, and MCT4, respectively. These kinetic differences could partly determine their distribution, with high-affinity transporters present in cells exhibiting monocarboxylate utilization and low-affinity, high-capacity transporters being preferentially expressed by cells producing large amounts of monocarboxylates.

Endothelial Cells Forming Blood Vessels Express MCT1, Whereas Astrocytes Have Both MCT1 and MCT4

MCT1 mRNA and protein are homogenously distributed throughout the whole rodent brain. In young and adult rodent brain, MCT1 protein (apparent molecular weight, ~45 kDa) is abundantly expressed in endothelial cells forming microvessels and ependymocytes lining the four brain ventricles. MCT1-positive glial end feet surrounding capillaries and glial-like processes are also visible using light and electron microscopy. Confocal microscopy using double labeling with glial markers such as GFAP or S100β confirmed association of MCT1 immunoreactivity with astrocytic processes, both *in vitro* and *in vivo* (Figure 1). Similarly, immunohistochemical investigations in the human brain showed that MCT1 is associated with blood vessels as well as expressed by astrocytes. In contrast, MCT4, a protein of ~43 kDa, is specifically expressed by glial cells in the adult rodent brain. MCT4 labeling in the cortex, the hippocampus, and the corpus callosum is restricted to astrocytes. In the cerebellum, both Bergmann glia in the molecular layer and astrocytes in the granular layer are labeled. The expression of MCT1 and MCT4 by astrocytes is consistent with their kinetic properties that confer them a prominent role in glycolytic tissues (e.g., fast-twitch muscle). Except in glia limitans, MCT2 protein expression has not been detected in glial-like cells of the mouse brain, whereas it may be visible in some endothelial cells forming brain capillaries. By contrast, MCT2 has been shown to be expressed by astrocytes in the rat brain using different antibody sources. This issue needs to be clarified.

Neurons Express Predominantly MCT2

It can be considered that MCT2 represents the major neuronal transporter in the rodent brain. MCT2 protein (molecular weight, ~40–43 kDa) is strongly

Figure 1 MCT1 immunoreactivity in the adult rat brain. MCT1 protein is strongly expressed on blood microvessels (a–c, arrows) and in astrocytes either surrounding capillaries (b) or isolated in the parenchyma (c). It is also visible in ependymocytes lining the ventricles (a, arrowheads). Immunoperoxidase stainings viewed with light microscopy. Reproduced from Pellerin L and Pierre K (2005) Monocarboxylate transporters and their dual role in efflux and influx across the blood–brain barrier and beyond. In: Taylor EM (ed.) *Efflux Transporters and the Blood–Brain Barrier*, pp. 193–217. New-York: Nova Science, with permission.

expressed in the cortex, the hippocampus, and the cerebellum of the rodent brain. Cortical neurons in culture exhibit MCT2 immunoreactivity at the surface and in the cytoplasm of their cell bodies and neurites (Figure 2). *In vivo*, MCT2 immunoreactivity is visible as a strong, punctiform labeling surrounding immunonegative neuronal somata. Double labeling experiments using the neuronal marker MAP2 showed a co-localization between MCT2 and MAP2-positive processes, both *in vitro* and *in vivo*. Moreover, intense MCT2 immunoreactivity was found in cerebellar Purkinje cell bodies and their processes as well as on mossy fibers in the cerebellum. Expression of the high-affinity transporter MCT2 by neurons is consistent with their important uptake and consumption of lactate as oxidative substrate.

Evidence suggests that part of MCT2 expression is associated with synapses. First, observation in developing neurons in cultures following double immunofluorescent labeling with the presynaptic marker synaptophysin and MCT2 revealed a parallel distribution. In the mouse brain cortex, a co-localization with PSD95, the major component of the postsynaptic density (PSD), was seen occasionally. Moreover, MCT2 immunoreactivity is present in the postsynaptic membrane of parallel fiber–Purkinje cell synapses in the rat cerebellum and co-localizes with postsynaptic δ2-glutamate receptors as revealed by electron microscopy. MCT2 has been shown to be located at the PSD of distinct glutamatergic synapses in the hippocampus and the cerebellum of the rat and mouse brain, respectively.

In addition to its main expression by astrocytes and endothelial cells, a faint MCT1 immunoreactivity was found in cultured mouse cortical neurons, although it remained undetectable using Western blot analysis on the same culture extracts. Cultured hypothalamic neurons were found to be heavily labeled for MCT1. Whether this expression is caused by cultured conditions rather than being a genuine characteristic of specific neuronal populations remains to be determined. *In vivo*, MCT1 immunoreactivity was undetectable in neurons throughout the mouse brain, whereas it was visible in a few scattered neurons in the rat brain.

Figure 2 MCT2 immunoreactivity in the adult mouse brain. A strong punctiform immunoreactivity for MCT2 is found in the neuropil surrounding immunonegative neuronal cell bodies throughout the entire brain (a, b, and c1). Double labeling using antibodies raised against MCT2 (c1, green) and the neuronal marker MAP2 (c2, red) revealed co-localization between MCT2 and MAP2 (c3, yellow) in neuronal dendrites. In addition, MCT2 immunoreactivity is detected in microvessel-like structures (b, arrows). (a) Immunoperoxidase staining viewed with light microscopy. (b and c1–c3) Immunofluorescence stainings viewed with light (b) and confocal (c1–c3) microscopy using appropriate filters. Reproduced from Pierre K, Magistretti PJ, and Pellerin L (2002) MCT2 is a major neuronal monocarboxylate transporter in the adult mouse brain. *Journal of Cerebral Blood Flow Metabolism* 22: 586–595.

Otherwise, MCT4 has never been localized in neurons, either *in vivo* or *in vitro*.

Regulation of MCT Expression in Brain

During early postnatal development, monocarboxylate uptake increases in parallel with a similar enhancement of its utilization by the brain. Thus, it is expected that the expression of MCTs both on endothelial cells forming blood vessels and on parenchymal cells is regulated in the developing brain because the availability of these major energy substrates varies considerably during peri- and postnatal development. Indeed, evidence suggests that MCT expression changes importantly during this period. For example, it was shown that mRNAs for both MCT1 and MCT2 increased during the early postnatal period to reach a maximum at approximately postnatal day 15 and decreased rapidly after weaning (approximately postnatal day 21) to stabilize at adult levels. Moreover, data indicate that alteration of MCT expression following nutritional modifications occurs in the adult brain. In the adult rodent, a ketogenic diet was found to induce brain MCT1 as well as MCT2 and MCT4 expression. However, the precise signals and mechanisms involved in this regulation are unclear.

Other types of regulation have begun to emerge. In cultured neurons, the level of MCT2 expression has been correlated with synaptogenesis, suggesting that its expression may be regulated by factors in relation with synaptic activity. MCT2 expression in neurons appears to be under the control of specific neuroactive substances. Thus, it has been shown to be enhanced by noradrenaline in cultured cortical neurons, an effect reproduced by the activation of

the cAMP-mediated cascade. Moreover, it has been demonstrated that this type of regulation of MCT2 expression occurs at the translational level.

Roles of MCTs in Brain

The expression of MCTs on endothelial cells forming blood vessels as well as on parenchymal cells early during development fulfills an obvious role in providing an adequate supply of energy substrates in this critical developmental period, during which glucose metabolism is not yet the predominant pathway to fuel brain function. The presence in the adult brain of distinct MCT isoforms on different cell types is more intriguing. An interesting observation is the fact that not only are MCT1 and the glucose transporter GLUT1 co-expressed on endothelial cells of adult brain microvessels but also their respective densities are correlated with several metabolic parameters within specific cortical areas (e.g., cytochrome oxidase staining). These data suggest that monocarboxylates provided by the circulation could represent a significant energy source for the brain in specific circumstances and their utilization could be correlated with the degree of functional activity within each cortical area. Indeed, it has been clearly shown that lactate produced during exercise that accumulates in the circulation is consumed by the brain. Moreover, raising plasma lactate levels directly leads to reduced brain glucose utilization. Lactate has even been found to support cognitive functions during hypoglycemic episodes, further supporting a putative role of lactate as an adequate brain energy substrate even for the adult brain. In this context, MCTs would be essential to facilitate delivery of lactate to the brain as well as to each cell type that would require/prefer it as a fuel.

The expression of the high-affinity transporter MCT2 by neurons is consistent with the notion that these highly oxidative cells have a preferential use of lactate as oxidative substrate. By contrast, the expression of MCT1 and, specifically, MCT4 by astrocytes (**Figure 3**) is in agreement with the high glycolytic capacity of these cells. It appears likely that under conditions in which glucose is the main substrate delivered to the brain, part of it will be converted to lactate by astrocytes and released in the extracellular space via MCT1 and MCT4. Because the extracellular lactate concentration in rodent and human brain is ~1 or 2 mM, neurons probably consume in parallel with glucose a certain amount of lactate via MCT2. It is also suggested that net lactate production by astrocytes and lactate consumption by neurons could be enhanced following brain activation within specific areas. Again, the presence of specific MCTs

Figure 3 Expression of MCT4 by astrocytes in various rat brain regions. Immunolabelings carried out with an antibody against MCT4 show immunopositive astrocytes in the cortex (top left), hippocampus (bottom left), paraventricular nucleus (PVN; top right), and capsula internalis (bottom right). Immunoperoxidase immunoreactivity viewed by light microscopy. Reproduced from Pellerin L, Bergersen LH, Halestrap AP, and Pierre K (2005) Cellular and subcellular distribution of monocarboxylate transporters in cultured brain cells and in the adult brain. *Journal of Neuroscience Research* 79: 55–64, with permission.

on both astrocytes and neurons would be essential to permit such interchange between the two cell types. The presence of MCT2 within the postsynaptic density at glutamatergic synapses further supports a role of MCT2 and neuroenergetics in synaptic transmission, although much more research is needed in this area.

Considering the previous discussion, it is tempting to speculate that both short-term and long-term mechanisms must exist to adapt the number of MCTs at the membrane of each cellular and subcellular compartment (endothelial cell, astrocyte, neuron, and synapse) in order to handle the changing energy requirements in different situations. It will be a challenge in the future to identify such mechanisms and determine their importance in various physiological and pathophysiological conditions.

Mood Stabilizers

H K Manji, C A Zarate, G Chen, and J Du, National Institute of Mental Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Bipolar disorder is a severe recurrent medical illness that afflicts approximately 1–3% of the population. Patients with bipolar disorder often present with high rates of comorbidities, relapse, recurrence, residual mood symptoms, and poor functioning and quality of life in spite of adequate treatment with current mood stabilizers. While preclinical and clinical knowledge has expanded at a tremendous rate in recent years, there have been no major breakthroughs in novel types of treatment for bipolar disorder. Developing new treatments may come from a better understanding of the mechanism of action of current mood stabilizers (e.g., lithium, valproate, and carbamazepine) and thereby designing novel drugs that mimics these mechanism(s).

Molecular and cellular targets of current mood stabilizers include lithium inhibitable enzymes (inositol monophosphatase, inositol polyphosphate 1-phosphatase, glycogen synthase kinase-3 (GSK-3), fructose 1,6-bisphosphatase, bisphosphate nucleotidase, phosphoglucomutase), valproate inhibitable enzymes (succinate semialdehyde dehydrogenase, succinate semialdehyde reductase, and histone deacetylase), and targets of carbamazepine (sodium channels, adenosine receptors, and adenylate cyclase (AC)). Tables 1–3 summarize the direct targets of lithium, valproic acid, and carbamazepine. Of these direct targets, only GSK-3 is reviewed, as brain-penetrant inhibitors for this target are likely to be soon available.

A major problem inherent in neuropharmacologic research is the difficulty in attributing therapeutic relevance to any observed biochemical finding. One powerful approach is to identify common biochemical targets, which are modified by drugs belonging to the same therapeutic class (e.g., mood-stabilizing agents) but possessing distinct chemical structures when administered in a 'therapeutically relevant' paradigm. In this context, it is noteworthy that both valproate and lithium, with different chemical structures, belong to the same therapeutic class and share common effects on downstream-signaling pathways. This approach has led to the identification of signaling pathways that are regulated by mood stabilizers of different classes (phosphoinositol/protein kinase C (PKC), cyclic AMP, arachidonic acid (AA), neurotrophic pathways); these downstream targets are the focus of this article.

Glycogen Synthase Kinase-3

GSK-3 may represent a therapeutically relevant target for lithium. GSK-3 is a serine/threonine kinase that is normally highly active in cells, and is deactivated by signals originating from numerous signaling pathways (e.g., the Wnt pathway, phosphoinositide 3-(PI3) kinase pathway, protein kinase A (PKA), PKC, among many others). Cellular targets of GSK-3 are numerous and often depend upon the signaling pathway that is acting upon it. For example, Wnt pathway inhibition of GSK-3 activates the transcription factor β-catenin, while in the insulin/PI3 kinase signaling pathway, inhibition of GSK-3 results in activation of the enzyme glycogen synthase. Targets of GSK-3 include, among others, transcription factors (β-catenin, cyclic AMP responsive element binding protein (CREB), c-Jun), proteins bound to microtubules (Tau, MAP1B), cell cycle mediators, and regulators of metabolism (glycogen synthase, pyruvate dehydrogenase).

GSK-3 is receiving foremost interest as a regulator of apoptosis and cellular resilience (Figure 1). In general, increased activity of GSK-3 is pro-apoptotic, while inhibiting GSK-3 attenuates or prevents apoptosis. At this point, it is critical to note that evidence suggests an association between mood disorders and impairments of neuroplasticity and cellular resilience, with both *in vivo* and postmortem studies suggesting neuron and/or glial cell loss or atrophy in circumscribed brain areas. Importantly, lithium has effects suggestive of neuroprotection clinically (see below), as well as in rodent and cell-based models. Lithium may exert these neuroprotective effects, at least in part, by inhibition of GSK-3.

Many of the behavioral effects of lithium may be due to inhibition of GSK-3. Pharmacological inhibition of GSK-3 attenuates d-amphetamine hyperlocomotion in rats. Further, mice overexpressing a constitutively active form of GSK-3β in the brain showed increased locomotor activity, as well as decreased habituation in an open field. Thus, underexpression of GSK-3β results in attenuation of stimulant-induced locomotion, while overexpression results in an endogenously high level of locomotion.

In addition to the effects on manic-like behaviors, recent studies have investigated the possibility that lithium may also exert antidepressant-like effects through GSK-3. Thus, O'Brien and colleagues reported that 10 days of lithium chloride administration resulted in an antidepressant-like effect (decreased immobility time) in the forced-swim test. We recently found that subacute intraperitoneal injections of ARA014418,

Table 1 Direct targets of lithium

Inositol monophosphatase (IMPase)	Rate-limiting enzyme in inositol recycling; lithium's inhibition of IMPase led to the inositol depletion hypothesis
Inositol polyphosphate 1-phosphatase (IPPase)	Enzyme involved in inositol recycling in phosphoinositol signaling; acts prior to IMPase
Bisphosphate nucleotidase (BPNase)	Removes phosphate from 3′-phosphoadenosine 5′-phosphate (PAP) to form adenosine 5′-phosphate (AMP); an increase in PAP inhibits sulfotransferases, which transfer sulfur to biological molecules
Fructose 1,6-bisphosphastase (FBPase)	Key enzyme in glyconeogenesis; catalyzes the removal of the 1-phosphate from fructose 1,6-bisphosphatase to form fructose 6-phosphate
Phosphoglucomutase (PGM)	Enzyme in glycogenolysis and glycogenesis; catalyzes the formation of glucose 1-phosphate from glucose 6-phosphate during glycogenolysis (and the reverse during glycogenesis)
Glycogen synthase kinase-3 (GSK-3)	Normally active kinase that is inhibited by the activity of many signaling pathways; inhibiting GSK-3 has been linked to neurotrophic support, neuroprotection, and possible modulation of circadian rhythms

Table 2 Direct targets of valproic acid

Succinate semialdehyde dehydrogenase (SSA-DH)	Converts succinate semialdehyde to succinate; succinate inhibits GABA-T; inhibiting GABA-T increases GABA levels
GABA transaminase (GABA-T)	Converts GABA to succinate semialdehyde; however, valproate inhibition appears to be above the therapeutic range
Succinate semialdehyde reductase (SSA-R)	Converts succinate semialdehyde to gamma-hydroxybutyrate (GHB)
Histone deacetylase (HDAC)	Enzyme that acetylates histones. Inhibition of this enzyme results in an increase in nonaceytlated histones and a resultant increase in transcription of some genes
Sodium channels	Inhibits sodium channel function at times of high-frequency firing

Table 3 Direct targets of carbamazepine

Sodium channels	Inhibits sodium channel function at times of high-frequency firing
Adenosine receptor	Antagonist at A1 subtype; increases adenosine receptor protein levels in rats. Adenosine has modulatory functions on neurotransmitter release and numerous behavioral and cognitive functions
Adenylate cyclase (AC)	AC forms cyclic AMP from ATP, and as such is a principle regulator of the AC signaling pathway; carbamazepine attenuates cyclic AMP signaling and appears to have an inhibitory effect on AC or an AC-associated protein

a GSK-inhibitor, reduced immobility time (increased activity) in the forced-swim test, compared to vehicle-treated rats.

Downstream Targets of Shared by Current Mood Stabilizers

A number of pathways that several mood stabilizers regulate and appear to be relevant to its mechanism of action include the AC, phosphoinositol, neurotrophic, and AA signaling pathways.

Cyclic AMP-Mediated Signal Transduction

In addition to the direct effects of carbamazepine on AC, significant modulation of cyclic AMP-mediated signaling has been noted with lithium (especially) and also valproate. G-proteins modulate intracellular cyclic adenosine monophosphate (cAMP) levels by mediating the effect of neurotransmitters (via extracellular receptors) on AC, an integral membrane protein of which there exist numerous subtypes. AC catalyzes the conversion of adenosine triphosphate (ATP) to cyclic AMP. Stimulation of G-proteins $G\alpha_s$ and $G\alpha_{olf}$ increases AC activity, while stimulation of $G_{\alpha i}$ results in a decrease in AC activity. The physiologic effects of cyclic AMP appear to be mediated primarily by activation of PKA, an enzyme that phosphorylates and regulates many proteins including ion channels, cytoskeletal elements, transcription factors, and other enzymes. One major central nervous system (CNS) target for the actions of PKA is the transcription factor CREB, which plays a major role in long-term neuroplasticity, and is a downstream target of monoaminergic-based antidepressants. One of the genes activated by CREB is brain-derived neurotrophic factor (BDNF), a protein implicated in neuronal survival and synaptic plasticity.

Figure 1 GSK-3 and intracellular signaling GSK-3 regulates diverse signaling pathways in the cell. These include insulin/insulin like growth factor (IGF-1) signaling, neurotrophic factor signaling, and Wnt signaling. Insulin signaling through its tyrosine receptor kinase (Trk) receptor activates PI3 kinase-mediated signaling, resulting in inhibition of GSK-3. Inhibition of GSK-3 activates glycogen synthase and eukaryotic initiation factor 2B (eIF2B) while inhibiting insulin receptor substrate-1 (IRS-1; an inhibitor of the insulin receptor). Insulin is generally thought to have minimal effects on CNS neurons; however, IGF-1 interacting with its cognate receptor appears to have similar functions. Neurotrophins (NT) act through tyrosine receptor kinase (Trk) receptors A, B, and C to activate PI3 kinase, AKT, and inhibit GSK-3. Many effectors have been implicated in GSK-3's neurotrophic effects including transcription factors (e.g., heat shock factor-1 (HSF-1), C-Jun, and cyclic AMP-responsive element binding protein (CREB)) and recently the proapoptotic Bcl-2 family member BAX. In the Wnt signaling pathway, secreted Wnt glycoproteins interact with the frizzled family of receptors and, through disheveled mediated signaling, inhibit GSK-3. Stability of this process requires the scaffolding proteins AXIN and adenomatous polyposis coli (APC). Normally active GSK-3 phosphorylates β-Catenin leading to its ubiquitin-dependent degradation. However, when GSK-3 is inhibited in the Wnt pathway, β-Catenin is not degraded, allowing for its interaction with (T cell-specific transcription factor) TCF to act as a transcription factor. β-catenin activity is modulated by the intracellular estrogen receptor (ER), which also affects transcription of an independent set of genes. As shown in the figure, and described in the text, medications useful for the treatment of mood disorders have both direct and indirect effects on GSK-3, and GSK-3 regulated cell signaling pathways. This includes direct effects of lithium and indirect effects of antipsychotics, amphetamine, and selective serotonin re-uptake inhibitors (SSRI's). These distinct pathways have convergent affects on cellular processes such as bioenergetics (energy metabolism), neuroplasticity, neurogenesis, resilience, and survival. Thus, our hypothesis is that lithium (and other medications) may act by enhancing these processes through inhibition of GSK-3. G_i refers to G_i/G_o; G_q refers to G_q/G_{11}. Modified from Gould TD, Zarate CAJ, and Manji HK (2004) Glycogen synthase kinase-3: A target for novel bipolar disorder treatments. *Journal of Clinical Psychiatry* 65: 10–21.

There is a growing body of data suggesting that agents, which directly modulate the cAMP/PKA/CREB/BDNF cascade, may have utility for the treatment of depression. In addition to antidepressant effects on cyclic AMP-mediated signaling, mood stabilizers also appear to regulate this pathway. Both lithium and valproate increase BDNF levels in the brains of rats treated chronically with these drugs and have inhibitory effects on stimulated AC-mediated signaling. Thus, it is helpful to take into account the multiple interactions between signaling pathways (e.g., CREB activity and BDNF expression are regulated by multiple signaling pathways including neurotrophic signaling pathways, as discussed later in this review), and that cyclic AMP signaling pathway does much more than simply regulate CREB activity.

In mouse cerebral cortex and cerebellar tissue, carbamazepine decreases the basal concentration of cyclic AMP. It also lowers cyclic AMP following stimulation by norepinephrine, adenosine, and the epileptogenic compounds ouabain and veratridine. In addition, carbamazepine appears to attenuate β-adrenoceptor and muscarinic cholinergic coupling to G-proteins in the rat cortex, decreases the levels of G_s and G_i, and attenuates cAMP-mediated phosphorylation of CREB in C6 glioma cells. Similarly, in pheochromocytoma (PC12) cells, carbamazepine inhibits cAMP-mediated increases in c-fos gene expression.

The literature describing the effect of lithium on G-proteins suggests that lithium both increases basal activity and inhibits stimulated AC.

There is some evidence that at therapeutically relevant concentrations in a cell line model, valproate decreased the density of βARs and attenuated both receptor- and post-receptor-stimulated cAMP production and levels of $G\alpha_s$ 45, but none of the other G-protein subunits examined were decreased. Thus, valproate may exert an effect on cAMP signaling at multiple levels.

Phosphoinositol-Mediated Signaling

Inositol phospholipids play a major role in receptor-mediated signal transduction pathways, involved in a diverse range of responses such as cell division, secretion, neuronal excitability, and responsiveness. The phosphatidylinositol (PI) pathway is initiated by the activation of G-protein-coupled receptors. Muscarinic (M1-2-3), noradrenergic (α1), and serotonergic (5HT2) receptors coupled to $G_{\alpha q/11}$ induce phospholipase C (PLC) hydrolysis of the membrane component phosphoinositide 4,5-biphosphate (PIP2). Hydrolysis of PIP2 by PLC results in the formation of the intracellular second messengers inositol-1,4,5-triphosphate (IP3) and 1,2-diacylglycerol (DAG; an endogenous activator of PKC). IP3 binds to the IP3 receptor facilitating the release of calcium from intracellular stores, in particular the endoplasmic reticulum. Among other proteins, the Ca^{2+}-receptor protein calmodulin (CaM) is activated, stimulating calmodulin-dependent protein kinases (CaM-Ks) that regulate the activity of diverse proteins, including ion channels, signaling molecules, proteins which regulate apoptosis, scaffolding proteins, and transcription factors. IPPase and IMPase (enzymes that are involved in recycling of IP3 back to PIP2) are directly inhibited by lithium (Table 1). Lithium's inhibition of these enzymes led to the inositol depletion hypothesis of lithium's action, which suggests that lithium, via inhibition of IMPase, decreases the availability of myo-inositol, and thus the amount of PIP2 available for G-protein-mediated signaling events that rely upon this pathway.

A number of studies have suggested the possibility that multiple mood stabilizers may regulate the PI signaling pathway. These include studies of the sodium/myo-inositol co-transport (SMIT), a high-affinity myo-inositol transport system that has been characterized in various cell types, including those of neural origin. The activity and expression of SMIT mRNA in cultured astrocytes is downregulated after chronic treatment with therapeutic concentrations of lithium. Downregulation of SMIT was also observed after valproate and carbamazepine treatment.

Another finding implicating phosphoinositol signaling in the actions of mood stabilizers comes from a study by Williams and colleagues. They used a novel tissue-culture assay that measures sensory neuron growth-cone stability and found that the depletion of neuronal inositol 1,4,5-trisphosphate (IP3) may be a common mechanism of action of lithium, valproate, and carbamazepine. In this study, they found that all three mood stabilizers inhibited the collapse of sensory neuron growth cones and increased growth cone area, effects which were reversed by inositol.

Both Lithium and Valproic Acid Regulate PKC Isozymes and MARCKS

PKC is a primary target of DAG, and as such has been an object of intense research with regard to the action of mood stabilizes on the PI pathway. It is an omnipresent enzyme, highly enriched in brain, where it plays a major role in regulating both pre- and postsynaptic aspects of neurotransmission. Recent studies have suggested that PKC activation may facilitate neurotransmitter release via a variety of mechanisms, including modulation of several ionic conductances regulating Ca^{2+} influx, upstream steps regulating release of Ca^{2+} from intracellular stores, recruitment of vesicles to at least two distinct vesicle pools, and the Ca^{2+} sensitivity of the release process itself. PKC has been demonstrated to be active in many other cellular processes including stimulation of transmembrane glucose transport, secretion, exocytosis, smooth muscle contraction, gene expression, modulation of ion conductance, cell proliferation, and desensitization of extracellular receptors.

PKC and PKC signaling appear to be a target of lithium and valproate. Chronic lithium treatment decreases the level of PKC isozymes α, and ε in cells and treated rodents. Further supporting the effect of lithium on PKC, lithium decreases the levels and phosphorylation of a major PKC substrate, myristoylated alanine rich C kinase substrate (MARCKS), following chronic treatment in rats.

Evidence also suggests that PKC is a target of valproate. In cultured cells, valproate reduces PKC activity in both membrane and cytoplasmic fractions. Valproate also selectively reduces the protein levels of the same PKC isozymes reduced by lithium, α, and ε, further suggesting possible importance in the treatment of bipolar disorder. The reduction in the α isozyme has also been confirmed in the brains of rats treated chronically with valproate at therapeutically relevant concentrations. Similar also to the effects of lithium, valproate decreases the levels of MARCKS. The mechanism by which valproate exerts these effects is unknown; however, they appear to be independent of myoinositol.

PKC Signaling in Animal Models of Mood Disorders

Current models of mania include kindling, behavioral/amphetamine sensitization, and glucocorticoid administration. Kindling is an animal model for epilepsy that has been proposed to have similarities with pathophysiological aspects of bipolar disorder, in which repeated administration of electrical stimulus (that are subthreshold to produce seizures *per se*) results in an epileptic focus and a permanent state of hyperexcitability to the stimulus. These studies on rats have consistently shown the upregulatory effect of hippocampal kindling on PKC activity and protein concentration, findings that were demonstrated to be valid in other brain structures such as the amygdala and neocortex as well.

Studies have also implicated alterations in PKC activity as mediators of long-term alterations in neuronal excitability in the brain following chronic stimulant use. Both acute and chronic amphetamine produce an alteration in PKC activity, its relative cytosol to membrane distribution, as well as the phosphorylation of a major PKC substrate, GAP-43 which has been implicated in long-term alterations of neurotransmitter release (Figure 2). Furthermore, PKC inhibitors have been shown to block the acute responses (as assessed by both behavioral and *in vivo* microdialysis studies) to both amphetamine and cocaine as well as cocaine-induced sensitization.

Abnormalities of circulating glucocorticoids are well known to be associated with affective symptomatology, and interestingly, elevated glucocorticoids have been associated with both depressive and manic symptomatology. Repeated administration of dexamethasone for 10 days results in a significant increase in B_{max} of [^{3}H]PDBu binding to PKC, augmented PKC activity, and raised the levels of PKCα and ε in the rat hippocampus. It is striking that behavioral sensitization and kindling (models which have been postulated to represent models of bipolar disorder and mania) as well as dexamethasone administration all produce alterations in the PKC signaling pathway in critical limbic structures, since

Figure 2 PKC in the treatment of mania. This figure depicts the potential mechanisms by which chronic lithium or valproate, or direct acting PKC inhibitors may have utility in the treatment of acute mania. Activation of PKC, which is known to occur by psychostimulants or stress, results in the phosphorylation of key substrates, notably GAP-43 (growth cone-associated protein) and MARCKS, thereby facilitating the release of neurotransmitters (e.g., dopamine (DA) and NE (norepinephrine)). Chronic lithium or valproate attenuates PKC signaling, effects which may be responsible for the treatment of various facets of the manic syndrome.

lithium and valproate also target the very same biochemical targets.

There is also evidence suggesting that chronic antidepressants may also modulate PKC activity in limbic and limbic-associated areas of rat brain, and PKC has been demonstrated to regulate the activity of norepinephrine, dopamine, and serotonin transporters. Whether these complex effects of antidepressants on PKC activity underlie their apparent ability to trigger manic episodes, and perhaps promote rapid cycling in susceptible individuals, remains to be determined.

PKC as potential therapeutic target In view of the pivotal role of the PKC signaling pathway in the regulation of neuronal excitability, neurotransmitter release, and long-term synaptic events, its modulation by both lithium and valproate, and supporting evidence from animal models of mania, it was postulated that the attenuation of PKC activity might have efficacy in treating mania. These findings led to a single-blind clinical trial investigating possible antimanic properties of the PKC inhibitor tamoxifen. While best known for its anti-estrogenic properties, tamoxifen is also a potent PKC inhibitor at high concentrations. The treatment resulted in a significant decrease in manic symptoms in five of seven patients enrolled in the initial trial. We recently conducted a double-blind placebo-controlled with tamoxifen in patients with bipolar mania and found it to have significant antimanic effects.

Neurotrophic Signaling Cascades

Neurotrophins (NTs) are a family of regulatory factors that mediate the differentiation and survival of neurons, as well as the modulation of synaptic transmission and synaptic plasticity. The NT family now includes, among others, nerve growth factor (NGF), BDNF, NT3, NT4/5, and NT6. BDNF and other neurotrophic factors are necessary for the survival and function of neurons, implying that a sustained reduction of these factors could affect neuronal viability. BDNF also has a number of much more acute effects on synaptic plasticity and neurotransmitter release, and facilitates the release of glutamate, γ-aminobutyric acid (GABA), dopamine, and serotonin.

Thus, BDNF is best known for its long-term neurotrophic and neuroprotective effects, which may be very important for its putative role in the pathophysiology and treatment of mood disorders. It is now clear that their survival-promoting effects are mediated in a large part by an inhibition of cell-death cascades. Increasing evidence suggests that neurotrophic factors inhibit cell-death cascades by activating the extracellular response kinase (ERK) signaling pathway, the PLC-γ cascade, and the phosphotidylinositol-3 kinase (PI-3K)/Akt pathway. Chronic stress (21 days foot-shock; an animal model of depression) induced a marked and persistent ERK1/2 hyper-phosphorylation in dendrites of the higher prefronto-cortical layers, while phospho-CREB was reduced in several cortical regions including frontal cortex. Since CREB is phosphorylated and activated by phospho-ERK1/2 directly, this reduction indicates that chronic stress could downregulate CREB phosphorylation indirectly, and subsequently downregulate the transcription of some genes such as Bcl-2 and BDNF. In this context, severe stress exacerbates stroke outcome by suppressing Bcl-2 expression. In this study, mice exposed to aggressive social stress expressed ~70% less Bcl-2 mRNA than unstressed mice following ischemia. Furthermore, stress greatly exacerbated infarct in control mice but not in transgenic mice that constitutively express increased neuronal Bcl-2. Finally, high corticosterone concentrations were significantly correlated with larger infarcts in wild-type mice but not in Bcl-2-overexpressing transgenic mice. Thus, enhanced Bcl-2 expression appears to be capable of offsetting the potentially harmful consequences of stress-induced neuronal endangerment, and suggests that pharmacologically induced upregulation of Bcl-2 may have considerable utility in the treatment of a variety of disorders associated with endogenous or acquired impairments of cellular resilience. The neurotrophic factor/ERK mitogen activated protein (MAP) kinase/Bcl-2 signaling cascade appears to play a vital role in cell survival in the CNS, and a fine balance is maintained between the levels and activities of cell survival and cell death factors. Dysregulation of the BDNF-ERK-CREB coordination may be a key mechanism by which prolonged stress induces atrophy of selective subpopulations of vulnerable neurons and/or distal dendrites.

In view of the important role of ERK MAP kinases in mediating long-term neuroplastic events, it is notable that lithium and valproate, at therapeutically relevant concentrations, have been demonstrated to activate the ERK MAP kinase cascade in human neuroblastoma SH-SY5Y cells and in critical limbic and limbic-related areas of rodent brain. Neurotrophic factors are now known to promote cell survival by activating MAP kinases to suppress intrinsic, cellular apoptotic machinery, not by inducing cell-survival pathways. Thus, a downstream target of the MAP kinase cascade, ribosomal S-6 kinase (Rsk), phosphorylates the CREB and this leads to induction of Bcl-2 gene expression. Consistent with an activation of neurotrophic signaling cascades, chronic treatment of rats with therapeutically relevant doses of lithium or valproate produces an increase in the activation of Rsk and CREB and a doubling of Bcl-2 levels in frontal

cortex, effects which are primarily due to a marked increase in the number of Bcl-2 immunoreactive cells in layers II and III of frontal cortex. Interestingly, the importance of neurons in layers II–IV of the frontal cortex in mood disorders has recently been emphasized, since primate studies indicate that these areas are important for providing connections with other cortical regions, and that they are targets for subcortical input. Further suggestive evidence that lithium and valproate activate the ERK MAP kinase pathway and/or targets of this pathway comes from the finding that both lithium and valproate increase the expression of BDNF in rodent brain following chronic treatment.

Consistent with its effects on neurotrophic signaling cascades, lithium has been demonstrated to be neuroprotective in cell culture models and animal models of ischemia and Huntington's disease. Recent evidence suggests that the neuroprotective effect of lithium in cortical neurons requires BDNF expression. Valproate also exerts neuroprotective actions in a number of cellular models including glutamate toxicity, β-amyloid toxicity, and following exposure to other toxins.

Human evidence for the neurotrophic effects of lithium Drevets and colleagues reanalyzed previous data demonstrating $\sim$40% reductions in subgenual prefrontal cortex (PFC) volumes in familial mood disorder subjects and found that the patients treated with chronic lithium or valproate exhibited subgenual PFC volumes which were significantly higher than the volumes in non-lithium- or valproate-treated patients, and not significantly different from control. In a further analysis of these data, unipolar patients exhibited reduced glial cell densities, whereas only the bipolar patients off chronic lithium or valproate exhibited similar reductions.

After four weeks of lithium treatment in depressed bipolar patients, a significant increase in *N*-aceytl-aspartate (NAA) levels (a putative marker of neuronal viability) was found with magnetic resonance spectroscopy (MRS); these effects were localized almost exclusively to gray matter. These findings indirectly support the contention that chronic lithium increases neuronal viability/function in the human brain. Furthermore, a $\sim$0.97 correlation between lithium-induced NAA increases and regional voxel gray matter content was observed, thereby providing evidence for co-localization with the regional specific Bcl-2 increases observed (e.g., gray vs. white matter) in the rodent brain cortices. These results imply that chronic lithium exerts robust neuroprotective effects (as has been demonstrated in a variety of preclinical paradigms) as well as neurotrophic effects in humans.

A follow-up volumetric MRI study demonstrated that 4 weeks of lithium treatment also significantly increased total gray matter content in the human brain, suggesting an increase in the volume of the neuropil (the moss-like layer comprised of axonal and dendritic fibers which occupies much of the cortex gray matter volume). A subregional analysis of this brain imaging data showed prominent effects in areas that have been implicated in depression, the hippocampus and caudate.

AA Metabolism

AA functions as an important mediator of second-messenger pathways within the brain. It is released from membrane phospholipids via receptor/G-protein-initiated activation of phospholipase A2. This action results in release of AA from the cellular membrane and cyclooxygenase-mediated production of eicosanoid metabolites such as prostaglandins and thromboxanes. These metabolites mediate numerous subsequent intracellular responses and transynaptic responses.

Chronic lithium and valproate treatment of rats results in selective reductions in the turnover rate in the brain phospholipids of AA. In addition, lithium downregulates the gene expression and protein levels of an AA-specific phospholipase A2 (cPLA2) and the protein levels of cycloxygenase-2 (COX-2). Valproate decreases turnover of AA and protein levels of COX-1 and COX-2. These findings suggest that effects of mood stabilizers on cell membranes, and specifically AA turnover, might be relevant to the pharmacological action of lithium and valproate. Further general support for the involvement of the AA signaling pathway in bipolar disorder comes from other preclinical and clinical studies. Administration of nonselective cycloxygenase inhibitors indomethacin and piroxicam in rats prevented amphetamine-stimulated locomotor activity and blocked cocaine sensitization (both are rodent models of mania). Furthermore, inhibition of COX-2 with NS-398 attenuates restraint stress (a model of depression)-induced oxidative changes. In humans cyclooxygenase-2 inhibitor celecoxib was recently found to have antidepressant effects in a double-blind, placebo-controlled trial.

Conclusions

There has been little progress in developing truly novel drugs for the treatment of bipolar disorder. Thus, there exists a critical need to develop novel approaches for the treatment of recurring mood disorders. We predict that they will likely derive from understanding both mechanisms of current drug actions. Of the direct targets, GSK-3 has received the most attention and GSK-3 inhibitors are rapidly being developed. In addition to the direct

targets of current mood stabilizers lithium, valproate, and carbamazepine, we also discussed signaling pathways regulated by these agents including phosphoinositol/PKC, cyclic AMP, AA signaling, and neurotrophic signaling pathways. Protein kinase C inhibition appears to be important to the antimanic effects of lithium and valproate as indicated by the efficacy of tamoxifen in reducing manic symptoms. Mechanisms to enhance neurotrophic pathways is a major focus for the treatment of neurodegenerative disorders, and it is likely that novel medications for this purpose may be soon available.

Morphogens: History

L Wolpert, University College, London, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Morphogens refer to substances thought to be involved in the patterning of cells during embryonic development. It is a term coined by Alan Turing in 1952 for a substance whose distribution by diffusion could determine the development of cells which would respond differently to different concentrations of the morphogen. But the patterning of cells in relation to varying concentrations of a substance, particularly graded concentrations, has a long history. Of particular importance is how the position of cells in the developing embryo is specified so that they develop in an appropriate manner. It is still not clear whether diffusible morphogens provide cells with positional information and so pattern a tissue during development.

Gradients and Polarity

In 1888, Wilhelm Roux, an embryologist, reported that when one of the cells at the two-cell stage of the frog embryo was killed, the remaining cell formed a half embryo. This was interpreted to mean that different structures were already specified to develop from the two cells. But then Hans Driesch, just 3 years later, set out to repeat the experiment on sea urchin embryos. Contrary to his expectation, he found that half an embryo could give rise to a small but normal whole embryo. This was the first example in a developing system of what is known as regulation. It showed that there is a fundamental distinction between prospective and possible fates of cells – the possible fates being greater.

Further experiments by Driesch on the sea urchin embryo at a later stage led him to believe that the prospective fate of any cell in the early embryo was determined by its position in relation to the whole embryo. The 'whole' was related to the three Cartesian axes that could be drawn on the embryo – the x, y, and z axes. So in his model, each cell had its position defined. He argued that no matter which part of the early embryo is removed, it will develop normally. This is not true, but he ignored evidence to the contrary.

His model was what he called a harmonious equipotential system; the fate of any cell, or group of cells, was a function of the size of the embryo and it relative position. Driesch rejected any chemical theories to explain his complex model and proposed the concept of 'entelechy,' a vitalistic mechanism. There was no further progress along these lines, but he had emphasized the importance of position in embryonic development.

For any system based on coordinates or position, polarity plays a key role, for it can determine the direction in which a coordinate can increase or decrease. Interest in polarity initially came from studies on regeneration. Thomas Hunt Morgan in 1905 was the first to clearly state the relationship between gradients and polarity. In studying the regeneration of earthworms he put forward the idea of gradients of formative stuffs. He found, for example, that the further back a cut is made, the longer it takes to regenerate a head. "...We might speak of the cells of the worm containing some sort of stuff that is more or less abundant in different parts of the body. The head stuff would gradually diminish as we pass posteriorly...." He came to a similar conclusion studying the regeneration of *Tubularia*: "We may assume that the gradation of the material is of such a kind that the hydranth forming material decreases from the apical towards the basal end." But Morgan did not pursue these important ideas on polarity and gradients.

They were, however, taken up by Child in 1911. Studying regeneration in planaria, he concluded, "All these facts indicate that a graded difference of some sort in the dynamic processes exists along the axis.... It is this dynamic gradation along the axis, together with the complex of correlative conditions associated with it, which I regard as constituting physiological polarity. According to this idea polarity is not a condition of molecular orientation, but is essentially a dynamic gradient in one direction...."

Child went on to propose that the gradient was in metabolism, and he introduced the concept of dominance, drawing an analogy between the organism and the state – both require authority. The dominant region at one end determines this metabolic gradient by determining the rates of reaction at other levels. He gave no indication of how this was done. In support of his ideas he used evidence from experiments in which poisons such as cyanide had less effect on regions with the highest metabolism and so they would die last. All the references in his 1915 book are, with one exception, to his own work. Even as late as 1941 he was still constrained by metabolism. He argued that "...if decrease in concentration of amount of a certain substance or substance-complex occurs in one direction along a gradient, there must be increase in concentration or amount of another substance or substances unless there is a decrease in

volume." It was only when metabolism was replaced with the concept of information that new ideas emerged.

Developmental biologists were at this time becoming interested in gradients in eggs and paid no attention to the work of Morgan or Child. For example, in 1915 the Swedish embryologist Runnstrom studied the effect of different ions on the development of the sea urchin embryo and concluded that there was a chemical material expressed along the axes of the embryo and this ". . . .material is localised in a way that different parts of the embryo have different concentrations. It creates a concentration gradient. The phenomenon of polarity is an expression of the presence of this concentration gradient." Later studies by Runnstrom and Horstadius provided further evidence for gradients. One of the most important experiments in 1935 which illustrated the quantitative nature of gradients along the main axis of the sea urchin embryo – the animal vegetal axis – involved showing that in order for normal development to occur, the number of vegetal cells that were required to be added to the animal pole fragment was greater that that required for a fragment from a slightly more vegetal region.

At this time another approach to embryonic development involved induction and the concept of the embryonic field. Spemann in the 1930s discovered induction of a new axis and the organizer in the amphibian embryo. One part of the embryo, the dorsal lip of the blastopore, the site where gastrulation begins, could, when grafted to another embryo, induce almost a complete second axis. This was a most influential discovery. Yet as early as 1909 it had been shown that the head region of hydra could, when grafted to the body of another animal, induce the formation of a new axis. Spemann also introduced the field concept, referring to different fields of organization in the embryo.

Perhaps the clearest views of gradients, some 30 years after their initial conception, came from Huxley and de Beer in 1934 based largely on studies on regeneration. Their rules were that the origin of polarity is to be sought in external factors, though in some cases it may already be polarized; in regeneration the apical, or head, region is the first formed and is autonomous; and the apical region influences adjacent regions and prevents them forming an apical region.

In 1938 he lectured on gradient theory, but one of the problems he recognized was understanding how quantitative differences along the gradient could give rise to qualitative differences, namely, complex cell patterns. How could discontinuities arise from a continuous gradient? A possible solution came from Dalcq and Pasteels. Considering early amphibian development, they introduced two factors: the yolk gradient V and a cortical factor C which was graded dorsoventrally. They then defined the product CV as the morphogenetic potential as well as the concept of a threshold. How parts of the embryo developed was then determined by whether CV was below or above a threshold.

Other specific models were developed, and that of Rose in 1968 was the first gradient model to generate a pattern. He suggested that the genesis of a cellular pattern could be the consequence of a hierarchy of self-limiting reactions, together with a spread of inhibition form one differentiating region to others further down the gradient. The gradient determined the rate of differentiation, with the reactions proceeding fastest at the high point of the gradient. The reaction that predominates is then that closest to the top of the hierarchy which has not yet been inhibited. Each reaction is self-limiting by virtue of the inhibitor it produces. However, there was no evidence for the proposed inhibitors.

Insects were to provide crucial information on the possible role and nature of gradients. The gradient concept gained considerable support from Klaus Sander's 1960 experiments on the axial body pattern of the leafhopper *Euscelis* embryo, with the results on the reversal of the segment sequence providing strong evidence for gradients. At about the same time, Locke had shown that the ripple patterns in the cuticle of the insect *Rhodnius* could be explained by a gradient along the segment.

Hidegard Stumpf interpreted these results in terms of a concentration gradient in a substance produced at one margin and destroyed at the other – the first clear statement as to how a concentration gradient could be set up. Using the abdominal segments of *Galleria*, which are divided axially into three parts, she then did experiments to determine whether this pattern was based on a gradient. She concluded that this was the case and that the gradient had two functions: to orient the scales in a direction of decreasing concentration, and to provide the cells with specific concentrations to determine their fate. At the same time, and quite independently, Lawrence had proposed a gradient model for the epidermis of the insect *Oncopeltus* based on the orientation of the hairs and bristles. His gradient model was based on a gradient in sand together with active transport against diffusion.

Positional Information

Again quite independently, the author put forward the concept of positional information similar to that

proposed by Stumpf, on the basis of the French flag problem. I had been very impressed that sea urchin embryos could develop a normal pattern of tissue proportions over an eightfold size range. Again, *Hydra* could have a normal pattern over a large range of sizes. The French flag problem addressed how a line of cells, each of which could differentiate into a blue, white, or red cell, could develop the French flag pattern – one-third blue, one-third white, one-third red. Moreover, this pattern would develop irrespective of the number of cells in the line. A clear solution was that each cell knew its position in the line of cells and then could differentiate in an appropriate manner to give the French flag. One way cells could have their position specified was by a gradient in some substance whose concentration was fixed at both ends of the line, one high, the other low, and that varied linearly between the two ends – simple thresholds would give the flag reliably. A very attractive feature of positional information was that it could account for genetic mosaics in the wing and antenna of the fruit fly *Drosophila*.

Curt Stern had shown that mosaics of leg and antenna tissue developed according to where they were along the proximo-distal axis – they had the same positional values but interpreted them differently because of their position along the main body axis.

In 1952 Alan Turing, the famous mathematician, code breaker, and inventor of computers, published a totally new approach to pattern formation. It was essentially a self-organizing mechanism for setting up a pre-pattern in a diffusible substance that could cause structures to form at specific sites.

> It is suggested that a system of chemical substances, called morphogens, reacting together and diffusing through a tissue, is adequate to account for the main phenomena of morphogenesis. Such a system, although it may originally be quite homogeneous, may later develop a pattern or structure due to an instability of the homogeneous equilibrium, which is triggered off by random disturbances. Such reaction-diffusion systems are considered in some detail in the case of an isolated ring of cells, a mathematical convenient, though biologically unusual system. It is found that there are essentially six different forms it might take. In the most interesting form, stationary waves appear on the ring. It is suggested that this might account, for instance, for the tentacle pattern of Hydra and for whorled leaves.

This approach has been extended by the reaction diffusion models of Gierer and Meinhardt which can set up and regulate axial gradients.

One feature of what might be systems in which positional information is involved is that they are relatively small, none being greater than 0.5 mm maximum linear dimension, and there are typically fewer than 30 cells along an axis where position is thought to be specified. The time required to specify position appears to be on the order of hours. This led Crick to propose the existence of a diffusible morphogen for setting up positional fields. A simple model would have the morphogen produced locally at a source at one end, and then it would spread by diffusion along the axis. The resulting concentration gradient could provide positional information.

By far the best evidence for such a gradient in a morphogen patterning a developmental system is the bicoid gradient in the *Drosophila* egg. The gradient in this protein is maternal and runs from anterior to posterior. However, it acts at a time when the embryo is multinucleate, there are no cell wall membranes for it to cross, and the nuclei share a common cytoplasm. At a specific concentration it activates the gene hunchback in the nuclei in the anterior region. Another example in the early embryo relates to the dorso-ventral axis. For cellular systems things are very much more complicated.

Positional signaling by morphogens has been quite widely investigated over the past two decades but it has not been established that this mechanism provides the basis for pattern formation in any multicellular system. In principle it can account for the pattern of digits in the developing wing of the chick embryo. At the posterior margin of the limb bud is a signaling region, the polarizing region, that produces a putative morphogen, the protein sonic hedgehog. The normal pattern of digits from posterior to anterior is 4, 3, 2. The polarizing region is posterior to the future digit 4. If an additional polarizing region is grafted to the anterior margin of the bud, the resulting pattern of digits is 4, 3, 2, 2, 3, 4. The best evidence that the signal is graded comes from the observation that manufacturing a reduced signal by grafting anteriorly a small number of polarizing tissue cells results in a reduced response; if only a small piece is grafted, then the pattern is 4, 3, 2, 2. This fits nicely with a simple graded diffusible signal of sonic hedgehog, but there is no good evidence to support it. Recent studies have shown that the time that the cells are in contact with the polarizing region also plays a role. Again, the elegant model for specification of neuronal subtypes in the vertebrate ventral neural tube is based on a gradient in sonic hedgehog, but direct evidence is still lacking.

Another well-studied multicellular system is the imaginal wing disc of the *Drosophila* embryo. The wing disc is divided into anterior and posterior compartments. The diffusible molecule Hedgehog is expressed in the posterior compartment, and this causes diffusible Decapentaplegic (DPP) to be expressed at the compartment boundary. DPP is indeed

distributed in a long-range concentration gradient; DPP moves without preferential direction at a speed of more than four cells per hour through the target tissue, in spite of which the shape of the gradient remains stable. However, DPP extracellular diffusion alone does not explain its distribution as a stable gradient and that receptor-mediated endocytosis is essential for DPP long-range movement. Although there are some indications that at specific DPP thresholds the genes omb and spalt are turned on, it is notable that even in this well-studied case there is scant if any reliable quantitative evidence for a gradient-dependent positional gene activation.

In early *Xenopus* embryo there is a presumed gradient of an activin-like morphogen activity. At high concentrations of activin the gene goosecoid is activated while Xbra is turned on at lower concentrations. This has been demonstrated by placing a bead of activin in the middle of a group of animal cap cells: goosecoid is turned on nearer the bead than Xbra. These results have been interpreted in terms of the morphogens binding to receptors. However, there is no evidence for an actual diffusion-mediated gradient of activin in the embryo.

One could list many other examples, with the conclusion that no clear case of a canonical morphogen has been found. But even in principle, could diffusing morphogens by themselves specify positional information? We do not know how precise specification of position has to be, but it could be at the single cell level. There are major difficulties. The molecular concentrations involved are invariably small, hence there is an intrinsic chemical noise. Candidate morphogens and their receptors are very dilute, and they operate in a complex physicochemical environment. This potentially makes morphogen propagation extremely unreliable. The extracellular matrix most likely will present a variety of binding sites for the morphogen, trapping it. There are indeed numerous examples of interaction between proposed morphogens and other extracellular proteins. In addition, the extracellular space is tortuous. It has been estimated that this can increase the effective diffusion times as much as fivefold. Many cellular factors can be expected to perturb and/or actively modulate these various constraints. There is also almost always some endocytosis of a diffusing molecule that binds to cell receptors, and this together with tortuosity makes a precise determination of morphogen concentrations problematic. Worse still, the binding of the morphogen to the receptors can have a very significant effect on the distribution and can even prevent a gradient in receptor occupation as receptors become saturated.

It may be that cell–cell interactions play a key role in specifying positional information. Cell–cell interactions figure prominently in all mechanisms relating to tissue polarity. Favorite model systems for studying planar polarization are the *Drosophila* wing and eye. It is widely assumed that one or several (some opposed) gradients are involved. Gradient-distributed molecules such as Dachsous, Four-jointed, and Fat have been identified. Remarkably, while all these candidate players are growth factors, all are membrane proteins; they intervene in cell adhesion and communication, but likely not by being transmitted between cells.

There is a model for polarity in the abdominal epidermis of *Drosophila* based on cell interactions which also provides the cells with positional information – no morphogen playing a key role. The proteins Four-jointed, Dachsous, and Fat are involved in setting up a gradient of an unknown factor X, which determines Frizzled activity. Reading the gradient are Frizzled itself, Prickle, and VanGogh/Strabismus, enabling cells to compare their level of X with that of their neighbors and to set their value as an average of these. On the other hand, there is a model for planar cell polarity based purely on cell-to-cell interactions and local (cell-scale) graded distributions, where factor X is dispensed with, and hence no global positional information is imparted to cells. The model posits that a weak Frizzled activity gradient is read by asymmetric molecular complexes built at cell interfaces around the cadherin Flamingo. Polarization happens robustly over hundreds of cell diameters even with much noise in the Frizzled gradient. It is probable that these last two models have the potential, if suitably extended, to provide positional information.

Mother–Infant Interaction in the Variable Foraging Demand Model

J D Coplan, J G Kral, E L P Smith, and L A Rosenblum, SUNY Downstate Medical Center, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Background

Although the etiology of psychiatric disorders has been difficult to ascertain, it is clear that early-life stress is a pivotal precursor to adult mood and anxiety disorders in humans. Teasing apart the complex interplay between genes and environment that shapes the vulnerability to the emergence of psychiatric disorder has progressed significantly. Genotyping for polymorphisms that predict vulnerability to early life stress, particularly allelic variants of the serotonin transporter protein-linked promoter region (5HTTLPR), have greatly advanced the field. Nevertheless, animal models afford the advantage of random assignment to differential rearing experimental conditions and standardize the early-life stressor, thereby minimizing the contribution of genetics plays in determining the nature and perception of early-life stress. Animal models are therefore predicted to account for an ever-increasing amount of variance contributed to by genetic contributions, early-life stress, and their interaction in determining the ultimate impact of these factors on the adult phenotype. One animal model of early-life stress, developed in nonhuman primates, focuses on the grown offspring of mothers confronting, during their infants' early development, significant environmental uncertainty in regard to the ease or difficulty of maternal food procurement (variable foraging demand (VFD)). As in humans, integrity of maternal care in nonhuman primates is symbolic of survival for the infant. This VFD model is therefore argued to represent an animal analog of the impact of emotional inconsistency in human parenting. Adverse early parenting may likely represent, for the affected infant, the earliest and potentially most profound of all life stressors. We have therefore demonstrated that VFD offspring exhibit, in comparison to consistently reared controls, both sustained and pervasive alterations within a diverse range of physiological and neurobiological systems that are consistently implicated in the pathogenesis of human mood and anxiety disorders.

Perhaps of greatest significance is that VFD offspring are subject to errant social functioning and manifest concurrent behavioral disturbances reflective of affective distress, thereby mirroring certain components of human depression and anxiety (Figure 1).

VFD and Control Rearing

VFD rearing is an early-life stress paradigm in which infant bonnet macaques are reared by mothers undergoing an experimentally induced 'perception' of food uncertainty. Although adequate food is always available, randomly assigned macaque mothers face unpredictability of food availability through exposure to the VFD procedure, whose duration is only 12–16 weeks within the first year of infant life. Hence, no differences in weight change are evident between VFD and non-VFD mothers or infants. We have shown that psychopathology can be experimentally induced in the infant by this discrete period of emotional compromise in the maternal behavioral repertoire, imparting pervasive and sustained biobehavioral effects within the developmental trajectory of the offspring, into adulthood. Notable is the absence of physical intervention or frank separation in the VFD model, thereby closely approximating, despite parental presence, the far-reaching experience of emotional unavailability, so frequently reported in symptomatic human adults.

Experimental Overview of the VFD

Rosenblum and Pauley developed VFD in 1984, in order to provide a more humanlike analog of disturbed mother–infant attachment patterns than that provided by the earlier studies of Harlow, in which frank maternal separation from the infant was conducted. The effects of stress on infant in the VFD model were indirect and were intended to be communicated via disruption of mothering following her stress response to unpredictable foraging conditions. Three different experimental rearing conditions were developed, with random assignment to each condition. In general, the VFD paradigm involves two alternating conditions across either a 12- or a 16-week period: (1) Under low foraging demand (LFD) conditions, abundant food can simply be picked from pans within a cart. (2) Under high foraging demand (HFD) conditions, to obtain their daily food ration, mothers are required to search and work for food by digging through clean wood-chip bedding that hides the less abundant yet adequate food located within mobile foraging carts that allow access to internal pans from a series of ports. (3) For the VFD mothers, the foraging demand varies between LFD and HFD conditions in 2-week blocks (3–4 LFD and 3–4 HFD) across the 12- to 16-week experimental rearing period. The quantity of food placed within the cart under the HFD portion of VFD and HFD rearing is adjusted on the basis of the amount of

Long-term impact of early-life stress on primate models of anxiety and depression

- Anxious and depressive-like behavior
- CRF dysregulation
  HPA axis activity alterations
- CSF monoamine metabolite elevations
- Somatotropic axis suppression
- Pro-inflammatory cytokine expression
- Metabolic syndrome profile
- Regional spectroscopic analysis of neuroanatomical structures
- Myelin integrity compromise on diffusion tensor imaging
- Serotonin transporter protein genotypic effects

Figure 1 The long-term impact of early life stress in the form of VFD in nonhuman primates in relationship to the pathophysiology of human anxiety and mood disorders.

Figure 2 VFD stress is transmitted to the offspring via the mother, with disruption of maternal attachment and affective reciprocity. Depicted here is a mother undergoing VFD; she is noted to be distracted from her infant, who appears pensive, despite her physical presence. We have described the VFD infant as undergoing a state of 'functional' separation.

food eaten each day. Although the requirements placed on the mothers for obtaining food differs in each condition, in all instances, adequate food is always available. Thus, food deprivation is not a factor, and weekly weight measures and daily health checks are performed to ensure normal growth and health in all infants and their mothers.

Prior to and following the experimental rearing period, ad lib food is available to all animals via food bins as in the rest of the primate facility. Water, via automatic drinking spouts, is constantly available to all mothers. VFD-reared subjects were found to be most disturbed on behavioral measures, whereas HFD-reared subjects were generally indistinguishable from LFD subjects. These early studies led to the conclusion that it was the unpredictability of foraging conditions that produced long-term abnormality in offspring, rather than difficulty of foraging *per se* as seen in the HFD. In most subsequent studies, VFD-reared subjects were compared to LFD-reared subjects.

VFD stress was hypothesized to be transmitted to the offspring via the mother, via disruption of maternal attachment and normative affective reciprocity. Thus, although the mother is physically present, a form of 'functional' separation exists (Figure 2). The VFD paradigm is also accompanied by synchronized elevations of maternal and infant cerebrospinal fluid (CSF) concentrations of corticotropin releasing factor (CRF).

VFD Behavioral Observations

VFD-reared monkeys, in comparison to LFD-reared subjects, demonstrate a range of behavioral abnormalities at successive stages of maturation. During infancy, in dyadic assessments shortly after the rearing experience, VFD rearing adversely affected the

Figure 3 Infants reared under VFD conditions exhibit an increased propensity to develop a separation despair response during periods of brief maternal separation. Depicted here is a 'VFD-monkey' infant undergoing a despair response following a brief period of maternal separation.

subjects' ability to separate from mother to explore a novel physical environment in comparison to LFD subjects. VFD-reared infants also manifest timidity, social subordinance, increased separation despair, and clinging behavior in novel environments. When tested during late adolescence using a social challenge paradigm, VFD exhibited diminished capacity for affiliative social engagement relative to LFD monkeys, to whom they were socially subordinate. The VFD 'syndrome' is remarkably similar to that seen in Kagan's behaviorally inhibited children and Suomi's genetically shy rhesus monkeys (Figure 3).

In examining whether VFD rearing produced affective disturbance in unperturbed home cage behavioral

observations in comparison to LFD-reared subjects, VFD juvenile subjects exhibit reduced social engagement, increased affective withdrawal, and increased social confrontation, manifest as an increase in social timidity in comparison to controls. Because of potential co-linearity of behaviors, a multiple regression model was employed, using rearing group as the predictor variable and these latter three behaviors as dependent variables. The model accounted for 70% of the variance for group differences. Taken together, the behavioral observations demonstrated a persistently abnormal behavioral profile analogous to certain aspects of anxiety and depression in human children and adults.

VFD Behavioral Findings in Response to an Acute Fear Stimulus

One method by which further information can be obtained regarding VFD rearing is to study behavioral deficits that only become apparent under challenge conditions. One such challenge condition is an acute fear stimulus represented by a masked intruder paradigm, the mask containing large fangs and consisting of unfamiliar colors. VFD and LFD subjects were observed at three stages over 3 days: at baseline, directly following exposure to the fear stimulus, and 1 day following exposure to the fear stimulus. VFD demonstrated, at baseline, marginally reduced gregariousness scores in comparison to normally reared control subjects. However, following a brief exposure to the fear stimulus, normally reared juvenile subjects exhibited a marked reduction in gregariousness scores, whereas VFD, in contrast, failed to shift from basal levels of gregariousness. Further evidence for a muted behavioral reaction to the fear stimulus was the failure of VFD subjects to exhibit emotional responsivity to the masked intruder, whereas LFD subjects showed a fivefold increase for this same measure upon stimulus presentation. LFD responded to the fear stimulus by reducing social engagement, whereas VFD showed a slight increase in social engagement. The differential pattern of behavioral response to an acute fear stimulus supported the notion that VFD showed a reduction of emotional reactivity, and suggested long-term disturbances in affect regulation following adverse early-life experience.

Neurobiological Sequelae in VFD-Reared Subjects

Since the long-term behavioral effects of VFD rearing bore a striking resemblance to certain traitlike aspects of human psychopathology, it was deemed that the VFD model may represent an important vehicle by which to determine the long-term neurobiological correlates of these errant primate behaviors. Using the VFD model, we have subsequently documented a diverse range of persistent sequelae, of relevance to both human psychiatric and medical disease states. We first examined the noradrenergic and serotonergic systems, as parallel 'cross-talk' between these systems has been implicated in the pathophysiology and treatment mechanisms of anxiety and mood disorders. In biobehavioral studies, adult VFD subjects exhibited abnormal behavioral responsivity to the noradrenergic probe, yohimbine, and the serotonin agonist, 2-(2-methyl-4-chlorophenoxy)propionic acid (MCPP). VFD-reared subjects were hyper-responsive to the anxiogenic effects of yohimbine and hyporesponsive to the behavioral effects of MCPP. Based on norepinephrine (NE) hyper-responsivity in the VFD-reared subjects, we examined concentrations of CRF, a known stimulant of the noradrenergic system, in the CSF of differentially reared primate subjects. CRF is a neuropeptide which coordinates the body's behavioral, neuroendocrine, and neuroimmunological response to stress, and CRF dysregulation had been implicated in the pathophysiology of mood disorders and posttraumatic stress disorder. Juvenile VFD subjects exhibited persistently elevated concentrations of CSF CRF with concomitant HPA axis suppression in comparison to both LFD- and HFD-reared subjects.

We postulated that sustained alterations of CRF/HPA axis function may be a marker of early-life stress and psychiatric disorder vulnerability. CSF was also assayed for concentrations of biogenic amines and somatostatin, an inhibitory peptide of somatotropic function. VFD subjects exhibited persistent elevations in CSF 5-HIAA (5-hydroxyindoleacetic acid – the chief serotonin turnover metabolite) and HVA (homovanillic acid – the chief dopamine turnover metabolite). CRF correlated positively with all three neurochemical variables in VFD-reared but not non-VFD-reared subjects. Since the CSF CRF elevations had been noted in juvenile VFD-reared subjects, if the finding was truly persistent, it would be important to replicate the finding in the identical subjects followed into adulthood. VFD adult subjects exhibited enduring elevations of CSF CRF in comparison to normally reared controls. Moreover, there was a positive correlation between juvenile and adult VFD CSF CRF, suggesting that CRF elevations were traitlike in their expression.

In a subsequent juvenile cohort, who had been exposed to VFD rearing at a later phase of development coinciding with weaning, paradoxically low CSF CRF and high plasma cortisol concentrations were observed in comparison to LFD control subjects, suggesting that the timing of the VFD stressor could influence the directionality of CRF dysregulation. However, both the early and late forms of VFD rearing exhibited

persistent increases in brain serotonin turnover as reflected by CSF 5-HIAA. Taken together, these studies suggest that one central feature of VFD rearing entailed disturbances of CSF CRF and cortisol, although the directionality of findings evidently varied as a function of rearing age at the time of VFD exposure.

A Hypothesis of Compromised Neurotrophic State in VFD

We hypothesized that a diffuse excitatory influence, possibly imparted by the ubiquitous excitatory amino acid glutamate, could conceivably account for the synchronized neurochemical activation of CRF, somatostatin, serotonin, and dopamine, with CRF as a potential intermediate vehicle of excitation. We therefore hypothesized that persistence of this diffuse neurochemical excitation in VFD-reared subjects may impart a compromise in neurotrophic state, or counter the optimum microenvironment for neuronal activity. One peripheral measure of trophic state is reflected by secretory activity of growth hormone (GH) in response to known secretagogs. It has been well documented that anxiety and mood disorders are generally associated with a reduced GH response to the α_2 agonist clonidine. We therefore determined whether the GH signal in response to clonidine was inversely suppressed in relationship to CSF CRF concentrations. The magnitude of serial CSF CRF concentrations in VFD-reared subjects inversely predicted the GH response to clonidine challenge. The data suggest that the persistent activation of central CRF systems in VFD is associated with a peripheral antitrophic effect, and suggested that central CRF elevation may contribute to the blunted GH response to clonidine observed in humans with mood and anxiety disorders. To test whether glutamate was integral to activation of noradrenergic and central CRF systems in the bonnet macaque, as had been observed in certain cohorts of VFD-reared bonnets, we tested whether LY354740, a metabotropic presynaptic receptor agonist, would block acute yohimbine-induced cortisol increases, and if chronic administration of the glutamate blocking agent would downmodulate the HPA axis. LY354740 attenuated both acute cortisol and MHPG response when administered intravenously. Daily oral administration of the drug led to cortisol reductions several weeks into treatment. Although no rearing group differences were observed in this study, the LY354740 results, in concordance with the field, suggested that glutamate excess could conceivably underlie a neurochemical milieu of excess NE and limbic-HPA axis activation, perhaps compromising neurotrophic state.

VFD and Magnetic Resonance Spectroscopic Imaging

In order to further assess neurotrophic state and regional glutamate concentrations, we conducted neuroimaging studies in VFD adult male primates versus age-matched controls using proton magnetic resonance spectroscopic imaging (^{1}H-MRSI). We evaluated spectral signals of *N*-acetyl-aspartate (NAA), a putative marker of neuronal integrity, while using choline (Cho) and creatine (Cr) as denominators, respectively, in the anterior cingulate cortex (ACC) and hippocampus. Choline is a putative marker of membrane turnover, whereas creatine is used as a control analyte, although this view has come under question. 'Glx' is a spectral signal that represents the combination of glutamate, glutamine, and GABA, although the major contributor to the signal is glutamate. Consistent with our hypothesis that VFD subjects were subject to an antineurotrophic state, NAA/Cr and NAA/Cho resonances were significantly reduced in the ACC of VFD subjects, without overlap with normal controls. The Glx/Cr signal was significantly elevated in the VFD ACC in comparison to controls. Finally, in ACC, Glx/Cr inversely predicted NAA/Cr, suggesting that higher glutamate states may exert an antineurotrophic effect within the ACC. In addition, in hippocampus, mean concentrations of Cho/Cr were elevated in VFD-reared subjects in comparison to controls. Moreover, in left hippocampus, left NAA/Cho was reduced in VFD-reared subjects versus controls. Of note, when combining VFD and non-VFD subjects, both elevated juvenile CSF CRF concentrations and elevated adult body mass index each positively predicted an increase in the right-to-left ratio of the NAA/Cr and NAA/Cho metabolites in hippocampus, suggesting that asymmetry of metabolite profiles within the hippocampus may represent a neural substrate of relevance to certain diverse aspects of the primate phenotype.

Immune Dysregulation

Transforming growth factor-β1 (TGF-β1) is a potent anti-inflammatory cytokine that inhibits T-cell activation. We determined plasma levels of TGF-β1 in VFD-reared subjects and its relationship to affective behavior because of its cross-regulatory interactions with HPA axis activity, serotonin, and other intermediaries. In juvenile subjects, brief confinement in a novel room resulted in higher levels of plasma cortisol and serum TGF-β1 in VFD-reared macaques compared to age-matched controls. In addition, levels of TGF-β1 and cortisol after stress were directly correlated with one another and with CSF 5-HIAA.

Further studies using affymetrix gene microarray methods in monocytes indicate that VFD-reared macaques are characterized by an imbalance in inflammatory homeostasis, as evidenced by a shift in global gene expression to a pro-inflammatory profile in response to stress, and, more significantly, by a marked decrease in gene expression of the anti-inflammatory cytokine TGF-β1 (see Table 1).

The role of TGF-β1 in the expression of behavior has not been previously investigated. Serum TGF-β1 concentrations following acute stress positively predicted the behavioral propensity to affiliate with one's peers after presentation of a fearful stimulus. In this regard, the inflammatory profile of the VFD-reared macaques after stress is similar to that described for clinical depressive illness.

Primate Metabolic Syndrome

An additional line of investigation in the VFD subjects was based on the potential effects of persistent HPA axis disturbance. The metabolic syndrome, which comprises insulin resistance, visceral adiposity, dyslipidemia, and hypertension, may be induced by chronic HPA axis disturbance. We therefore hypothesized that VFD subjects would exhibit an accelerated onset of a primate form of the metabolic syndrome, which we have observed to occur spontaneously within our bonnet macaque colony. VFD-reared offspring at the juvenile phase of development had greater body mass index, abdominal circumference, and very low density lipoprotein (VLDL) lipids in comparison to controls. In addition, using a euglycemic clamp methodology, VFD subjects exhibited insulin resistance in comparison to controls. These data are relevant to the overall theme of a reduced brain neurotrophic state in VFD-reared subjects, inasmuch as reductions in brain insulin receptor activation by insulin-like growth factor are associated with reductions in neuroprotection and neurogenesis rates in the dentate gyrus of the hippocampus.

Table 1 Cytokine gene array response to restraint stress in adult VFD[a]

Proinflammatory genes which were upregulated >3-fold ($P < 0.05$) in VFD post stress
TNF-α
IL-1 β
IL-6
IL-13 receptor
Heat shock protein 90
Interleukin 7 receptor
Anti-inflammatory genes which were downregulated by >3-fold ($P < 0.05$) in VFD post stress
TGF-β1
TGF-β receptor II
Bone morphogenetic factor
IL-10

[a] Corresponding effects in non-VFD were not significant.
TNF, tumor necrosis factor; IL, interleukin; TGF, transforming growth factor.

VFD and White Matter Integrity

Diffusion tensor imaging (DTI), an application of magnetic resonance imaging (MRI), measures the extent and direction of water diffusion in neural tissue. Fractional anisotropy (FA) determines the magnitude of directionality of diffusion in brain white matter (WM), is greatest in tracts of parallel axons, and decreases in demyelinating conditions.

The rationale of performing DTI in VFD is based on the observation that humans and nonhuman primates exposed to early life stress exhibit deleteriously affected WM structures, such as the corpus callosum. One plausible mechanism whereby early life stress may affect WM integrity entails alterations in neurotrophic factor gene expression such as brain-derived neurotrophic factor (BDNF), which stimulates myelin basic protein production by differentiating oligodendrocytes. VFD exhibits long-term reductions in FA in the WM of anterior but not posterior internal capsule in comparison to control subjects. VFD also produces prominent alterations in patterns of FA concordance between anterior corpus callosum and anterior internal capsule. In control subjects, high FA correlation between anterior corpus callosum and anterior internal capsule conceivably suggests a common regulatory mechanism of myelin deposition related to neurotrophic factor gene expression. The corresponding correlations were significantly reduced in VFD subjects, indicating disruption of between-region FA homogeneity.

Integrity of frontal WM, as reflected by FA, may represent (1) a mechanism for affective disturbance via disruption of 'top-down governance' and (2) a potential indicator of neurotrophic status of brain regions implicated in human anxiety and mood disorders.

Interaction of Early-Life Stress and Serotonin Genotype on Infant Attachment Behavior

The serotonin transporter is a protein critical to the regulation of serotonin function in the brain, because it terminates the action of serotonin in the synapse via reuptake. The variant site is commonly known as 5-HTTLPR (serotonin transporter-linked promoter region). There are two common functional alleles of 5-HTTLPR, the short ('s') allele and the long ('l') allele. The s allele encodes an attenuated promoter

segment, and is associated with reduced transcription and functional capacity of the serotonin transporter relative to the l allele. Four independent investigations with child, adolescent, and young adult subjects reported associations between 5-HTTLPR variation and risk for depression following adverse life experiences. Specifically, the s allele of 5-HTTLPR was associated with the development of depression, but only in individuals with histories of child maltreatment or recent stressful life events. In the absence of these experiences, the s allele was not associated with an increased risk for depressive symptoms.

Serotonin transporter genotyping was available on infant male subjects who were studied while undergoing 16 weeks of the VFD procedure. During the final LFD/HFD cycle, repeated behavioral observations were performed that were designed to reflect the extent of infant attachment to its mother. Aggregate measures of infant proximity to mother were separately evaluated for the final LFD and final VFD period, assigning values from 1 to 5, where 1 indicated the greatest degree of infant proximity whereas 5 indicated the greatest magnitude of distance possible of infant from mother. Results indicated that, during the final LFD period, infants with the short allele of the 5-HTTLPR exhibited a significantly greater degree of proximity to mother than their long allele counterparts.

For the corresponding HFD period, no effect of genotype was noted. In conclusion, these preliminary data suggest an influence of serotonin transporter

Table 2 Summary table of biological consequences of VFD stress in comparison to experimental control subjects

Condition	*VFD effect*	*VFD implications*	*Cohort*
Oral yohimbine challenge	Behavioral hyper-responsivity	Noradrenergic dysregulation	Cohort 1 adult phase
Oral *m*-CPP challenge	Behavioral hyporesponsivity	Serotonergic dysregulation	
CSF tap under ketamine anesthesia	↑ CSF CRF (pg ml^{-1})	Central CRF activation in early VFD	Cohort 2 juvenile phase
	↓ CSF cortisol (ng ml^{-1})	HPA axis suppression in early VFD	
	↑ CSF somatostatin (pg ml^{-1})	Somatotropic axis suppression	
	↑ CSF 5-HIAA (ng ml^{-1})	Serotonin turnover ↑	
	↑ CSF HVA (ng ml^{-1})	Dopamine turnover ↑	
	↑ CSF CRF (pg ml^{-1})	Persistent central CRF activation	Cohort 2 adult phase
	↓ CSF CRF (pg ml^{-1})	Paradoxical CRF ↓ in late VFD	Cohort 3 juvenile phase
	↑ CSF 5-HIAA (ng ml^{-1})	Serotonin turnover ↑ consistent in early and late VFD	
Plasma sample under ketamine	↑ Plasma cortisol (mg dl^{-1})	Basal HPA axis activation in late VFD	
Mild novelty stress and plasma samples	↑ Plasma TGF-β1 (ng ml^{-1})	Compensatory anti-inflammatory Cytokine ↑	Cohort 3 juvenile phase
	↑ Plasma cortisol (mg dl^{-1})	HPA axis hyper-reactivity	
Acute restraint stress and monocyte gene microarray	↑ Gene expression of inflammatory, cytokines	Pro-inflammatory state under acute stress conditions	Cohort 3 adult phase
^{1}H-MRSI under ketamine anesthesia	↓ NAA/Cr in ACC	↓ Neuronal integrity in area critical for executive function	Cohort 2 and 3 adult phase
	↑ Glx/Cr in ACC	Hyperglutamatergic state (but could be GABA or glutamine)	
	↑ Cho/Cr in hippocampus	Abnormal metabolite profile in neurotrophic area	
	↓ NAA/Cho left hippocampus	Compromised neuronal integrity	
Morphometry	↑ Body mass index (kg m^{-2})	Primate metabolic syndrome	Cohort 4 juvenile phase
Ketamine and plasma samples	↑ VLDL (nmol l^{-1})	Dyslipidemia	
	↑ Glucagon-like protein 1 (pM)	Incretin compensation	
Ketamine and euglycemic clamp	↓ Glucose utilization (mg kg^{-1} min^{-1})	Insulin resistance	
DTI under ketamine	↓ FA Internal capsule anterior limb	Disruption of myelin integrity	

The table provides a comprehensive summary of the biological consequences of the VFD stress apparent in the VFD offspring. The first column provides a brief statement of the condition under which the findings were acquired; the second column summarizes the main finding observed in VFD subjects in comparison to experimental controls; the third column situates the finding within the context of its biological implications; and the fourth column lists the successive cohorts studied and the phase of development of subjects at the point of study.

VFD, variable foraging demand; *m*-CPP, *meta*-chlorophenylpiperazine; CSF, cerebrospinal fluid; CRF, corticotropin releasing factor; HPA axis, hypothalamic–pituitary–adrenal axis; 5-HIAA, 5-hydroxyindoleacetic acid; HVA, homovanillic acid; TGF-β1, tranforming growth factor β1; ^{1}H-MRSI, proton magnetic resonance spectroscopic imaging; NAA/Cr, *N*-acetyl-aspartate/creatine; 'Glx', glutamate, glutamine, and γ-aminobutyric acid (GABA); Cho, Choline; VLDL, very low density lipoprotein; DTI, diffusion tensor imaging.

genotype on infant behavior within the context of the VFD paradigm. Moreover, the findings were in the predicted direction, with VFD-reared infants possessing the s/s allele exhibiting greater degrees of 'reactive attachment', a putative measure of infant anxiety, than their l/l counterparts. Thus, the VFD-rearing experience appears to interact at a behavioral level with the allelic variant of the 5-HTT.

Conclusions

The VFD model has been extended from one providing only behavioral outcome measures, to a paradigm which demonstrates that early-life stress can significantly alter the following: (1) behavioral effects of pharmacological probes of monoamine systems, (2) stress neuropeptides and monoamine metabolite concentrations in CSF, (3) HPA axis measures, (4) neuroendocrine measures of the hypothalamic–pituitary–somatotropic, (5) neurochemical systems that are dependent on glutamatergic neurotransmission, (6) measures of cytokines and microarray studies of cytokine gene expression, (7) the occurrence of metabolic syndrome and insulin resistance, (8) regional neuroimaging data of metabolite profiles using magnetic resonance spectroscopy, and (9) measures of myelin integrity using DTI. Future studies can be interfaced with VFD genotyping to identify vulnerable versus resilient subjects. VFD-reared subjects have shown significant differences from non-VFD-reared control subjects (see Table 2) for literally all the biobehavioral measures that have been studied, suggesting that the impact of maternal stress upon the infant's developmental trajectory is persistent and widespread.

The latter observation alone serves to underscore the profound effect of a relatively nontraumatic early-life stressor on behavior and biology and serves to highlight the critical importance of emotional availabiltiy in the determining the integrity of the mother–infant experience. An additional consideration is that the abnormalities we have observed in the VFD offspring seldom occur in isolation but rather emerge within a constellation of biobehavioral abnormalities, begging the question of 'which came first'. Perhaps these findings are best conceptualized within the framework provided by McEwen, when discussing 'allostasis' as representing a chronic adapative homeostatic state in the face of chronic stress, leading to longstanding deviations in normative biology. The VFD model does have important clinical implications. It suggests that patients who have suffered early-life stress and have developed psychiatric or medical disorders are probably best conceptualized as having incurred damaging effects at multiple levels, both at the level of the central nervous system and in its interaction with the periphery.

Motion Sickness

J R Lackner, Brandeis University, Waltham, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The term 'motion sickness' was originally introduced to provide a nosological category for disorders elicited by exposure to unusual patterns of motion during passive transport, such as on boats and trains (causing seasickness and train sickness). The term came to subsume airsickness as well, and in recent years, simulator sickness, space sickness, and cybersickness (virtual environment sickness). It is now recognized that both space sickness and cybersickness are complex syndromes that include many sensorimotor and postural components in addition to motion sickness. Motion sickness is often equated with nausea and vomiting. However, the signs and symptoms of motion sickness are much broader, involving a wide range of autonomic nervous system activity, primarily of the sympathetic branch. Table 1 lists some of the more prominent features.

The pattern of motion sickness symptom development and expression depends on the nature of the exposure conditions and on an individual's inherent susceptibility. Nearly all persons with normal vestibular function are susceptible to varying degrees, although their susceptibility may differ in different background force levels (*g* levels) for the same pattern of body motion. With relatively unprovocative stimulation, such as gentle rocking, 'head signs' (e.g., headache and drowsiness) may predominate. With more provocative stimulation, such as making head movements during rotation, 'gut signs' (e.g., nausea and vomiting) are more prominent. Motion sickness can be difficult to identify under nonlaboratory conditions when it does not involve prominent pallor or nausea. For example, drowsiness is an early sign of motion sickness during exposure to relatively unprovocative motion stimulation. Individuals with total loss of vestibular function are generally immune to motion sickness and those with unilateral loss are less susceptible than normal persons. Recently, it has been reported that some individuals with total labyrinthine functional loss can be made motion sick by exposure to optokinetic stimulation, albeit their threshold is much higher than that of normal individuals.

Vestibular Function

The vestibular component of the inner ear consists of the semicircular canals and otolith organs. The receptor mechanisms of the three orthogonally oriented canals in each inner ear are influenced by angular acceleration of the head in their planes. They have high resting discharge rates that are increased by ampullopetal deflection and decreased by ampullofugal deflection. The change in discharge rate for natural voluntary head movements is proportional to head velocity. Pairs of canals in the same plane operate in a push–pull fashion and participate in the angular vestibuloocular reflex (VOR). Voluntary fixation of a target to suppress the VOR can result in motion sickness. Exposure to impulsive deceleration from constant velocity rotation leads to a pattern of afternystagmus which has a time constant longer than that of the cupula–endolymph system of the semicircular canals. This phenomenon is referred to as 'velocity storage' and reflects the fact that the oculomotor neurons driving the eyes receive a direct pathway signal from the canals, and an indirect one reflecting integration of the direct pathway signal. This integrated signal is also contributory to the sense of body rotation and displacement with respect to the external surroundings. Integration of the direct pathway signal is suppressed in weightlessness.

The otolith organs are influenced by inertial and gravitational accelerations and give rise to a linear VOR during translation of the body, and ocular counterrolling during tilt of the body relative to gravity. Vertical oscillation of the body alone can give rise to motion sickness and is an important factor in seasickness. The motion sickness response is frequency dependent and is greatest around 0.1–0.2 Hz.

The vestibular nuclei of the brain stem receive projections from the semicircular canals and otolith organs, but also visual, auditory, somatosensory, and proprioceptively related signals and a variety of other afferent signals, including from the cerebellum. They in turn have projections to the oculomotor nuclei, spinal cord, cerebellum, cerebral cortex, and other sites where they participate in a broad range of functions subserving postural and balance control, gaze stabilization, and perception of body orientation and motion. The circuitry is extremely complex, not fully identified, and operates largely automatically, although attentional factors can be contributory. Cortical projections of the labyrinth are to parietal cortex, which is involved in the representation of body orientation.

Modification of vestibular function occurs after injury – for example, half-sided loss of function, exposure to unusual background force level conditions, and during sensory 'rearrangements' that disrupt the compensatory effect of the VOR in maintaining target fixation during voluntary or passive head movements.

Table 1 Diagnostic categorization of different levels of severity of acute motion sickness

Category	*Pathognomonic 16 points*	*Major 8 points*	*Minor 4 points*	*Minimal 2 points*	*AQS*[a] *1 point*
Nausea syndrome	Vomiting or retching	Nausea[b] II, III	Nausea I	Epigastric discomfort	Epigastric awareness
Skin		Pallor III	Pallor II	Pallor I	Flushing
Cold sweating		III	II	I	
Increased salivation		III	II	I	
Drowsiness		III	II	I	
Pain					Headache
Central nervous system					Dizziness Eyes closed > II Eyes open III
Levels of severity identified by total points scored					
Frank sickness (S) >16 points	Severe malaise (M III) 8–15 points	Moderate malaise A (M IIA) 5–7 points	Moderate malaise B (M IIB) 3–4 points		Slight malaise (M I) 1–2 points

[a]AQS, Additional qualifying symptoms.
[b]III, severe or marked; II, moderate; I, slight.

Such modifications usually lead to motion sickness. Over time, however, adaptation generally occurs to restore normal or near-normal function. The extent and time course of adaptation are highly dependent on the exposure conditions, and adaptation is more complete with gradual, rather than abrupt, functional alterations. Such adaptive changes are an important component of the abatement of motion sickness with continued exposure to otherwise provocative situations.

Theories, Mechanisms, and Manifestations

At present, there is no fully adequate theory of motion sickness. Vestibular 'overstimulation' theories have largely been abandoned because, for example, low-frequency linear oscillation, even though it feels gentle, can be more provocative in eliciting symptoms than high-frequency, seemingly intense, stimulation. Variations on 'sensory conflict' theories are currently the most popular explanations of motion sickness. These theories relate the elicitation of sickness to 'conflicts' between the body motion the vestibular system is transducing and that which other senses (e.g., vision) are signaling, or between the motion the canals and otoliths are specifying about ongoing body orientation. Sensory conflict theories have great generality and applicability to circumstances eliciting motion sickness. Almost all such situations involve some form of visual–vestibular or canal–otolith or other form of sensory conflict. However, such theories lack predictive power and cannot identify why some conflicts are provocative and others not, nor why exposure to certain forms of motion, such as linear oscillation, are provocative primarily for specific frequencies, nor why some individuals are susceptible, and others are not, to particular conflicts.

Evolutionary theories of motion sickness emphasize its similarity to a poison response with two primary components, stomach emptying and a stress reaction. From this standpoint, motion sickness leads to emesis, which empties the stomach of ingested poisons and induces immobility, which would decrease the rate of blood circulation of toxins. Dogs have been found to show a profound decrease in susceptibility to many (but not all) emetic drugs after bilateral labyrinthectomy. (Dogs are commonly used in animal studies of motion sickness because of the similarity of their response to motion to that of humans.) Most of the autonomic and endocrine changes occurring during motion sickness do accompany stress responses as well. Removal of the nodulus and uvula, the vestibular projection areas of the cerebellum, renders monkeys insusceptible to motion sickness. It is yet to be determined whether such lesions also eliminate the vomiting response to emetic drugs. How motion sickness could develop evolutionarily to mimic or constitute a poison response remains unclear. The time course of emesis evoked by motion sickness is generally too slow to be of functional significance for ejecting toxins.

Emesis is achieved by the coordinated activity of both smooth and somatic muscles to generate appropriate changes in intra-abdominal and intrathoracic pressures, and opening of the esophageal sphincters. The central nervous system coordinating mechanisms are complex and only recently have become well understood. In severe motion sickness involving multiple bouts of vomiting, alkalosis may develop

because of hydrogen ion loss and may lead to increased renal excretion of potassium bicarbonate, producing a potassium deficiency that can cause muscle weakness, constipation, and cardiac arrhythmias. Sodium loss can lead to hypotension. Antidiuretic hormone release is also increased. The presence of a functioning vestibular system is not necessary for vomiting to be produced, and emesis can be evoked by activation of a variety of peripheral and central afferent mechanisms. Earlier notions of a well-defined 'vomiting center' in the brain stem have not been supported by neurophysiological and neuroanatomical studies, which point instead to a more broadly distributed neuronal representation in the medulla oblongata. The input circuitry controlling emesis is plastic, allowing changes in the sensitivities of other pathways when one pathway is interrupted.

Predicting Susceptibility to Motion Sickness

Motion sickness has been a persistent problem for the military, with air, sea, and land vehicle sickness being ubiquitous operational concerns. Consequently, there have been many attempts to develop both questionnaires and experimental tests of susceptibility to screen for motion sickness. Comprehensive questionnaires developed to screen individuals for susceptibility show that persons reporting multiple experiences of motion sickness are more likely to experience sickness when tested in experimental devices than are individuals without a history of susceptibility. Women more often than men report a past history of motion sickness, and women are also more likely to report having used anti-motion-sickness drugs. Individuals who are classified as highly susceptible on the basis of their questionnaire answers are more likely to have highly susceptible parents or siblings, which may be partially attributable to similar exposure histories. Motion sickness susceptibility may in part be genetically determined, and Asians have been found to be more susceptible than Caucasians.

Motion sickness questionnaires provide a means of identifying that small fraction, about 10% of the population, that is highly susceptible to motion sickness. However, susceptible subjects tend to avoid situations that are likely to elicit motion sickness (e.g., carnival rides or boats). Disadvantages of questionnaires are that it is not possible to determine quantitatively the individual's prior exposure to provocative stimulation, and that most people equate motion sickness with nausea and vomiting, and there are many other symptoms that may accompany motion sickness (e.g., pallor, changes in salivation, sweating, drowsiness, stomach awareness, and stomach discomfort). When a motion sickness questionnaire is being used as a selection or screening device, candidates may not answer truthfully; moreover, questionnaires can provide information about past episodes of motion sickness, but not about the person's ability to adapt to provocative motion or about his or her rate of recovery. Many questionnaires are long and cumbersome and difficult to fill out. However, Golding has developed a short questionnaire that is easy to complete and that has been validated in laboratory assessments of susceptibility. It is likely to serve as the standard in the field of motion sickness studies.

Gender Differences in Susceptibility

Women typically report a greater incidence of motion sickness on questionnaires than do men. It has been questioned whether such reports reflect actual susceptibility differences or, instead, differences in willingness to talk about illness; this is unclear, as is whether in the general population males may have had more experiences in stressful motion environments. Some experimental studies contrasting male and female susceptibility have not found any significant differences. Other studies have found that women are somewhat more susceptible than men are, and that women also vary in their susceptibility, being more susceptible during their menstrual cycle. Other studies have failed to find susceptibility variations related to the female menstrual cycle. An excellent analysis of these issues is provided by Golding.

Laboratory Tests of Motion Sickness Susceptibility

Predicting susceptibility to motion sickness in operational environments from laboratory procedures is very difficult. Susceptibility in one exposure condition may not generalize to another. Although the vestibular system is usually essential for motion sickness, susceptibility is not related to vestibular sensitivity *per se*. Motion sickness can be induced, for example, by motions that stimulate separately or in combination the semicircular canals and otolith organs of the inner ear, moving patterns of visual stimuli, or by the voluntary suppression of reflexive eye movements. Artificial alteration of the effective gain of the vestibuloocular reflex by means of lens systems readily induces symptoms until adaptive compensations are made. Head movements made during passive body rotation produce a bizarre pattern of stimulation of the canals and otolith organs; this pattern, known as Coriolis cross-coupling stimulation, is highly provocative under ground-based conditions, only mildly provocative under weightless conditions,and extraordinarily provocative under conditions of increased background force level (e.g., high-*g* conditions). In weightless conditions, velocity storage

of semicircular canal signals is attenuated, reducing the time constant of vestibular nystagmus and reducing the perception of body angular displacement. As a consequence, head movements out of the axis of passive body rotation are less provocative in weightless environments than in high-force environments.

Almost all nonlaboratory situations that are provocative involve more than one etiological or predisposing factor. Individuals often vary in their susceptibility to these different forms of stimulation. This largely accounts for why it is difficult to generalize from laboratory assessments of susceptibility involving one or a few factors to more complicated, natural exposure situations, which can involve both passive and active head and body movements and voluntary locomotion. However, persons who are extremely sensitive to one type of motion exposure (e.g., angular acceleration) tend to be very sensitive to others as well. The highly susceptible constitute about 5–10% of the population. Golding has raised the possibility that there may be a general motion sickness susceptibility factor as well as specific factors related to susceptibility for particular types of provocative motion. This perspective helps explain why there can be such variability in susceptibility across sometimes seemingly similar exposure conditions.

It has been especially difficult to predict susceptibility to space motion sickness. In spaceflight, in addition to 'lifting' of the tonic 1 *g* acceleration of earth gravity (owing to the free-fall conditions), the entire pattern of sensorimotor control and support of the body is changed. Such altered sensorimotor demands during head and body movement are provocative in themselves when mimicked under terrestrial conditions. It is not surprising, therefore, that reports of motion sickness are also commonplace with the use of virtual reality devices, which can produce alterations in visuomotor control and apparent self-motion. Such cybersickness can be as disruptive during exposure to virtual environments, as space sickness is in space flight. The 'sopite syndrome' is an important aspect of space motion sickness and of cybersickness (from the Greek *sopor*, for 'drowsiness'). It refers to the tiredness, mood swings, lack of initiative, and apathy that can develop and persist during prolonged exposure to relatively unprovocative situations. Under some conditions, and for some individuals, the sopite syndrome can be the primary or sole expression of motion sickness. Its presence can be difficult to identify in nonlaboratory settings.

Preventing and Treating Motion Sickness

Prevention of motion sickness and recovery from motion sickness can be complex. A small percentage of normal individuals are highly susceptible for nearly all exposure situations, a small percentage are highly insusceptible, and most are in between. The best prevention for the highly susceptible is avoidance. For other individuals, spaced exposure of short duration can lead to a buildup of adaptation to the provocative situation. This is especially effective if only minor symptoms of motion sickness are allowed to develop before terminating each exposure period. Alternatively, incremental exposure to gradually increasing levels of provocative stimulation (e.g., making head movements during exposure to passive body rotation at higher and higher rotation velocities) can allow adaptation to be achieved without motion sickness being elicited, even at stressor levels that, if achieved in a single step, would be intolerably provocative.

Behavior modification techniques, such as autogenic feedback, have been promoted as a way of preventing motion sickness. In autogenic feedback training, the individual is trained to detect changes in heart rate, respiration, skin temperature, and other parameters and learns how to prevent alterations in these parameters. The notion is that preventing the physiological changes associated with motion sickness will prevent the development of motion sickness. One comprehensive study, with proper controls, evaluated the efficacy of autogenic feedback training. Test participants were initially required to make head movements during passive body rotation to determine baseline susceptibility. They were then divided into three groups, matched for susceptibility. One group received autogenic training with accurate feedback about their autonomic nervous system responses, one control group received false feedback, and another control group received no treatment. Autogenic feedback training did not enable test group members to withstand exposure to provocative stimulation any better than was seen in the two control groups. Acupressure devices, worn on the wrist, are available in various forms commercially, and, like autogenic feedback, are proposed as a way of preventing motion sickness. There is no scientific evidence to support such claims. Such devices may, however, have a placebo effect in individuals who are convinced that they work. Placebo effects are commonplace in experimental studies of anti-motion-sickness drug efficacy, in which placebo controls are essential.

Some studies have reported a close correlation between tachygastria – electrogastrogram activity elevated above the normal 3 cycles per minute (cpm) rate, to 6–12 cpm – and motion sickness, raising the possibility that preventing tachygastria could suppress motion sickness. Controlled studies have shown, however, that tachygastria can occur before, during, or after symptoms have developed or even

abated. Tachygastria, in fact, appears to be most correlated with anxiety and apprehension. Importantly, it has been found that individuals remain abnormally sensitive to provocative motion for 3–4 h after all overt symptoms seem to have abated following provocative motion testing.

A variety of drugs are available to reduce susceptibility to motion sickness. Over-the-counter drugs with some efficacy include dimenhydrinate (Dramamine), meclizine (Bonine), and cyclizine (Marezine). The prescription transderm patch can provide protection for 24 h or more. The most effective anti-motion-sickness drugs, including the relatively weak ones mentioned here, have adverse side effects, generally including drowsiness and dry mouth. More potent drugs and drug combinations include scopolamine (often used in association with amphetamine, 'Scopdex,' to counteract sleepiness) and promethazine (often with ephedrine). In cases of fully developed, severe motion sickness, intramuscular injections of scopolamine or promethazine may be necessary to provide relief. Effective antiemetic drugs have anticholinergic, antihistaminic, or sympathomimetic properties; however, not all of the central sites of drug action are understood, and these drugs tend to be relatively unselective in their effects. New families of receptor subtypes are being discovered that open the possibility of developing anti-motion-sickness drugs that block only certain types of neurotransmitter binding sites, thereby leading to fewer undesirable side effects.

Distribution and Neurotransmitter Content of Sensorimotor Nerves

Sensorimotor nerves are a subpopulation of nociceptive primary afferent nerves, which have a dual sensory (afferent) and motor (efferent) function (Figure 1). They comprise predominantly unmyelinated, slowly conducting C-fibers with small-diameter cell bodies, together with a smaller population of myelinated, fast-conducting Aδ-fibers with large-diameter cell bodies. Their cell bodies lie in dorsal root, trigeminal, and nodose ganglia. Each sensorimotor nerve has a single axon which divides at the cell body into a centrally projecting and peripherally projecting branch. The central branch forms synapses in the central nervous system (CNS) with second-order sensory neurons. The peripheral branch, which may have a number of branches or collaterals, terminates in its target organs and tissues in the periphery. In the periphery, there are no specialized synapses between the nerve and the target tissue; instead, neurotransmitters are released from specialized swellings of the axon known as varicosities.

In the CNS, glutamate, aspartate, and adenosine 5′-triphosphate (ATP) are the principal neurotransmitters of sensorimotor nerves, being released along with other neurotransmitters, including the peptides calcitonin gene-related peptide (CGRP), substance P (SP), and neurokinin A (NKA). In the periphery, the archetypal sensorimotor neurotransmitters are CGRP, SP, and NKA. The peptides are synthesized in cell bodies in sensory ganglia and transported to the periphery. There is considerable overlap in the expression of CGRP and SP, consistent with their being cotransmitters in sensorimotor nerves, although both neurotransmitters are not always coexpressed and/or coreleased. There is evidence that a number of other peptides and nonpeptides (e.g., vasoactive intestinal polypeptide, ATP, and bombesin) are cotransmitters in the peripheral terminals of sensorimotor nerves.

Classically, the distribution of sensorimotor nerves in tissues has been studied by mapping immunoreactivity for sensory neuropeptides (mainly CGRP and SP) and, importantly, by showing that the immunoreactivity is not present in experimental animals treated with capsaicin to destroy selectively C- and Aδ-fibers. Functional studies examining tissue responses to stimulation of sensorimotor nerves and measurements of neurotransmitter release (mainly CGRP and SP) have confirmed the widespread distribution of sensorimotor nerves in peripheral tissues. Collectively, these provide evidence for sensorimotor innervation of a variety of organs and tissues, including the heart, blood vessels (including those of skin), smooth muscle of the bladder and airways, skeletal muscle, and gastrointestinal tract.

Sensory neuropeptides may be differentially expressed in the peripheral endings of C- and Aδ-fibers. For example, in trigeminal sensorimotor nerves innervating cranial blood vessels, SP is contained predominantly in C-fibers, whereas CGRP is contained in both C- and Aδ-fibers. In general, CGRP mediates vasodilatation and SP mediates plasma extravasation. Accordingly, low-intensity, brief electrical stimulation, which recruits only trigeminal Aδ sensorimotor nerves, causes CGRP release and neurogenic vasodilatation, whereas only the additional activation of C-fibers, by high-intensity sustained electrical stimulation, leads to a release of both SP and CGRP from activated C-fibers, which in turn causes plasma extravasation as well as vasodilatation (neurogenic inflammation). Similarly, there is evidence in skin that Aδ-fibers are involved in vasodilatation but not plasma extravasation, indicating that these Aδ-fibers also contain predominantly CGRP and not SP.

The use of selective antagonists has shown a differential role of various sensorimotor neurotransmitters in different tissues. For example, the CGRP receptor antagonist CGRP[8–37] blocks sensorimotor neurogenic vasodilatation in mesenteric arteries, whereas the NK1 selective antagonist CP 96 345 blocks sensorimotor neurogenic contraction in the iris (indicating involvement of SP/NKA).

Activation of Sensorimotor Nerves

Sensorimotor nerves are a subpopulation of nociceptive primary afferent nerves (not all nociceptive primary afferents have an efferent/motor function). The majority are polymodal nociceptors, being activated by a variety of stimuli including noxious levels of pressure, heat and pH, and a variety of agents (classically by the vanilloid capsaicin), acting through specific cell surface receptors. When the peripheral terminals of sensorimotor nerves are activated by one of these noxious stimuli, there is a release of neurotransmitter at the central terminals, which elicits pain and triggers avoidance/protective reflexes. Concomitantly, neurotransmitter is released from the peripheral terminals of sensorimotor nerves in an efferent or motor function, which leads, in general, to the promotion of tissue recovery and repair.

The peripheral release of sensory neurotransmitter can take place through different mechanisms

Figure 1 Dual role of sensorimotor nerves. As their name suggests, sensorimotor nerves have a dual function, being able to convey information about a stimulus to the central nervous system and being able to release neurotransmitter (typically neuropeptides) from their peripheral endings to elicit a motor or efferent function. The motor function can be elicited by three mechanisms: direct release of neurotransmitter from the same terminal that is activated by the stimulus, release of neurotransmitter from a collateral ending following antidromic conveyance of the impulse in the axon reflex, and electrical stimulation of the nerve trunk to cause antidromic activation (not shown). Adapted from Holzer P (1992) Peptidergic sensory neurons in the control of vascular functions: Mechanisms and significance in the cutaneous and splanchnic vascular beds. *Reviews of Physiology, Biochemistry, and Pharmacology* 121: 49–146.

(Figure 1). There may be a direct and local release of sensory neuropeptides from the same peripheral terminals that are activated by the stimulus. Because this does not involve axonal conveyance of impulses, it is insensitive to tetrodotoxin blockade of voltage-gated sodium channels. Another mechanism involves a release of neuropeptides at varying distances from the stimulus site that is due to antidromic conveyance of the impulse to collateral terminals (axon reflex) and accordingly is tetrodotoxin sensitive. Its physiological manifestation can be seen in the flare response in skin, a spread of increased blood flow some distance outward from the stimulus, which can be blocked by capsaicin defunctionalization of sensorimotor nerves. The efferent function of sensorimotor nerves can also be elicited by antidromic activation of the nerve trunk by electrical stimulation. This effect is not mimicked by periaxonal administration of capsaicin (which locally defunctionalizes the nerves) and is sensitive to blockade by tetrodotoxin.

Sensorimotor nerves express a number of different cell surface receptors through which both their afferent and efferent functions are activated. The receptor which has undoubtedly received the most interest, because of its key role in nociceptive signaling, is the vanilloid type 1 receptor (or TRPV1), which is part of the transient receptor potential (TRP) superfamily of ion channels. The other TRPV family members are thermosensitive nonselective cation channels (TRPV1, TRPV2, TRPV3, and TRPV4) and calcium selective channels involved in calcium absorption and reabsorption across epithelia (TRPV5 and TRPV6). Only TRPV1 is activated by capsaicin, a vanilloid and naturally occurring pungent compound found in hot peppers, and by the structurally related plant-derived compound resiniferatoxin. Because TRPV1 receptors are not expressed by most other autonomic neurons, motorneurons, and central neurons, this confers on capsaicin a remarkable (but not exclusive) selectivity for primary afferent C- and Aδ-fibers and has led to the widespread use of this agent in the study of the physiology and pharmacology of sensorimotor nerves. TRPA1 is a novel channel expressed on sensorimotor nerves that is activated by tetrahydrocannabinol and sulfur compounds derived from mustard oil and garlic, and it mediates pain and vasodilatation.

Capsaicin and other stimuli of TRPV1 act at TRPV1 receptors to cause depolarization, calcium influx, and consequent neurotransmitter release from sensorimotor nerves. Following activation, capsaicin can block sensorimotor nerve conduction and neurotransmitter release through a combination of effects including TRPV1 desensitization and blockade of voltage-gated Ca^{2+} channels. Used chronically, capsaicin is neurotoxic. These effects have been widely utilized in the identification and characterization of sensorimotor

nerves. Blockers of TRPV1, including ruthenium red, 5′-iodoresiniferatoxin, 6-iodonordihydrocapsaicin, and capsazepine, have also been useful in characterizing TRPV1 responses and the properties of sensorimotor nerves.

TRPV1 receptors act as polymodal nociceptors and confer on sensorimotor nerves their sensitivity (their afferent and efferent responsiveness) to specific noxious stimuli. In addition to capsaicin, TRPV1 receptors, and hence sensorimotor nerves, are activated by noxious heat (threshold of approximately 43 °C), acidosis (pH < 6) (which may occur upon ischemia, inflammation, muscle exercise, or damage to the stomach mucosal barrier), resiniferatoxin, phenylacetylrivanil, olivanil, allicin, camphor, some eicosanoids (e.g., 12-HPETE, 15-HPETE, 5-HETE, and leukotriene B_4), and certain endocannabinoids (anandamide, *N*-arachidonoyl-dopamine, and *N*-oleoyl-dopamine). TRPV1 receptors can be sensitized by a variety of mechanisms, including phospholipase C-mediated hydrolysis of PIP_2; PKA-mediated phosphorylation, which prevents rapid desensitization of TRPV1; PKB-mediated phosphorylation, which enhances the probability of TRPV1 channel gating; and mild acidosis (pH 6–7), which does not itself activate the receptor but lowers the threshold for TRPV1 activation by heat.

Sensorimotor nerves express a number of excitatory receptors in addition to TRPV1. 5-Hydroxy tryptamine (5-HT), which is released from activated platelets and mast cells, acts via 5-HT_3 receptors to activate sensorimotor nerves, and 5-HT_3 receptor antagonists are anti-inflammatory, analgesic, and block 5-HT-evoked reflexes. Histamine, released from mast cells, acts principally via H_1 receptors to activate sensorimotor nerves. Bradykinin is a locally produced blood plasma protein which has a number of proinflammatory effects including stimulation of sensorimotor nerves, leading to pain and reflex responses (largely through B_2 receptors), and CGRP and tachykinin release, leading to motor effects including plasma protein extravasation in skin and airways and to positive chrono- and inotropic effects in isolated atria. Activation of TRPV1 can cause sensorimotor nerves to become unresponsive to the previously mentioned stimuli.

Arachidonic acid metabolites are key players in inflammation because they are produced by other inflammatory mediators and can activate sensory nerves both via TRPV1 (12-HPETE and 15-HPETE) and independently of TRPV1 (e.g., prostacyclin and lipoxin A_4). They can also potentiate, by causing sensitization, both the sensory and the efferent functions of sensorimotor nerves. Platelet-activating factor is a lipid mediator of inflammation that activates sensorimotor nerves. Sensorimotor nerves express nicotinic receptors that mediate a release of tachykinins and/or CGRP, which accounts for the motor effects of acetylcholine in a variety of tissues, including heart, bronchus, and lung. Other substances shown to activate sensorimotor nerves include *N*-formyl-methionyl-leucyl-phenylalanine (FMLP), interleukin-1, neurotensin, nitric oxide, γ-aminobutyric acid (GABA; via $GABA_A$), adenosine (via A_2 receptors), ouabain, and Ca^{2+}.

ATP can be released from many different types of cells during normal processes and tissue injury, and there is some evidence that it can be released as a neurotransmitter from both the central and the peripheral terminals of some sensorimotor nerves. ATP and its analog cause depolarizing currents in dorsal root ganglion (DRG) and trigeminal neurons, an action mediated via $P2X_3$ homomeric receptors and/or $P2X_{2/3}$ heteromeric receptors. In DRG cells, the depolarization can lead to glutamate and peptide release. ATP also excites the peripheral terminals of C- and Aδ-nociceptive afferents and elicits pain responses *in vivo*. However, ATP has not been shown to be effective at evoking an efferent function at the peripheral terminals of sensorimotor nerves. Indeed, a lack of involvement of capsaicin-sensitive sensorimotor nerves has been shown in functional responses to ATP and α,β-methylene ATP (a P2X-selective ligand) in mesenteric arteries. Similarly, in atria ATP does not activate the efferent function of sensorimotor nerves but, rather, inhibits, via adenosine P1 receptors, the positive inotropic efferent function caused by transmural stimulation of sensorimotor nerves.

Inhibition of Sensorimotor Nerves

A number of agents inhibit the release of sensorimotor neurotransmitter at the peripheral and central terminals. Inhibitory neuromodulators include opioids, noradrenaline (via α_2-adrenoceptors), neuropeptide Y (NPY) (via Y_2 receptors), adrenomedullin, galanin, corticotrophin-releasing factor, and somatostatin. Adenosine acts via A_1 and A_{2A} receptors found centrally, and A_1 receptors found peripherally, to inhibit pain and sensorimotor neurotransmitter release. An adenosine receptor-independent inhibitory modulation through direct binding of adenosine and its analogues to TRPV1 has been described. Thus, adenosine, which can be formed by ectoenzymatic metabolism of ATP, provides a potential brake for the P2X receptor-mediated excitatory actions of ATP on sensorimotor neurotransmission. An important source of ATP, noradrenaline, and NPY is sympathetic nerves, from which they are released as cotransmitters, suggesting

that interactions between sympathetic and sensorimotor nerves may occur.

Some substances that are able to inhibit prejunctionally sensorimotor neurotransmission also have stimulatory effects (described previously), which is explained by actions at their different receptor subtypes. Prejunctional inhibitory effects of histamine (via H_3 receptors), 5-HT (via 5-HT_1-like receptors), and GABA (acting via $GABA_B$ receptors) on sensorimotor neurotransmission have been shown. Whether a substance excites or inhibits sensorimotor neurotransmission may depend on the relative affinities of the different receptor subtypes involved.

Certain cannabinoids can elicit both excitatory and inhibitory effects on sensorimotor nerves. Anandamide and methanandamide inhibit capsaicin-evoked plasma extravasation in rat skin via CB_1 receptors. These cannabinoids are also ligands at TRPV1, and virtually all TRPV1-expressing DRG neurons express CB_1. Thus, cannabinoids are able to mediate opposite actions at sensorimotor nerves, namely excitation via CB_1 and inhibition via TRPV1. In rat skin and DRG neurons, anandamide is more potent at CB_1 than at TRPV1 receptors, so low doses of anandamide inhibit neurotransmission, whereas higher doses are excitatory in a TRPV1-dependent manner, the latter possibly involved in sensorimotor nerve excitation in pathophysiological conditions. Similar potencies of anandamide at recombinant CB_1 and TRPV1 receptors suggest that other more subtle forms of differentiation might exist, perhaps involving relative rates of activation and/or inactivation of the receptors or differential modulation by factors such as pH and second messengers. Inhibitory effects of cannabinoids on sensorimotor neurotransmission in mesenteric arteries appear to be mediated via CB_1 and non-CB_1, non-CB_2 receptors.

Prolonged activation of TRPV1, classically by capsaicin, inhibits prejunctionally sensorimotor neurotransmission through a combination of effects, including TRPV1 desensitization and blockade of voltage-gated Ca^{2+} channels.

Inhibition of sensorimotor neurotransmission can be achieved through the use of selective antagonists to block the postjunctional receptor and, therefore, the actions of the released sensory neurotransmitter on its target tissue. This has provided important information about the roles of sensorimotor nerves and of the identity of the sensorimotor neurotransmitter(s) involved in the motor response.

Roles of Sensorimotor Nerves

The primary role of sensorimotor nerves appears to be as a system of defense acting against challenges to homeostasis. They are ideally designed for this purpose because their sensory role allows them to convey information to the central nervous system about the stimulus and to elicit reflexes to take evasive action if necessary, whereas the motor component promotes tissue recovery and repair. Many of the stimuli activating sensorimotor nerves are mediators of inflammation, which accounts for the involvement of sensorimotor nerves in the inflammatory response ('neurogenic inflammation'). This was first described in skin, and in this process sensorimotor nerves both activate and are activated by cells of the immune system through the actions of their neurotransmitters/mediators. However, there is evidence for wider roles of sensorimotor nerves under different physiological as well as pathophysiological conditions (**Figure 2**). A dissociation of the pain and cardiovascular effects of sensorimotor nerves has been reported, in that cardiovascular effects can be elicited with stimuli that are subthreshold for pain stimulation. This suggests that sensorimotor nerves may operate at different levels according to the duration or intensity of stimulation, with an efferent-only function operating under physiological conditions and a dual sensorimotor function under pathophysiological conditions. In addition, sensorimotor nerves in some mesenteric arteries have synaptic contacts with enteric neurons which allow them to respond to physiological stimuli (cholycystokinin, bile, and distension) of the intestine. Finally, there may be an ongoing release of sensorimotor neurotransmitter that is involved in trophic effects.

In neurogenic inflammation, sensorimotor nerves convey information about the inflammatory response to the central nervous system and promote recovery and tissue repair by causing arteriolar vasodilatation, an increase in vascular permeability, degranulation of mast cells, and effects on leukocytes and fibroblasts. The arteriolar vasodilatation is caused mainly by sensory nerve CGRP, a potent vasodilator, and the increase in blood flow promotes the delivery of phagocytic cells to the affected area. Ultrastructural evidence suggests that a close relationship exists between sensorimotor nerves and mast cells, and that a bidirectional functional interaction exists between them. SP released from sensorimotor nerves causes a release of histamine, 5-HT, prostaglandins, and nitric oxide from mast cells. The increase in vascular permeability that occurs is caused by SP and other tachykinins released from sensorimotor nerves, as well as by mast cell histamine. This allows antimicrobial chemicals and clotting proteins to seep into the interstitial space of the damaged tissue ('plasma protein extravasation'). Histamine, acting via H_3 receptors on sensorimotor nerves, can act as

Figure 2 Motor/efferent function of sensory nerves. Calcitonin gene-related peptide (CGRP), substance P (SP), and neurokinin A (NKA) are coreleased from stimulated sensorimotor nerves to elicit a variety of different effects on the target tissue innervated. There are a number of different stimuli of sensorimotor nerves, including inflammatory mediators released from mast cells, macrophages, and other leukocytes. Following stimulation of sensorimotor nerves, the released sensory neurotransmitters evoke motor responses which lead to the promotion of tissue recovery and repair and also restoration of homeostasis.

part of an inhibitory feedback loop on sensorimotor neurotransmission. However, the functional interactions between mast cell mediators and sensory nerves are complex because prostaglandins, for example, can sensitize sensory nerves. Interactions can also take place between sensorimotor neurotransmitters. For example, although CGRP does not induce an increase in vascular permeability, it facilitates the SP-induced increase in permeability. Both CGRP and SP have effects on monocytes/macrophages, including a release of cytokines, prostaglandins, leukotrienes, and thromboxanes, which in turn affect vessel diameter, permeability, and sensorimotor nerve excitability (typically causing sensitization).

The study of sensorimotor nerves in a range of blood vessels outside of skin has allowed a fuller understanding of their roles in the cardiovascular system. This has confirmed that sensorimotor neurogenic vasodilatation is mediated principally by CGRP. Accordingly, electrical stimulation of nonadrenergic, noncholinergic nerves in certain blood vessels produces a long-lasting vasorelaxation that is abolished by capsaicin, blocked by CGRP receptor antagonism, and mimicked by exogenous CGRP (and capsaicin). Moreover, CGRP release can be detected during vasodilatation due to electrical stimulation of capsaicin-sensitive nonadrenergic, noncholinergic perivascular nerves. SP and other tachykinins do not appear to have a role in sensorimotor vasodilatation. In many tissues and organs, parasympathetic nerves provide a functional counterpart to the actions of sympathetic nerves. Most blood vessels, however, are not innervated by parasympathetic nerves. It seems as though in this case vasodilator sensorimotor nerves provide a neurogenic counterpart for vasocontractile sympathetic nerves. A decrease in vascular sensorimotor innervation and motor function (nonadrenergic, noncholinergic vasodilatation) has been shown in animal models of aging and hypertension.

In the heart, capsaicin is a potent cardiostimulant mediating positive inotropic and chronotropic effects due to activation of sensory nerves. CGRP, SP, and NKA are coreleased from cardiac sensory nerves, and CGRP mimics the actions of capsaicin. Cardiac sensorimotor nerves are activated by several mediators of inflammation and ischemia.

Activation of reflexes by sensorimotor nerves has been shown *in vivo*. In experimental models, administration of capsaicin into the hindlimb induces a fall in blood pressure and an increase in ventilation that is blocked by capsaicin pretreatment and the vanilloid antagonist capsazepine, indicating an action at TRPV1 on sensorimotor nerves. The cardiovascular and respiratory responses to capsaicin were blocked by sectioning of the femoral and sciatic nerves, indicating the involvement of a reflex action. Additional local effects of capsaicin at TRPV1 in the femoral artery, involving the efferent function of sensory nerves, are likely. The type of response is likely to be dependent on the dose of capsaicin because low doses, which may be more physiologically relevant, may activate the efferent function of sensorimotor nerves and cause local femoral vasodilatation without eliciting cardiovascular reflexes.

Sensorimotor nerves are present in the genitourinary and gastrointestinal tracts and can be activated by distension as well as chemical stimuli. Activation of sensorimotor nerves causes contraction and relaxation of smooth muscle in ureter. In the iris sphincter, electrical stimulation evokes large, slow contractions which are capsaicin sensitive and partly blocked by an NK1 antagonist. Activation of sensorimotor nerves in the airways mediates bronchoconstriction and protective reflexes such as coughing and wheezing. Tachykinins can cause bronchus constriction, airway edema, and mucus secretion. Capsaicin pretreatment prevents the induction of airway hyperresponsiveness in an experimental model of asthma and attenuates antigen-induced bronchospasm.

There may be an ongoing basal release of neurotransmitters from the peripheral terminals of sensorimotor nerves and these may be involved in trophic effects. In wound healing, SP, NKA, and CGRP stimulate proliferation of endothelial cells, smooth muscle cells, and skin fibroblasts, whereas destruction of capsaicin-sensitive afferents reduces survival of skin flaps and leads to the appearance of skin wounds. These trophic effects of sensorimotor nerves may occur in the normal physiological control of body function.

Motor Control of Feeding and Drinking

Organization of Feeding

Feeding behavior is commonly divided into appetitive and consummatory phases. The appetitive phase of feeding, seeking out and finding food, is highly variable. We can, for example, make elaborate dinner plans and travel great distances to find our favorite restaurant, or simply stumble into the kitchen and open a can of soup. Equally diverse are the antecedents or coincidents of appetitive behavior, which involve a vast array of neural and hormonal signals reflecting metabolic need or surfeit, and the subsequent activation of hypothalamic pathways that lead to the search for food. Habits, time of day, and social pressure further induce one to eat. However, once food is in the mouth, the behaviors exhibited are far less variable, as one need only reduce the food to a size commensurate with swallowing, perhaps pausing long enough to enjoy the flavor, before propelling it toward the stomach. In comparison to the vast array of sensory and regulatory signals associated with body weight regulation or appetitive behavior, the highly stereotyped motor actions of mastication, licking, suckling, and swallowing are guided by a considerably more restricted set of gustatory and orotactile receptors.

Consummatory behavior can be subdivided based on behavioral, cinefluorographic, and electromyographic analyses. Although highly species specific, there are behavioral commonalities. Thus, the consummatory phase of eating begins with ingestion (putting food in the mouth), followed by transport of the bolus to an interdental position for mastication, and followed by a further transport phase to the back of the tongue for swallowing. Mastication can be further subdivided into a fast-closing phase that ceases when food makes contact with the bolus, at which point there is a slow-closing phase. Subsequent jaw opening begins with a slow jaw-opening phase followed by a fast jaw-opening phase. The act of swallowing is subdivided into oral, pharyngeal, and esophageal phases.

The seemingly simple motor problem of transporting food from the front of the mouth to the stomach belies an underlying complexity of coordination among a large number of muscles. Although mastication/licking and swallowing are inextricably linked during eating, sharing muscles of the tongue and jaws, historically they have been studied largely independently. This view is beginning to change as it is recognized that the generation of these behaviors does not derive from entirely dedicated circuits, but rather from multifunctional networks coordinating other oral motor behaviors, including respiration and, perhaps, even vocalization. Nevertheless, herein, the discussion will proceed from the perspective of acute neurophysiological studies in which mastication/licking and swallowing appear to have relatively distinct, spatially separate brain stem circuitry.

Mastication and Licking

The rhythmic consummatory actions of mastication, licking, and swallowing are organized by central pattern generators. By definition, this means that the critical timing information necessary to affect motor pattern switching (e.g., the transition from jaw opening to jaw closing) is not of peripheral origin. Rather, rhythmic jaw opening and closing can be centrally elicited by electrical brain stimulation (EBS) or pharmacological stimulation in select brain areas, and these rhythmic patterns can be induced in the absence of peripheral feedback following selective deafferentation or paralysis. Because mastication/licking and swallowing can be elicited in decerebrate preparations, the fundamental motor patterns are organized in the lower brain stem. However, there are intimate connections between brain stem preoromotor sites and forebrain sites involved with metabolic regulatory function, including the hypothalamus, circuits involved with motivation and reward (such as the nucleus accumbens and striatum), and cortical circuits mediating voluntary movements. Sensory feedback from intraoral gustatory and somatosensory fibers further modulates the motor pattern. Also, the motor neurons cannot be excluded from active participation in pattern generation. Although central pattern generators for mastication/licking and swallowing are not organized within the motor nuclei, oromotor neurons are not simply passive recipients of excitatory and inhibitory inputs. Rather, intrinsic membrane properties of the motor neurons facilitate rhythmic bursting behavior.

Muscles

Muscles of mastication The muscles of mastication are divided into jaw-openers (mandible depressors) and jaw-closers (mandible elevators); however, natural masticatory movements are rarely so simple. In humans, the mandible rotates forward during

opening and the temporomandibular joint allows lateral movements as well. Muscles that depress the mandible and thus open the jaw include the anterior digastric, mylohyoid, and inferior head of the lateral pterygoid. Jaw-closer muscles consist of the masseter, temporalis, medial pterygoid, and superior head of the lateral pterygoid. Because the jaw-closing muscles do most of the work of chewing during the closing powerstroke, these muscles are larger with more motor units.

The muscles of mastication show specializations indicative of their specific roles during chewing. For example, only the jaw-closing muscles are endowed with muscle spindles. Efferent feedforward to the intrafusal fibers of these spindles means that when the jaw-closing muscles meet resistance as they contact a food bolus, intrafusal fibers will become momentarily stretched in relation to their extrafusal counterparts. This stretch initiates a jaw-closing reflex via mesencephalic trigeminal nucleus afferents; this reflex monosynaptically further excites jaw-closing motor neurons, and thus facilitates the powerstroke. A (minimally) disynaptic jaw-opening reflex serves a different function. Unlike jaw-closing motor neurons that are centrally inhibited during the jaw-opening phase of mastication, jaw-openers are not subject to inhibition during jaw closing. This lack of inhibition on jaw-opener motor neurons allows a protective jaw-opening reflex to be initiated by high-threshold nociceptors, should, for example, the (sharp) teeth slide off a food bolus and make contact with the soft tissues of the mouth. In further evidence of specialization, the muscles of mastication have a greater number of hybrid isoforms of contractile proteins that endow them with intermediate contraction speeds and fatigue resistance, compared with muscles of the leg or trunk. In particular, the jaw-closing muscles, which do most of the work associated with mastication, have a larger number of slow and hybrid muscle isoforms, compared with jaw-opening muscles. Jaw opening is a relatively ballistic movement that is not against a load, and consequently relies on myosin heavy-chain isoforms (e.g., MHC-IIA) with fast conduction and fatigue-resistant qualities.

Lingual muscles The lingual muscles are divided into those intrinsic to the body of the tongue (affecting tongue shape), and the extrinsic tongue muscles with bony insertions (affecting tongue position). Intrinsic muscles include the superior and inferior longitudinal muscles in which fibers are parallel to the long axis of the tongue, vertical muscles that are perpendicular to the long axis, and transverse muscles that course across the breadth of the tongue. Of the extrinsic muscles, the genioglossus is the major lingual protrudor, and the hyoglossus and styloglossus muscles are the major lingual retractors. The geniohyoid is not, strictly speaking, a lingual muscle, but its contraction against the hyoid bone also functions to protrude the tongue. The tongue is remarkably flexible and serves prehensile actions in some species. This flexibility derives, in part, from the synergy between intrinsic and extrinsic muscles. The hydrostatic theory of lingual action makes clear this synergistic action. Stated simply, the tongue is considered a closed bag. Thus, contraction of the intrinsic longitudinal muscles will shorten the body of the tongue and facilitate retraction if coactivated with the styloglossus and hyoglossus muscles. Likewise, contraction of the vertical and horizontal fibers will lengthen the tongue and facilitate protrusion, together with the genioglossus and geniohyoid.

As with the muscles of mastication, there is specialization of muscle fiber phenotypes. The anterior tongue, which is composed exclusively of intrinsic fibers, has a large proportion of MHC-IIA fast fibers. The posterior tongue, in contrast, has many slow-contraction MHC-I fibers as well as hybrid isoforms. There are a small number of muscle spindles within the lingual muscles, but whether they provide monosynapatic input to hypoglossal motor neurons is unclear, and a role in rhythmic protrusion and retraction has not been demonstrated. Lingual reflexes in general play important protective roles, such as protecting the tongue from the teeth during chewing. Other muscle groups that contribute to ingestive oromotor behaviors include the posterior belly of the digastric (innervated by the accessory facial nucleus) and the obicularis oris and buccinator and zygomatic muscles (innervated by the facial nucleus) that position food within the mouth and form a seal to facilitate suckling or drinking.

Motor Nuclei

Trigeminal The motor neurons innervating the muscles of mastication are myotopically organized within the motor trigeminal nucleus (**Figure 1(a)**). Jaw-closer motor neurons that constitute the majority of the motor neurons are dorsomedial to those innervating the jaw-openers. During mastication, jaw-closer and jaw-opener motor neurons receive alternating waves of excitatory glutamatergic input. In addition, during the jaw-opening phase of mastication, jaw-closer motor neurons are under phasic glycinergic inhibition. Such inhibition may dampen jaw-closer reflexes initiated by passive stretching of muscle spindles in jaw-closer muscle fibers, thus making for a smoother and more rapid widening of the mandible. The membrane properties of trigeminal motor neurons have been studied in detail by SH Chandler's group. In the presence of serotonin, trigeminal motor neurons

Coronal sections adapted from Paxinos G and Watson C (2005) *The Rat Brain in Stereotaxic Coordinates*, 5th edn. Amsterdam: Elsevier.

display plateau potentials and rhythmic bursting behavior, produced by conductance changes in L-type calcium channels. The membrane properties of these motor neurons are further dependent on Ca^{2+}-dependent K^+ channels and Na^+/K^+-ATPase pump currents, which regulate burst termination during the afterhyperpolarization. Serotonergic input to the motor trigeminal nucleus comes from brain stem raphe nuclei and could thus facilitate rhythmical bursting via these intrinsic motor neuron membrane properties to augment excitatory phasic input coming from a central pattern generator.

Hypoglossal The hypoglossal nucleus controls tongue movement and is myotopically organized with lingual retractor motor neurons dorsal and protrudor motor neurons ventral (Figure 1(c)). Motor neurons controlling intrinsic lingual muscles are located along the midline of the nucleus. The nucleus is further spatially organized such that intrinsic muscle motor neurons controlling the tip of the tongue are located caudally toward the spinal cord and more posteriorly located extrinsic lingual muscles innervated by motor neurons rostral within the nucleus (i.e., the 'motor map' is reverse-oriented, with the tip toward the spinal cord). Hypoglossal motor neurons do not show phased inhibitory currents during electrical brain stimulation-induced rhythm movements. The implication is that they receive primarily excitatory inputs during behaviors such as licking.

Reticular Formation

The largest concentration of preoromotor neurons is in the brain stem reticular formation (RF), and it is all but certain that these neurons are important elements in a central pattern generator for mastication/licking. These preoromotor neurons are concentrated in the intermediate zone of the medullary reticular formation (IRt), but significant numbers of preoromotor interneurons are also found further lateral in the parvocellular RF (PCRt), as well as in regions of the RF immediately adjacent to the oromotor nuclei (Figure 1). The significance of the IRt/PCRt substrate is evident from behavioral pharmacology studies. Consummatory licking is reduced or eliminated following focal RF infusions of the γ-aminobutyric acid ($GABA_A$) agonist muscimol or excitatory amino acid antagonists, but appetitive responses such as approach and posturing to drink from the water bottle are not affected.

Neurophysiological evidence also indicates that this RF substrate provides excitatory and inhibitory interneurons that are essential to the normal functions of the oromotor nuclei. A majority of these premotor neurons are glutamatergic, with a relatively

smaller number of GABA-containing neurons. Neurons in the IRt/PCRt are rhythmically active during both natural consummatory behavior or following EBS, and three distinct classes of premototrigeminal interneurons have been identified: excitatory interneurons with projections to (1) jaw-opener or (2) jaw-closer motor neurons, and (3) inhibitory interneurons with projections only to jaw-closer motor neurons. Similar populations of excitatory interneurons to the hypoglossal nucleus have been proposed. Neurons in the IRt/PCRt thus have the necessary connectivity to be considered important pattern-generating neurons for mastication/licking. A small population of these neurons has projections to more than one oromotor nucleus, and they provide a basis for synergistic action between lingual, masticatory, and facial movements.

While there is general agreement over the location of final common interneurons that provide the drive to the appropriate oromotor neurons, there are alternative theories with regard to the origin of the fundamental rhythm for mastication/licking. Based on studies using EBS of the orbital gyrus to evoke masticatory-like (fictive) responses, the medial core of the medullary RF comprising multiple subdivisions of the nucleus gigantocellularis (Gi) was initially thought to provide the basis for the fundamental masticatory rhythm (Figure 1(b)). This rhythm-generating substrate was thought to project to pattern-generating neurons located further lateral in the IRt/PCRt region. However, recent studies have shown (1) that infusions of muscimol into Gi did not disrupt the rhythm of natural licking and (2) that interneurons adjacent to the motor trigeminal nucleus were capable of producing a masticatory-like rhythm (Figure 1(a)). Thus, unlike the respiratory central pattern generator, which has a clear locus for rhythm generation in the pre-Bötzinger complex, the origin of a masticatory/licking substrate remains obscure.

Sensory Inputs

Oromotor consummatory circuits are modulated by oro- and viscerosensory inputs at the brain stem level. As demonstrated by decerebrate preparations, the gustatory system has access to oromotor circuits. Intraoral infusions of preferred sweet stimuli lead to ingestive oromotor responses, while infusions of bitter nonpreferred stimuli, such as quinine, initiate an oral rejection response. These gustatory modulatory inputs can reach the IRt/PCRt via either the rostral (gustatory) nucleus of the solitary tract (NST) (Figure 1(b)) or via projections from the waist (gustatory) region of the parabrachial nucleus (Figure 1(a)). There is also evidence that visceral afferents from the gut can influence oromotor circuitry via brain stem pathways. Loading the stomach diminishes ingestive responses in decerebrate preparations, suggesting that second-order vagal afferents from the caudal NST influence the oromotor pattern generator, in much the same way as their rostral (gustatory) counterparts do.

Trigeminal afferents play key roles in oromotor ingestive function. In addition to trigeminal mechanoreceptors that guide the intraoral transport of food, Ruffini endings in the periodontal ligament reflexively trigger salivation during chewing, providing an important lubricatory and predigestive substrate. Afferent fibers of mesencephalic trigeminal neurons may contribute to the masticatory rhythm. In addition to innervating the periodontal ligament, mesencephalic trigeminal neurons innervate muscle spindles in jaw-closer muscles and are thus active during chewing. By virtue of a persistent inward sodium current, mesencephalic neurons burst when depolarized and may 'resonate' with the masticatory rhythm. Because the central connection of these afferent neurons is on trigeminal motor neurons, this resonant property could facilitate the masticatory rhythm. Trigeminal afferents are also subject to modulation by the central patterning substrate, and orosensory afferents are presynaptically inhibited during masticatory movements in order to dampen unnecessary reflex function.

Descending Control

Widespread regions of the midbrain and forebrain control the motor substrates for ingestion organized in the lower brain stem. Forebrain projections descend in parallel (Figure 2). For example, EBS of a cortical

Figure 2 Parallel projections from the forebrain to hindbrain regions organizing consummatory ingestive responses. ARC, arcuate nucleus; LHA, lateral hypothalamus; NTS, nucleus of the solitary tract; PBN, parabrachial nucleus; PVN, paraventricular nucleus; RF, reticular formation. masticatory area (CMA) located in the frontal, orbital gyrus elicits rhythmic mouth movements, as well as movements of the tongue, salivation, and swallowing. EBS of different cortical areas can elicit mouth movements that resemble different components of the ingestive sequence (e.g., gnawing, mastication, intraoral transport, and even licking). Direct projections from these cortical sites reach the medullary RF, including the IRt/PCRt, but they also access the RF immediately adjacent to the motor trigeminal nucleus, and perhaps even the motor neurons. However, the prefrontal cortex is also intimately connected with the nucleus accumbens, the amygdala, and other ventral forebrain structures involved with motivation and reward, structures that also make connections with the RF. In fact, the consummatory licking response from pharmacological manipulation of the nucleus accumbens is prevented by inhibiting the lateral hypothalamus, which also has direct projections to the medullary RF. Thus, the ventral forebrain can potentially influence oromotor consummatory circuits via both cortical and lateral hypothalamic pathways. In addition to cortical, lateral hypothalamic, and amygdala projections to a lower brain stem central pattern generator, the substantia nigra and superior colliculus located in the midbrain offer additional indirect projections from the forebrain to lower brain stem circuits.

The cerebellum further modulates consummatory ingestive behavior. Ensembles of Purkinje cells show time-locked activity to rhythmic licking, and they project to the deep cerebellar nuclei. Outputs from the deep cerebellar nuclei reach the IRt/PCRt. Although not necessary to the generation of rhythmic ingestive responses, stimulation of the deep cerebellar nuclei, (nucleus lateralis and nucleus intermedius) alters the masticatory rhythm, while ablation of the cerebellum slows the chewing rate.

Swallowing

Swallowing is divided into a voluntary, preparatory 'oral' phase, followed by involuntary pharyngeal and esophageal phases. Because the pharyngeal phase includes activation of several oral muscles, this phase is more accurately described as the oropharyngeal phase. Thus, the involuntary reflex components of swallowing are generally described as consisting of oropharyngeal and esophageal phases. The oropharyngeal phase consists of contracting the posterior tongue and soft palate together, in order to force a food bolus into the upper pharynx. The lowest threshold site for initiating the involuntary components of the oropharyngeal phase consists of receptors lining the mucosa of the larynx, the epiglottis, and the portal to the pharynx (vallecullae, fauces), which are innervated by the superior laryngeal branch of the vagus (SLN). Glossopharyngeal-innervated receptors on the posterior tongue are somewhat less effective trigger sites. Sequential activation of pharyngeal constrictor muscles propels the bolus into the esophagus. Thus, the apposition of the posterior tongue against the soft palate forms an initial upper seal that demarcates the initiation of the oropharyngeal phase, and the contraction of the esophageal sphincter (cricopharyngeal muscle), once the bolus is in the esophagus, demarcates the initiation of the esophageal phase.

As many as 25 muscles are recruited into the swallowing sequence. These muscles include those innervated by the motor trigeminal, facial, hypoglossal, and ambiguus nuclei as well as motor neurons located in the upper cervical spinal cord. Muscle groups can be divided into those essential for swallowing (i.e., obligate muscles) and those that may or may not be recruited (i.e., facultative muscles). Facultative muscles include those of the tongue and face that participate in the oral phase of sequestering and organizing the bolus within the mouth. Obligate muscles of the leading complex of the oropharyngeal phase include trigeminal (mylohyoid, anterior digastric), lingual (styloglossus, genioglossus), hyoid (geniohyoid, stylohyoid), palatal (palatoglossus, palatopharyngeus), and pharyngeal (superior constrictor) muscles. Sequential activation of obligate middle and inferior constrictor muscles propels the bolus past the relaxed esophageal sphincter. Contraction of the cricopharyngeal muscle closes the esophageal sphincter, and esophageal peristalsis propels the bolus into the stomach.

Electromyographic recordings indicate that central inhibition plays an important role in the swallowing sequence, with muscle excitation preceded by activity levels below background levels. Thus, the middle and inferior pharyngeal constrictor muscles as well as the cricopharyngeal muscles are relaxed during activation of the leading complex. Such inhibition facilitates movement of the bolus. A similar pattern of sequential inhibition followed by excitation is also evident during esophageal peristalsis.

Central Control of Swallowing

Swallowing is organized by two major constellations of neurons in the caudal medulla (Figure 1(c)). A dorsal group includes neurons in the caudal NST and subjacent RF. These neurons receive peripheral afferent input from sites that reflexively trigger swallowing, in particular the SLN. The dorsal group is also the target for descending cortical input that initiates voluntary swallowing. Electrical stimulation, lesion, and recording studies all suggest that the dorsal swallowing group

functions as a pattern generator to sequentially activate the premotor (and esophageal motor) neurons. Thus, the caudal NST is the lowest threshold central site for eliciting swallowing via central stimulation, and NST lesions prevent both cortical-induced and peripherally induced swallows. Recording studies confirm that single neurons in the caudal NST fire during different phases of the swallowing reflex.

These dorsal group neurons, however, do not project directly to the motor neurons innervating the swallowing musculature. Rather, they project to premotor neurons located in the ventrolateral RF; these constitute a ventral group of swallowing-related neurons (**Figure 1(c)**). These neurons fire later than do their dorsal group counterparts, and tracing studies confirm that they connect to the oropharyngeal motor nuclei. In fact, some neurons in this region project to multiple oromotor nuclei, further establishing a role for this region in orchestrating the simultaneous activation of the diverse musculature that characterizes the oropharyngeal phase. Tracing studies using the transynaptic properties of viruses further confirm that esophageal 'generator' neurons in the dorsal group contact motor neurons in the nucleus ambiguus in the absence of additional (reticular formation) interneurons. Sections along the midline indicate the existence of a central pattern generator for swallowing on each side of the medulla. Coordination between the two central pattern generators to produce bilateral muscle activation is mediated by connections across the midline (e.g., between the two dorsal or ventral groups) and by bilateral projections from each ventral group to oromotor neurons.

The dorsal group of swallowing neurons is further differentiated into neurons generating the oropharyngeal and the esophageal phases. Neurons active during the oropharyngeal phase are located in the interstitial, intermediate, lateral, and ventrolateral subdivisions of the caudal NST (**Figure 1(c)**). Esophageal neurons are located in the intermediate and central subdivisions (**Figure 1(c)**). Lesion studies indicate that these populations of generator neurons can function independently – that is, a lesion in the central subnucleus will leave the oropharyngeal phase intact. Despite this spatial separation, the neuron groups are closely coupled through excitatory cholinergic and inhibitory GABAergic pathways (**Figure 3**). Infusions of cholinergic antagonists into the caudal NST suppress the esophageal phase while leaving the oropharyngeal phase intact. Similarly, infusions of the $GABA_A$ antagonist bicuculline 'releases' esophageal peristalsis, presumably from oropharyngeal generator neuron-mediated inhibition. Activation of the oropharyngeal phase requires excitatory amino acid receptors, particularly *N*-methyl-D-aspartate (NMDA) receptors.

The pattern generators for swallowing organized in the dorsal group are also modulated by monoamines, and there is increasing evidence for roles by other neuromodulators such as leptin. Leptin receptors are located in the dorsal vagal complex, and local infusions suppress SLN-elicited swallowing, reinforcing the view put forth by H Grill that the brain stem contains neural substrates with the capacity for ingestive function regulation.

A theory of pattern generation for swallowing has been put forth by A Jean. The essential element of this theory is that generator neurons in the dorsal group that are active early in the swallow sequence (e.g., oropharyngeal-related neurons) excite a second population of generator neurons, which in turn excite a third population, and so forth. In addition to a chained excitatory network, neurons inhibit all of the generator neurons down the chain. Thus, neurons last in the chain receive the most inhibition. Such a schema could explain the sequential activations of specific muscles that are preceded by relaxation (inhibition) below basal rate. The demonstration of transient K^+ currents (A currents) in potential generator neurons in the caudal NST adds weight to the theory. Neurons with A currents display delayed excitation as a function of the strength of hyperpolarization. Thus, generator neurons destined to drive esophageal muscles would receive more inhibition than would generator neurons innervating preinferior constrictor neurons, and, perhaps, generator neurons for the

oropharyngeal phase would have the least inhibition. The strength of this inhibition is further dependent on sensory feedback and can be increased by peripheral stimuli that mimic bolus size. As such, a particularly large bolus might suppress excitation, delaying transit. Thus, although swallowing is centrally programmed, it is sensitive to sensory feedback.

Descending Control of Swallowing

Cortical projections to the NST likely account for initiation of voluntary swallows. Although imaging studies in humans suggest numerous cortical sites involved in swallowing (sensorimotor, prefrontal, anterior cingulate, and insular cortex), only relatively restricted sites in the anterolateral cortex evoke 'pure' swallowing when stimulated in experimental animals. Because stimulation of cortical swallowing sites affects primarily brain stem neurons active during the 'early' (oropharyngeal) phase, the cortex likely functions to trigger swallowing.

Coordination between Consummatory Responses

To what extent do mastication/licking and swallowing share central substrates? Clearly they share oromotor neuron pools innervating the tongue, jaws, and facial muscles. However, swallowing further recruits pharyngeal and esophageal muscles as well as laryngeal muscles to protect the airway. At the interneuron level, although the oropharyngeal phase of swallowing can be evoked from the caudal NST, a structure that appears to have little to do with initiating mastication/licking – the ventral group of swallowing interneurons – appears to overlap with substrates identified as necessary to mastication/licking. Thus, the ventral group of swallowing-related interneurons extends into the IRt/PCRt, though perhaps not extending dorsal to the ventral border of the rostral NST, an area rich in prelingual/masticatory interneurons. Chronic unit-recording studies confirm that some neurons in the IRt/PCRt that are active during licking are also active during swallowing. Other RF neurons are active during various combinations of swallowing, vocalization, respiration, licking, and oral rejection. Though unproved, it is thought that such interneurons form a multifunctional substrate to coordinate oral behaviors. And oral behaviors are clearly coordinated: the lick cycle is interrupted by swallowing, and swallowing is closely coupled to the respiration rhythm. Swallowing generally takes place between late inspiration and expiration and produces a brief period of apnea. During the oropharyngeal phase, the airway is protected by reflex laryngeal elevation as well as by closure of the larynx by laryngeal muscles. Although the initiation of the normal respiratory rhythm is usually attributed to the ventral lateral RF (e.g., pre-Bötzinger complex), gasping responses, which recruit both lingual and masticatory muscles to a greater extent than in normal respiration, appear also to be organized in the IRt/PCRt substrate, further emphasizing the critical role this area plays in orchestrating oromotor activity.

Motor Gait and Falls

W Mathiyakom and J L McNitt-Gray, University of Southern California, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Falls are a major cause of morbidity and mortality in older adults. More than one-third of adults older than 65 years of age fall each year (Figure 1). The incidence of falls increases with age (Figure 1) and is also higher in institutionalized older adults (Figure 2). The consequences of falls experienced by older adults often extend far beyond minor injury to significant loss of functional independence and death. By 2020, the cost of fall-related injuries is expected to be $43.8 billion. Epidemic studies suggest that falls are associated with multiple factors, such as medical, biomechanical, physiological, psychological, and environmental factors. The interaction between these factors is complex and is further complicated by the heterogeneity of the aging process. Current clinical research related to fall prevention focuses on population-specific strategies for maintaining balance and balance recovery.

A fall can be defined as a sudden drop in body position. The position and velocity of the body can be controlled by generating reaction forces when the body is in contact with the environment. Maintaining balance requires that the body (often represented as a single point, the center of mass (CM)) is positioned over the base of support. During standing, the trajectory of the CM is kept within the base of support by regulating the reaction forces generated at the foot–surface interface. A reaction force (RF) is a push or pull that occurs during contact with the environment. The point of force application or center of pressure (CP) describes the centroid of the pressure distribution at the foot–surface interface. The CP location represents where a resultant reaction force would be applied to the foot to reflect the effect of all forces applied to the foot. The magnitude and direction of the RF and the CP are regulated by coordinated activation of multiple muscles. If the trajectory of the CM moves beyond the base of support, compensatory responses (e.g., step in the direction of movement) may be required to avoid a fall. If the net response is ineffective in controlling the CM relative to the base of support, a sudden drop in body position will result (a fall).

Maintenance of balance while performing activities of daily living is a critical factor contributing to aging in place. Effective interaction between the control (neural) and dynamic (musculoskeletal) systems is required to maintain and recover balance during both expected and unexpected situations. As an individual develops, he or she learns how to take advantage of the ever-changing set of neural and musculoskeletal capabilities to reliably perform functional movements. As one ages, alterations in the nervous and/or musculoskeletal system capabilities introduce age-related constraints that influence how an individual plans and executes daily tasks.

Age-related alterations in the neural system affect balance. The aging process alters sensory input (visual, vestibular, and somatosensory systems), the central processing (the planning and executing of movement), and cognitive domain in both expected and unexpected perturbations during interaction with the environment. Visual input provides the central nervous system with information regarding vertical and horizontal orientation of the body in relation to a reference system. During standing, vision detects slight changes in body orientation relative to the environment. The vestibular system provides information to the central nervous system (CNS) regarding head position and movement and helps resolve conflicting information between the visual input and the real movement. Somatosensory (e.g., proprioceptive and vibratory) input also provides important information to the CNS regarding segment and joint motion with respect to the support surface.

Previous research demonstrates that the abundance of sensory input allows the nervous system to effectively maintain balance. The absence of sensory input from multiple sensory systems amplifies body sway and increases the incidence of falls. For example, in younger adults, alteration in vision (no visual and inaccurate visual input) slightly increases body sway during stance. However, body sway significantly increases (approximately 3 times greater) when alterations in visual input occur in combination with inaccurate somatosensory (unstable surface) input. Likewise, in older adults, alteration in visual input in combination with inaccurate somatosensory input results in significant increases (approximately 2 times greater) in body sway compared to that of younger adults. In patients with vestibular loss, altered visual input or inaccurate somatosensory input slightly increases body sway, whereas vestibular loss in combination with altered visual input and inaccurate somatosensory input results in a high incidence of falls. These observed behaviors under compromised sensory conditions illustrate the role of multiple sensory systems in maintaining balance in a standing posture.

Figure 1 Mean (range) of annual fall incidence reported by different age groups of community-indwelling older adults. The mean of fall incidence increased as the age increased. Adapted from Rubenstein LZ and Josephson KR (2002) The epidemiology of falls and syncope. *Clinics in Geriatric Medicine* 18: 141–158.

Figure 2 Mean (range) of annual fall incidence reported by different age groups of institutionalized (hospital and longer-term care) older adults. Note that the fall incidence was much higher than that reported by community-dwelling older adults within the same age group. Large variation in the number of falls reflects the interaction and the differences between the age-related pathology, activity levels, and fall prevention strategies and programs among facilities. Adapted from Rubenstein LZ and Josephson KR (2002) The epidemiology of falls and syncope. *Clinics in Geriatric Medicine* 18: 141–158.

Motor Strategies Used to Maintain Postural Stability

Classic research by Horak and Nashner provides a framework for classifying motor strategies used to maintain balance during upright postures under a variety of biomechanical and environmental constraints. This line of research has explored how the nervous system uses the sensory input, processes it in the context of previous learning experience, and executes a modified preprogrammed motor program appropriate for the perturbation, biomechanical, and environmental constraints. Control strategies used to maintain balance when unexpectedly perturbed are described as ankle, hip, and stepping strategies.

Ankle Strategy

An ankle strategy is commonly observed when the perturbation applied to a body is relatively small and the base of support is relatively wide. In this strategy, the body moves about the ankle joint as if it is a rigid body. To counter a forward sway of the body in response to a backward movement of the platform relative to the body, the muscles posterior to the ankle, knee, and hip are activated in a distal-to-proximal order (e.g., gastrocnemius, hamstrings, and paraspinal). In contrast, to counter a backward sway of the body, muscles anterior to the ankle, knee, and hip are activated (tibialis anterior and quadriceps). The latency of muscle activation is approximately 100–120 ms post perturbation. The set of observed muscle activation patterns appears to serve as a mechanism for redirecting the RF relative to the CM. If the RF acts anterior to the CM, a backwards moment about the CM is generated (to counter a forward sway). If the RF acts posterior to the CM, a forward moment about the CM is generated (to counter a backward sway). The magnitude of the moment about the CM is determined by the vector cross-product ($\mathbf{r} \times \mathrm{RF}$) of the position vector ($\mathbf{r}$), from the axis of rotation (CM) to the point of force application (CP), and the reaction force vector (RF). If the line of action of the RF vector is aligned with the CM, the RF does not cause rotation about the CM.

Hip Strategy

A hip strategy is typically observed when the perturbation is relatively large and the base of support is relatively small. In this strategy, the primary movements are observed about the hip joint. During a forward sway, the anterior muscles of the trunk (abdominal), hip, and knee (quadriceps) are activated, resulting in the use of hip flexion as a means of returning the CM over the base of support. In contrast, during a backward sway, posterior muscles of the trunk (paraspinal), hip, and knee (hamstrings) are activated. As a result, a hip extension movement is used to return the CM over the base of support. Motion of the trunk serves as a mechanism for relocating approximately 50% of the body mass (mass above the hip).

Muscle activation patterns used by older adults during balance recovery vary among individuals and populations. In some older adults (~40%), the order of muscle activation is reversed (distal to proximal). Older adults without a history of falls also exhibit a longer latency in distal muscle activation compared to young adults. Older adults who have fallen exhibit a longer latency of the distal muscle activation (tibialis anterior) and less ankle plantar flexor and dorsiflexor

strength than older adults without a history of falls. A reduction in muscular strength in combination with a longer latency in muscle activation may contribute to reductions in RF generation and/or the ability to reorient the RF relative to the CM to restore balance. Variations in balance control strategies among populations may represent the differences in scaling of the sensory inputs, previous experience, cognitive status, the state of the musculoskeletal system, and the ability to effectively interact with the environment.

Stepping Strategy

When a forceful perturbation is applied to the body (e.g., tripping), the ankle and hip strategies may not be sufficient for regaining balance and a stepping strategy is introduced. The stepping strategy requires coordination of both the supporting (stance) and recovery (swinging) legs. The role of the recovery leg is to establish a larger base of support and to provide a mechanism for redirecting the RF relative to the CM to counter the forward translation and rotation of the CM resulting from the trip. The stepping strategy is initiated by stabilizing the supporting leg and moving the recovery leg in the direction of the CM trajectory. While the recovery leg is in contact with the ground, the forward placement of the foot relative to the hip and CM allows the lower extremity to generate a backward and upward directed RF that passes anterior to the CM. The orientation of the RF relative to the CM counters the movement (translation and rotation) of the body associated with the trip, thereby providing a mechanism for regaining balance.

Age-related delays associated with the use of a recovery leg to regain balance influence the ability to regain balance during a forward fall. As the forward lean of the body prior to the fall increases, older adults are less likely to recover their balance than are younger adults. At small lean angles, the reaction and movement times of the recovery leg are similar between young and older adults. However, at maximum lean angle prior to the fall, the velocities of lower extremity joint flexion and extension during swing phase and the reaction and movement times are significantly different between young and old adults. These relationships were observed in both male and female groups. Variation in muscle activation patterns used to control the recovery leg also varied between older and younger adults. During the swing phase of the recovery leg, the onset of vastus lateralis activation occurs earlier (~40 ms) and the onset of rectus femoris activation occurs later (~90 ms) in older adults compared to younger adults. No significant differences in activation of the ankle plantar flexors, dorsiflexors, and hamstrings are observed between younger and older adults. These results indicate that the ability to regain balance from a forward lean position is limited by the ability to quickly orient the recovery leg.

Load distribution among the lower extremity joints of the recovery leg during contact also differ between young and older adults. Early in foot contact (~30 ms), ankle plantar flexor, knee flexor, and hip extensor net joint moments (NJMs) contribute to the control RF. Later in foot contact (~50 ms), ankle, knee, and hip extensor NJMs are observed. Older adults use smaller knee extensor but larger hip and ankle extensor NJMs compared to younger adults. These differences in load distribution strategy suggest that, compared to younger adults, older adults may impose a greater mechanical demand on the muscles controlling the ankle and hip when regaining balance using a stepping strategy.

Early RF redirection by the support leg also serves a mechanism to counteract the forward rotation of the body. Younger adults recover from a forward trip by using the support leg to redirect the RF anterior to the CM at ~150 ms post trip initiation. This RF creates a backward moment about the CM, thereby counteracting the forward rotation created by the trip. The upward component of the RF generated by the stance leg also translates the CM upward as indicated by hip elevation, thereby allowing more time for the recovery leg to be placed anterior to the CM. Redirection of the RF by the stance leg is achieved by a set of ankle plantar flexor, knee flexor, and hip extensor NJMs that are significantly different from those observed during the propulsive phase of gait. Generation of these moments by the stance leg during balance recovery requires significantly greater activation of the biarticular hamstrings, gastrocnemius, and uniarticular soleus muscles than during gait. These results indicate that effective balance recovery relies on the ability to quickly alter muscle activation patterns so that moment generated by the RF about the CM arrests the fall.

In older adult nonfallers, the patterns of the RF redirection relative to the CM, elevation of CM, lower extremity NJMs, and activation of muscles controlling the support leg during forward fall recovery are similar to those of younger adults. However, the magnitude and rate of development of muscle activation, rate of development of knee NJMs, and hip elevation are significantly slower for the older adult nonfallers than for younger adults. Older adults with a history of falls do not use their stance leg to redirect the RF anterior to the CM during forward fall recovery. After trip initiation, the RF generated by the stance leg is directed forward but passes posterior to the CM, contributing to both forward translation and rotation of the CM about the support foot.

The inability to redirect the RF anterior to the CM observed in older adult fallers is accompanied by relatively lower ankle plantar flexor NJMs and rate of development of ankle, knee, and hip NJMs compared to those of younger adults. These results indicate that alterations in lower extremity dynamics influence the RF redirection and forward fall recovery in older adult fallers. The reduction in magnitude and rate of force generation by lower extremity muscles may place older adults at risk for falls.

Postural Stability in Patients with Parkinson's Disease

Parkinson's disease (PD) is one of the most common neurological disorders associated with falls and recurrent falls. It has been estimated that 70% of PD patients fall at least once each year. The prevalence of severe injury resulting from falls (e.g., fractured hip) is 2.5–3.4 times greater in patients with PD compared to those without PD. Extrapyramidal signs (e.g., bradykinesia, axial rigidity, and tremor), as a result of the affected dopaminergic pathway in basal ganglia, alter several important mechanisms used to restore balance. These altered mechanisms include postural instability during unexpected perturbations, inability to regulate and redirect the RF relative to the CM during transition phases of goal-directed tasks, and coordinated activation of muscles responsible for coupling and decoupling body segment motion.

Research has demonstrated direction-specific instability in PD patients. When PD patients are perturbed by a moving platform, a high incidence of falls is observed in the backward and lateral directions. The incidence of falls is amplified when PD patients assume a more narrow base of support during stance. The decline in balance control observed in PD patients is primarily attributed to the inability to regulate the displacement of the CP at the foot–surface interface, thereby reducing the functional base of support and the ability to redirect the RF relative to the CM. When standing in a narrow stance, the peak CP displacement in all directions is significantly smaller for patients with PD than for healthy older adults. However, in wide stance condition, the reduction in peak CP displacement in PD patients is mainly observed in the backward direction. In healthy older adults, a decrease in base of support results in an increase in the rate of development of peak CP. In PD patients, the rate of development in peak CP during both narrow and wide base of support stance is slower than in healthy older adults. These results indicate that balance control in patients with PD is limited by the ability to regulate CP displacement.

Regulation of the CM displacement during multidirectional perturbation also contributes to postural instability observed in PD patients. During multidirectional perturbations, PD patients displace the CM significantly more than older healthy subjects. In narrow stance conditions, the magnitude of CM displacement is significantly larger in PD patients than in healthy adults in all directions except the forward direction. In wide stance conditions, the magnitude of CM displacement is comparable between healthy adults and PD patients. However, PD patients are slower in reversing the CM displacement compared to healthy adults, particularly when using a narrow base support. Significantly larger magnitudes of CM displacement and slower rates of CM reversal are attributed to significantly smaller amplitude of frontal hip movements and sagittal plane knee movements in order to bring the CM back over the base of support observed in PD patients compared to healthy older adults. Slower rates of CM regulation, reversal of CM orientation, and reduction in knee and hip motion indicate that postural bradykinesia commonly observed in PD patients may be related to higher background muscle activation and coactivation of muscles crossing both sides of the joints.

Restrictions in CP displacement in combination with increases in CM displacement contribute to smaller stability margins in PD patients. Stability margins during narrow stance are significantly smaller in all directions of perturbation for PD patients compared to healthy older adults. During wide stance, the stability margins are significantly smaller during backward and backward/lateral directions for PD patients compared to healthy older adults. Inability of PD patients to regulate safety margins in backward and lateral directions appears to be linked to limitations in regulating CP displacement in the backward direction and controlling the RF relative to the CM.

Regulation of the horizontal component of the RF serves as a mechanism for redirecting the RF relative to the CM during balance recovery. PD patients, however, demonstrate differences in horizontal RF generation in response to multidirectional perturbations compared to healthy older adults. Healthy older adults appear to use an asymmetrical strategy in controlling the horizontal component of the RF applied to the loaded and unloaded legs. In contrast, PD patients use a more symmetrical strategy. In healthy older adults, the loaded leg (ipsilateral side as the body sway) directs the horizontal RF in the lateral direction opposite to the direction of perturbation. The RF generated by the loaded leg returns the CM over the base of support. Simultaneously, the unloaded leg directs the horizontal RF in the anterior/posterior direction. This action by the unloaded leg serves to redirect the RF relative to the CM, thereby counteracting the rotation of the body. This differentiated role

of the loaded and unloaded legs allows healthy older adults to simultaneously control both translation and rotation of the body. In contrast, PD patients use both legs to generate diagonal horizontal RFs to counteract the translation and/or rotation imposed by the perturbation. Although this symmetrical RF redirection strategy may allow PD patients to maintain balance, the stability margin (CP–CM) is relatively small, particularly in the backward and backward/lateral direction. The symmetrical strategy used by PD patients may be related to an inability to initiate differentiated motor patterns when the conditions quickly change.

Coordinated and direction-specific activation of lower extremity and trunk muscles affects control of the RF relative to the CM. For example, during the right-backward body sway, older healthy adults exhibit direction-specific activation patterns of the lower extremity and trunk muscles. In the loaded (right) leg, the soleus, tibialis anterior, tensor fasciae latae, and erector spinae are activated, whereas in the unloaded (left) leg, the hip adductor and left abdominal muscles are activated. Evidence of direction-specific muscle activation patterns is also observed in PD patients. However, greater magnitude and shorter latency of the antagonistic muscles, acting in opposition to these muscles, are observed in PD patients compared to older healthy adults. The presence of muscle coactivation may result in more symmetrical net horizontal RFs observed in PD patients compared to older healthy adults. As the stance width decreases, the activation levels of the agonistic muscles significantly increase in healthy older adults. However, PD patients do not exhibit changes in muscle activation levels in response to the change in the base of support. These results suggest that coactivation of the antagonist muscles may impede the ability of PD patients to scale the magnitude of the agonistic muscles relative to the demand of the tasks and to regulate horizontal RFs in response to changes in the base of support.

Deficits in the nervous and musculoskeletal systems associated with the aging process and diseases prevalent in older adults introduce age-related constraints on mechanisms used for maintaining balance and balance recovery. These limitations in control appear to impede the ability of older adults and patients with neurological disorders such as PD to (1) regulate the segment and joint movements as indicated by reducing hip and knee displacement during perturbation, (2) reorient the total body CM relative to the base of support as a result of reduction of segment and joint motion, (3) reestablish a functional base of support as indicated by restricted excursion of the CP during stance and limitations imposed on stepping strategies, and (4) redirect the horizontal RF relative to the CM.

Motor Neuron Specification in Vertebrates

Motor Neuron Progenitors: Extrinsic Signals

During early stages of neural tube development, multiple signaling activities intersect with one another and are responsible for specifying the identity of neuronal subtypes within the spinal cord. In the ventral neural tube where motor neurons and multiple classes of interneurons differentiate, cell fate specification occurs in a highly stereotypical manner based on the position of cells along the rostrocaudal (RC) and dorsoventral (DV) axes. Embryonic cell position and fate are linked because the location of undifferentiated progenitors is correlated with the types and concentrations of extrinsic factors they encounter – and it is the extrinsic factors that activate signaling pathways involved in establishing cell identity.

Motor neurons are located within the caudal regions of the nervous system, including the hindbrain and spinal cord. In the absence of extrinsic factors, progenitor cells default to an anterior identity, and as a consequence their progeny have characteristics of forebrain neuronal classes. A variety of extrinsic factors produced by Hensen's node and the mesoderm flanking the neural tube have been implicated in 'caudalizing' progenitor cells, including wnts, retinoic acid (RA), fibroblast growth factors (FGFs), and growth/differentiation factor 11 (gdf11). Although the interplay between these factors is still poorly understood, their graded activity appears to shift cells toward a progressively more posterior fate. Caudalizing signals play a critical role in establishing precursor cells that can give rise to motor neurons, whereas progenitors located at anterior levels do not encounter these transforming signals and therefore are not competent to generate motor neuron progeny. Based on studies of RC signaling in embryos, *in vitro* differentiation protocols using mouse and human embryonic stem cells to generate motor neurons typically incorporate RA and FGF to shift the rostrocaudal identity of the neural progenitors to a caudal identity appropriate for motor neuron specification.

RC patterning is not only involved in establishing progenitor cells competent to produce motor neurons but also contributes to the further diversification of motor neurons into individual subclasses. In large part, motor neurons develop in RC register with their peripheral targets. For example, limb-innervating motor neurons are located at limb levels (lower cervical and lumbar), whereas craniofacial-innervating motor neurons are located within the hindbrain. Grafting studies in chick embryos have shown that the early RC position of cells within the neural tube has a major influence on the eventual formation of motor neuron subclasses. Studies that alter RA, FGF, and/or Gdf11 signaling have shown that the identity of developing motor neuron subclasses is shifted along the RC axis of the neural tube. The influence of these signals also contributes to the precise assignment of motor neuron 'pools,' the unit representing a group of motor neurons that target specific muscles. Thus, caudalizing signals not only play a role in establishing precursor cells that can give rise to motor neurons but also operate at an extremely high resolution in defining what subtypes of motor neurons will develop along the RC axis of the embryo. These RC signals likely begin to influence progenitor cell identity prior to, and independently of, the DV signals that trigger motor neuron development.

Progenitor cells within the ventral portion of the caudal neural tube generate many cell types, including astrocytes, oligodendrocytes, floor plate cells, a diverse array of interneuronal classes (e.g., V0–V3), and motor neurons. Classical cell grafting studies have shown that graded signals along the DV axis of the neural tube influence cell fate specification. Sonic hedgehog (Shh) is produced as a secreted glycoprotein from the notochord and floor plate, establishing a high ventral-to-low dorsal gradient. With remarkable accuracy, neuroepithelial cells are able to readout different concentrations of Shh and respond by initiating specific differentiation programs. *In vitro* studies suggest that Shh activates signaling pathways for altering gene expression in the 0.5–10 nM range. Concentration differences as small as twofold lead to the activation of entirely different differentiation programs. At spinal cord levels, a narrow range of Shh triggers motor neuron development, whereas higher or lower levels of Shh trigger the differentiation of other cell types. Although Shh appears to only trigger the differentiation of a single generic population of ventral-exiting motor neurons (v-MNs) at spinal cord levels, the situation is more complex at hindbrain levels. Here, graded Shh appears to contribute to the specification of two major motor neuron classes. In the hindbrain, high concentrations of Shh have been linked to the development of dorsal-projecting visceral motor neurons (d-MNs), whereas progenitor cells located more dorsally in the neural

tube encounter lower levels of Shh and respond by differentiating as ventral-projecting somatic motor neurons (v-MNs). Thus, the intersection of RC and DV signals is integrated to specify motor neurons of appropriate subtypes at specific locations within the developing nervous system.

Motor Neuron Progenitors: Intrinsic Factors

RC and DV extrinsic signals are converted into intrinsic regulatory programs by activating the expression of multiple families of transcription factors, many of which contain a homeodomain for DNA binding. Along the DV axis, graded levels of Shh lead to the expression of unique combinations of transcription factors that define five separate progenitor cell domains within the ventral neural tube. An interesting cell-intrinsic mechanism is used to ensure that cells which fall close to the threshold level of Shh for two different progenitor cell domains are decisively resolved into a genetic program for a single cell type. This is achieved by having transcription factors for one progenitor cell type negatively regulate the expression of the factors expressed in adjacent cell domains. If cells initially start to express transcription factors for two different cell types, the reciprocal inhibition of the factors ensures co-expression is not tolerated, which rapidly leads to one set winning the cross-inhibitory 'battle.' Thus, a gradient of Shh is converted into all-or-nothing responses at the level of gene regulation controlled by progenitor domain-specific transcription factors.

The progenitor cells for motor neurons within the spinal cord reside within a 'domain' called the pMN region of the ventricular zone. pMN cells express a unique constellation of homeodomain transcription factors that distinguishes them from the progenitor cells for other neuronal types in the spinal cord. Furthermore, progenitor cells for d-MNs (restricted to hindbrain and upper cervical levels), such as trigeminal and spinal accessory neurons, arise from a unique pMN domain marked by Nkx2.2, Nkx2.9, Nkx6.1, Nkx6.2, and phox2b, whereas pMN cells that generate v-MNs express Nkx6.1, Nkx6.2, Pax6, and Lhx3. v-MN progenitors also express basic helix–loop–helix (bHLH) transcription factors that control the process of neurogenesis, a genetic subroutine involved in converting neural stem cells into postmitotic neurons. Two bHLH factors have been identified in pMN cells that have antagonistic functions toward one another: Olig2, which seems to hold pMN cells in a dividing progenitor cell state, and Ngn2, which favors neuronal differentiation. The counterrelationship between Olig2 and Ngn2 might serve as a mechanism for first expanding the pMN precursor population before allowing progeny cells to differentiate since precocious motor neuron differentiation would likely deplete the number of progenitor cells for motor neurons. The coordination of pMN growth and differentiation appears to be based on the timing of Olig2 and Ngn2 expression in pMN cells: Olig2 is expressed initially, but then it activates the expression of Ngn2, which begins to accumulate in the cells as development proceeds. The high Olig2 level in early pMN cells favors their growth, whereas the accumulation of Ngn2 beyond a threshold level over time appears to drive neuronal differentiation (neurogenesis) at later stages.

The high caudal-to-low rostral gradient of FGF in the embryo influences the expression of nested sets of Hox class transcription factors along the RC axis of the neural tube. Motor neurons that innervate the same muscle cluster their cell bodies into pools within the spinal cord, which typically span two to four spinal cord segments, vary in cell number in relationship to the size of the muscle they innervate, and extensively overlap with other motor pools spread along the RC axis. Gain- and loss-of-function studies have shown that Hox transcription factors are involved in establishing motor pool subtype identity. Like the progenitor cell factors involved in DV patterning, Hox genes involved in the development of different motor pools have cross-inhibitory regulatory interactions that help to convert graded extrinsic signals of RC position into unambiguous patterns of gene regulation for cell identity. By tuning the relative strength of the cross-inhibitory interactions for Hox factors, this could represent a mechanism for allowing some motor pools to expand in size at the expense of others so that motor neuron numbers within individual motor pools are roughly matched to the size (i.e., muscle fiber number) of the peripheral target.

Stepwise Progression in Motor Neuron Diversification

As progenitor cells generate postmitotic motor neurons, many changes in gene expression occur with the final cell division. The postmitotic birth of d-MN cells is tightly linked to the initiation of expression of the LIM-homeodomain (LIM-HD) factor Isl1 and the homeodomain factor Phox2a. On the other hand, v-MN cells express Isl1 and homeodomain factor Hb9 when they are born and maintain their expression of the LIM-HD 'progenitor' factor Lhx3 (Figure 1). Nevertheless, many of the other progenitor transcription factors found in pMN cells such as Olig2 and Pax6 are downregulated in newly formed postmitotic motor neurons. Little is known about the molecular basis for the further diversification of d-MN cell

Figure 1 Motor neuron subtypes and their stepwise specification by LIM-HD factors. Motor neurons are classified based on their cell body position, axonal trajectory, and targets. Generic: Dorsal-projecting motor neurons (d-MNs) located at the hindbrain/upper cervical levels occupy dorsolateral positions and extend axons dorsally from the neural tube. There are many subclasses of d-MNs (not shown), and each has a slightly different cell body position and axonal trajectory. This diagram is a schematic representation of d-MNs that is not intended to indicate their precise position and axonal trajectory. Ventral-projecting motor neurons (v-MNs) extend axons ventrally from the neural tube forming ventral roots. Class: v-MNs at spinal levels are divided into two subclasses – somatic motor neurons innervate skeletal muscles and visceral motor neurons (forming a preganglionic motor column (PGC) in the intermediolateral spinal cord) innervate sympathetic neurons. Column: Somatic motor neurons are composed of multiple motor columns named based on their mediolateral cell body position – median motor column (MMC) neurons and lateral motor column (LMC) neurons. Division: Individual motor columns are divided into medial and lateral subdivisions – medial MMC cells extend axons dorsally and innervate axial muscles, lateral MMC cells extend axons ventrally and innervate body wall (intercostal) musculature, medial LMC (LMCm) cells extend axons into the ventral limb, and lateral LMC (LMCl) cells extend axons into the dorsal limb. Pool: Subsets of motor neurons clustered together within a single motor column such as the LMCl and LMCm that innervate the same muscle. The expression profile of LIM-HD factors is listed. Lhx3 has a paralogous gene Lhx4 (Gsh4) that has the same expression as Lhx3 and therefore is not listed for simplicity.

types, but numerous additional steps in the subspecialization of v-MN cells have been defined (Figure 1). Newly formed v-MN cells all extend axons out through the ventral root of the neural tube, but soon after this step additional changes occur in their profile of transcription factor expression reflecting the emergence of different v-MN subtypes. These dynamic and highly selective patterns of gene expression correlate with the migration of subclasses of v-MN cell bodies to specific locations within the neural tube and the growth of their axons along specific pathways in the periphery (Figure 1).

At thoracic spinal cord levels, v-MN cells can be divided into two major subclasses: somatic motor neurons innervating skeletal muscles and visceral motor neurons innervating sympathetic targets. Somatic motor neurons upregulate the LIM-HD factor Isl2, whereas visceral motor neurons downregulate Lhx3 and Hb9 but continue to express Isl1 as their cell bodies migrate dorsomedially to form a preganglionic motor column (PGC). Somatic motor neurons contribute to the formation of many different motor columns that are classified as either median (MMC) or lateral (LMC) based on their mediolateral cell body position in the ventral horn. The median and lateral motor columns are further subdivided into medial and lateral divisions to create four motor columns containing cells that innervate distinct peripheral targets: MMCm cells innervate axial muscles, MMCl cells innervate body wall musculature, LMCm cells innervate ventral limb targets, and LMCl cells innervate dorsal limb targets (Figure 1). Each of these motor columns is marked by a specific combinatorial pattern of LIM-HD genes. MMCm cells express Isl1, Isl2, Lhx3 (also called Lim3), and Lhx4 (also called Gsh4); MMCl cells found only at thoracic levels and LMCm cells found only at limb levels express Isl1 and Isl2; and LMCl cells express Isl2 and Lim1 (also called Lhx1). A variety of genetic studies have shown that the LIM-HD factors function in a combinatorial manner to control the expression of genes within motor columns that mediate axon pathfinding.

Motor columns can be further subdivided into motor pools which correspond to cells that are clustered together within a column and are related to one another by virtue of innervating the same muscle, expressing the same pattern of cadherins, and being gap junctionally interconnected. Individual motor pools express specific patterns of Hox and Ets class transcription factors. Ets factors such as Pea3 and Er81 are upregulated in motor pools by retrograde neurotrophin signaling activated by neurotrophin 3 (NT-3) and glial-derived neurotrophic factor (GDNF) produced by cells encountered by motor axons in the periphery. The Ets factors mediate a number of later functions in motor pools, whereas gain- and loss-of-function studies with *Hox* genes such as *Hoxc8*, *Hox5*, and *Hoxc6* have linked these factors to the actual specification of motor pool identity within the brachial (lower cervical) spinal cord. Taken together, the stepwise process whereby the subclass identity of 'generic' v-MN spinal motor neurons becomes progressively more refined is reflected in the sequential changes in the transcription factor 'coding' that take place during postmitotic stages of motor neuron development (Figure 1).

The LIM Code and Motor Neuron Diversification

LIM-HD genes evolved in early metazoans, and many studies have linked their function to the regulation of cell fate during the development of numerous tissues. The *Caenorhabditis elegans* LIM-HD factors Mec-3 and Lin11 are involved in specification of mechanosensory neurons and vulval cells, respectively. In *Drosophila*, the LIM-HD factor Apterous specifies dorsal cell identity during wing development. Likewise, LIM-HD factors in vertebrates are found in diverse organs, such as the developing pituitary, retina, limbs, pancreas, spinal cord, and brain, and are expressed with highly restricted expression patterns in specific cell types. As noted previously, motor neurons express unique combinations of LIM-HD genes during several phases of their development (Figure 1). v-MN cells express Isl1, Lhx3, and the Lhx3 paralog Lhx4 when they extend axons out through the ventral root, whereas d-MN cells express only Isl1. The first demonstration of the combinatorial function of LIM-HD genes was based on the finding that ectopic expression of Lhx3 in d-MN cells converted them to v-MNs, and conversely double knockouts of Lhx3 and Lhx4 converted v-MNs into d-MNs. Thus, the presence or absence of Lhx3/4 activity in newly formed motor neurons is thought to control the v-MN versus d-MN fate decision.

Interestingly, LIM-HD factors also contribute to the further diversification of v-MN subclasses at later stages of motor neuron development. Following the generation of v-MN cells, the emergence of motor columns is associated with the appearance of unique combinatorial arrays of five different LIM-HD factors (Figure 1). The refinement of motor neuron subtype identity is associated with both up- and downregulation of specific LIM-HD genes at postmitotic stages of neuronal development. Genetic studies in mice have shown that at later stages Lhx3 is involved in MMCm motor column development, Lim1 (Lhx1) is involved in LMCl development, and Isl2 is involved in PGC development. Taken together, functional studies on

the LIM-HD transcription factors indicate that they contribute to the development and subclass refinement of motor neurons by acting in a combinatorial manner at several stages in the stepwise development of these cells. Thus, they contribute to motor neuron subtype diversification at two levels: by functioning at multiple time points and by functioning in a combinatorial manner. These features of the LIM-HD factors enhance the ability of this relatively small gene family to contribute to the generation of an extraordinary level of cellular diversity within the spinal cord. Since all 12 members of the LIM-HD gene family are expressed by developing neurons in the peripheral and central nervous system, it is not surprising that studies have defined functions for these transcription factors in cortical, retinal, pituitary, and sensory neuron development as well.

The Molecular Underpinnings of the LIM Factors

The LIM motif is a cysteine–histidine-rich sequence which creates a tandem zinc finger structure that functions as a protein–protein interaction domain. Although numerous studies support the view that the LIM domain mediates interactions for higher-order ternary complexes, only a limited set of binding partners are well defined. Structural analyses and biochemical studies have demonstrated that the LIM domains derived from the nuclear LIM proteins encoded by 4 LIM-only genes and 12 LIM-HD genes can interact with the nuclear LIM interactor (NLI) protein (also called Clim and Ldb) (Figure 2). NLI is a widely expressed (probably ubiquitous) nuclear factor containing a self-dimerization domain and a LIM interaction domain. The protein-interaction characteristics of NLI suggest that it serves as a scaffold for assembling complexes with multiple LIM-HD proteins (Figure 2). A simple example of these LIM-HD complexes is found in V2a interneuron development – a population of Lhx3-expressing cells that form dorsal to motor neurons in the spinal cord. Biochemical and structure–function studies indicate that stoichiometric complexes of 2-Lhx3:2-NLI molecules regulate gene expression and specify V2a interneuron cell identity (Figure 2).

v-MN motor neurons expressing Isl1, Lhx3, and NLI represent a more complicated situation that illustrates a general issue with combinatorial codes based on reusing elements in a context-dependent manner. The co-expression of multiple LIM-HD factors, such as Isl1 and Lhx3 in the case of v-MN cells, raises the possibility that a mix of LIM complexes could form (i.e., 2-Lhx3:2-NLI, 2-Isl1:2-NLI, and Lhx3:2-NLI:Isl1). However, if this occurred, it is expected that the 2-Lhx3:2-NLI complex would inappropriately activate V2a interneuron genes, leading to a hybrid phenotype in v-MN cells. In this case, biochemical studies found that the LIM domain of Lhx3 is also able to bind with high affinity to the C-terminal portion of Isl1, leading to the formation of a hexameric complex

Figure 2 Ternary LIM-HD complexes regulate gene expression. The LIM domain of Lhx3 can bind to both NLI and Isl1. In V2a interneurons in which Lhx3 is expressed without Isl1, Lhx3 binds to NLI, which dimerizes to form a tetrameric 2-Lhx3:2-NLI complex for DNA binding. In v-MN motor neurons, Isl1 displaces Lhx3 from NLI, thereby preventing the V2a interneuron tetrameric complex from forming. Instead, Lhx3 binds to Isl1's C-terminus leading to the formation of a hexameric complex composed of 2-Lhx3:2-Isl1:2-NLI. This complex synergizes with bHLH factors such as Ngn2, NeuroM, and NeuroD (green) to activate high transcription levels. This synergy couples the activity of LIM-HD factors to proneural bHLH factors ensuring that neuronal differentiation and subtype specification are linked.

composed of 2-Lhx3:2-Isl1:2-NLI (Figure 2). The binding of Lhx3 to Isl1 results in a competitive situation whereby Lhx3–NLI interactions needed for V2a interneuron gene regulation are depleted at the expense of forming hexameric complexes for v-MN specification. Thus, neuron-specific protein–protein interactions represent one way in which LIM-HD factors can be used to regulate gene expression in different cellular contexts.

Although Isl1 and Lhx3 specify v-MN cell identity, until recently it was unclear how the activity of LIM-HD factors was tied to bHLH class transcription factors in developing motor neurons. Ngn2, NeuroM, and NeuroD are expressed by motor neuron progenitor cells and differentiating motor neurons and have proneural activity, meaning that they trigger cell cycle exit and activate generic neuronal genes such as β-tubulin. Transcription studies have found that the hexameric LIM complex containing Isl1 and Lhx3 (Figure 2) has a low inherent transactivating capacity. However, the binding sites of Isl1 and Lhx3 within the motor neuron-specific gene Hb9 promoter were found to flank E-box elements for bHLH factors. In the presence of Ngn2, NeuroM, or NeuroD, the activity of the LIM-HD and bHLH factors synergizes to greatly enhance v-MN gene activation. This synergistic link requires the dimerization of NLI (Figure 2), suggesting a conformational change occurs that mediates efficient transcription in the presence of LIM-HD and bHLH transcription factors. This cooperative link serves as a coincident detector that provides a means for integrating and coordinating the activity of factors for neuronal differentiation with those that control subtype properties.

Motor Neuron Soma Migration

Once generated, newborn motor neurons undergo stereotypical patterns of cell migration. Individual subclasses of motor neurons often settle in different positions from one another. For example, somatic motor neurons within the spinal cord typically settle in the ventral horn in specific medial and lateral columnar and pool positions (Figure 3). In contrast, thoracic visceral motor neurons migrate dorsomedially away from the ventral horn and settle at intermediate positions in response to reelin. Multiple transcription factors have been implicated in the control of motor neuron cell body positioning. For instance, misexpression of Lhx3 (normally in medial MMC cells) among non-MMCm neurons in *Lhx3* knockin mice shifted the settling position of motor neurons to a medial (MMCm-like) position. Likewise, *Isl2* null mice display defects in the mediolateral distribution of MMC neurons, and LMCl neurons require Lim1 induction for their normal migration. Ets class transcription factors such as Pea3 have been implicated in the positioning of motor pools within motor columns. The clustering

Figure 3 Stages of motor neuron development and maturation. v-MNs and d-MNs arise from different progenitor cell populations (pMN(d), purple; pMN(v), red) generated in response to different levels of Shh. The cell bodies of d-MNs move dorsolaterally and their axons exit the neural tube dorsally. The cell bodies of somatic v-MNs migrate laterally and form longitudinally aligned columns: medial MMC (MMCm, blue), medial LMC cells (LMCm, green), and lateral LMC cells (LMCl, red). All v-MN axons exit the spinal cord ventrally but select specific pathways in the periphery. LMC neurons grow to the base of the limb. LMCm cells innervate the ventral limb, whereas LMCl cells innervate the dorsal limb. MMCm neurons turn dorsally to innervate axial muscles. As motor neuron subtypes mature, they form peripheral branches and develop characteristic dendritic patterns which may contribute to the formation of specific connections for controlling their activity.

of like-motor neurons into motor pools has been linked to the cadherin gene family, encoding adhesion molecules that are selectively expressed by different motor neuron subtypes.

At hindbrain levels, the cell bodies of d-MNs (also called branchiomotor and visceromotor cranial motor neurons) migrate extensively. These classes of motor neurons often migrate dorsally along dorsolateral pathways, radially to the pial surface, and, in the case of facial cranial motor neurons, caudally along 'tangential' pathways. Although individual classes of d-MN cells follow different migratory pathways, some of the regulatory factors that control diverse migratory behaviors are shared among d-MN cells, including Tbx20 and Nkx6.1. In contrast, factors such as Ebf1, the planar cell polarity signaling pathway, and VEGF164 signaling appear to control a single process – the tangential migration of facial motor neurons.

Axon Pathfinding

Motor neurons share the unique property of extending axons into the periphery. All v-MN cells initially follow a common ventral pathway out of the spinal cord, but soon after exiting they are confronted with a choice point that branches toward three targets: MMCm cells select a dorsal pathway toward axial muscles; LMC and MMCl motor neurons select a ventral pathway toward the limbs and body wall muscles, respectively; and PGC axons grow ventrally toward sympathetic ganglia (Figure 1). Once LMC neurons reach the base of the limb, LMCl cells choose to grow into the dorsal region, whereas LMCm neurons enter the ventral limb compartment (Figure 1). Although arrays of LIM-HD transcription factors such as Isl1 and Lhx3 initially play a pivotal role in assigning motor neuronal fates, the expression of LIM-HD factors becomes progressively restricted to the selective motor neuron subtypes in postmitotic motor neurons (Figure 1). The specific expression of these factors precedes the selective axonal pathway and target innervation of neuronal subtypes, indicating that the combinatorial expression of LIM-HD factors (the LIM code) may guide the subtype-specific axon projection toward the target muscles. For instance, whereas most motor neurons rapidly extinguish Lhx3 and Lhx4 expression, MMCm neurons continue to express Lhx3 and Lhx4. Mouse genetic studies demonstrated that in the absence of Lhx3 and Lhx4, MMCm axons abnormally choose their exit points dorsally from the neural tube. Furthermore, when Lhx3 is stably expressed in all motor neurons as in *Lhx3* knockin mice, non-MMCm neurons extend axons toward axial muscles. This phenotype has been linked to Lhx3's regulation of FgfR1, which mediates chemoattraction toward the Fgf4/8-expressing axial muscles. LMCm neurons which innervate ventral limb muscles express Isl1, whereas LMCl neurons which innervate dorsal limb muscles express Lim1 (Lhx1). LMCl axons grow normally to the base of the limb in *Lim1* mutant mice, but they randomly select both the dorsal and the ventral limb compartment. Lim1 has been linked to regulation of EphA4, which mediates repulsion from the ephrin-A5-expressing region of the ventral limb. Individual motor columns contain motor pools which innervate the same muscle. Misexpression and knockdown studies with Hox genes such as *Hox5* and *Hoxc8* have shown that these factors control motor pool subtype identity and their altered expression influences axonal targeting.

Locomotor Circuitry: Dendrite Patterning and Synaptogenesis

Motor neuron cell bodies occupy specific positions and develop elaborate dendritic arbors for receiving input from presynaptic connections (Figure 3). Many classes of interneurons, corticospinal neurons, and sensory neurons synapse with motor neurons to control their activity; however, the mechanisms that control the precise pattern of input are just beginning to emerge. Individual motor pools display unique dendritic morphologies with regard to their branching pattern, size, and orientation. Genetic studies of *Pea3* mutant mice have found that the pattern of dendrite organization within specific motor pools requires the Ets transcription factor Pea3. After motor axons reach their target muscles, axons branch across the surface of the muscle and form neuromuscular synapses. Axons of specific motor pools display muscle-specific branching patterns, suggesting the presence of intrinsic branching programs. This is supported by the finding that *Pea3* mutants exhibit defects in the terminal arborization of motor neurons innervating the cutaneous maximus and latissimus dorsi muscles.

Motor neurons receive proprioceptive feedback input from Ia sensory neurons (Figure 3). This connectivity develops with incredible precision so that homologous motor and sensory neurons form monosynaptic connections. Interestingly, Ets factors Pea3 and Er81, which are selectively expressed in specific motor pools, are also present in subsets of sensory afferent neurons. Labeling studies have shown that there are preferential connections between sensory neurons expressing a particular Ets factor and the motor cells expressing the same factor. This finding suggests that Ets factors control multiple aspects of motor neuron maturation, including cell body position, dendritic pattern, and possibly Ia sensory input.

Conclusion

During the past decade, rapid progress has been made in defining the genetic pathways that control motor neuron subtype diversification. Characterization of the inductive signals and downstream transcription factors in motor neurons has provided great insight into the process of neuronal diversification. It seems likely that other neuronal populations will use similar DV and RC inductive cues and cross-repressive interactions to become diversified. Although our understanding is still fragmentary, the characterization of the factors involved in motor neuron subtype regulation is beginning to provide insight into the processes that control the development of locomotor circuitry.

Motor Primitives

S F Giszter, Drexel University College of Medicine, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Data from several lines of research suggest that the lower levels of the motor system may possess a set of motor primitives. These are compositional or constructive 'building blocks.' In a fashion similar to primitives used in computer graphics or robotics, they may simplify the problem of early movement construction and form an initial scaffold for motor learning. The motor primitives for limb movement are likely to reside in the vertebrate spinal cord. This article reviews the rationale for primitives, the development of an experimental framework, the current theoretical approaches, and recent data relating to spinal cord motor primitives and then concludes with a discussion of important open questions for future work.

The Degrees of Freedom Problem and the Rationale for Suggesting Primitives

The degrees of freedom problem in motor control was first strongly stated by Bernstein. The excess degrees of freedom available at the joint level for positioning the limbs, and the redundancy of muscles available to generate torques at these joints, make the issue of choosing the best limb postures, trajectories, and muscle activation patterns potentially complex (the so-called 'curse of dimensionality'). Wolpert, Ghahramani, and Flanagan have pointed out that human 'muscle space' comprises about 600 muscles and considering only contracted versus relaxed muscles leads to 2^{600} patterns, a number larger than the sum of atoms in the known universe! Of course, simultaneously, the available degrees of freedom enable immense flexibility. They can allow new motor strategies and the rapid use of novel tools. These new motor strategies may include types of movement never employed routinely or perhaps never employed previously in evolutionary history, (e.g., the Fosbury-flop strategy in the high jump). However, the great flexibility available with these degrees of freedom comes at a cost.

To make the problems and potential costs of the flexibility of the motor apparatus concrete, consider the wildebeest calf born in the Serengeti or a newly hatching turtle on a Caribbean beach. Both are subject to predation by a range of carnivores and are likely to soon be eaten if they fail to rapidly organize directed locomotion. Natural selection will thus favor their rapid development of effective movement and their efficient management of motor complexity through development. Modularity is an obvious way to solve several problems in motor control. It can help (1) manage complexity, (2) provide a basis to build more-complex motions, and (3) provide a 'seed' or bootstrap to motor learning, based on expectations about the world. Finer adjustments of the motor nervous system to the specifics of the individual motor apparatus, and novel motor adaptations or inventions, can then be added on timescales of development and individual life span. Notions of modularity in this spirit have arisen in ethology and neuroethology (e.g., fixed action patterns), in developmental biology, and in neurophysiology (the Sherringtonian reflex and interneuron classes in the work of Lundberg and Jankowska).

Research on motor primitives examines several issues: (1) What modularity can be identified in motor behavior? (2) Does modularity simplify the organization and control of biomechanical properties and movement? (3) Is modularity adequate to support both flexibility and the construction and learning of new movements? and (4) is modularity (a) hardwired, (b) developed in critical periods, or (c) simply an optimal short-term solution to an animal's specific and immediate task? The relationships of motor primitives to limb and body biomechanics and to the control and computation needed for movement are thus central issues. To this extent, a review such as this must draw on several approaches and avenues of research.

The remainder of this article will first introduce research on frogs (the section titled 'Motor primitives in frog spinal cord from microstimulation') which has shown that the spinal cord could potentially organize a collection of simple constructive or compositional elements quite directly linked to the limb biomechanics. Prior to these experiments, work on spinal cord already supported modularity from several different perspectives, and these data and approaches will be reviewed, putting the idea of motor primitives in context (the section titled 'Other historical, converging, and intersecting approaches to spinal modularity'). A body of theory on motor primitives has been elaborated from several different perspectives. A brief overview of these theoretical approaches to

primitives will be presented (the section titled 'Computational approaches to motor primitives'). The more recent research on spinal motor primitives in tetrapod vertebrates including mammals and man will follow, with a discussion of the relationship between reflex systems, pattern generators, and primitives indicated by some of these data (the section titled 'Current approaches to spinal motor primitives'). Finally, several important open questions are discussed that must be addressed in future work (the section titled 'Future issues in spinal motor primitives').

Motor Primitives in Frog Spinal Cord from Microstimulation

What the Spinal Cord Can Do

The spinal cord of vertebrates can organize complex and adapted movements in isolation. The spinal cord of the lamprey or dogfish can organize swimming; the spinal cord in rat or cat can organize the motor patterns needed to walk, trot, and gallop; and the spinal cord of rat, cat, turtle, and frog can organize precisely directed scratches. These involve coalescing and controlling many degrees of freedom of the joints and muscles.

Microstimulation: Hypothetical Possible Outcomes, Experimental Approach

The spinal basis for the abilities of frogs to make fine directed movements was investigated by Bizzi, Mussa-Ivaldi, and Giszter. By using microstimulation, they activated, with currents less than 10 μA, small regions of spinal cord in the intermediate gray matter in the spinalized frog. Both muscle activity and forces were recorded with the limb held isometrically at different limb locations. *A priori*, several kinds of outcomes appear possible with this experiment: First, random assemblies of muscles might be activated. Second, muscles might be activated in proportion to the underlying motor pool motor neuronal densities. Third, the circuitry of cord might be organized so as to define a continuum of kinematic actions or goals, such as final postures or specific directions or velocities of motion. Fourth, the circuitry might define a modular set of groups of muscles and feedback able to organize specific forces in the limb. The last two outcomes are not strictly exclusive of one another, but they do differ in various details, since Newton's laws specify it is not possible to control position and force simultaneously. Results of stimulation were expressed as force fields (Figure 1).

Results of Stimulation: Stable Force Fields

By moving the limb about the limb workspace, a set of force field patterns resulting from microstimulation of different regions of cord can be constructed. Passive (prestimulus) and active forces are distinguished (Figure 2). In stimulation directly of motor pools, patterns similar to those predicted based on motor pool composition are found. However, the outcome of stimulation in intermediate gray were found to be a collection of force fields which were conservative (i.e., emulated behavior of a passive mechanical system). These were all convergent in Cartesian (or external) space. All elicited fields were represented in joint space as torque/angle fields, and it was clear that all elicited fields were elastic. However, some fields did not exhibit torque reversals and therefore did not strictly define equilibria. Nonetheless, their elastic forces approached zero near joint limits. The stimulation defined neither a single unique force direction across the limb workspace nor a particular and unique movement direction. Instead, the elastic force fields (actually viscoelastic force

Figure 1 Construction of a force field following microstimulation or skin stimulation. (a) A collection of forces is recorded at several different spatial locations (circles). (b) A minimum perimeter (Delaunay) tessellation of the nine points is constructed. Within each triangle, vectors are estimated using an exact linear interpolation based on the three corner vectors. Thus, vector **v** is calculated using vectors at vertices a, b, and c. (c) The interpolated field is used to find any equilibria (EP). (d) The interpolated force field is shown in relation to the frog in the apparatus. From Giszter SF, Mussa-Ivaldi FA, and Bizzi E (1993) Convergent force fields organized in the frog spinal cord. *Journal of Neuroscience* 13: 467–491.

Figure 2 Estimation of the force field activated by stimulation. 'Resting fields and separation of active and resting fields'. Top, three different resting fields that were collected from a single frog during 6 h. These have an almost constant structure. Bottom, an example of the removal of the resting field (measured at 200 ms prior to stimulation) from the total peak field measured at 450 ms (250 ms following stimulation). The vector-by-vector subtraction used to obtain the active data is equivalent to the removal of baseline forces. The removal generates an 'active field.' It can be seen that in this case, the active field was convergent. Parameters: 9 μA at 60 Hz for 300 ms at 400 pm depth in cord. From Giszter SF, Mussa-Ivaldi FA, and Bizzi E (1993) Convergent force fields organized in the frog spinal cord. *Journal of Neuroscience* 13: 467–491.

fields measured isometrically) could move the limb to postures in the workspace or to workspace limits (Figure 3, panel 2). These fields showed several interesting properties of scaling and superposition.

Scaling of Force Fields over Time

Following stimulation at a site in the spinal cord, force fields that were elicited first developed smoothly and then relaxed (Figure 3). Throughout this process they remained a scaled version of the peak or maximum field. This property was not *a priori* expected. Spinal feedback systems activated by initial contractions could (in principle) alter muscle and torque balances later in the activity, but this was not observed. Either feedback played no part in the patterns seen or feedback conspired to support the force structures rather than dissolve them. In fact, subsequent experiments have shown that feedback regulation does contribute but that these contributions are not strictly necessary to the basic structure. Force fields also scaled with stimulation. If stimulation was increased, the peak amplitude was scaled, but structure was preserved.

A Small Number of Behaviorally Relevant Force Fields

If the electrode is moved throughout the intermediate gray of lumbar spinal cord in many frogs, a thorough sampling of the force patterns elicited throughout the cord can be made. Surprisingly, only about six different force patterns are elicited. Clustering all patterns using inner product measures shows that six fields account for the results. Some of the fields elicited by microstimulation are very similar to those found by skin stimulation to elicit reflex wiping or withdrawal. The small number of field structures are thus behaviorally relevant elements.

Combination of Force Fields

Dual stimulation of spinal cord to elicit different fields showed that these combined vectorially in 85% of tests and that one or the other field was suppressed in the remaining 15% (Figure 4). This observation is an extremely significant one and is the basis for considering the fields compositional or constructive elements of the spinal cord. It is interesting that to replicate blending, switching, and transition zones of scratch or wipe, a mixture of blending combinations and occasionally exclusive switching mechanisms is necessary.

Capacity to Drive Movement

The identification of a combination mechanism suggested that arbitrary limb postures and motions might be constructed through vector superposition of the few fields. Tests by Lemay showed that stimulation in the frog allowed adjusted control of limb position. Taken together, the fixed force field structures, the small number of structures, the combination mechanisms, and the capacity to organize and control movements led Bizzi, Mussa-Ivaldi, and Giszter to suggest the microstimulation results represented force field motor primitives from which a repertoire might be constructed. A theoretical framework, reviewed in the section titled 'Computational approaches to motor primitives,' was further elaborated.

Spinal Interneuronal Origins: Chronic Deafferentation

A clear concern, given the close relationship of stimulation results to reflex behaviors, has been whether afferents are the primary stimulation targets and whether the apparent organization observed is dynamic and transient. If so, the primitives are less likely to be available or present in other contexts. A number of experiments speak to this issue, but the most salient regarding afferent stimulation is to perform a chronic deafferentation and transection before microstimulation. After this manipulation, while interneuronal targets of afferents remain, the peripheral sensory fibers and descending fiber projections and synapses in the spinal cord are all stripped

Figure 3 Continued

away and cannot contribute to, or organize, the patterns that result from stimulation. This experiment has been conducted in both frogs and rats, and in both preparations the basic observation of a collection of a few force fields that can be recruited by microstimulation survives this procedure.

Reflex and Sensorimotor Topography in Frogs

One idea that has arisen from microstimulation is that a topography of the motor primitives may exist. This observation of a topography of 'hot spots' for recruitment of primitives provides little information about the circuitry for primitives. The circuitry itself could be localized or distributed. Stimulation hot spots could be very important for prosthetics. However, the idea is not necessary for thinking about motor primitives. Topography has been much harder to pin down across species than the motor modularity and force field primitives. However, there are known topographies associated with afferents and sensorimotor reflex mappings in frog, rat, and cat. These topographies and their targets in the frog might be responsible for some of the spatial organization observed in microstimulation. The motor pools contributing to motor primitives are broadly distributed over multiple segments, and thus a broadly projecting collection of distribution interneurons must be involved in organizing primitives. It remains possible that the cell bodies of these interneurons may be highly distributed rather than localized. The topography observed in the frog, while experimentally convenient, is unlikely to be an important feature of all spinal motor primitives.

The observation of a small number of primitives forming a modular capacity to organize limb mechanical properties and movements drawn from the frog spinal cord is actually in keeping with a great many other avenues of research. The next section discusses these relationships.

Figure 4 Vector superposition of force fields from spinal motor primitives. Results of costimulation of the lumbar gray matter in a frog. Two results are found: (1) vector summation (~85% of cases) and (2) winner-take-all (~15% of cases). Examples of vector summation. Upper left, fields (a) and (b) were obtained by separate stimulation of two different sites, A and B. Below, the observed costimulation fields (&) and summation field (+). This was by far (87.8% of cases) the most common outcome. The quality of fit of summation to observed is determined as the inner product derived Cosine. cos(a/b) close to 1.0 indicates near identity of two tested fields, a and b. In this panel cos(&/+) = 0.967. (Right) An example in which the costimulation (&) did not correspond to the sum (+) of the two fields (c) and (d) from two different stimulation sites C and D, but instead to a 'winner-take-all' case (D is the winner). Cos(D/&) = 0.949; but Cos(+/&) = 0.770. From Mussa-Ivaldi FA, Giszter SF, and Bizzi E (1994) Linear combination of primitives in vertebrate motor control. *Proceedings and National Academy of Sciences of the United States of America* 91: 7534–7538.

Other Historical, Converging, and Intersecting Approaches to Spinal Modularity

Reflex Circuitry and Central Pattern Generation

Spinal cord modularity arises naturally in the Sherringtonian conception of reflexes and its subsequent developments. The interneuron targets of reflex pathways from group II afferents, and the last-order interneurons described by Lundberg, Jankowska, Schomburg, and colleagues, may be closely related to the primitives

Figure 3 Behavior and characteristics of force fields from spinal motor primitives. (a) Normalized active fields are almost constant. To obtain this figure, active fields were obtained by removing the resting field from the fields shown in Panel 2. Stimulation parameters are 1.5 mA and 0.6 ms-duration pulses at 40 Hz for 300 ms. These active fields were then scaled to a constant average value to produce a normalized active field. (b) The magnitude of the scalar by which each of the normalized fields would have to be multiplied in order to obtain the original active field magnitude is shown in the graph to the lower right. Notice that after about 250 ms, the normalized field had an almost constant structure until 600 ms (when it begins to relax). A similarity measure for each active field relative to the peak active field was calculated and is in the upper right. After 250 ms, the similarity measure value dropped below the criterion value. This means the fields can be viewed as the same by this measure. The action of the microstimulation over time can thus be taken to be a scaling of the amplitude of a normalized active field of invariant structure. (c) Temporal evolution of the total force field. The total force field specifies the mechanical equilibrium of the limb. Over time, the field stiffens and alters as a result of microstimulation. The equilibrium point of each total field is shown. The motion of this equilibrium forms the virtual trajectory, which is shown to the right. The equilibrium alters as a result of microstimulation. The equilibrium point of each total field is shown. The time shown in the upper left of each field was measured relative to the stimulus train onset. Compare the pattern of motion of the equilibrium in the figure with the active field behavior shown in (a) for the same field. From Giszter SF, Mussa-Ivaldi FA, and Bizzi E (1993) Convergent force fields organized in the frog spinal cord. *Journal of Neuroscience* 13: 467–491.

identified as biomechanical and muscle synergies. Similarly, the C3–C5 neurons of Alstermark and L2–L3 propriospinal interneurons of Edgely and Jankowska may be very closely related.

Modular oscillators or unit pattern generators have been proposed by Grillner and Wallen, and unit burst generators have been suggested by Jordan. In turtle, Stein has identified modular burst generators or shared core structures. A central issue in relating pattern generator elements to primitives is how basic rhythmogenesis, multilimb and multijoint phase synthesis for gait, and pattern shaping are organized and interrelated and whether they are separable (see the section titled 'Supporting data in mammals').

Kinematic Decompositions of Movement

Kinematic modularity and kinematic trajectory strokes, submovements, or primitives have been identified and evaluated in a number of ways in human movements and in monkeys. This effort began with studies of Terzuolo and Viviani, and continued in work by Soechting and Flanders; Flash, Hogan, and Krebs; Sanger, Milner, and their various colleagues (see Figure 5). Miller, Houk, and colleagues have

Figure 5 Kinematic submovements as primitives. Kinematic primitives may exist at the movement planning level. These are likely to differ from execution primitives. It is not known whether the kinematic primitives for voluntary movements are represented in spinal cord. Panel 1 (left): submovements in motor adaptation. Normal individuals learn to 'coarticulate' primitive submovements into new compound kinematic 'primitives' through adaptation. The learned strokes transfer from clockwise to counterclockwise motions about the points. The evolution of the geometrical 'primitive' during adaptation. (A) Training trajectories and transfer trajectories, generated in the same training day, for one representative participant. For each training day, the upper left plot denotes 20 training paths (pink) and average training path (red); lower left plot denotes average velocity profile. The rightmost plots denote 20 transfer paths (pink) and average transfer path (red). (B) Transfer paths of three participants who practiced for 7 days only the transfer condition (single block each day). Data from Sosnik R, Hauptmann B, Karni A, and Flash T (2004) When practice leads to co-articulation: The evolution of geometrically defined movement primitives. *Experimental Brain Research* 156: 422–438. Panel 2 (right): submovements in recovery from stroke; simulated vs. actual speed profiles. (a)–(d) Progressive blending of two minimum-jerk curves at various states of blending. See 'Materials and methods' of paper for a detailed description of the simulation. (e)–(h) Actual patient speed profiles; (e) and (f) are taken from the first and last therapy sessions of an inpatient; (g) and (h) are taken from the first and last therapy sessions of an outpatient. Simulated speed profiles qualitatively resemble the actual patient data. (a) Two distinct speed peaks, just as the patient speed profile (e). Continuing down the columns, (b)and (f) are qualitatively similar, (c) somewhat resembles (g), and (d) is similar to (h). Progression from the first to the last therapy sessions qualitatively suggests an increase in submovement blending. In addition, the movements of the participant that are longer poststroke (outpatient) have characteristics of more highly blended submovements compared with those of the inpatient. From Rohre B, Fasoli S, Krebs HI, et al. (2002) Smoothness during stroke recovery *Journal of Neuroscience* 22(18): 8297–8304.

tested similar decompositions in monkey corrections. In 'lower' animals, similar ideas of kinematic primitives have been proposed and evaluated by Full and Koditschek in locomotion, and in an ethological framework by Golani and Fentress. Related execution-level kinetic analyses of human movement in terms of force pulses have been developed by Gottlieb, Argawal, and Corcos.

The Russian physiologist Bernstein in the 1930s put forth the notion of a more fluid and transient development of modularity and coalescing of degrees of freedom, following his initial discussion of the degrees-of-freedom problem. This perspective is carried forward by experimental and theoretical work of Berkinblitt, Feldman, and Latash, with subsequent additions of Schoner and Scholz and others. Many of the issues raised by Bernstein in this perspective are now being addressed formally in several ways by Harris and Wolpert, Kawato, and Jordan and Todorov.

Computational Approaches to Motor Primitives

In Marr's decomposition of problems in computational neuroscience, analysis of a problem can be made at the task, algorithm, or implementation level. Motor primitives could be considered useful descriptors at each level, depending of the formulation. Several types of computational motor primitives have been suggested, and these differ in how they would fit in a Marr scheme. A primary division of theoretical work is into analysis of (1) kinematic motor primitives offering decomposition at a more abstract planning level and (2) force field primitives, more directly associated with execution. Kinematic primitives are probably best classified in task or algorithm level in Marr's scheme, and force field primitives are best classified as algorithmic or implementation. Although the emphasis here is on spinal motor primitives and these are thought to be force field execution elements, kinematic representations and body schemes may exist in spinal cord, and briefly considering both types of elements and their elaboration and implications is useful here.

Kinematic primitives have been developed by Schaal, Ijspeert, and colleagues. They address primarily planning issues: how to build compact dynamical representations of multijoint task kinematics that guarantee task achievement and stability. Their representations are of two types. The first type is discrete point-to-point kinematic motions, with static attractors. The second type is limit cycle oscillators at joints. If these two classes of elements are coupled, a scheme is developed that allows optimization of dynamic patterns in a relatively simple and a highly principled fashion. The scheme supports imitation learning in biomorphic robots and gives a plausible account of kinematic imitation learning in man. Execution details are managed downstream from these kinematic representations (by a separated inverse-dynamics capacity). These primitives are thus in the tradition both of kinematic decompositions (Figure 5) and of unit oscillators reviewed in the section titled 'Reflex circuitry and pattern generation.'

Force field primitives related to the work in spinal cord have been developed by Mussa-Ivaldi and colleagues and represent execution elements. Following their descriptions, activity of muscles and feedback pathways as a group can be generically represented as a multidimensional time-varying elastic field in joint space:

$$F(q, \dot{q}, t) = C(q, \dot{q}, u(t)) \qquad [1]$$

where q, $\dot{q}$ are joint angles and angular velocities, $u(t)$ represents the vector of control variables, t is time, F is the force field in joint torque, and general joint coordinates, C is a (noninvertible) function transforming muscle activations to F.

As F drives motion, limb or body dynamics can be written as follows:

$$M(q)\ddot{q} + G(q, \dot{q}) + E(q, \dot{q}, t) = F(q, \dot{q}, t) \qquad [2]$$

where M represents intertial terms; G, interaction terms; E, environmental forces; and F, the torque generation from eqn [1].

The problem of movement generation is to deliver an appropriate set of forces F to satisfy the task constraints, which may be purely kinematic (e.g., pointing, gesture, or dance), purely counteracting an environmental force/load (e.g., stationary support of a book while reading), or a combination of target motions and interaction forces with the environment (e.g., locomotor stance phases or manipulation).

Spinal motor primitives provide a modular basis for constructing an arbitrary field. Mussa-Ivaldi showed an arbitrary smooth static field may be approximated with a combination of n static circulating and conservative fields:

$$F(q) = \sum_i \Phi_i(q) + \sum_i \Psi_i(q) \qquad [3]$$

where the Ψ are circulating fields and Φ are conservative fields

The fields found in practice in experimental work show no significant circulation and thus emulate passive conservative systems, and Ψ can be eliminated in the approximation in eqn [3]. This is consistent with constraints on guaranteeing passive stability

Figure 6 Continued

in interaction that were formalized and identified by Hogan and Colgate. Thus, for the biological primitives, the approximation needed can be written as follows:

$$F(q, \dot{q}, t) = \sum_i a_i(t)\Phi_i(q, \dot{q}) \qquad [4]$$

where a viscous term is added and $a(t)$ represents the time course of a viscoelastic force field.

Mussa-Ivaldi has used this framework to create fields from pulse- and step-activated primitives that generate two-joint planar limb kinematics.

In the spinal and semi-intact frog, experimental data support a fixed time course pulsatile force field element potentially initiated at arbitrary phases, and the trajectory formation can be expressed as follows:

$$F(q, \dot{q}, t) = \sum_i A_i a(t + \tau_i)\Phi_i(q, \dot{q}) \qquad [5]$$

where A is the amplitude of the pulse; τ, the timing of the pulse; and $a(t)$ similar for all primitives.

The problem of movement construction is then simply the selection of the number, timing, and amplitude of a sequence or repeating rhythm of such pulses. For example, a rhythmic central pattern generator (CPG) comprising a collection of coupled oscillators forming interlimb gait and timing synthesis could organize such elements in a pattern shaping layer for gait.

However, this degree of simplicity, namely, a fixed duration pulsed force field as primitive, may be peculiar to 'lower' tetrapods or the preparations

Figure 6 Superposition of motor primitives' force fields during online correction behaviors executed by the spinal cord. A single kinematic stroke, motion to a target with a unimodal velocity profile during wiping/scratch movements is executed by sequencing of motor primitives. Rapid online correction of this single stroke trajectory employs superposition of a new primitive, added into the pattern when triggered by cutaneous input from collision with an obstacle. Other aspects of the motor pattern are unaltered by the summation of the new element. Panel 1: corrective force components are directionally stable. (a)–(c) Circular histograms of the directions of force vectors generated over wiping in five trials (600 ms duration trials, 250 Hz sampling rate; thus 750 samples total) are shown for each condition: with feedback and correction response (a) and without cutaneous feedback or a correction response (b). The derived corrective vectors are shown in (c). Each bin represents 12°. See (d) for orientation of the circular histograms to the frog's body and wiping limb. (a) With feedback intact, vector directions exhibited two clusters: an initial cluster directed toward the midline and a second cluster directed away from the frog. The first cluster was broadly spread and spanned four bins. (b) Without cutaneous feedback, the initial cluster of vector directions was more focally distributed to the midline, that is, mainly in one bin (78 –90°), whereas the second cluster of forces was similar to that with feedback intact (252–264°). (c) Corrective vectors were obtained by subtracting time-matched forces in (b) from (a). The directions of the corrective vectors clustered tightly in a single bin from 108° to 120° and were directed to the hip joint. Thus, the corrective vectors summed with the initial set of wiping vectors directed to the midline and resulted in the rostral spread of these midline-directed force clusters when feedback was intact. Panel 2: cutaneous reflex pathways signaling obstacle contact recruited a corrective force field that summed with an underlying force field sequence produced during wiping. Time series of force fields are shown after initiation of wiping both with feedback intact and after cutaneous deafferentation. A typical electromyograph (EMG) pattern of representative muscles associated with field generation is shown to the right of each time series. For the fields, a single vector represents the force generated at that position at the specified latency after wiping initiation. The black dot marks the location of the hip joint. The lightly shaded ellipse indicates the region of contact with the target limb in free limb trials. (a) With feedback intact, force fields were initially directed to the midline, where target limb contact normally occurred (bold line overlaid on the 130 ms field shows the unrestrained ankle path up to limb contact. At 210 ms up to 330 ms, force fields rotated rostrally toward the hip and away from the target region. At 330 ms, force fields began to rotate back to the target region. The hip extensor burst began around this time (see EMG record to the right; rectified EMGs from BI knee flexor, RI hip extensor, and IL/RA-hip flexors are shown for a single trial taken from the middle of the workspace. EMGs are in millivolts). (b) After removal of cutaneous feedback, initial force fields were directed to the midline. Subsequent fields (210–330 ms) converged to the target region and did not rotate to the hip joint. The strong IL/RA activation was absent without cutaneous feedback (see EMGs to the right). At 330 ms, the field began to rotate caudally because of hip extensor activation. (c) Procedure used to produce corrective force fields. Time-matched fields in (b) were subtracted from corresponding fields in (a). The procedure was performed at each time point after wiping initiation. (d) Corrective fields are shown at three times, at 40 ms intervals. Corrective fields were structurally similar (similarity measures, 0.95) over a 100 ms period starting shortly after IL EMG onset. These rostrally directed fields summed with the underlying wiping force field patterns. Panel 3: path obstacles evoked force fields in panel 2 causing trajectory correction responses during kinematics of hindlimb wiping movements. (a)–(d) Digitized stick figures of the wiping and target limbs (thigh and calf) and the ankle path of both limbs (traced by a bold line; arrows mark direction of movement along path) are shown after initiation of the wiping reflex in four experimental manipulations. Each stick figure is separated in time from the next by 16.67 ms (1/60 s). Bold stick figures mark the initial limb configurations and their configuration at target limb contact. The frog's body would be above each stick figure. (a) The unobstructed kinematics of the wiping limb with feedback intact consisted of a knee flexion and hip extension that resulted in the ankle moving along a trajectory directed to a midline region of stimulus contact. A final knee extension ('whisk') occurred on stimulus contact. (b) When the wiping limb collided with a path obstacle en route to stimulus contact, a hip flexion was evoked that enabled the limb to clear the obstacle. Once the limb was clear, there was an enhanced knee flexion. Target limb contact occurred at a similar midline site and at a time similar to unobstructed trials. (c) After local removal of cutaneous feedback from the wiping limb, unobstructed free limb kinematics showed no apparent differences from the kinematics seen with feedback intact (compare (a) and (c)). (d) When obstacles were placed in the path of the locally deafferented limb, corrective responses were no longer evoked, and the limb was driven further into the obstacle (compare (b) and (d)). BI, biceps femoris (Ecker) or iliofibularis; RI, rectus internus; IL, iliopsoas, RA, rectus anticus. From Kargo WJ and Giszter SF (2000) Rapid corrections of aimed movements by combination of force-field primitives. *Journal of Neuroscience* 20: 409–426.

Figure 7 Continued

tested. Adding a dilation term ω to each pulse is supported by motor pattern decompositions in humans (see the section title 'Support in humans.'):

$$F(q, \dot{q}, t) = \sum_i A_i a(\omega_i t + \tau_i)\Phi_i(q, \dot{q}) \qquad [6]$$

Construction of Primitives: How Do Primitives Arise?

Several methods of resolving motor control redundancy issues *de novo*, via optimization approaches, have been developed by Sanger and Todorov, Gharamani, and Jordan, and specific examples have been elaborated by Ting, by Berniker, and by Haruno and Wolpert. Probably the major issue in relation to thinking about spinal primitives, besides whether they account for the spinal organization observed, is the extent to which such optimizations may operate transiently on the short timescales of movement construction in adults and the extent to which they are deeply embedded in the neural organization by development and by evolution.

Current Approaches to Spinal Motor Primitives

Support in Lower Vertebrates

Experiments geared to examine motor primitives have been performed, most specifically in the frog. However, earlier and current work in the turtle, which is couched in modular pattern generator terms, corresponds closely. Both frog and turtle show occasional modular deletions of synergy bursts. Often these deletions do not cause any alteration of other activity or change the ongoing timings or rhythmic structure. These spontaneous deletions are consistent with superposition of modular elements or primitives downstream from rhythmogenesis and phase synthesis.

In the frog, a trajectory correction primitive has been identified (Figure 6). It represents one of the set

Figure 7 Pulsatile organization of motor primitives. Motor patterns in frogs are organized from almost fixed duration pulses. This is demonstrable in wiping corrections. Panel 1: correction response amplitude was regulated both by motor phase and by feedback arising from obstacle contact. (a) Rectified and filtered SA electromyographs (EMGs) are overlaid for multiple trials ($n = 11$) in which obstacle collision occurred at a fixed latency. For each trial, obstacle collision occurred within 16.67 ms after movement onset (the mean time of movement onset and the standard deviations (SDs) from the mean are shown as bold and dotted vertical lines, respectively). Collision occurred slightly after the second dotted line. Evoked responses represent scaled versions of one another. (b) The peak magnitude of the evoked SA EMG is plotted versus the highest contact force before SA onset as the limb collided with the obstacle. The peak SA EMG was significantly correlated with the highest preceding contact force ($p < 0.05$). This relationship could indicate regulation of corrective strength by contact force or covariation of corrective strength with wiping motor pattern strength. (c) SA EMG duration at half peak showed no correlation with the magnitude of obstacle collision. (d) In a second frog held under isometric conditions, impacts of varying strength were generated with a stepping motor to accelerate a mass into the normal site of obstacle contact. Rectified and filtered peak IL EMG ($n = 34$ trials) significantly covaried with the applied force ($p < 0.01$) independent of motor program strength, strength of correction, and time of collision. (e) The rectified and filtered EMGs of evoked IL response are shown for multiple trials ($n = 12$) in which obstacle collision occurred at different distances (and therefore times) along the movement path of the wiping limb. The IL EMG was evoked at progressively longer latencies from movement onset because contact occurred at later times. (f) The peak magnitude of the evoked IL EMG is plotted vs. the time of obstacle contact. Successful responses (f) were positively correlated with the time of obstacle contact ($r^2 = 0.73$). After RI onset (second solid vertical line), IL responses were no longer evoked. Close to RI onset, some evoked correction responses failed to successfully clear the obstacle (e). Evoked IL responses had reduced amplitudes in these trials, departing from the linear relationship with impact force. (g) The duration of evoked IL responses showed no correlation with the time of obstacle contact and varied by <10 ms. (h) The contact force showed a significant linear correlation with the time of obstacle contact ($p < 0.001$). Panel 2: the activation waveform of EMGs comprising the correction response had a shape and duration that were similar to the activation waveforms of other muscles' EMGs in different phases of the wiping motor pattern. (a) In the top two rows, the averaged EMG waveforms of ST and RI from movement onset up to target contact are shown. In the bottom row, the individually evoked IL responses are shown (from panel 1). IL responses were evoked by obstacle contact that occurred at different times in the interval between movement onset and RI onset. This was a 100 ms time window. The averaged time of movement onset is marked by the first set of vertical lines; dotted lines represent 1 SD about this. (b) The averaged EMG waveforms of ST, RI, and the corrective IL burst during trajectory correction trials ($n = 11$) for the data in (a) are shown in the top three rows. Averages were constructed by aligning individual EMGs from each trial ($n = 11$) at their initial peak value (ST and RI exhibit multiple bursts in the wiping motor pattern) and normalizing this peak to a value of 1 before averaging the resultant waveforms. SDs are shown around the averaged EMGs. The dotted lines indicate the inferred relaxation of the activation waveform in the absence of the later, overlapping phases (note, however, that in frog BF64 in (c), the relaxation of RI can be directly observed). These were obtained by assuming waveform symmetry and reflecting the rising phase of the EMG. In the bottom row, the three averaged EMG waveforms for RI, ST, and IL are overlaid. These waveforms have a similar shape and duration despite occurring at different phases of the motor program, and all lie within 1 SD of the IL waveform. (c) The same averaging procedure was performed in a second frog. Individual EMG waveform averages were similar and showed low variance. Overlaid EMG waveforms have a similar shape and duration. (d) The ST, RI, SA, and IL EMG waveforms for the two frogs shown in (b) and (c) are overlaid. The EMG waveforms in these spinal frogs all exhibit similar shape and duration. The data suggest that different motor primitives may all have common activation dynamics even when recruited in different phases and combinations during reflex behaviors. SA, sartorius; RI, rectus internus; IL, iliopsoas; ST, semitendinosus outer head. Data from Kargo WJ and Giszter SF (2000) Rapid corrections of aimed movements by combination of force-field primitives. *Journal of Neuroscience* 20: 409–426.

of six primitives which is added to the motor pattern following a collision. This addition acts to modify motion so as to circumvent an obstacle. Superposition of primitives is thus used in a contingency fashion by the spinal cord. Remarkably, as a result of the primitive addition, the limb reaches the target region within 50 ms of the unperturbed arrival time. In addition, the spinal cord recruits the primitive only following a collision during the period of motion when superposition can achieve this. The primitive addition initiates a hip flexion. Collisions can no longer recruit the primitive as soon as the more powerful hip extensor muscles begin being recruited into the pattern (Figure 7, panel 1). The spinal cord thus appears to assemble and use these elements based on their potential utility in achieving the task goal and in some way represents these contingent relationships. The degree to which this result should be thought of as representing the existence of a predictive internal model of the task is currently unclear, but it is an interesting issue.

Corrections in the frog are pulsatile and of fixed duration (Figure 7), and this observation leads directly to the idea that the frog uses fixed-duration pulses of activity more broadly. Indeed, the spinal motor primitives and the associated force fields in frog appear to have a fixed time course. Adjustments in phase and amplitude of the premotor drive pulses are thus the primary method of movement construction and adjustment in frogs.

This perspective can be confirmed by detailed decomposition of the electromyogram motor patterns of frog into premotor drives and their driving pulses (similar to eqn [5] above). This was accomplished using independent components analysis and wavepacket analysis. The premotor drive pulses can be observed directly in the electromyograms of the correction behavior but are extracted statistically from the whole repertoire of behavior. The drive structures found across different behaviors imply neural and sensory projection patterns and properties. The sensory control of the pulse amplitudes and timing of pulses, as well as the neural underpinnings, are presently being investigated.

The competence of a few modules to capture the electromyogram patterns of 'intact frogs' is now also established. In the intact frog, the method of nonnegative matrix factorization has been used. Time-varying synergies were extracted rather than pulsed muscle synergies. However, it is likely that these represent 'chunking' of simpler pulses in sequences since no additional and sometimes less variance was accounted for by time-varying synergies, compared with the other methods.

Supporting Data in Mammals

Many of the same experiments conducted in frog and turtle have also been conducted in mammals. Tresch and Bizzi showed a set of a few force fields or spinal motor primitives can be elicited from the isolated unanesthetized rat spinal cord (Figure 8). These had properties similar to those of frog: fixed force structures scaling in amplitude with stimulation. The fields had major actions in the parasagittal plane, consistent with roles in locomotion. Vector superposition was demonstrated. In addition, the fields were also shown to be recruited from sets of chronically spinalized and deafferented frogs and so did not simply represent afferent or descending projection patterns.

Lemay and Grill used the same paradigm as in frog and rat in the decerebrate cat or chloralose anesthetized cat. They also showed a modularity of a small number of fields (Figure 9). However, winner-take-all interactions, which were seen in only 20% of frog costimulations, occurred in all sites examined in their data.

Corrections, omissions, and deletions in the cat have been demonstrated by McCrea and colleagues in fictive preparations (Figure 10). Like the phenomena in frog and turtle, these data comprise additions or deletions of bursts, often without perturbation of the remaining pattern. This behavior is difficult to achieve readily with a nonhierarchical pattern

Figure 8 Spinal motor primitives in mammals: the rat. An example of a force field measured in the three-dimensional workspace of the rat hindlimb. Forces evoked from microstimulation in the spinal cord were measured at ankle positions in three sagittal planes, one directly below the hip, one 1 cm lateral to the hip, and one 1 cm medial to the hip. Three views of the force field are shown here. In addition to the perspective view shown on the left, a lateral view and a dorsal view are shown. This response was obtained from microstimulation of a site at a depth of 750 μm with a current of 8 μA in L5. From Tresch MC and Bizzi E (1999) Responses to spinal microstimulation in the chronically spinalized rat and their relationship to spinal systems activated by low threshold cutaneous stimulation. *Experimental Brain Research* 129(3): 401–416.

Figure 9 Spinal motor primitives in mammals: the cat. Panel 1: field measurements in the cat used in Panels 2 and 3. Construction of a force field from measurement of isometric force vectors at the endpoint of the limb. Left: With the femur held fixed via pins, the endpoint was moved on a 3 x 3 cm grid where the dots indicate the spatial locations where forces were recorded. Thin lines indicate orientation of the limb at different endpoint positions. Right: measured force vectors (thick dark arrows), triangles dividing the workspace, and the interpolated force vectors (thin light arrows). Forces represented are total forces evoked by intraspinal microstimulation (active and passive) minus forces due to gravity. The field exhibited convergence, that is, net endpoint forces went to 0 at a location in the workspace indicated by the black circle. Panel 2: four types of active force field evoked at the endpoint of the hindlimb by intraspinal microstimulation. (a) Caudal flexion (depth, 3400 μm); (b) rostral flexion (depth, 3400 μm); (c) rostral extension (depth, 4600 μm); and (d) caudal extension (depth, 5000 μm). Panel 3: dissimilarity matrix of grouping of endpoint force patterns. Matrix of the squared euclidean distance was arranged so that fields in the same cluster are adjacent to one another in rows and columns. Lighter squares indicate smaller distances, and darker squares indicate larger distances. Lighter squares along the diagonal represent clusters. Caudal flexion responses extend from cases 0 to 34, rostral flexion is represented by a single square, rostral extensors extend from cases 36 to 45, and caudal extensors extend from cases 46 to 68. Note how the caudal extensor square along the diagonal is composed of two squares corresponding to two subgroups, 2–48 and 24–43, and similarly the caudal flexion square is formed by two squares corresponding to two subgroups. From Lemay MA and Grill WM (2004) Modularity of motor output evoked by intraspinal microstimulation in cats. *Journal of Neurophysiology* 91(1): 502–514.

generator. Using modeling and data, McCrea and colleagues suggested a rhythmogenic part of the CPG that synthesizes gait patterns, and a pattern-shaping layer that can add or subtract burst modules as demanded by task constraints and events, without necessarily altering the normal pattern. This latter is similar to a collection of motor primitives, and their model organization is reminiscent of recent ideas for organizing kinematic primitives in biomorphic robots advanced by Schaal and colleagues.

Ting, MacPherson, and colleagues have shown that a small number of muscle synergies account for phasic postural adjustments in the cat and that the structure and recruitment patterns of these may also closely resemble the patterns predicted by optimization schemes.

Support in Humans

Predating most work on spinal motor primitives, in an analysis of human gait, Vaughan showed that factor analysis of human electromyograms allowed their representation by a reduced set of four to six muscle groups. Zajac and colleagues also attacked the issue in cycling. More recently, Ivanenko, Poppele, Lacquaniti, and colleagues have very elegantly used principal components/factor analysis to clearly demonstrate modularity of human locomotion (Figures 11 and 12). The modular elements they identified can be related to both pattern generation and motor primitives and are likely to have a strong spinal component. Their data show conservation of most aspects of the modular elements across many voluntary tasks incorporated in walking or running, such as kicking a soccer ball. Their elements, while all similar in duration within a step cycle, are also modulated in duration along with the step-cycle duration and in phase depending on the activity (Figure 12). Thus the bursts can be dilated or compressed in time as a function of cycle period, as the locomotor cadence changes. Leg muscle synergies or balance and composition within bursts showed small adjustments but also remarkable consistency.

Future Issues in Spinal Motor Primitives

Development

The development of motor primitives and their subsequent plasticity are important issues. Are these

Figure 10 Deletions of parts of motor patterns as units in the decerebrate cat. Panel 1: deletions of extensor activity during fictive scratch in the decerebrate cat. (a) Dotted box indicates where, after the five rhythmic bursts illustrated, the medial gastrocnemius nerve became inactive (a complete deletion). During this period the posterior biceps and semitendinosis (PBSt) and semimembranosis and anterior biceps (SmAB) bursts were reduced in amplitude (partial deletions). Ankle flexor activity (tibialis anterior; TA) was modulated but did not return to baseline. Intervals on the horizontal bar were calculated from the immediately preceding five cycle periods (197 ms, SD 2). Interval spanning the deletion was not significantly different from control two-cycle intervals ($p > 0.40$). (b) Another example of a deletion of activity during fictive scratch in the hip extensor (SmAB) as well as the bifunctional PBSt and the ankle flexor (peroneous longus; PerL) nerves. This deletion is accompanied by sustained activity in another ankle flexor (TA). Scratch cycle period indicated on the horizontal bar was 204 ms (SD 14). Rhythmic bursts after the deletion reappear at an interval corresponding to three control step-cycle periods (three vertical tick marks). Interval spanning this deletion was not significantly different from three-cycle intervals taken from the control period ($p > 65$). Panel 2: maintenance of cycle period timing during deletions of fictive scratch activity. (a) A bout of fictive scratch in which there were three deletions (arrows) of extensor motor neuron (lateral gastrocnemius; LG) activity. (b) Overlay of all the cycles of rhythmic activity in an episode of fictive scratch. Top four traces are rectified and integrated electroneurographic records, and the bottom two traces are simultaneous recordings from a pair of LG and soleus (LGS) motor neurons. Records of normal activity (dotted lines) are overlaid with those obtained during extensor deletions (solid lines). Deletion interval was not significantly different from two-cycle intervals in the control period ($p = 0.95$). (c) Portions of the same traces during partial deletions (dotted lines) overlaid with the corresponding trace during the complete deletion (solid line). Panel 3: schematic representation of the proposed architecture for the central pattern generator, which consists of separate networks for rhythm generation (clock) and for pattern formation (i.e., the distribution of excitation and inhibition to motor neuron pools). Pattern formation modules include circuitry for reciprocal inhibition of antagonist motor pools and control the activity of subsets of motor neurons. Deletions that include a change in the locomotor rhythm are indicated by the arrow affecting the rhythm generator network. Deletions in which cycle timing is maintained are hypothesized to occur by disturbances at the level of the pattern formation networks and may affect individual pattern formation networks differentially. E, extensor; F, flexor. Data from Lafreniere-Roula M and McCrea DA (2005) Deletions of rhythmic motoneuron activity during fictive locomotion and scratch provide clues to the organization of the mammalian central pattern generator. *Journal of Neurophysiology* 94(2): 1120–1132.

Figure 11 Motor patterns in human locomotion. Ensemble averaged activity patterns recorded from eight participants for 32 muscles. Electromyographic records were filtered with a low-pass cutoff of 10 Hz. Top: stick diagrams of locomotion stepping. Bottom: EMG Data were plotted vs. a normalized cycle. As the relative duration of stance varied across participants, a hatched region on the bar below indicates an amount of variability in the stance phase duration across participants. These complex pattern data form the basis for the decomposition and analysis in **Figure 12**. Data from Cappellini G, Ivanenko YP, Poppele RE, and Lacquaniti F (2006) Motor patterns in human walking and running. *Journal of Neurophysiology* 95(6): 3426–3437.

elements hardwired or self-organizing, and are they long-term stable entities or transient neural organizations? Specific work on spinal motor primitives is currently lacking. However, *in ovo* and *in utero* and subsequent neonatal motor development of reflexes and pattern generation are the subject of intense research by several laboratories, such as Kiehn, Clarac, Bradley, Stehouwer, and Schouenborg. Initial motions

Figure 12 Motor pattern modularity in human locomotion. All walking and running motor patterns in the limb can be simply expressed as a collection of five appropriately timed pulses, which represent coordinated recruitment of muscles as a group. Pulse durations scale to the locomotor step-cycle duration. Many muscle groups represented in the pulses are also stable across the conditions, although there are some variations (e.g., component 4 in panel 2). This scheme somewhat resembles the scheme in **Figure 10** and the formulation in eqn [6] in the text. From Cappellini G, Ivanenko YP, Poppele RE, and Lacquaniti F (2006) Motor patterns in human walking and running. *Journal of Neurophysiology* 95(6): 3426–3437. Panel 1: activation temporal components derived from averaged muscle activity patterns (see **Figure 11**). (a) Superimposed activation components in walking and running. Note a prominent phase shift of the timing of the main peak of the second component in running. (b) Weighting coefficients (across 32 muscles) of the five basic temporal components (comps) during walking and running at the same speed (7 km h^{-1}). The correlation of weighting patterns between walking and running is shown at the right of each record for both the leg/lower trunk (tibialis anterior (TA) – rectus abdominis, superior portion (RAS)) and upper trunk/shoulder (latissimus dorsi (LD) – sternocleido mastoideus (STER)) muscles separately. Panel 2: the authors' interpretations are based on the data of the original study. Hypothetical motor programs for walking (a) and running (b) in terms of the characteristic timing of muscle activations and their pulsed activity. In both programs, four activation components (comp 1, 3, 4, and 5) occur relative to the touchdown (TD) phase of the cycle, and comp 2 occurs relative to the liftoff (LO) phase, at about 20% of the cycle preceding LO. As one gait mode is switched to the other, the timing of LO relative to TD changes along with the relative timing of comp 2 with respect to the other four comps. CPG, central pattern generator. Data from Cappellini G, Ivanenko YP, Poppele RE, and Lacquaniti F (2006) Motor patterns in human walking and running. *Journal of Neurophysiology* 95(6): 3426–3437.

both *in ovo* and *in utero* are largely unconstrained other than by viscosity and limb inertia. Subsequently the embryo becomes more confined and the limbs become loaded by the egg or uterine wall. Thus some opportunity for both kinematic and kinetic experiences of self-generated motion exist in a protected and simplified environment. However, much of the basic patterning seen in neonates can be developed without descending influences and without sensory feedback. The hardwiring of motor pools and primary afferent patterns is consistent with the possibility of hardwired spinal motor primitives. However, proceeding more

centrally, such hardwired structures are likely to be replaced with far more flexible topologies and far more adjustable synaptic weights. Schouenborg and colleagues have shown how distal reflexes can become exquisitely refined. Where primitives reside on this continuum is not yet known.

Plasticity and Recovery after Injury

The role of motor primitives in recovery after injury, rehabilitation, and neuroprosthetics is likely to depend on the relative stability of primitives. Infant motor patterns such as grasp, routing, and Babinski sign reveal themselves intact after adult injury, suggesting long-term stability. However, it has also been established by Wolpaw and colleagues that the spinal circuitry is subject to continuous adjustment by corticospinal and other mechanisms. Hogan, Krebs, and colleagues, examining stroke recovery, have shown that a set of coarse kinematic submovements in point-to-point movement reveal themselves early following stroke and then become blended or coarticulated through recovery. They are also examining the electromyographic basis for this process.

Relationship to Other Ideas about Spinal Organization

The detailed relationships of pattern generators, unit burst generators, pattern shaping systems, and the spinal motor primitives are still an area of investigation. In particular the neural underpinnings, circuitry, and processes that give rise to the modular separability at the level of function are not well understood despite the great wealth of excellent research on spinal circuits.

Relationship to Motor Learning and Evolution

From a Bayesian and evolutionary perspective, low-level execution primitives are useful only insofar as they adequately capture *a priori* expectations of the useful movement types and the adaptations needed (e.g., as in the wildebeest example). At the same time, they should be robust to and adapted to any structural variations in the musculoskeletal system throughout life. The best compromise between these potentially competing requirements of adaptive flexibility and long-timescale hardwiring of motor structures is not currently well understood. If primitives represent near optimal decompositions of tasks, as some suppose, are they organized transiently by spinal cord and brain, are they organized in restricted critical periods, or are they hardwired into development by evolution?

How spinal motor primitives are incorporated into learned behaviors and the extent to which they constrain early learning or skilled behaviors are not understood. The relations of learning basis functions, which have also been termed 'primitives' by Thoroughman and Shadmehr, to spinal motor primitives is unclear. Bracha and Bloedel have shown a strong influence of cerebellar adaptation processes on spinal reflex elements, supporting their use as a partial basis for organizing learning. Work of Bastian on human locomotor adaptation further supports this notion.

It is worth noting with regard to the developmental, learning, and theoretical issues here that the biological motor apparatus is a structure with a long evolutionary history. Coadaptation of mechanical plant and control are almost certain to have occurred. These might be extremely well tuned. However, both the mechanical structure and its controls may also be rife with historical 'appendices' and 'spandrels.' There may be a historically important structure with better algorithms overlaid on the cruder and older competences. An ideal *de novo* engineered structure might bypass this potential mass of 'legacy' structure, but the biology may be stuck with it, at least on the timescale of modern science!

Conclusions

Motor primitives laid down by evolution simplify early motor control in developing organisms, seed motor learning, and allow rapid adapted reflex trajectories and stepping adjustments. Evidence for such modularity now exists across limbed vertebrates. These spinal motor primitives may be equivalent to the keyboards on which voluntary and pattern generator systems play out motor patterns and with which they initially synthesize novel motion.

The motor plan for an arm movement to a target is ultimately defined by the distance and the direction from the hand to the target. Most commonly, such movements are effected to a seen target and, accordingly, the target's location is defined by its projection onto the retina. That is, the target's location is initially specified in a retinotopic frame of reference. Conversely, vision of the arm is not needed to make a reasonably accurate movement and the hand's location can be derived from proprioception. Thus, the problem of making goal-directed arm movements is one of combining information across sensory domains. This process of sensorimotor integration has been viewed as a mapping of information into a common frame of reference. Hand location derived proprioceptively is defined in a frame of reference fixed to the body, and because the eyes can move in the head and the head can move relative to the body, the retinotopic and proprioceptive frames of reference will generally not be aligned.

Initial behavioral experiments that addressed this problem led to a model in which visual information was mapped into the proprioceptive (body-fixed) frame of reference and a movement vector was defined in this coordinate system. However, recent behavioral experiments and electrophysiological recordings have refined this model to incorporate additional steps in the formulation of a movement plan. In this model, hand location is initially remapped into a retinocentric (eye-fixed) frame of reference and the initial movement vector is defined in this frame of reference. At subsequent stages, this movement vector is ultimately remapped into an arm-fixed frame of reference. This model appears counterintuitive because it introduces additional coordinate transformations and, accordingly, potentially more sources of error. However, as argued here, such a process would facilitate visually mediated, online error corrections – corrections that would be especially important when there is motion of the body or the target.

How Is the Motor Plan Defined?

The arm movement vector is defined by the location of the target relative to the hand. There are several lines of evidence to support this contention. The first is that the arm posture at the end of a reaching movement depends on the initial arm posture. The arm (neglecting the wrist) has a redundant degree of freedom since there are three degrees of freedom of motion at the shoulder joint and one at the elbow joint, but only three degrees of freedom are required to define the location of the hand in space. The extra degree of freedom can be characterized simply by the plane defined by the upper arm and the forearm. It has been found that the arm plane at the target depends in a predictable and consistent manner on the initial arm posture.

Second, electromyographic activity in arm muscles is tuned to the direction of movement. Generally, the pattern of muscle activity for whole arm movement has roughly the same characteristics as the pattern for simpler movements restricted to a single joint: an initial agonist burst for acceleration followed by an antagonist burst to decelerate the motion. The amplitude of these bursts shows directional tuning in that it decreases by an amount proportional to the cosine of the angle between the direction of motion and the 'best' direction of that particular muscle. Furthermore, neuronal activity in primary motor cortex (M1) is also tuned with respect to the direction and the amplitude of the arm movement.

The distance from the hand to the target is independent of the reference frame in which this vector is described. However, this is not the case for the movement's direction. Two frames of reference come to mind readily: an extrinsic one (perhaps fixed to the body) and another that is fixed to the arm. An extrinsic frame of reference is motivated by perception: we commonly define movements with respect to the cardinal axes, such as 'straight ahead' or '45 degrees to the right.' However, the mechanical actions of muscles depend on the posture of the arm and, accordingly, the tuning of arm muscle activity will change (for the same direction of movement defined in trunk-fixed coordinates) when the posture of the arm changes. In fact, early experiments suggested that the tuning of neurons in M1 was constant in an arm-fixed frame of reference.

Recent experimental results, however, point also to a frame of reference that is intermediate to these two – that is, a frame of reference that rotates by half of the amount of arm rotation. The mechanical actions of muscles at the shoulder and at the wrist have been found to follow such a 'half-angle' rule, as have the extraocular muscles of the eye. Furthermore, a considerable number of neurons in the wrist area of M1 show tuning that is 'muscle-like' in that their

preferred direction changed with wrist orientation (pronation–supination). However, half of the neurons in M1 show tuning in a trunk-fixed frame of reference.

How Is Hand Location Defined?

Although vision can be used to define the initial location of the hand, proprioceptive information is generally used for this purpose. The strongest evidence that proprioception is needed to encode the location of the hand in space comes from the fact that patients with proprioceptive deficits resulting from large-fiber sensory neuropathy exhibit large directional errors in hand movements. However, vision also contributes to the encoding of hand location since these directional errors were reduced when these patients could see their arm prior to the onset of the movement. Movement errors can also be induced in normal subjects if the apparent visual location of the hand relative to the target is altered. Behaviorally, subjects typically foveate the target prior to movement onset, rather than the hand, and it appears that vision contributes primarily indirectly by calibrating proprioceptive information about hand location. Visually mediated feedback of hand location does not appear to be prominent during arm movements. In fact, when executing movements to a sequence of targets, subjects typically saccade to the subsequent target before the hand arrives at the previous one.

How proprioceptive information from the muscles and skin is processed to derive the location of the hand in space is not well understood, either behaviorally or electrophysiologically. Behavioral experiments suggest that arm posture is perceived with respect to cardinal axes (vertical and parasagittal) as an angular elevation and yaw of each of the limb segments.

Coordinate Transformations Deduced from Psychophysical Studies

The question of how the location of the hand and that of the target are represented has been addressed behaviorally by analyzing the pattern of errors in pointing movements executed under open-loop conditions. In such experiments, subjects are presented with a target, asked to remember its location, and then, after the target is removed, asked to point to the remembered location. Constant errors (the average error for a particular target location) and variable errors (the variance about this mean) have been analyzed.

Errors (constant and variable) were not homogeneous in three-dimensional space. Furthermore, they depended on the location of the target relative to the subject, but neither on the starting location of the hand nor on the distance from the hand to the target. The hand's location at the end of the pointing movement tended to match the target's direction to a much better degree than its distance from the subject; directional errors were much smaller than distance errors. The initial experiments were performed in the dark. In this condition, distance errors in pointing depended only on the target's distance when distance and direction were measured from the shoulder. They were skewed when an eye-centered coordinate system was used. Thus, the pattern of errors suggested that target location was encoded in a spherical coordinate system that was shoulder centered. This interpretation implied a transformation of the representation of target location from an eye-fixed to a body-fixed frame of reference (with an intermediate head-fixed representation because the eyes can move relative to the head). It was suggested that using a shoulder-centered spherical coordinate system simplified the mapping of target location into intended arm posture by means of simple, linear transformations that were only approximately correct and led to the observed errors.

Other experiments were consistent with this interpretation. Subjects did not make errors in distance when they put the tip of a handheld pointer on the remembered target location, implying that the pointing errors did not arise from a misperception of the target's location. Furthermore, they were able to point to a location halfway between the target and the shoulder, a task that is simple if target location is encoded in shoulder-centered coordinates but becomes much more difficult if the location is encoded in eye-centered coordinates. Another analysis that made no *a priori* assumptions about the origin of the coordinate system for target location indicated that it was centered at a point approximately halfway between the shoulder and the eyes in the frontal plane. This estimate was obtained by taking the error vectors on each trial (the difference between target location and hand location) and extrapolating them to determine their point of intersection. Since not all of the vectors intersected at a common point, there was some uncertainty in the estimated location; however, the 95% confidence limits did not include the shoulder or the center of the head.

A similar analysis of results obtained when subjects could view their hand, but not the target, suggested that in this instance the target was represented in a retinocentric frame of reference. Other experimenters, analyzing the pattern of variable errors, arrived at the same conclusion. The major axis of the ellipsoid defining the variance of the errors pointed toward

the head, irrespective of the location of the target or the starting location of the hand. For movements performed in the dark but with the eyes open, the orientation of the major axis of the error ellipse depended on the interval between the presentation of the target and the onset of the movement. For short memory delays, these vectors pointed toward the head, shifting toward the shoulder at longer time delays. Other experimenters introduced errors in the visually perceived location of the finger at one target location and examined how such a visuomotor remapping generalized to other target locations. The remapping was best described in a spherical eye-centered coordinate system.

Typically, subjects foveate the target to which they point. For eccentric targets in a retinocentric frame of reference, subjects overestimate the eccentricity when making a pointing movement in the absence of visual feedback of the target location. Results of experiments that took advantage of this phenomenon also indicated that target location was represented in a retinocentric frame of reference and that this location could be remapped if there was an intervening eye movement.

These experimenters presented subjects with a target straight ahead and asked them to foveate it and to make a saccade to an eccentric location after the target was removed, before pointing to the remembered target location. Directional errors in pointing reflected the eccentricity of the gaze and were indistinguishable from errors in pointing to eccentric target locations in the absence of eye movements.

All of these results suggest that, in the initial stages of processing, the hand movement vector is defined in a retinocentric frame of reference – that is, in the frame of reference in which the target location is initially defined visually. This conclusion implies that the location of the hand is also mapped into this frame of reference, even when vision of the hand is unavailable. In the dark, this representation gradually shifts to a body-fixed, shoulder-centered frame of reference. It also implies that the movement vector is subsequently remapped from an eye-centered frame of reference into one that is more closely aligned with arm posture (i.e., from retinal coordinates to muscle-based coordinates). Electrophysiological evidence from behaving primates is in accord with this conclusion.

Neural Correlates of the Coordinate Transformations for Reaching

The neural correlates of coordinate transformations have been investigated most extensively in the posterior parietal cortex (PPC). Although the initial focus of these studies was on eye movements, reaching movements have recently received the most attention. In these studies, animals made reaching movements under conditions in which both the hand location at the start of the movement and the target location were held fixed in one frame of reference but varied in others. Under such conditions, the criterion for identifying the frame of reference that best captures the neural responses is reasonably straightforward. For example, if neurons encode the target and initial hand location in a retinocentric frame of reference, then the firing rates of these neurons should not vary if hand and target position are held fixed with respect to the direction of gaze, even if gaze direction varies with respect to the body or in space. Similarly, if neurons encode hand and target position in a body-centered reference frame, then their activity should not vary as long as these positions are held fixed with respect to the body, even if body position changes in space.

In the parietal reach region (PRR), neurons encode reach-related information in a manner that is consistent with a retinocentric reference frame. Neural responses in this area are relatively invariant as long as the target location for a reach falls on the same part of the retina. A subset of PRR neurons are also modulated when the initial hand position is changed. Importantly, varying the initial hand position does not alter the tuning of a neuron for target position; that is, the cell continues to respond best for the same retinal location of the target. Instead, varying the hand position modulates the gain of target-related responses. Such 'gain fields' for body position signals are ubiquitous in the brain and have been postulated to play a role in coordinate transformations, among other functions. A surprising feature of these hand position gain fields in PRR is that they do not appear to encode the location of the hand with respect to the body, as one might expect of a signal derived in part from proprioceptors. Rather, PRR neurons appear to encode hand position in the same reference frame that is used to encode the target (i.e., a retinocentric one). Since neurons in PRR encode information about the locations of both the target and the hand with respect to gaze, PRR can be said to provide a retinocentric representation of the hand movement vector.

The issue of reference frames has been taken up in another part of the PPC as well, namely area 5. Neuronal activity in this area seems to represent the remapping of the movement vector into a frame of reference more closely aligned with arm posture. Some neurons in area 5 do not encode the movement vector in any single frame of reference; rather, the responses of these neurons appear to reflect the use

of a retinocentric frame in conjunction with one that is more closely linked to the arm. Other area-5 neurons do not appear to use retinocentric coordinates at all; these neurons explicitly encode the difference between the current target and hand locations (motor error) in a manner that is independent of gaze direction. It is unclear whether this latter activity is best described as encoding a motor error in extrinsic coordinates or a motor error that is expressed in the intrinsic coordinates of the joints or muscles (an arm-centered one). In any event, within the PPC there is a continuum of responses, from neurons whose tuning is purely eye centered (PRR) to neurons that are purely hand/arm centered or that show a mixture of these two reference frames (area 5). The presence of such a continuum, as well as the paucity of neurons encoding reach-related information in head-centered reference frames, has led to the proposition that, at least in contexts in which the hand and target positions can be directly compared via vision, coordinate transformations for reaching involve a direct transformation from a retinocentric reference frame to a hand/arm-centered one (Figure 1).

Understanding subsequent transformational stages depends critically on the precise nature of the hand/arm-centered representation in area 5. An arm-centered representation is ultimately required by the motor system, that is, simply knowing the direction and distance the hand must move to reach the target is insufficient to specify a control signal for the reach, as this control signal must account for the fact that the arm's mechanical properties vary as a function of arm configuration. Thus, the continuum of responses described previously either must reflect the direct remapping of a retinocentric movement vector onto arm coordinates or transformations occurring 'downstream' of area 5 must incorporate a mechanism for transforming a hand-centered (extrinsic) representation into the appropriate reference frame for activating the muscles.

An early multiplexing of visual signals with signals related to eye, head, and arm orientation would provide support for the idea that the PPC directly maps a retinocentric representation of the movement vector onto arm muscle-based coordinates. In support of this idea, neurons in PRR, which is thought to occupy a processing stage functionally antecedent to area 5, appear to encode eye orientation as well as the retinocentric location of the target and hand. It is unknown whether head position signals are encoded by PRR neurons in the same way as eye position because the relevant experiments have yet to be performed, but access to such signals is implied by the responses of neurons in other parts of the PPC, namely 7a and the lateral intraparietal area. Regarding arm

Figure 1 Schematic of the reference frame transformations for reaching, based on psychophysical and neurophysiological studies. In general, a hand movement vector in retinal coordinates is mapped directly to an arm motor error expressed in muscle coordinates (center arrow). The precise mechanism underlying this transformation may be context dependent. In the absence of continuous and reliable visual feedback (e.g., for movements generated in the dark or following long delays), targets are remapped from eye to body-centered coordinates and then compared to the body-centered hand location to derive the arm motor error (left arrow). In contrast, when the hand and target are easily viewed, hand position is remapped from body to eye coordinates to determine the hand movement vector in eye coordinates (right arrow), which is subsequently remapped into muscle coordinates. Note that although explicit head-centered representations are not required for either mechanism, head (and eye) position signals play an important role in both mechanisms.

orientation, it has been shown that the preferred directions of neurons in area 5 rotate with changes in arm posture in much the same way as they do in M1. This phenomenon is at least consistent with a role for the PPC in transforming retinocentric information into a reference frame that is in line with the one used to specify muscle activations.

The existence of an intrinsic, arm-centered frame of reference in area 5 would not necessarily mean that the PPC is involved in specifying the joint torques or muscle activations required to move the arm. As stated previously, neurons in M1 and the dorsal premotor cortex also show evidence of 'muscle-like' tuning and thus any one or all three of these areas could support the transformation from kinematic to kinetic signals. Moreover, it should be noted that area 5 activity does not appear to reflect the time course of the forces that generate arm movements as well as activity in M1. Thus, area 5 could simply represent an

intermediate transformational stage that is intrinsic in nature but 'dynamics free.' Alternatively, the representation in area 5 may be part and parcel of a role in estimating limb position on the basis of visual and somatosensory information and previous motor commands. Integration of the latter two signals would seem to require an arm-centered frame and would also predict some degree of sensitivity to changing arm dynamics, which has been reported in area 5. This last scenario would also fit well with the results of transcranial magnetic stimulation (TMS) studies in humans, which have reported impairments in the learning of novel arm dynamics with stimulation of the PPC.

Conclusion

Remapping hand position into an eye-centered frame of reference requires at least as many transformational stages as a scheme requiring remapping of target position into body-centered coordinates. What, then, is the benefit of a retinocentric representation of the hand? Recoding hand position in retinal coordinates would facilitate online updating of reaching movements because the target and hand could then be rapidly and directly compared. This may be especially important in conditions in which there is relative motion of the target with respect to the body, a situation that has been studied rarely experimentally but one that occurs quite commonly in everyday tasks. Interestingly, TMS studies of normal human subjects as well as studies of patients strongly implicate the PPC in rapid online corrections of arm movements. Visual feedback of the hand is generally considered to be too slow to effectively mediate such corrections; thus, a retinocentric representation of hand position would be most beneficial for online control if it were based on other signals besides vision. The existence of this type of representation is supported by recordings of neurons in the PPC: in at least some of these neurons, hand position appears to be encoded in a retinocentric frame of reference even in the absence of concurrent visual input.

Introduction

Motor learning refers to two different processes: adaptation and skill acquisition. Adaptation relates to our ability to compensate for environmental changes, including visual, kinematic, or dynamic changes in the characteristics and attributes of external stimuli and/or objects. On the other hand, the ability to learn a movement sequence and the incremental improvement in its performance refer to the sequence learning aspects of still acquisition which are the main focus of our present discussion. The generation of sequential actions is central to most of human intelligent behaviors ranging from everyday skills such as tying one's shoe laces to using a computer or playing the piano. The acquisition, representation, and retention of motor sequences are believed to build on and benefit from the availability of basic, simple motion elements ('primitives'), which are then ordered and concatenated into particular sequences, thus giving rise to the diverse, complex, goal-directed motor repertoire of humans and other animals. Long-lasting changes in motor performance related to sequence learning are known to evolve following several distinct phases and usually require many practice sessions. Subsequent sections discuss several topics related to sequence learning, starting with the presentation of two different mechanisms of sequence learning (i.e., explicit vs. implicit). The article then describes up-to-date theories concerning the specificity of these different learning mechanisms and their time course and discusses the neural substrates and brain areas subserving sequence learning. Finally, it reviews some of the current literature, pertinent to sequence learning, concerning shifts in representation, consolidation, and the effect of sleep on the retention and off-line improvement in the performance of learned sequences.
