Different from the other PC null mice, multiple studies on PC7 null mice embryos revealed no apparent abnormal phenotype under resting conditions. This may be explained by the fact that PC7 expression extensively overlaps with that of Furin. Many reports show that PC7 and Furin process the same substrates, such as PDGF-AA, PDGF-BB, vascular endothelial growth factor C, and bone morphogenic protein. Alternatively, the most conserved convertase PC7 may be involved in the processing of a panel of nonessential substrates. Double knockouts of Furin and PC7 may help resolve the issue of the possible critical functions of PC7 during embryogenesis in a Furin null background.

SKI-1 is a key enzyme in the regulation of lipid metabolism and cholesterol homeostasis that cleaves the transcription factors sterol regulatory element binding proteins (SREBP-1 and SREBP-2). The latter are synthesized as precursors harboring two transmembrane domains separated by a short ER luminal loop and comprising N- and C-terminal cytosolic domains. These precursors are cleaved in an SREBP cleavage-activating protein (SCAP) and insulin-induced gene (Insig)-dependent manner. When cellular cholesterol levels are high, the insulin-regulated proteins Insig-1 and/or Insig-2 bind and retain the SCAP–SREBP complex in the ER. When cells are deprived of sterols, Insigs separate, allowing the transport of the SREBP–SCAP complex to the Golgi. Therein, a two-step proteolytic process starting with SKI-1 at the sequence R-X-V-L↓ (Figure 2) and then site 2 protease (S2P) releases the cytosolic N-terminal segments of SREBPs from cell membranes, allowing their translocation to the nucleus (nSREBP), where they activate transcription of more than 35 mRNAs coding for proteins/enzymes required for the biosynthesis and uptake of cholesterol and unsaturated fatty acids, as well as the low-density lipoprotein receptor (LDL-R).

Similar to SREBPs, the ER-anchored type II membrane-bound transcription factor ATF6 plays a major role in the unfolded protein response. Under normal conditions, it is held in the ER by the chaperone BIP, with its N-terminal DNA-binding domain facing the cytosol and its COOH terminus in the ER lumen. Accumulation of improperly folded proteins in the ER, which can be induced by calcium depletion (thapsigargin) or inhibition of N-glycosylation (tunicamycin), leads to an ER stress response resulting in BIP dissociation from proATF6. The latter is then translocated in a SCAP-independent manner to the Golgi, where it is first cleaved by SKI-1 and then by S2P. This releases the cytosolic N-terminal domain, which reaches the nucleus (nATF6) to activate ER stress target genes.

Other type II membrane-bound substrates include at least six CREB-like basic leucine zipper transcription factors. BDNF is a soluble substrate and the study of its processing led to the initial cloning of SKI-1. We also showed that the soluble prosomatostatin is cleaved by SKI-1 to release the N-terminal peptide Antrin.

The essential roles played by SKI-1/S1P are evident from the fact that deletion of its gene results in

embryonic death at the earliest stages of cell division (i.e., from one- to two-cell stage), thus preventing blastocyst formation. The importance of this enzyme in the central nervous system is yet to be unraveled using tissue-specific knockout mice. When this was done in liver, the level of circulating total cholesterol was decreased by 50%, emphasizing its critical control of cholesterol synthesis and uptake. This gene has not been found to be polymorphic, and no single nucleotide polymorphic variation has been identified that could be genetically associated with a known pathology.

Convertases PC5/6 and PACE4

The convertases PC5/6 and PACE4 seem to form a class of their own based on their primary structures and their ability to bind the cell surface via their C-terminal Cys-rich domains, which bind TIMPs and HSPGs and, in many cases, inactivate HSPG-bound proteins such as endothelial and lipoprotein lipases and possibly adhesion molecules. Because in cellular experiments and *in vitro* many of the substrates processed by either enzyme can also be cleaved by Furin and/or PC7, the specific physiological substrates of PC5/6 and PACE4 have not been identified. In the central nervous system, it has been shown that PC5/6 can process the neural adhesion molecule L1, assisting in neuronal repair and migration. Ontogeny and tissue distribution analysis of these convertases showed that PC5/6 expression is detected early during embryonic development, appearing first in extraembryonic tissues. By E9, it is also specifically expressed in cells of the maternal–embryonic junction, where no other convertase is expressed. Data strongly suggest unique tissue-specific functions of PC5 and PACE4. Thus, PC5/6 mRNA was detected only in neuronal cells, whereas PACE4 mRNA was expressed in both neuronal and glial cells. In areas that are rich in neuropeptides, such as cortex, hippocampus, and hypothalamus, mRNA levels of PC5 were high but PACE4 levels were low or undetectable. In regions such as the amygdaloid body and thalamus, distinct but complementary distributions of PC5 and PACE4 mRNAs were observed. The medial habenular and cerebellar Purkinje cells expressed very high levels of PACE4 mRNA.

The knockout of PACE4 and PC5/6 genes in mice resulted in different phenotypes. Thus, whereas the PACE4 knockout results in a 75% viable phenotype with bone morphogenesis defects, that of PC5/6 causes death at birth, due in part to the lack of processing of the TGF-β-like growth factor GDF11 and to the lack of various homeotic transformations. What are the other precursors that need such specific processing events and what is the role of TIMPs and HSPGs in this process are open questions that may be resolved by tissue-specific knockouts and careful analysis of the cell surface proteome of various tissues in the presence or absence of these convertases.

Convertase PCSK9 (Originally Named NARC-1)

PCSK9 was first characterized by our group in 2003. It is highly expressed in adult liver, gut, and kidney. During development, PCSK9 mRNA levels are transiently high in telencephalon (E12–E15), in the rostral extension of the olfactory peduncle, and in cerebellar neurons. Under resting conditions, the expression of PCSK9 in adult brain is restricted to the olfactory peduncle and cerebellum. Overexpression of PCSK9 in telencephalic progenitor cells enhances proliferation and neuronal differentiation. Whether specific signals can regulate the levels of PCSK9 in the central nervous system is yet to be defined. PCSK9 expression in liver hepatocytes is upregulated by SREBP-2 and downregulated by cholesterol. We established the first association between single point mutations in PCSK9 and autosomal dominant hypercholesterolemia in two French families. Later, it was shown that nonsense PCSK9 mutations, likely resulting in a loss of function, are associated with hypocholesterolemia in approximately 2% of black subjects. Accordingly, mutations associated with hypercholesterolemia result in a gain of function of PCSK9 that triggers the degradation of LDL-R in acidic compartments, likely endosomes. By an unknown mechanism, high levels of PCSK9 lead to a faster rate of degradation of cell surface LDL-R, resulting in increased circulating LDL-cholesterol as LDL uptake in hepatocytes by LDL-R is diminished. In agreement, *Pcsk9* null mice exhibit increased LDL-R protein, but not mRNA, and a twofold decrease in circulating cholesterol, whereas mice overexpressing PCSK9 following recombinant adenoviral infections or in liver transgenic mice exhibit high levels of circulating cholesterol. A 32-year-old educated female aerobic instructor with two compound heterozygote mutations leading to complete loss of PCSK9 expression was recently identified. Although healthy, fertile, and normotensive, with normal liver and renal functions, her LDL-cholesterol is remarkably low ($14\,\mathrm{mg\,dl^{-1}}$). This and the observation that loss-of-function nonsense mutations could lead to 88% reduction in the risk of developing cardiovascular artery disease (CAD) during a 15-year period, indicate that inhibition of PCSK9 may represent a safe and effective strategy for the primary prevention of CAD. The role of PCSK9 in the brain is less clear, and it may only become apparent under stressful or pathogenic conditions such as cerebral stroke.

Summary

The nine-member family of PCs comprises seven basic amino acid-specific subtilisin-like serine proteinases related to yeast kexin, known as PC1/3, PC2, Furin, PC4, PC5/6, PACE4, and PC7, and two other subtilases that cleave at nonbasic residues called SKI-1/S1P and PCSK9. Except for testicular PC4, all other convertases are expressed in brain and play a critical role in various neuronal functions, including the production of diverse neuropeptides as well as neural growth factors and receptors, the regulation of cellular adhesion/migration, cholesterol and fatty acid homeostasis and repair mechanisms, and growth/differentiation of progenitor cells. Some of these convertases process proteins implicated in neuropathologies such as Alzheimer's disease β-secretase (BACE1), neural growth such as NGF, as well as adhesion molecules such as L1. N-CAM and N-cadherin, which are important for cancer malignancies and neuronal regeneration and repair following injury. The development of specific inhibitors/modulators of convertases may find applications in the control of some of these pathologies.

Neuroendocrinology

Neuroendocrinology encompasses the brain's regulation of and interaction with the endocrine system. The neuroendocrine system can be subdivided by anatomic, physiologic, and biochemical characteristics. The major anatomic components are the hypothalamus and extrahypothalamic regions, the hypothalamic–pituitary stalk and portal vessels, and the pituitary. Once designated as the master gland, the pituitary is to a large extent subservient to the neuroendocrine apparatus of the medial basal hypothalamus. The pituitary is divided anatomically into three regions that are embryologically distinct and separately regulated.

The anterior pituitary (adenohypophysis) secretes six well-characterized hormones important for distant endocrine regulation: adrenocorticotropin (ACTH) stimulates the adrenal cortex; thyroid-stimulating hormone (TSH), or thyrotropin activates the thyroid gland; luteinizing hormone (LH) and follicle-stimulating hormone (FSH), both gonadotropins, act on the ovaries and testes; prolactin stimulates milk production in the breast; and growth hormone (GH) or somatotropin exerts metabolic effects essential for attainment of full somatic growth and maintenance of normal metabolic homeostasis. These hormones are produced by individual cell types, except for LH and FSH, which are produced in the same cell. The major cell types of the anterior pituitary are called corticotropes, thyrotropes, gonadotropes, lactotropes, and somatotropes, and can be distinguished from one another by immunocytochemistry and electron microscopy. An additional cell type, the somatomammotrope, produces both GH and prolactin, and another, the folliculostellate cell, produces several substances, including vascular endothelial growth factor, interleukins, and lipocortin. The adenohypophysis originates embryologically from the joining of Rathke's pouch, an outpouching of the primitive gut, with portions of the ventral placodes of the neural ridges, which also give rise to the hypothalamus.

The posterior pituitary (or pars nervosa) is derived from primitive hypothalamic tissue. As it evaginates from the base of the brain, it forms the infundibulum of the third ventricle, the median eminence of the hypothalamus, and the pituitary stalk. The neural lobe contains the axons of hypothalamic neurons located in the paired supraoptic and paraventricular nuclei and forms the site of terminal storage in cells, termed pituicytes, for the neurohypophysial hormones vasopressin and oxytocin. Synthesized in the neurons of the supraoptic and paraventricular nuclei, vasopressin and oxytocin are transported axonally through the pituitary stalk to the posterior pituitary and are released by axonal depolarization. Such nerve cells – capable of synthesis, transport, storage, and depolarization-induced hormone release – are called neurosecretory neurons.

The intermediate lobe of the pituitary, while prominent in lower mammals, is rudimentary in primates. It is the source of β-endorphin and MSH (melanin-stimulating hormone) in some species, but has little known function in humans. It is innervated in rodents primarily by dopaminergic nerve fibers arising in the hypothalamus.

The pituitary is connected to the hypothalamus by a stalk that permits two types of communication: vascular and neuronal. The vascular connections are essential for the regulation of anterior pituitary function by the hypothalamus. The anatomical features of the vascular supply are unique. Shortly after exiting from the cavernous sinus, the internal carotid arteries provide bilateral arterial branches, the superior hypophyseal arteries which penetrate the median eminence of the hypothalamus, dividing into a capillary network that extends into the outer layer of the basal hypothalamus. The capillaries are juxtaposed on the axonal terminals of the hypothalamic hormone-secreting neurons. The fenestrated endothelial cells, unlike other capillaries of the brain, permit diffusion of the neurohormones from the nerve terminals into the portal capillaries. In most mammals, the capillaries of the median eminence coalesce to form six to ten portal veins that traverse the pituitary stalk from the brain downward, and then divide to form the vascular sinusoids that bathe the secretory cells of the anterior pituitary.

Neurons located in the anterior and medial basal hypothalamus synthesize hormones and transport them axonally to the vicinity of the capillaries of the median eminence, from which they freely diffuse into the vessels and are carried to the anterior pituitary. The hypothalamic hormones, all but one of which are peptides, are frequently called releasing or inhibiting hormones (or factors) and are relatively specific for each of the anterior pituitary hormones (Figure 1). Their isolation and characterization were initially accomplished by quantitative purification of hundreds of thousands of sheep or pig hypothalamic extracts. The work of Schally and Guillemin and their collaborators elucidated the structure of thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), and somatostatin (somatotropin release-inhibiting

Figure 1 Hypothalamic hormone–pituitary hormone relationships. Symbols in interrupted lines have not yet been fully characterized. hormone, SRIH) for which they were awarded the Nobel Prize in 1971. Corticotropin-releasing hormone (CRH) was isolated from rat hypothalamus and growth hormone-releasing hormone (GHRH) from pancreatic tumors and subsequently human hypothalamus one decade later.

Neuroanatomical studies, using immunocytochemical and *in situ* hybridization techniques, have demonstrated distinct hypothalamic localization within neurons for each of the peptides. TRH is found primarily in the anterior periventricular region, with some cells interposed with the cells of the periventricular nucleus. GnRH is found in arcuate nucleus of primates and in the medial preoptic area of rodents. Somatostatin is located in anterior periventricular cells, and to a lesser extent in the arcuate nucleus. CRH is located in periventricular cells and, as with TRH, in cells within the magnocellular paraventricular nuclei. GHRH is found almost exclusively in the arcuate nucleus. Prolactin secretion is regulated principally by an inhibitory hypothalamic influence. The primary prolactin inhibitory factor (PIF) is dopamine, found also in arcuate neurons. There is now considerable physiologic evidence for the presence of one or more prolactin-releasing factors (PRFs). Vasoactive intestinal peptide is believed to represent one such PRF, and there is evidence for another PRF in the neurointermediate lobe. The hypothalamic hormones are not entirely cell specific, because TRH stimulates both TSH and prolactin release and somatostatin inhibits both GH and TSH release.

The actions of the releasing hormones on pituitary cells are mediated by cell receptors. Receptors for TRH, GnRH, somatostatin, CRH, GHRH, and dopamine have been cloned. GHRH and ACTH activate the adenylyl cyclase-protein kinase A system and increase intracellular Ca^{2+} within somatotropes and corticotropes, respectively; TRH and GnRH act primarily through the phosphoinositol-protein kinase C system in thyrotropes and gonadotropes, respectively; and somatostatin inhibits adenylyl cyclase in somatotropes. The actions of the releasing hormones are rapid; secretion of hormones can be detected within minutes after administration both *in vitro* and *in vivo*. In addition, at least one hypothalamic hormone (GHRH) exhibits independent effects on pituitary hormone (GH) synthesis and mitogenesis in somatotropes.

The discipline of neuroendocrinology, broadly defined, encompasses the mechanisms, processes, and physiologic responses that coordinate and integrate the internal hormonal milieu. These responses are necessarily complex and diverse in the intact animal. All pituitary hormones are secreted dynamically in episodic bursts or pulses. Each hormone has its own characteristic pattern of secretion, during short periods (ultradian), on a daily basis (circadian), and during more prolonged periods (seasonal). These complex patterns of secretion are generated in the brain and transduced into appropriate hormonal signals by the neurosecretory cells of the hypothalamus. Hormone secretion is determined by numerous behavioral events (e.g., stress, sleep, and emotions) and metabolic events. For example, vasopressin release is regulated by osmotic changes in the circulating blood, volume changes induced by hemorrhage, and stress. GH secretion is stimulated by nutrient ingestion (protein), stress, slow-wave sleep, and pharmacological agents that activate β-adrenergic, dopaminergic, or serotonergic neurotransmitter systems.

The hypothalamus is situated in anatomical and functional proximity to the limbic system. Neural structures important in regulating neuroendocrine responses include the amygdala, hippocampus, septum, and limbic midbrain. In the latter, the biogenic amine systems, which originate in the brain

stem and include the noradrenergic systems arising in the locus coeruleus and other nuclei and the serotonergic system located in the raphe nuclei, are of particular importance.

Recent developments have considerably extended concepts of the boundaries of neuroendocrinology. In addition to the releasing hormones and the influence of biogenic amines, many other neurotransmitters and neuropeptides can act to modify neuroendocrine responses. Histamine, γ-aminobutyric acid (GABA), glutamate, and acetylcholine each influence releasing hormone secretion. The opioid peptides are involved in the secretion of prolactin, GH, and the gonadotropins, and nitric oxide has been implicated in the regulation of several releasing hormones, particularly GHRH. Disorders of gonadotropin release caused by intensive exercise (e.g., ballet, prolonged athletic activity) or by anorexia nervosa and other forms of caloric deprivation or malnutrition may be attributable, in part, to overactivity of central opioid systems. A number of other neuropeptides including substance P, neurotensin, and bombesin are found in abundance in the hypothalamus and are localized in nerve terminals in the median eminence. Their physiologic role in neuroendocrine regulation remains to be fully characterized.

Considerable interest has recently developed in the role of peripheral peptides with actions on hypothalamic feeding regulation, such as leptin, and hypothalamic peptides with similar actions, such as the orexins and neuropeptide Y. In addition to their effects on metabolic homeostasis, these peptides influence the secretion of several pituitary hormones, such as GH and the gonadotropins, through hypothalamic-mediated mechanisms. These findings have provided evidence for the mediation of the effects of nutrition on reproductive function. For example, kisspeptin, a recently identified neuropeptide with profound stimulatory effects on GnRH secretion through its GPR-54 receptor, appears to act as an intermediary between leptin and GnRH neurons. Another peptide, ghrelin, is found primarily in the stomach, although it is also present in the hypothalamus. Its receptors are present in both hypothalamus and pituitary, and the peptide has potent effects on GH secretion through a protein kinase C pathway, thereby explaining the profound effects of alterations in nutritional status and GH secretion. It is of interest that these effects may be mediated through changes not only in peptide concentrations but also in their receptors.

Finally, considerable interest has emerged in the interaction of the immune and neuroendocrine systems (neuroimmunoendocrinology). Interleukins 1 (IL-1) and 6 (IL-6), as well as other cytokines, have been implicated in the release of SRIH, GH, and ACTH and may serve as central nervous system peptide modulators of the stress response. In addition, they may function as regulators of the pathophysiologic responses to stimuli that provoke immunologic responses.

Neuroendocrinology of Affective Disorders

D A Gutman and C B Nemeroff, Emory University School of Medicine, Atlanta, GA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Our understanding of the neurobiology of depression and other major psychiatric disorders has been advanced to a considerable extent by the systematic analysis of various circulating hormones in patients and normal comparison subjects. The occurrence of prominent psychiatric symptoms in patients with well-documented endocrine disorders, including Cushing's disease and primary hypothyroidism, provided the original rationale for exploring the connection between endocrine function and both affective and cognitive function. Work during the past 50 years has highlighted the complex interplay between endocrine gland secretions and the central nervous system (CNS).

The neuroendocrine control systems are generally organized in a hierarchical manner and are composed of three major components (Figure 1) that are briefly outlined here. At the zenith of each is a collection of neurons in the hypothalamus that integrate signals from higher order centers in the brain. These neurons synthesize and release factors that either promote or inhibit the release of anterior pituitary hormones, the hypothalamic hypophysiotropic hormones also known as release or release-inhibiting factors. These peptide hormones, as summarized in Table 1, are synthesized in the neuronal perikarya by transcription of the DNA sequence for the peptide prohormone. After translation in the endoplasmic reticulum, these prohormones are processed during axonal transport and packaged into vesicles destined for the nerve terminals. These now biologically active peptides are then released, following appropriate physiological stimuli or as part of a circadian cycle, from the most ventral portion of the hypothalamus termed the median eminence. These peptides, secreted directly into the hypothalamo-hypophyseal portal vessels, are transported humorally in this collection of blood vessels that connects the hypothalamus (which is contained inside the CNS) and the anterior pituitary gland (Figure 2). These peptides arrive in high concentration in the sinusoids of the anterior pituitary (adenohypophysis), where they bind to specific membrane receptors on their targets, the pituitary trophic hormone-producing cells. Activation of their receptors promotes (or inhibits) the release of the anterior pituitary hormones into the systemic circulation. The increase or decrease in the plasma concentrations of these pituitary hormones produces a corresponding increase or decrease in the plasma concentrations of the end organ hormones. The hormones of the end organ axes, such as gonadal and adrenal steroids or thyroid hormones, feedback on both pituitary and hypothalamic cells to reduce further release of trophic hormones or releasing factors, respectively, often referred to as 'long-loop' negative feedback. Short-loop negative feedback circuits have also been identified in which pituitary hormones directly feedback upon hypothalamic neurons to prevent further release of hypothalamic releasing factors.

Disturbances in the feedback regulation of the hypothalamic–pituitary–end organ axes are of considerable interest in psychiatry. As noted previously, the common occurrence of psychiatric symptoms in many primary endocrine disorders, such as hypothyroidism and Cushing's syndrome, served as an impetus for investigation into the regulation of neuroendocrine systems in common and severe psychiatric disease states such as depression, schizophrenia, and bipolar disorder. Thus, a large part of psychoneuroendocrinology has focused on identifying changes in basal levels of hypothalamic, pituitary, and end organ hormones in patients with psychiatric disorders.

Corticotropin-Releasing Factor in Depression and Anxiety Disorders

Basic Biology

The hypothalamic–pituitary–adrenal (HPA) axis is among the most intensely studied systems in psychiatry. At the pinnacle of this system is the neuropeptide corticotropin-releasing factor (CRF), also known as corticotropin-releasing hormone, a 41-amino-acid peptide. From a classical neuroendocrine standpoint, CRF is the master hormone controlling the activity of the HPA axis (see Figure 3).

CRF is primarily synthesized in parvocellular neurons located in the paraventricular nucleus (PVN) of the hypothalamus and projects to the median eminence. CRF neurons in the PVN (Figure 1) receive input from a variety of brain regions, including the amygdala, bed nucleus of the stria terminalis, and other brain stem nuclei. In response to stress, the CRF PVN neurons are activated, releasing CRF from the median eminence into the hypothalamo-hypophyseal portal system, where it is transported to the anterior pituitary activating CRF receptors on corticotrophs. In addition, CRF promotes the synthesis of proopiomelanocortin

Figure 1 Overview of the common organizational motif of the neuroendocrine axis. The neurosecretion of hypothalamic factors into hypophyseal portal vessels is regulated by a set point of activity from higher brain centers. Neurohormones released from the hypothalamus into hypophyseal portal vessels in turn stimulate cells in the pituitary. These adenohypophyseal hormones then regulate the hormone output from the end organ. The end organ then exerts negative feedback effects at the pituitary and hypothalamus to prevent further neurohormone and pituitary hormone release via 'long-loop' negative feedback. Short-loop negative feedback may also occur where pituitary hormones feed back directly on hypothalamic neurons to prevent further neurohormone release. and the release of its posttranslation products, adrenocorticotropic hormone (ACTH), β-endorphin, and others. ACTH released from the anterior pituitary into the general circulation then stimulates the production and release of cortisol from the adrenal cortex. (For a general schematic of HPA axis regulation, see Figure 2.)

HPA Axis Abnormalities in Depression

Evidence linking HPA axis abnormalities to psychiatric symptoms dates back more than 100 years. The relatively frequent occurrence of depression and other psychiatric symptoms in both Cushing's and Addison's diseases, associated with excess and deficient levels of circulating cortisol, respectively, served as an impetus for researchers to scrutinize HPA axis function in patients with primary psychiatric disorders. Some of the earliest studies demonstrated abnormalities in glucocorticoid function in depressed patients, including elevated plasma and cerebrospinal fluid (CSF) cortisol concentrations, increased 24 h urinary free cortisol concentrations, and increased levels of cortisol metabolites in urine (Table 2). The next major advance occurred with the discovery of the neuropeptide CRF in 1981, the primary physiological secretagogue of ACTH, and ultimately cortisol.

A number of tests have been developed to assess HPA axis activity, and one of the most common is the dexamethasone suppression test (DST). In this standardized test, 1 mg of dexamethasone is administered orally at 11 p.m. and blood samples are obtained at various times on the following day (e.g., 8 a.m., 4 p.m., and 11 p.m.) and cortisol concentrations measured. Dexamethasone is a synthetic glucocorticoid and, similar to cortisol, it suppresses ACTH secretion, and consequently cortisol release, in healthy volunteers. Nonsuppression of plasma glucocorticoid concentrations postdexamethasone is relatively common in depression, at much higher rates than in normal volunteers. The rate of cortisol nonsuppression after dexamethasone administration generally correlates with the severity of depression; in fact, nearly all patients with major depression with psychotic features exhibit DST nonsuppression. Although this test is used primarily in research labs and not routine clinical practice, the overwhelming conclusion is that a sizeable percentage of depressed patients exhibit HPA axis hyperactivity. Unfortunately, the specificity of the test for diagnostic purposes is unacceptably low, with nondepressed patients with eating disorders, anxiety disorders, and dementia, among others, exhibiting false positives. Moreover, we have suggested that HPA axis hyperactivity may be more related to early life trauma than depression.

A CRF stimulation test has also been developed to assess HPA axis activity. In this paradigm, CRF is administered intravenously (usually in a dose of

Figure 2 Diagram of the neurovascular anatomy of the hypothalamic–pituitary axis. 1 μg kg^{-1} or a fixed dose of 100 μg) and the ensuing ACTH and cortisol response is measured at 30 min intervals during a 2 or 3 h period. Numerous studies have demonstrated a blunted ACTH and β-endorphin response to exogenously administered ovine CRF or human CRF in depressed patients compared to non-depressed subjects. The blunted ACTH response to CRF occurs in depressed DST nonsuppressors but not in DST suppressors. The attenuated ACTH response to CRF is likely due, in part, to chronic hypersecretion of CRF from nerve terminals in the median eminence, which results in downregulation of CRF receptors in the anterior pituitary. This receptor downregulation results in a reduced responsivity of the anterior pituitary to CRF, as has been demonstrated in laboratory animals. Chronic hypercortisolemia likely also contributes to the blunted ACTH response to CRF by cortisol action on the corticotroph. The abnormalities in the CRF stimulation test and DST also appear to be state dependent because they generally normalize following recovery from depression.

A combined dexamethasone/CRF test has also been developed, and it is arguably the most sensitive measure of HPA axis function. In this test, 1.5 mg of dexamethasone is administered orally at night (11 p.m.), and subjects receive an i.v. bolus of 100 μg of human CRF at 3 p.m. the following day. Patients with HPA axis dysfunction, which is reportedly seen in 40–60% of depressed patients, display a paradoxically increased release of ACTH and cortisol following CRF challenge relative to controls. These abnormalities disappear following remission of depression, and normalization of HPA axis function seems to precede full clinical remission. Conversely, the absence of normalization of the HPA axis in clinically remitted depressed patients is associated with later relapse. The combined DEX/CRF test appears to exhibit much higher sensitivity for detecting subtle alterations in HPA axis function; approximately 80% of patients with major depression exhibit an abnormal response to the DEX/CRF test. In contrast, only approximately 44% of patients with major depression demonstrate an abnormal response when DST is administered alone. Furthermore, otherwise healthy individuals with first-degree relatives with an affective illness, which greatly increases their own risk for a mood disorder, had cortisol and ACTH responses in the DEX/CRF test which were greater than those of a control group but considerably reduced in magnitude compared to those of patients currently suffering

Figure 3 Overview of the feedback mechanism of the HPA axis. Following relevant stimuli, including stress, CRF is released from the hypothalamus into the hypophyseal portal vessels, where it is transported in high concentrations to the pituitary gland. CRF then promotes the release of ACTH, which in turn promotes the release of cortisol from the adrenal glands. Cortisol acts as an inhibitory signal at both the hypothalamus and the pituitary, preventing further CRF and ACTH release, respectively. Reproduced with permission of Tomo Narashima from Nemeroff CB (1998) The neurobiology of depression. *Scientific American* 278:42–49.

from major depression. This suggests that a defect in corticosteroid receptor function may render these individuals more susceptible to developing affective disorders.

Extrahypothalamic CRF and Depression

A rich body of literature primarily on rodents and nonhuman primates has highlighted the extensive network of CRF-containing neurons in extrahypothalamic sites. In rodents, primates, and humans, CRF and its receptors have been heterogeneously localized in a variety of brain regions, including the amygdala, thalamus, hippocampus, and prefrontal cortex. These brain regions are important in regulating many aspects of the mammalian stress response and in regulating affect.

Table 2 HPA axis changes demonstrated in depression

↑ Corticotropin-releasing factor (CRF) in cerebrospinal fluid[a]
↓ Adrenocorticotropic hormone response (ACTH) to CRF stimulation

Involvement of extrahypothalamic CRF systems in the pathophysiology of depression is supported by numerous studies showing elevated CRF concentrations in the CSF of patients with major depression, although discrepant results have been reported. Elevated CSF CRF concentrations have also been observed in depressed suicide victims. A reduction in CSF CRF concentrations has been reported in healthy volunteers treated with the tricyclic antidepressant desipramine and in depressed patients following treatment with fluoxetine, amitriptyline, or ECT, providing evidence of interactions between antidepressants, noradrenergic and serotonergic neurons, and CRF systems. Elevated CSF CRF concentrations appear to represent a state, rather than a trait, marker of depression (i.e., a marker of the state of depression rather than a marker of vulnerability to depression). Furthermore, high and/or increasing CSF CRF concentrations despite symptomatic improvement of major depression during antidepressant treatment may be the harbinger of early relapse, as we have previously reported for DST nonsuppression.

Although the exact mechanism contributing to CRF hyperactivity remains obscure, studies from our group and others have documented long-term persistent increases in HPA axis activity and extrahypothalamic CRF neuronal activity after exposure to early untoward life events, such as neglect and child abuse, in both laboratory animals (rat and nonhuman primates) and humans. A large database indicates that early life stress permanently sensitizes the HPA axis and increases the activity of CRF neurons leading to a greater risk of developing depression later in life. In one schema, the persistent increase in the activity of CRF neuronal systems results in heightened responses

to stress later in life. To measure HPA responsivity to stress in humans, the Trier Social Stress Test (TSST) was developed. This laboratory paradigm involves a simulated 10 min public speech coupled with a mental arithmetic task. The TSST has been validated as a potent activator of the HPA axis in humans. Our group has reported increased plasma ACTH and cortisol concentrations, presumably due to hypersecretion of CRF, after exposure to the TSST in depressed women who were exposed to severe physical and emotional trauma as children. Studies by our group, using the combined DEX/CRF test described previously, in adult men with early life trauma and comorbid major depression revealed markedly increased HPA axis activity, consistent with the TSST test results in women and with the CRF hypersecretion hypothesis. These data provide evidence for hyperactivity of CRF systems associated with early adverse life events.

CRF and Anxiety Disorders

Involvement of CRF in anxiety disorders has been less well studied in both animal models and human studies than has depression, but the results are nevertheless quite promising. Patients with posttraumatic stress disorder (PTSD; i.e., Vietnam combat veterans) have been reported to exhibit elevated CSF CRF concentrations, as well as a blunted ACTH response to CRF challenge. A study using an indwelling cannula for the repeated collection of lumbar CSF for several hours after the initial lumbar puncture further confirmed elevated CSF CRF concentrations in combat veterans with PTSD. In contrast, low serum cortisol and urinary free cortisol concentrations have repeatedly, yet unexpectedly, been observed in PTSD, especially after dexamethasone administration. One potential mechanism for this finding is heightened negative feedback within the HPA axis in chronic PTSD resulting in reduced basal cortisol concentrations (Figure 3).

Although CSF CRF concentrations are not increased in panic disorder patients, a blunted ACTH response to CRF administration has been observed. Increased or normal concentrations of CSF CRF have been reported in patients with obsessive–compulsive disorder, although significant decreases in CSF CRF concentrations occur with a therapeutic response to clomipramine. Patients with generalized anxiety disorder, however, exhibit similar CSF CRF concentrations as normal controls. In summary, although HPA axis hyperactivity exists in patients with certain anxiety disorders, such perturbations do not exist in the patterns suggestive of chronic CRF hypersecretion as documented in patients with major depression.

Glucocorticoid Receptor Antagonists and Depression

As discussed previously, nonsuppression of cortisol in the DST is very common in patients with major depression with psychotic features. Therefore, one proposed treatment for psychotic depression is the use of mifepristone (RU-486), which at high concentrations is a glucocorticoid receptor antagonist. An initial open-label study showed some efficacy in psychotic major depression following 1 week of treatment with mifepristone. A subsequent larger (~110 patients per treatment group), placebo-controlled trial demonstrated that 7 days of mifepristone followed by 21 days of treatment as usual resulted in significant improvement in psychotic but not depressive symptoms. Overall, this large-scale, double-blind, placebo-controlled trial did not demonstrate efficacy of mifepristone in psychotic depression, although this may be due to the unusually high placebo response rate observed. A second double-blind, placebo-controlled study also failed to demonstrate any separation of mifepristone from placebo, although this study also showed abnormally high placebo response rates. However, similar to the initial study, an abnormally high response rate was noted in both groups, with 95% of patients in both arms of the study demonstrating a response by day 56. There is also evidence suggesting that antiglucocorticoid therapy may improve depressive symptoms in patients in the depressed phase of bipolar disorder. It is reasonable to propose that 1 week of antiglucocorticoid therapy may serve to reset the HPA axis, resulting in subsequent improvement in clinical symptoms.

The HPA Axis in Depression and Anxiety: Conclusions

Numerous studies have documented that when CRF is directly injected into the CNS of laboratory animals, it produces many effects reminiscent of the cardinal symptoms of major depression and certain anxiety disorders, including decreased libido, reduced appetite and weight loss, sleep disturbances, and neophobia. These findings, taken together with the numerous clinical studies described previously, suggest that CRF_1 receptor antagonists represent a novel putative class of antidepressants and/or anxiolytics. Such compounds show activity in nearly every preclinical screen for antidepressants and anxiolytics currently employed. To date, only one open-label study examining the effectiveness of a CRF_1 receptor antagonist, R121919, in patients with major depression has been published. Severity measures of both anxiety and depression were significantly improved. Several studies with novel CRF_1 receptor antagonists are ongoing.

Thyrotropin-Releasing Factor, the Hypothalamic–Pituitary–Thyroid Axis, and Depression

Biology

Dysfunction of the hypothalamic–pituitary–thyroid (HPT) axis has for many years been known to be associated with numerous psychiatric disturbances ranging from mild depression and anxiety to overt psychosis. The HPT axis controls the release of the thyroid hormones tri-iodothyronine (T_3) and thyroxine (T_4). The tripeptide thyrotropin-releasing hormone (TRH) causes the release of adenohypophysial thyroid-stimulating hormone (TSH) into the general circulation, and TSH in turn acts directly on the thyroid to induce thyroid hormone secretion. TRH was the first of the hypothalamic-releasing hormones to be isolated and characterized. It is synthesized predominantly in the hypothalamic paraventricular nucleus, stored in nerve terminals in the median eminence, and released into the vessels of the hypothalamic–hypophyseal portal system. Like the other releasing hormones, TRH is then transported to the sinusoids in the anterior pituitary, where it binds to TRH receptors on the thyrotropes, promoting the release of TSH into the systemic circulation. TSH acts on receptors in the thyroid gland to release the major thyroid hormones, T_3 and T_4. Besides their well-known metabolic effects on a variety of tissues, T_3 and T_4 feed back to the hypothalamus and adenohypophysis, respectively, to regulate the synthesis and release of TRH and TSH.

Within the CNS, the actions of thyroid hormone are mediated by thyroid hormone receptors, which are members of the large superfamily of nuclear hormone receptors. Upon binding to its receptor, the thyroid hormone/receptor complex binds to thyroid hormone response elements located in the promoter region of specific target genes. Within the CNS, rodent studies have demonstrated a relatively high density of thyroid hormone receptors in cortex, hippocampus, hypothalamus, and olfactory bulbs. The importance of thyroid hormone in the CNS is further highlighted by the devastating effects of hypothyroidism on the developing CNS. Fetal and neonatal hypothyroidism can lead to cretinism, which is associated with a number of fetal abnormalities, including severe mental retardation, short stature, thickened skin, and neurologic impairments.

Psychiatric Manifestations of Thyroid Dysfunction

Primary thyroid axis disorders can be associated with a wide range of psychiatric manifestations ranging from depression and anxiety to overt psychosis. Regardless of the precise etiology, hypothyroidism leads to a number of clinical manifestations, including slowed mentation, forgetfulness, decreased hearing, cold intolerance, and ataxia. Decreased energy, weight gain, depression, cognitive impairment, or overt psychosis ('myxedema madness') may also result. Due to the overlapping symptoms with major depression, thyroid hormone deficiency must be ruled out when evaluating patients with depression.

Studies conducted in the late 1960s and early 1970s scrutinized psychiatric morbidity in patients with hypothyroidism, and a substantial number of these patients demonstrated signs of depression, anxiety, and/or cognitive disturbances. Treatment of the underlying thyroid condition alone generally resulted in significant improvement or resolution of these symptoms. Cognitive disturbance is also common in hypothyroidism. Depression and anxiety symptoms are also common in hypothyroidism, occurring in up to 50% and 30% of unselected patients, respectively. Manic and hypomanic states are rarely reported in hypothyroid patients. Although psychosis is the most common reported symptom in the case literature on hypothyroidism, it accounts for only approximately 5% of the psychiatric morbidity in an unselected sample, presumably because the more severe symptoms are more likely to be documented in the clinical literature. It is important to note that occult primary hypothyroidism is among the leading medical causes of refractory depression.

TRH and TSH in Depression

Considerable evidence indicates an increased incidence of HPT axis dysfunction in patients with major depression. More than 30 years ago, research groups led by Prange and by Kastin demonstrated that approximately 25% of patients with major depression exhibit a blunted TSH response to TRH. This has been postulated to be due to hypersecretion of TRH from the median eminence, which leads to TRH receptor down-regulation and consequent reduced sensitivity of the pituitary to exogenous TRH. This hypothesis is supported by reports of elevated TRH concentrations in the CSF of drug-free depressed patients. Depressed patients have also been shown to have an increased rate of symptomless autoimmune thyroiditis, defined by the abnormal presence of antithyroglobulin and/or antimicrosomal thyroid antibodies consistent with grade 4 hypothyroidism. Studies of the elderly have suggested that subclinical hypothyroidism substantially increases the risk for depression, perhaps even more than overt hypothyroidism. However, a separate large-scale study of the elderly found no clear association between TSH, T_4, and depression, anxiety, or cognition, although the authors discussed a number

of confounding factors that may have impacted their results. A large epidemiological study evaluated a population of more than 30 000 individuals and measured plasma TSH concentrations in all women and 50% of the men in the study population. Individuals with abnormally high TSH levels were further screened for the presence of thyroid peroxidase autoantibodies. In this large study of nonselected patients, the authors were unable to detect a significant association between antithyroid antibodies and the prevalence of depression or anxiety.

T_3 augmentation has been reported to be effective in the treatment of refractory depression when combined with tricyclic antidepressants (TCAs). A metareview of the literature on combination TCAs–thyroid hormone supported their efficacy in refractory depression. Since then, selective serotonin reuptake inhibitors (SSRIs) have replaced TCAs as first-line treatment for depression. A small study of 12 patients evaluated the efficacy of thyroid hormone augmentation in patients with treatment-resistant depression. The patients in this study had failed to demonstrate a satisfactory antidepressant response after at least 6 weeks of antidepressant treatment with an SSRI (17-item Hamilton Rating Scale for Depression score >18 at study entry). These patients were also carefully screened and had both normal basal TSH concentrations and normal results of a TRH stimulation test. Although this study was not blinded, thyroid hormone (T_3) augmentation (25 $\mu g\,day^{-1}$ increased to 50 $\mu g\,day^{-1}$ after the first week) was shown to be highly effective in producing a clinical response in 42% of patients during the 3-week study follow-up. The efficacy of thyroid hormone augmentation was also highlighted in the STAR*D study. In this large multicenter, placebo-controlled trial of antidepressant efficacy, 142 patients were randomized to augmentation with either lithium (up to 900 $mg\,day^{-1}$) or T_3 (50 $\mu g\,day^{-1}$) after failing to adequately respond to an initial trial with citalopram and then a second medication switch or augmentation trial. During the 14-week follow-up, in this relatively treatment-resistant population, 24.7% of patients receiving T_3 attained clinical remission. However, a blinded placebo-controlled trial which evaluated T_3 augmentation (25 or 50 $\mu g\,day^{-1}$) in depressed patients receiving paroxetine showed no advantage of thyroid hormone compared to placebo.

There is also some question as to the ideal dosing regimen when using thyroid hormone as an augmenting agent. In one study, hypothyroid patients being treated with T_4 were monitored for two 5-week periods and underwent physiological, biochemical, and neuropsychiatric testing. During one of the periods, their normal T_4 replacement dose was decreased by 50 μg and replaced with 12.5 μg of T_3. The T_3/T_4 combination improved results on several mood and neuropsychologic measures. Although these results are by no means conclusive, they do raise the possibility that combined T_3/T_4 augmentation strategies may have superior efficacy than T_4 alone. Because thyroid hormone is both inexpensive and safe, it remains a viable augmentation strategy compared to other newer strategies that are not necessarily more efficacious.

Although there is evidence suggesting hypersecretion of TRH in a subset of depressed patients, it is unclear how common or important this finding is. Interestingly, lumbar intrathecal infusion of 500 μg of TRH in medication-free inpatients with refractory depression produced a clinically robust, but short-lived, improvement in mood and suicidality, which led the authors to propose that elevated CSF TRH levels might be a compensatory response in depression. Similar antidepressant responses were seen after intravenous nocturnal TRH administration in patients with bipolar disorder, type I or II, currently in a depressed phase. Although this work is preliminary, it raises the interesting possibility that a systemically administered TRH receptor agonist may possess antidepressant properties.

Bipolar Disorder and HPT Abnormalities

HPT axis abnormalities have also been reported in patients with bipolar disorder. Both elevated basal plasma concentrations of TSH and an exaggerated TSH response to TRH have been observed. There is also evidence that bipolar patients with the rapid cycling subtype have a higher prevalence of hypothyroidism (grades I–III) than other bipolar subtypes. A blunted or absent evening surge of plasma TSH, a blunted TSH response to TRH, and the presence of anti-thyroid microsomal and/or anti-thyroglobulin antibodies at higher rates than those of normal comparison subjects have also been demonstrated in bipolar patients. High doses of T_4 have also been reported to be effective in the treatment of rapidly cycling bipolar disorder patients.

Thyrotropin-Releasing Hormone Alterations in Anxiety Disorders

The HPT axis has been relatively poorly studied in anxiety disorders. A blunted TSH response to TRH has been observed in panic disorder patients, but in one of these studies, this effect was only demonstrated in patients with concurrent major depression. Another study found a normal TSH response to TRH in panic disorder patients. No alterations in CSF TRH concentrations have been reported in patients with panic disorder, generalized anxiety disorder, or obsessive–compulsive disorder.

Growth Hormone and Somatostatin

Biology

Growth hormone (GH) is synthesized and secreted from somatotrophs in the anterior pituitary. Its release is unique in that it is controlled by two hypothalamic peptide hormones – growth hormone-releasing factor (GHRF) and somatostatin – and secondarily by classical neurotransmitters such as dopamine (DA), norepinephrine (NE), and 5-hydroxy tryptamine (5-HT), which innervate the releasing factor-containing neurons (Table 3). Somatostatin, also known as growth hormone-release inhibiting hormone or somatotrophin-release inhibiting factor (SRIF), was first isolated from ovine hypothalamus in 1974. It is a tetradecapeptide containing a disulfide bridge linking the two cysteine residues. Somatostatin is synthesized predominantly in neurons in the periventricular and paraventricular nucleus of the hypothalamus, is released from nerve terminals in the median eminence, and inhibits GH release. Somatostatin also inhibits the release of both CRF and ACTH and has been termed 'panhibin.' Somatostatin has a wide extrahypothalamic brain distribution, including the limbic system, cerebral cortex, hippocampus, and amygdala.

GHRF is a 44-amino-acid peptide that has the most limited CNS distribution of all the hypothalamic-releasing hormones thus far identified. GHRF-containing neurons are concentrated primarily in the infundibular and arcuate nuclei of the hypothalamus and stimulate the synthesis and release of GH. Dopamine-, NE-, and 5HT-containing neurons innervate GHRF neurons and thereby modulate GH release. Both GHRF and SRIF are released from nerve terminals in the median eminence into the hypothalamo-hypophyseal portal system, where they act on somatotrophs in the anterior pituitary to regulate GH release. Negative feedback is provided by GH, which stimulates SRIF release, thus preventing further GH release. The hypothalamic–growth hormone axis is unique in that it does not have a single target endocrine gland but instead GH acts directly on a myriad of tissue targets, including bone, muscle, and liver. However, GH does release somatomedin from the liver.

Table 3 Releasing and inhibiting factors for growth hormone

GH and Affective Disorders

Several findings suggest dysregulation of GH secretion in depression. A blunted nocturnal GH surge in depression has been demonstrated, whereas daylight GH secretion has been reported to be exaggerated in both unipolar and bipolar depressed patients. A number of studies have also demonstrated a blunted GH response to drugs that increase noradrenergic activity (clonidine and desipramine) and, to a lesser extent, dopaminergic agonists (apomorphine) in depressed patients. Two studies have suggested that the blunted GH response to apomorphine in depressed patients is predictive of suicidal behaviors. The blunted GH response to clonidine has been demonstrated to be unrelated to age or sex and may be secondary to decreased α_2-adrenergic receptor sensitivity in depression. No changes in basal GH secretion were observed in patients with panic disorder who were monitored by blood sampling every 15 min during a 24 h period. Another group failed to find changes in GH secretion following apomorphine in either unipolar depressed or bipolar patients.

A GHRF stimulation test, analogous to the CRF and TRH stimulation tests, has also been developed. Two studies found a blunted GH response to GHRF in depressed patients, whereas our group failed to confirm the results in a study of 19 depressed and 19 matched controls.

A comprehensive review of GHRF stimulation tests in depression, anorexia nervosa, bulimia, panic disorder, schizophrenia, and Alzheimer's disease was conducted, and it was found that the results of this test are apparently not always consistent and in some cases are contradictory. Some of the confounding factors, including the variability of GHRF-stimulated GH release among controls and age- and gender-related effects, may account for some of this variability. Additional studies to standardize the GHRF stimulation test for application in psychiatry are clearly needed.

Somatostatin and Psychiatric Disorders

Decreased CSF SRIF concentrations in patients with depression, dementia, schizophrenia, and Alzheimer's disease have been demonstrated. Reduced CSF SRIF concentrations have been reported in DST nonsuppressors, whether diagnosed with schizophrenia or depression, and are negatively correlated with the maximum postdexamethasone cortisol plasma concentration in patients with major depression. Although there is evidence of normalization of CSF SRIF concentrations after recovery from depression, other studies have noted no such changes despite clinical improvement with antidepressants or ECT treatment. Somatostatin concentrations are markedly reduced in cerebrocortical and hippocampal postmortem tissue in Alzheimer's disease. Somatostatin also inhibits the release of both CRF and ACTH, indicating a possible direct interaction between the growth hormone and HPA axes. No differences in CSF SRIF concentrations between patients with generalized anxiety disorder and controls were observed. No published studies measuring GHRH concentrations or GHRH mRNA expression have been conducted of postmortem tissue of depressed patients and matched controls that, in light of the evidence presented here, is of interest. Similarly, no CSF studies of GHRH in psychiatric patients have been reported.

Alterations of the hypothalamic–pituitary growth hormone axis and SRIF concentrations have been reported in major depression. Whether these changes represent primary pathophysiological alterations or epiphenomena remain to be determined. Arguably, the blunted GH response to clonidine seen in depression may be one of the most reproducible and specific findings in the biology of affective disorders. Diminished availability of SRIF might plausibly contribute to CRF hypersecretion and increased HPA axis activity. Further elucidation of SRIF receptor function and the effects/utility of SRIF receptor agonists and antagonists may provide important information regarding the pathophysiology of major depression.

Hypothalamic–Prolactin Axis

Biology

Unlike other anterior pituitary hormones, prolactin (PRL) release is largely regulated via tonic inhibition by a prolactin-inhibitory factor, determined not to be a neuropeptide but, rather, the monoaminergic neurotransmitter DA. Neurons in the tuberoinfundibular system of the hypothalamus release DA from nerve terminals in the median eminence that directly inhibit PRL release from lactotrophs. Prolactin can also inhibit its own release by a short-loop negative feedback to the hypothalamus. Prolactin is believed to play a role in the behavioral aspects of reproduction and infant care. Serum PRL concentrations are normally low throughout life in males. Basal PRL levels increase in females following parturition, and suckling stimulates PRL release. Prolactin stimulates breast growth and lactation. TRH, oxytocin, serotonin, estrogen, and other neuroregulators have prolactin-releasing factor (PRF) activity.

Prolactin-Releasing Factor

A putative peptidic PRF has also been identified. PRF-containing cell bodies have been detected in a number of brain regions, including the nucleus tractus solitarius, the ventral and lateral reticular nuclei in the medulla, and the dorsomedial nuclei of the hypothalamus. These neurons project nerve fibers to a wide range of brain areas. After its initial characterization and the demonstration both *in vivo* and *in vitro* that PRF can indeed induce PRL secretion, considerable debate persists as to whether PRF is a major physiological secretagogue of PRL. It is important to note that PRL may also be involved in the regulation of energy and food balance, sleep regulation, and may also interact with CRF and the HPA axis.

PRL and Psychiatric Disorders

Excess circulating PRL can lead to a number of clinical symptoms. The most common causes of hyperprolactinemia are tumors, usually microadenomas of pituitary lactotrophs. Treatment with typical antipsychotic medications and some atypical antipsychotics (e.g., risperidone at high doses), because of their potent blockade of D_2 DA receptors, can also cause hyperprolactenemia. Hyperprolactinemia often leads to reduced testosterone secretion in men, and decreased libido, lactation, and gynecomastia can be seen in both men and women. Women may also display menstrual cycle irregularities including amenorrhea. Patients may also complain of depression, stress intolerance, anxiety, and increased irritability that usually resolve following treatments that reduce serum PRL levels. Consistent alterations in the hypothalamic–prolactin axis have not been clearly demonstrated in psychiatric disorders. Because PRL release is inhibited by DA, the PRL response to infusions of DA agonists has also been used to estimate CNS dopaminergic activity, although it is likely only an accurate reflection of the tuberoinfundibular hypothalamic DA system.

Many reports have used provocative tests that increase serotonergic neurotransmission and PRL secretion in patients with psychiatric disorders.

Briefly, these tests use agents that increase serotonergic transmission such as L-tryptophan, 5-hydroxytryptophan, and fenfluramine. In general, the PRL response to agents that increase serotonergic activity is blunted in depression, as well as in patients with cluster B personality disorders. In contrast, a study of 20 patients with major depression demonstrated an exaggerated PRL response to L-tryptophan. These authors suggested that concomitant psychotropic medications or hypercortisolemia may have confounded earlier studies. However, the available data suggest that the altered PRL response seen in depression is, in part, mediated by an alteration in 5-HT_{1A} receptor responsiveness.

Arginine–Vasopressin

Biology

Arginine–vasopressin (AVP), also known as antidiuretic hormone, is a nonapeptide synthesized in the lateral magnocellular neurons of the paraventricular and supraoptic nuclei of the hypothalamus, and it is released directly into the bloodstream from axon terminals in the posterior pituitary. These AVP-containing neurons terminate in the neurohypophysis of the pituitary and secrete AVP into the systemic circulation, although they also project nerve terminals to the hypothalamo-hypophyseal portal system. Another group of AVP-containing neurons project from the medial parvocellular subdivision of the PVN to the median eminence. Within the median eminence, the parvocellular-derived AVP is released from axon terminals, secreted into the hypothalamo-hypophyseal portal circulation, and transported to the anterior lobe of the pituitary gland. Extrahypothalamic AVP-containing neurons lie within limbic structures such as the septum and amygdala, as well as in the brain stem and spinal cord. AVP and the other major posterior pituitary hormone, the nonapeptide oxytocin, are believed to play a role in modulating neural activity in hypothalamic, limbic, and autonomic circuits.

AVP has prominent roles in controlling fluid balance via its effects on the kidney, in regulating blood pressure by its vasoconstrictive effects on blood vessels, and it can directly promote thirst. AVP can also act synergistically with CRF to promote the release of ACTH in humans and laboratory animals following stressful stimuli. Chronic stress or adrenalectomy increases the activity of the parvocellular AVP system. CRF and AVP are co-localized in the parvocellular cells of the human hypothalamus and may be secreted together into the human hypothalamic-hypophyseal portal circulation. The amount of AVP and CRF released into the hypothalamic-hypophyseal portal circulation varies in different species and in response to different stressors.

AVP in Anxiety and Depression

CSF AVP concentrations in patients with major depression, particularly those with atypical depression, were reported to be reduced in comparison to those of control subjects. CSF AVP is likely largely extrahypothalamic and not reflective of PVN AVP circuits. Basal plasma concentrations of AVP (secreted from the magnocellular neurons of the PVN after osmotic and/or baroreceptor stimulation) in depressed patients are also reportedly decreased in comparison to those of age-matched controls, although others have found no such difference. In one study, reduced plasma AVP concentrations, as well as a blunted GH and AVP response to both clonidine and apomorphine, were reported in depressed patients; no differences in basal or stimulated oxytocin concentrations were observed.

Combined infusion of lysine–vasopressin and human CRF produced nonsuppression of cortisol following the DST in healthy controls; in these same patients, neither agent infused separately produced DST nonsuppression. This suggests that both CRF and AVP contribute to the HPA axis hyperactivity characteristic of depression. AVP serum concentrations following the DST have also been reported to be elevated in both patients with chronic major depressive disorder and patients with symptomatic and remitted bipolar disorder.

A mildly blunted ACTH response to exogenous AVP administration has been reported in depression, but this finding was not replicated in two other studies. In a postmortem tissue study, an increase in the number of PVN AVP neurons, as well as those that co-localize AVP and CRF neurons, was reported in depressed patients compared to controls. Increased AVP mRNA expression has been reported in the PVN and supraoptic nucleus (SON) of nine depressed patients compared to eight control subjects. This is of interest in view of the ability of AVP to potentiate the actions of CRF at corticotrophs.

Interestingly, elevations in CSF and plasma AVP concentrations have been reported in manic patients in comparison to patients with unipolar depression and controls. Clearly, hypothalamic and extrahypothalamic AVP circuits are regulated independently. Additional work is warranted, especially in view of the emerging evidence of antidepressant activity of AVP receptor antagonists in a variety of animal models. Whether the perturbations of AVP secretion in patients with neuropsychiatric disorders are state or trait dependent has yet to be elucidated.

Oxytocin

Biology

Oxytocin is a nonapeptide synthesized primarily in magnocellular neurons located in the SON and PVN of the hypothalamus. It shares significant homology with AVP, differing in only two of nine amino acids. Similar to AVP, it is primarily released into the general circulation from the posterior lobe of the pituitary gland (i.e., the neurohypophysis). Oxytocin-producing neurons in the PVN also project to a number of extrahypothalamic sites, including the hippocampus, amygdala, striatum, hypothalamus, nucleus accumbens, locus coeruleus, and the nucleus of the tractus solitarius.

Oxytocin serves a number of physiologic functions, but much of the research on this peptide has focused on its role in reproduction. Oxytocin promotes contraction of the uterus during labor, as well as milk letdown during lactation. A role for both oxytocin and vasopressin in affiliative behavior and social bonding in animals has been demonstrated. Compelling preclinical studies have also suggested a very significant role for oxytocin in the entire panoply of maternal behaviors, including nest building, licking and grooming pups, and nursing.

Oxytocin and Psychiatric Disorders

In an investigation of 25 medication-free depressed patients and 25 age- and gender-matched controls, no significant differences in serum oxytocin concentrations were detected either at baseline or following both apomorphine and clonidine stimulation tests. In this same experiment, basal vasopressin concentrations were significantly lower in depressed patients and reduced following apomorphine and clonidine challenge. GH responses were similarly blunted in depressed patients after either clonidine or apomorphine treatment. Intranasal oxytocin has also been shown to influence willingness to engage in social risks. Due to its role in affiliative behavior and social interactions, there is increasing interest in understanding what role, if any, oxytocin may have in autism spectrum disorder. A putative role for oxytocin in postpartum depression is another area worth exploring.

Clinical Implications and Conclusions

Careful clinical observations of patients with psychiatric disorders associated with primary endocrine disorders such as Cushing's syndrome and hypothyroidism have led to a broader understanding of the role of neuroendocrine disturbances in a variety of psychiatric disorders, most notably in mood disorders. These studies have led to major advances in biological psychiatry by helping to elucidate the brain circuits involved in the pathophysiology of mood and anxiety disorders. Foremost among these is the CRF theory of depression, which is supported by studies using a variety of experimental approaches and has led to the development of a putative novel therapeutic class of antidepressants – CRF receptor antagonists. Furthermore, this body of work has provided a neurobiological mechanism to explain the increase in depression seen in patients exposed to trauma early in life, first suggested by Freud in the early twentieth century. If CRF truly is the 'black bile' of depression, CRF antagonists may represent a novel class of antidepressants with a unique mechanism of action distinct from currently available antidepressants.

In addition to the HPA axis and CRF alterations observed in depression, HPT axis abnormalities are also very common; the majority of depressed patients, in fact, exhibit alterations in one of these two axes. Furthermore, the blunted GH response to clonidine or apomorphine and the blunted PRL response to serotonergic agonists in depressed patients have been widely replicated.

It is obvious that the vast majority of studies have focused on patients with mood disorders, particularly unipolar depression. Other disorders, including eating disorders, anxiety disorders, autism, schizophrenia, and axis II diagnoses, should also be evaluated for neuroendocrine dysfunction. The availability of selective receptor ligands that can be utilized with positron emission tomography will mark the next major leap in our understanding of the neuroendocrine axes in psychiatric disorders. The ability to determine peptide receptor alterations in the brain and pituitary of patients with psychiatric disorders will contribute immensely to our understanding of the neurobiological underpinnings of such disorders.

Finally, an increasing number of studies have demonstrated that depression is a systemic disease that increases vulnerability to other disorders. Depressed patients demonstrate an increased incidence of coronary artery disease and stroke, osteoporosis, and perhaps cancer. These observations may at least, in part, be attributed to the endocrine alterations observed in depression. Neuroendocrine alterations in depression may well contribute to this phenomenon.

Neuroendocrinology of Puberty

A Lomniczi, V Matagne, and S R Ojeda, Oregon Health and Science University, Beaverton, OR, USA

© 2009 Elsevier Ltd. All rights reserved.

General Concepts

Puberty is the phase of life when individuals become capable of reproducing, and females are able to sustain a pregnancy to term. In all mammalian species, secondary sexual characteristics become established at puberty as a result of increasing sex steroid levels. In males, an increased androgen production induces enlargement of the testes and penis, as well as growth of the accessory sex organs (seminal vesicles and prostate). In females, estrogen induces development of the mammary gland, as well as development of the internal (uterus and oviduct) and external (vagina and vulva) genitalia. In human males, puberty results in increased body hair and muscle mass, along with voice deepening. In human females, there is a widening of the pelvis and accumulation of fat in the hips, thighs, buttocks, and breasts. Humans also undergo a growth spurt at puberty, but this is not observed in other species (except great apes).

The pubertal phase of genital development, initiated and sustained by gonadal steroids, is known in humans as gonadarche. Gonadarche results from reactivation of the hypothalamic–pituitary–gonadal axis, which is active during early postnatal life and operates at a reduced pace during childhood. As a consequence of this reawakening, gonadal steroid secretion increases, leading to virilization in boys and breast development (thelarche) followed by the first menstruation (menarche) in girls. Gonadarche is preceded by a phase of increased adrenal androgen secretion known as adrenarche. A peculiarity of humans and great apes, adrenarche in humans is responsible for the appearance of pubic and axillary hair. No such changes in adrenal activity are observed in other species.

The Hypothalamic–Pituitary–Gonadal Axis

The medial basal hypothalamus in primates, and the preoptic area (POA) in rodents, contains 800–1000 neurosecretory neurons that govern pituitary gonadotropin secretion via release of gonadotropin-releasing hormone (GnRH). GnRH reaches the pituitary gland by a vascular route provided by the portal vessels that connect the median eminence of the hypothalamus to the pituitary gland. Pituitary gonadotropes respond to GnRH with release of the gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which act on the gonads to promote the secretion of steroids and peptides, in addition to maturation of germinal cells. In turn, gonadal hormones control the release of GnRH and gonadotropins via negative and positive feedback mechanisms (Figure 1).

Central Role of the GnRH Neuron

For many years, it has been accepted that GnRH neurons arise from the olfactory epithelium and migrate to the forebrain along the olfactory nerve pathway. This view has been challenged by evidence suggesting that subpopulations of GnRH neurons originate from different embryonic neural sites, and that one of these populations associates transiently with the olfactory placode en route to the basal forebrain. Notwithstanding these results, the subject remains controversial because other authors have presented findings confirming the validity of the initial interpretation.

In rodents, most GnRH neurons take residency in the POA; in primates, they continue caudally to colonize the medial basal hypothalamus. This migration requires at least three genes – *KAL1* (which encodes an extracellular matrix glycoprotein), *FGFR1* (a receptor for fibroblast growth factor), and *NELF* (a cell surface migratory factor). Loss-of-function mutations of each of these genes result in isolated hypothalamic hypogonadism (IHH), a syndrome characterized by the relative absence of gonadotropin secretion and failure of the gonads to develop.

GnRH neurons transduce neuronal and glial signals into periodic discharges of GnRH. This cell–cell communication complex, collectively known as the 'pulse generator,' is responsible for maintaining a pulsatile mode of GnRH release. Intriguingly, immortalized GnRH-secreting neurons also release GnRH in a pulsatile manner, suggesting that periodic GnRH secretion is an intrinsic property of these neurons. Studies have shown the involvement of cyclic AMP and Na^+ channels associated with oscillatory increases in intracellular calcium and gap junction communications to be key components of this self-sustained system.

Pulsatile GnRH release is already evident during GnRH neuronal migration into the brain. In humans and nonhuman primates, gonadotropin secretion (likely driven by changes in GnRH output) reaches peak levels by midgestation and decreases toward term due to the establishment of steroid negative feedback. In rodents, gonadotropins secretion is initiated near the end of gestation. In all these species,

Figure 1 Current hypothesis concerning the central mechanism responsible for setting puberty in motion. Hypothalamic GnRH promotes the secretion and synthesis of pituitary gonadotropins (LH and FSH), which in turn stimulate the secretion of gonadal steroids (estrogen and progesterone) and gonadal peptides, such as inhibin and activin. During the juvenile period, GnRH secretion is low because of a reduced excitatory tone, in the presence of relatively unopposed inhibitory transsynaptic inputs. Puberty is initiated in a gonad-independent manner after a coordinated increase in excitatory inputs (transsynaptic and glial), coupled with a reduction in inhibitory transsynaptic inputs to the GnRH network. The initiation of puberty is accompanied by increased gonadal responsiveness to gonadotropins.

circulating gonadotropin levels are elevated during the infantile period and decrease thereafter (Figure 1). In primates, this decrease is gonad independent. The central mechanisms causing it have been traditionally considered to result from enhancement of a restraining influence; nevertheless, a paucity of excitatory inputs to GnRH neurons is a likely alternative.

The most striking difference between rodents and primates as animal models for the study of the pubertal process is the apparent absence in rodents of the juvenile hiatus in gonadotropin secretion. This difference might not be absolute, however, because an ovary-independent juvenile decrease in FSH release has been reported to occur in rats. Importantly, pulsatile gonadotropin secretion increases in a diurnal manner at the end of juvenile development in both primates and rodents, signaling the initiation of the pubertal process (Figure 1).

What are the mechanisms underlying the pubertal increase in GnRH release? Work from several laboratories has led to the conclusion that both the reduced gonadotropin output during juvenile development and the reemergence of an increased GnRH pulsatility result not from an intrinsic alteration in GnRH neuronal activity or a modification in gonadal feedback control but, rather, as a consequence of coordinated changes in transsynaptic and glial inputs to the GnRH neuronal network. According to this concept, such events are initiated in a gonad-independent manner. The changes in transsynaptic communication that initiate puberty involve an increase in excitatory inputs accompanied by a decrease in inhibitory

neurotransmission. The changes in glial inputs involve an enhanced growth factor-mediated glial-to-neuron signaling. Figure 1 schematizes these events.

Transsynaptic Control of the GnRH Neuronal Network

The transsynaptic control of GnRH secretion is mostly exerted by neuronal networks that utilize amino acids, catecholamines, and neuropeptides for either excitatory or inhibitory neurotransmission.

Classical Inhibitory Neurotransmission

GABA γ-Aminobutyric acid (GABA) is the dominant inhibitory neurotransmitter in the hypothalamus. GABA is synthesized from glutamate via a decarboxylation reaction catalyzed by the enzyme glutamic acid decarboxylase (GAD). Although the initiation of puberty is not accompanied by major changes in expression of the genes encoding GAD-65 and GAD-67, the two GAD enzymes, GABA release decreases in both rats and monkeys during the peripubertal stage, suggesting that in both species the initiation of puberty is preceded by a loss in GABA-mediated inhibitory neurotransmission.

GABA appears to mainly use $GABA_A$ receptors to reduce GnRH secretion because puberty is strikingly advanced in female monkeys when these receptors are blocked. For many years, it has been assumed that an inhibitory, $GABA_A$ receptor-mediated effect of GABA on GnRH secretion is directly exerted on GnRH neurons. However, studies indicate that these neurons respond to $GABA_A$ receptor stimulation with excitation instead of inhibition, and that a direct GABAergic inhibition may be mediated by $GABA_B$ receptors. Some researchers, however, argue that activation of $GABA_A$ receptors in GnRH neurons is inhibitory instead of excitatory.

Opioid peptides The function of different opioid peptides on pubertal GnRH release has not been completely elucidated. An inhibitory effect is indicated by the ability of naloxone (a μ-opioid receptor antagonist) to elicit precocious puberty when administered to female rats soon after birth. More direct evidence is the decreased effectiveness of opioids to suppress LH secretion detected during the onset of rat puberty. Although opioid peptides as a group do not appear to restrain primate puberty, the role of specific opioid systems (enkephalins, endorphins, etc.) has not been examined in detail.

Classical Excitatory Neurotransmission

The most important excitatory neuronal system controlling puberty utilizes glutamate as neurotransmitter. Another well-established stimulatory system, perhaps subservient to glutamatergic neurons, utilizes norepinephrine for neurotransmission.

Glutamate Glutamate is the major excitatory neurotransmitter in the hypothalamus. GnRH neurons are directly innervated by glutamatergic fibers. The facilitatory control they exert on GnRH neurons increases gradually during the infantile–juvenile period as shown by the increasing ability of glutamate receptor stimulation to enhance GnRH release during this phase of development. In the rat, hypothalamic glutamate concentrations increase with age, reaching a maximum after the onset of puberty. In the female rhesus monkey, prepubertal glutamate release is very low at the level of the median eminence and increases markedly during the early pubertal period, remaining elevated at midpuberty.

Endogenous glutamate exists as four different pools: transmitter, metabolic, glial, and GABA precursor. There is little information concerning the dynamics of each at the time of puberty, but as indicated previously, changes in the neurotransmitter pool appear to be critical for the pubertal activation of glutamatergic synaptic transmission.

Glutamate is the endogenous ligand of two major receptor families: (1) ionotropic receptors, consisting of NMDA, AMPA, and kainate receptor subtypes, and (2) metabotropic receptors, which are G-protein-coupled receptors. All these receptors are abundant in the hypothalamus. Activation of NMDA, AMPA, and kainate receptors stimulates the release of GnRH and LH in several species, including rats and monkeys. The importance of NMDA receptors in the control of sexual development is evidenced by the advancement of puberty elicited by NMDA receptor stimulation in both female rats and male monkeys and by the delay in puberty caused by pharmacological blockade of these receptors. Further evidence for this involvement is provided by the gonad-independent increase in ligand-dependent activation of hypothalamic NMDA receptors seen at puberty and the greater number of GnRH neurons expressing NMDA receptors in pubertal than in immature female rats. AMPA receptors may play a complementary role, facilitating the progression of puberty, because they are necessary for the preovulatory surge of gonadotropins. Also, kainate receptors appear to be involved because the number of GnRH neurons expressing kainate receptor subunits essential for receptor function increases during the days encompassing the initiation of rat puberty. These observations indicate that an increased direct excitatory tone to the GnRH neuronal network is an intrinsic component of the pubertal

process. A pubertal augmentation in dendritic arborization and spine formation observed in GnRH neurons reinforces this concept because spine density reflects the degree of excitatory inputs to neurons. Electrophysiological studies employing green fluorescence protein-tagged GnRH neurons have provided irrefutable evidence that GnRH neurons are indeed subjected to a strong glutamatergic control, exerted via NMDA and AMPA/kainate receptors.

Catecholamines A role for catecholamines in the onset of puberty was first shown by the delayed vaginal opening that follows inhibition of brain catecholamines synthesis. In both rats and monkeys, pharmacological approaches have shown that the principal catecholamine involved is norepinephrine, which acts via α_1 and α_2 receptors to elicit GnRH secretion. Norepinephrine turnover, a measure of catecholaminergic activity, increases in the hypothalamus at the time of rat puberty, with maximal values being attained on the day of first proestrus. Noradrenergic neurons located in the brain stem are thought to be responsible for the increased noradrenergic stimulation of GnRH release at the time of the first preovulatory surge of gonadotropins. However, it does not appear that this change is the primary change responsible for the initiation of puberty because it is estrogen dependent.

Neuropeptide Y A facilitatory effect of neuropeptide Y (NPY) on the initiation of rat puberty was suggested by the delay in vaginal opening that results from the intraventricular infusion of an NPY antiserum and by the advancement of the vaginal opening caused by the intraventricular injection of NPY. NPY neutralizing antibodies delivered into the median eminence of monkeys also resulted in suppression of GnRH release in pubertal, but not prepubertal, monkeys. In contrast to these results, an inhibitory role of NPY has been reported in rats and monkeys. The reasons for these discrepancies remain to be determined.

The Novel Kisspeptin–GPR54 Signaling System

The kisspeptin–GPR54 receptor signaling pathway is a novel system involved in the hypothalamic control of GnRH secretion. In 2003, two groups reported that mutations in the GPR54 gene resulted in IHH. One of these groups also showed that mice lacking *Gpr54* exhibit a similar phenotype. Proteolytic cleavage of the primary product of the *KiSS1* gene, a 53-amino-acid peptide known as kisspeptin or metastin, generates the decapeptide kisspeptin-10, which is a potent stimulator of LH release. Because kisspeptin is equally effective in stimulating LH release when administered either intracerebrally or systemically, it may have a dual hypothalamic–pituitary site of action or a main effect at the median eminence of the hypothalamus. Kisspeptin-containing neurons are mainly located in the arcuate nucleus (ARC) of the hypothalamus and the anteroventral periventricular nucleus (AVPV) of the POA, with some neurons also present in the periventricular nucleus. The kisspeptin receptor, GPR54, is more diffusely distributed, suggesting that kisspeptin affects the activity of more than one neuronal subset.

GnRH neurons contain GPR54 receptors, suggesting that they are directly targeted by kisspeptin neurons. Evidence for this direct site of action was provided by the demonstration of an excitatory effect of kisspeptin on the bursting activity of GnRH neurons. This study also showed that although mouse GnRH neurons already display GPR54 receptors during early postnatal development, these receptors acquire the ability to excite GnRH neurons in response to kisspeptin only during the transition from the juvenile stage into adulthood. Interestingly, kisspeptin expression is differentially regulated by gonadal steroids in the hypothalamus and POA. Whereas the number of KiSS1-expressing neurons increases in the ARC in response to ovariectomy and decreases after estrogen or androgen treatment, KiSS1 expression is increased in the AVPV neurons in response to sex steroids. These opposite changes suggest that kisspeptin may be involved in mediating the positive feedback effects of estrogen in the POA and estrogen negative feedback in the ARC.

Glial Control of the GnRH Neuronal Network

A fascinating aspect of the GnRH neuronal network is the intimate association that exists between GnRH neurons and glial cells. Studies of both nonhuman primates and rodents have shown that this association is dynamic and remarkably plastic. It involves both astrocytes (**Figure 2(a)**) and a type of modified ependymoglial cells lining the wall of the third ventricle, known as tanycytes (**Figure 2(b)**). Astroglial processes abundantly appose the GnRH cell membrane, and this apposition is particularly evident along the secretory axons projecting to the median eminence. Although species differences exist (mostly manifested as a much less abundant astroglial ensheathment of GnRH neuronal perikarya in rats than in monkeys), the degree of glial apposition changes in relation to the endocrine status of the animal in both species. This plastic relationship is most evident in the median eminence, in which tanycytes control the access of GnRH nerve terminals to the portal vasculature via end feet specializations that alternatively advance or

Figure 2 Immunohistofluorescence confocal microscopy images showing astroglia–GnRH neuron and astroglia–tanycyte associations in the prepubertal female rat hypothalamus. (a) Astrocytes identified by their glial fibrillary acid protein (GFAP) staining (red) wrap GnRH cell bodies and neuronal processes (green) in the preoptic area. (b) Tanycytes (identified by the presence of vimentin (green)) line the floor of the third ventricle and send long processes to the external layer of the median eminence to contact the endothelial wall of the portal system. Astrocytes (identified by the presence of GFAP (red)) are located immediately below the layer of tanycytic cell bodies, with which they establish intimate contact and also send processes to the external layer of the median eminence.

retract according to the stage of the estrous cycle. When estradiol levels are high, preceding the preovulatory surge of gonadotropins, the end feet retract, allowing direct access of the GnRH nerve ending to the portal system and thus resulting in unhindered release of the decapeptide to the portal system. In addition to plastic rearrangements, glial cells contribute to the control of GnRH release by releasing growth factors and other chemical messengers, and by amplifying the facilitatory effects of glutamatergic neurotransmission on GnRH neurons.

Glial Growth Factors

Astroglial cells synthesize and release several growth factors, including transforming growth factor β_1 (TGF-β_1), basic fibroblast growth factor (bFGF), insulin-like growth factor (IGF-1), and members of the epidermal growth factor (EGF) family. In this article, we consider only the latter. It is well-established that the EGF relatives, transforming growth factor-α (TGF-α) and the neuregulins (NRGs), are key components of this glia-to-neuron communication pathway. By binding to glial erbB receptors (erbB1 and erbB4, respectively), TGF-α and NRGs recruit an auxiliary receptor termed erbB2 and elicit the release of chemical messengers, such as prostaglandin E_2 (PGE_2), that act directly on GnRH neurons to stimulate GnRH secretion.

Various approaches have been used to demonstrate the involvement of this erbB receptor-mediated astrocytic signaling system in the control of female sexual development. Pharmacological blockade of erbB1 receptors or a natural mutation in the erbB1 gene result in delayed puberty. Conversely, transgenic or anatomically targeted (to the median eminence) TGF-α overexpression advances female puberty. The TGF-α–erbB1 signaling complex is also a key determinant of the plastic changes that tanycytes exhibit during the preovulatory surge of GnRH. Activation of erbB1 receptors in tanycytes results in release of PGE_2, which enhances TGF-β_1 release. In turn, TGF-β_1 induces tanycytic retraction by facilitating dissolution of the extracellular matrix.

The importance of erbB2 for appropriate hypothalamic erbB-mediated signaling has been shown by the delay in puberty resulting from the *in vivo* disruption of hypothalamic erbB2 receptor synthesis via infusion of an antisense oligodeoxynucleotide.

Finally, involvement of a glial NRG–erbB4 signaling complex in the control of female puberty was initially suggested by the presence of both the ligands and the receptor in astrocytes of the immature female rat hypothalamus and then by the increase in hypothalamic content of erbB2 and erbB4 mRNA that occurs at the end of the juvenile period. This increase occurs first in a gonad-independent manner and is subsequently driven by ovarian steroids, suggesting that the initial activation is a component of the centrally mediated, steroid-independent change in hypothalamic activity (the 'central drive') that initiates puberty. Transgenic animals expressing a dominant mutated form of the erbB4 receptor targeted to astrocytes exhibit a reduced astrocytic (PGE_2) response to NRG stimulation, a blunted GnRH response to astrocyte-conditioned medium, a decrease in plasma gonadotropin levels, and delayed puberty. The use

of double mutant animals carrying both a dominant negative form of erbB4 and a point mutation of the erbB1 receptor demonstrated that both receptors act coordinately to control GnRH secretion and, hence, female sexual development.

Glutamate

Astrocytes control extracellular glutamate levels in a variety of ways, including uptake reversal of glutamate transporters, the Cl^-/HCO_3^- anion exchange system, calcium-dependent exocytosis, and diffusion through ionotropic purinergic receptors. Astrocytes can also modify intracellular glutamate levels directly via astrocyte–astrocyte gap junction communication. The identification of these mechanisms has led to the recognition of astrocytes as a third component of synaptic communication, in addition to the pre- and postsynaptic neuronal specializations.

Astrocytes also play a major role in glutamate metabolism. During the onset of female puberty, there is an increased ability of the hypothalamus to release glutamate. There are also opposite changes in the hypothalamic content of glutamate dehydrogenase (GDH), an enzyme responsible for the synthesis of glutamate, and glutamine synthetase (GS), the enzyme that catalyzes the metabolism of glutamate to glutamine. GDH content increases and GS decreases at the time of puberty, whereas the abundance of the neuronal-specific glutamate synthesizing enzyme phosphate-activated glutaminase remains unchanged. Because both GDH and GS are predominantly expressed in astrocytes, these results suggest that a glial glutamatergic input to GnRH neurons is an intrinsic component of the hypothalamic regulatory system controlling the onset of female puberty.

Small Bioactive Molecules

As indicated previously, PGE_2 mediates the stimulatory actions that TGF-α and NRGs exert on GnRH release. Glutamate also directly stimulates astrocytic release of PGE_2, which in turn promotes a calcium-dependent glial release of glutamate. In addition, glutamate can increase its own availability by enhancing the release of astroglial arachidonic acid, which inhibits glutamate uptake into glial cells. Another small molecule released by astrocytes in a calcium-dependent manner is ATP. GnRH neurons respond to extracellular ATP, through $P2X_2$ and $P2X_4$ receptors, with an immediate increase in intracellular calcium and release of GnRH. These interactions are likely to be important for the regulation of GnRH secretion during sexual development.

Neuron-to-Glia Communication

During the past few years, it has become clear that the activity of glial cells is influenced by neuronal inputs. In the neuroendocrine brain, stimulation of astrocytic glutamatergic receptors induces the activation of the erbB signaling system. Hypothalamic astrocytes express both metabotropic and ionotropic (AMPA) glutamatergic receptors. Combined metabotropic/AMPA stimulation results in phosphorylation of erbB receptors. This activation requires the activity of a metalloproteinase that promotes the cleavage of both TGF-α and NRG precursors, making them available for interaction with their respective receptors. In the case of TGF-α, the metalloproteinase involved is termed tumor necrosis factor-α converting enzyme (TACE). TACE activity increases in the rat median eminence at the time of the first preovulatory surge of gonadotropins, suggesting a role for TACE in the control of GnRH release. Consistent with this view, blockade of TACE activity in the median eminence decreases GnRH secretion and delays puberty in the female rat.

It is therefore evident that glutamate controls GnRH neuronal activity not only via a transsynaptic mode of communication but also by utilizing the astrocytic erbB signaling system coupled to PGE_2 release to facilitate GnRH secretion.

Transcriptional Control of the Onset of Puberty

The complexity of the aforementioned cell–cell communication pathways suggests a level of control provided by gene networks that, operating within the neuroendocrine brain, coordinate neuronal–glial interactions in a developmentally regulated manner. Regulatory control systems such as this have the potential for thousands of interactions. Nevertheless, the 'heart' of such complex systems always consists of a handful of genes encoding transcription factors. Little is known about the hierarchy of such 'upstream' transcriptional regulators controlling the onset of mammalian puberty, but three potential candidates have been identified. One is Oct-2, a transcriptional regulator of the POU domain family of homeobox-containing genes. Because Oct-2 proteins are more abundant in cultured astrocytes than in neurons, they may be important for the transregulation of astroglial genes. TGF-α is one of these target genes because the transcriptional activity of the TGF-α promoter is increased by Oct-2. The physiological implications of this relationship have been made evident by several observations, including the gonad-independent increase in hypothalamic Oct-2 mRNA levels that occurs during juvenile development, the concomitant activation of both Oct-2 and TGF-α expression in astrocytes near the site of puberty-advancing lesions of the anterior hypothalamus, and the reduction in astrocytic TGF-α synthesis associated with a delay in the age at first ovulation resulting from

blockade of hypothalamic Oct-2 synthesis with antisense oligodeoxynucleotides.

The second candidate is another homeobox gene known as TTF-1 (NKx2.1). TTF-1 is required for diencephalic morphogenesis; like Oct-2, it remains expressed after birth in discrete neuronal and glial populations of the hypothalamus, where it acts to regulate cell-specific functions. For instance, TTF1 enhances GnRH, KiSS1, and erbB2 promoter activity, but it inhibits preproenkephalin gene transcription. Neuron-specific deletion of the TTF-1 gene results in delayed puberty and decreased reproductive capacity – deficiencies associated with increased preproenkephalin mRNA and reduced GnRH and KiSS1 mRNA levels in the hypothalamus.

A third candidate was discovered using cDNA arrays examining the primate hypothalamus at the time of puberty. This gene, previously known as chromosome 14 open reading frame 4 (C14ORF4), has been termed EAP-1 (enhanced at puberty). EAP-1 encodes a nuclear protein that, like TTF-1, is expressed in neurons involved in the stimulatory and inhibitory control of GnRH secretion, including GnRH neurons, as well as glutamatergic, GABAergic, and proenkephalinergic neurons. EAP-1 also has dual transregulatory activity; it activates the GnRH promoter but represses the preproenkephalin gene, which is inhibitory to the pubertal process. Reducing hypothalamic EAP-1 expression using siRNAs delayed puberty and disrupted estrous cyclicity, indicating that EAP-1 is necessary for the timely activation of GnRH secretion at puberty.

These observations suggest that upstream genes, such as TTF-1, Oct-2, and EAP-1, control the pubertal process by coordinating the activity (and therefore the interactions) of neuronal and glial subsets involved in the developmental control of the GnRH neuronal network (Figure 3).

Figure 3 The transcriptional control of the GnRH neuronal network at puberty by upstream controlling genes. Changes in the secretory activity of GnRH neurons are specified by transsynaptic and glial inputs. These inputs are determined by subordinate genes, which in turn are controlled at the transcriptional level by upper-echelon genes such as Oct-2, TTF-1, and EAP-1. It is believed that this hierarchical arrangement is required to initiate and maintain an enhanced level of pulsatile GnRH secretion at puberty. Modified from Ojeda SR, Lomniczi A, Mastronardi C, et al. (2006) Minireview: The neuroendocrine regulation of puberty: Is the time ripe for a systems biology approach? *Endocrinology* 147: 1166–1174, copyright 2006, The Endocrine Society.

An Integrated View

The principal cellular interactions and cell–cell communication molecules believed to control the initiation of mammalian puberty are illustrated in Figure 4. As indicated previously, the onset of puberty appears to result from the coordinated activation of excitatory transsynaptic inputs to GnRH neurons (e.g., glutamate and kisspeptin) coupled with a reduction in inhibitory neurotransmission (e.g., GABA and opioid peptides) and an increase in growth factor-mediated glia-to-neuron signaling (e.g., TGF-α and NRGs). Absent from this model is the clock mechanism

Figure 4 Neuronal and glial factors involved in the control of GnRH secretion. The transsynaptic control of GnRH secretion is exerted by excitatory neurons that utilize glutamate or kisspeptin for neurotransmission/neuromodulation and inhibitory neurons that employ GABA or opioid peptides (represented by preproenkephalinergic neurons) for inhibition. Astrocytes and ependymoglial cells stimulate GnRH secretion via release of growth factors that can act directly on GnRH neurons (e.g., TGF-β, bFGF, and IGF-1) or growth factors (e.g., TGF-α and NGRs) that need the intermediacy of small bioactive molecules (e.g., PGE_2). At the time of puberty, the excitatory component of this regulatory network predominates over the inhibitory component, resulting in enhanced GnRH secretion. +, stimulation; −, inhibition; ?+/−, not known.

that coordinates the changes in diurnal activity of this regulatory system. Such an entrainment is characteristic of the pubertal process in both primates and rodents because in these species the GnRH-dependent activation of gonadotropin secretion has a diurnal rhythm (Figure 1). Emerging evidence suggests that integrations of neuron-to-neuron and reciprocal glia–neuron interactions leading to the initiation of the pubertal process require a higher level of control provided by a transcriptional machinery composed of genes able to modify gene expression in a cell- and promoter-dependent manner (Figure 3).

Neuroendocrinology of Social/Affiliative Behavior

Introduction

Affiliative behavior can be defined as any prosocial behavior that brings two or more individuals into close proximity. The formation of social units, such as mating pairs, family units, colonies, or even societies is critical for the survival of most species, including humans. Affiliative behavior depends on several neurobiological processes, including the ability to recognize familiar individuals based on social stimuli, the motivation to engage in social interactions, and the formation of selective social bonds. In recent years, great strides have been made in understanding the underlying neurobiological processes that drive affiliative behaviors, including social bond formation. Much attention has focused on the role of the neuropeptides oxytocin (OT) and arginine vasopressin (AVP) in the regulation of specific types or components of affiliative behavior, including social recognition, parental care, and social bonding. This article discusses the roles of these peptides as well as other neuroendocrine factors in the regulation of affiliative behaviors in animal models, and it concludes with a brief discussion of the implications for this research on human behavior.

Oxytocin and Vasopressin: Neuropeptides of Affiliation

OT and AVP are closely related nonapeptides that are synthesized predominantly in magnocellular neurons of the paraventricular nucleus (PVN) and supraoptic nucleus (SON) of the hypothalamus, which project heavily to the posterior pituitary, where these peptides are secreted into the bloodstream. Peripherally released OT facilitates uterus contractions during parturition and milk ejection during lactation. Peripherally released AVP, also known as antidiuretic hormone, controls water reabsorption in the kidney and vascular tone. OT and AVP are also synthesized in parvocellular neurons in the PVN as well as extrahypothalamic sites, such as the medial amygdala and the bed nucleus of the stria terminalis, which project centrally and are thought to mediate the central effects of the peptides. Because of the blood–brain barrier and independent release, the peripheral and central effects of OT and AVP are considered to be independent. Interestingly, the production of AVP in certain brain regions is sexually dimorphic and highly dependent on testosterone such that males have significantly more AVP than females within these specific circuits. The actions of OT and AVP are mediated by four G-protein-coupled receptors: oxytocin receptor (OTR) and V1a, V1b, and V2 subtypes of the vasopressin receptor. The V1a and V1b subtypes are localized in the brain, and the majority of the behavioral effects of AVP appear to be regulated by the V1a receptor (V1aR).

Centrally released OT and AVP have been implicated in the regulation of a variety of social behaviors, including parental care, social recognition, sexual behavior, and aggression in a wide range of vertebrate taxa. Not surprisingly, due to its sexually dimorphic expression in the brain, AVP has predominately been implicated in the modulation of male-typical social behaviors. This article focuses on the roles of OT and AVP and other neuroendocrine factors in animal models of social recognition and parental care in rodents, mother–infant bonding in sheep, pair bond formation in prairie voles, and the potential role of OT and VP in human social behavior.

Social Recognition in Rodents

Social recognition is best defined as the ability to recognize a familiar conspecific based on salient social cues. This process is the foundation for the formation of all social relationships and is therefore necessary for the survival of a species. Visual and auditory cues are primarily used in human and nonhuman primate social recognition, whereas olfactory cues are predominantly used to differentiate familiar and nonfamiliar individuals in rodents.

Since rodents rely on olfactory cues to distinguish individuals, social recognition in rodents can be assessed by determining the amount of time an animal spends investigating a familiar individual upon subsequent exposures or the relative amount of time an individual spends investigating a novel compared to a familiar individual. This social recognition test is based on the fact that rodents spend less time investigating familiar individuals compared to novel individuals. Upon repeated exposures to the same individuals, rodents typically habituate to the familiar individual, resulting in decreased duration of olfactory investigation.

The role of AVP in social recognition was first investigated using Brattelboro rats, which are natural mutants for AVP. Male Brattelboro rats display severe deficits in social recognition, but normal social recognition is

restored by infusion of AVP into the lateral septum. Later studies reported that V1aR selective AVP antagonist infused into the lateral septum of normal rats blocks social recognition, whereas infusion of AVP into the lateral septum increases the duration of the memory from less than 2 h to more than 24 h. AVP appears to be involved in the consolidation or recall of the social memory since AVP is necessary only after the initial social encounter.

Several molecular and transgenic studies have confirmed the role of AVP in modulating social recognition. Infusion of a V1aR antisense oligonucleotide into the lateral septum of rats decreases V1aR density and inhibits social recognition. Artificially increasing V1aR expression in the lateral septum of rats using a viral vector enhances social recognition. Finally, V1aR knockout mice fail to display social recognition since they do not habituate to familiar individuals. These mice perform normally on nonsocial learning and memory tasks, such as the Morris water maze, as well as tests for sensorimotor gating, such as prepulse inhibition, indicating that nonsocial cognitive processes are intact. This deficit is also not due to a general disruption in olfaction since V1aR knockout mice habituate to nonsocial odors. Social recognition in these animals can be restored by expressing the V1aR in the lateral septum using viral vector-mediated gene transfer.

OT is also required for social recognition, although it appears to have a different function than AVP. OT antagonists inhibit social recognition, and mice genetically deficient in the OT gene fail to habituate to familiar individuals upon repeated exposures. Like V1aR knockout mice, OT knockout males display normal olfactory memory for nonsocial scents and perform normally in nonsocial cognitive tasks, confirming that this deficit is selective for social learning and memory. This social recognition deficit was reversible with a single central injection of OT before, but not after, the initial encounter with a stimulus female. Thus, unlike AVP, OT appears to be critical for the neural processing of the social cues required for the formation of the memory rather than consolidation or recall. Furthermore, OT appears to be acting in the medial amygdala, rather than in the lateral septum, since infusion of OT in this region restores social recognition (Figure 1).

Studies of female OT knockout mice suggest that OT is also involved in assessing mate quality. Female mice use olfaction to distinguish between suitable, healthy mates and those infected with parasites. Interestingly, OT knockout females fail to display a preference for uninfected males, further suggesting that OT is involved in the processing of social cues and potentially in mate selection.

Figure 1 Social recognition in wild-type (WT) and oxytocin knockout (OTKO) male mice. (a) Olfactory investigation in mice. During a social recognition test, the duration of time in which the experimental mouse investigates the stimulus mouse is quantified after multiple exposures. Typically, WT mice will show a decline in investigation time after subsequent exposures. (b) Olfactory investigation of ovariectomized female mice by WT and OTKO male mice. Olfactory investigation is measured during four successive 1 min trials separated by 10 min. A fifth dishabituation trial using a novel female demonstrates that the decline in investigation in WTs is due to recognition of the initial female. A significant decrease (asterisks) occurred between each trail for WT males, but no decline was detected in the OTKO males. Data depict mean ± 1 SEM. (2000) Social amnesia in mice lacking the oxytocin gene. *Nature Genetics* 25(3), 284–288), copyright 2000.

Neuroendocrine Control of Parental Behavior in Rodents

Maternal Care in Rats and Mice

The proper regulation of parental care is critical for reproduction in all mammals. Virgin female rats, like most mammals, show no interest in or even avoid pups, but at parturition they rapidly switch to displaying high levels of maternal behavior and being attracted to pups. This change in behavior represents a change in motivational state rather than

the development of selective social attachments since female rats will readily adopt any pup that they encounter.

The neuroendocrine changes associated with pregnancy and parturition play a critical role in the induction of maternal responsiveness. Circulating estrogen, progesterone, and prolactin concentrations increase during pregnancy, followed by a decrease in progesterone secretion at parturition. These hormonal fluctuations are critical not only for priming the uterus and mammary tissue in preparation for birth but also for the induction of maternal care through their actions on receptors in specific brain regions. Priming with estrogen and progesterone, followed by progesterone withdrawal, as well as infusion of prolactin, stimulates the initiation of maternal care in ovariectomized, virgin rats. Interestingly, these hormones are not essential for the maintenance of maternal care because once maternal behavior has been established, it is not diminished by removal of these hormones.

The medial preoptic area (MPOA) plays a significant role in the neuroendocrine regulation of maternal behavior. Lesions of the MPOA or its projections disrupt the onset of maternal behavior. The MPOA has a high concentration of estradiol, and progesterone receptors and prolactin receptors increase in the MPOA as parturition approaches. Implants of estradiol into the MPOA facilitate maternal behavior. Studies on knockout mice confirm the role of estrogen and prolactin in regulating the onset of maternal behavior. Estrogen receptor-α knockout mice have poor maternal behavior, whereas estrogen receptor-β knockout mice successfully raise their young, suggesting that estrogen receptor-α is the substrate with which estrogen interacts in the MPOA. Prolactin receptor knockout mice also have deficits in pup retrieval and nesting deficits.

In addition to estrogen, progesterone, and prolactin, centrally released OT is involved in the initiation of maternal responsiveness in rodents. OT is released from the posterior pituitary into the bloodstream at parturition and during lactation via the synchronous firing of magnocellular PVN and SON neurons. More than 25 years ago, two studies demonstrated that central infusion of OT facilitated the onset of rapid maternal behavior in virgin female rats. Later studies confirmed that OT antagonists and lesions of the PVN delay the onset of maternal behavior in primiparous female rats. However, PVN lesions do not disrupt maternal behavior in animals that are already maternal, again demonstrating that neuroendocrine factors mediate the onset but not the maintenance of maternal behavior. Finally, OT receptor antagonists injected directly into the MPOA inhibit maternal behavior.

OT also appears to be acting in the olfactory bulb to modulate the olfactory response to pup odors. Infusion of OT into the olfactory bulbs of parturient rats facilitates the onset of maternal behavior, whereas the application of an OT antagonist inhibits the onset of maternal behavior. Initial reports on OT knockout mouse suggested that maternal behavior was not disrupted. However, more careful analysis of their maternal behavior demonstrated that these mutant mice do in fact have impaired maternal responsiveness. In addition, OT receptor knockout mice display profound impairments in maternal behavior.

Spontaneous Maternal Care in Prairie Voles

Prairie voles are monogamous rodents that display high levels of affiliative behavior and have thus become important models for investigating the neurobiology of affiliation. Interestingly, juvenile female prairie voles, and approximately half of adult female prairie voles, display 'spontaneous' maternal care as virgins. OT receptor density in the nucleus accumbens is correlated with the quality of spontaneous maternal care both in juveniles and in adults. That is, individual prairie voles with higher densities of OT receptor in the nucleus accumbens display higher levels of maternal care. Furthermore, infusion of OT receptor antagonist into the nucleus accumbens inhibits spontaneous maternal care in female prairie voles. Interestingly, mice and meadow voles do not show spontaneous maternal care as juveniles, and they also have little or no OT receptors in the nucleus accumbens. In contrast, juvenile rats, which do display maternal behavior prior to puberty, have moderate levels of OT receptors in the accumbens, but these levels decrease as the developmental pattern of maternal behavior declines.

Paternal Care

Monogamous mammals, representing only 3–5% of mammalian species, display paternal care in addition to maternal care. Several studies have implicated a role for AVP in the regulation of paternal behavior, particularly in male prairie voles. Male prairie voles display an increase in paternal behavior after cohabitating with a female. AVP immunoreactivity in the lateral septum decreases and AVP mRNA in the bed nucleus of the stria terminalis increases concomitantly with these changes in behavior. This is consistent with a release of AVP from terminals in the septum and an increase in AVP synthesis in the neurons giving rise to those terminals. A more direct indication of a role for AVP in inducing paternal behavior came from studies in which infusions of AVP into the lateral septum facilitated, and a V1aR

antagonist blocked, paternal care in male prairie voles. In a separate study, male prairie voles with elevated levels of V1aR expression in the lateral septum displayed higher levels of paternal care than males with lower levels of receptor in the same region. The role of AVP in regulating paternal behavior has not been explored in other species; however, one study found a dramatic increase in V1aR protein in the cortex of monogamous male marmosets associated with paternal experience.

Social Bonding

Social bonding is a special form of affiliative behavior in which selective social attachments strengthen social relationships. Social bonding requires both social recognition processes and motivational systems to be activated. In many species, neither mating pairs nor parent–infant relationships develop selective bonds. However, two models of social bonding – mother–infant bonding in sheep and pair bonding in monogamous prairie voles – have provided significant insights into the neuroendocrine regulation of social bonding.

Mother–Infant Bonding in Sheep

As in rats, hormonal fluctuations during pregnancy and parturition facilitate the onset of maternal behavior in sheep. However, unlike rats, the ewe forms a selective bond with her lamb such that she provides maternal nurturing only to her own lamb and rejects other lambs. This bonding process is necessary for sheep since many ewes give birth to precocial (i.e., mobile) lambs simultaneously, and it ensures that all maternal resources are directed to the ewe's offspring. The selective bond between the ewe and the lamb is formed within a few hours after birth, after which the mother rejects all other lambs.

OT has been shown to be critical for the formation of mother–infant bonds in sheep. Estrogen and progesterone stimulation increases maternal responsiveness in sheep, but this behavior is disorganized and slow to develop. However, vaginocervical stimulation in these same animals results in the rapid acceptance of a foreign lamb, often within 5 min. Vaginocervical stimulation, either artificially or during parturition, results in the central release of OT in the brain and the olfactory bulb. Finally, central infusion of OT in a hormonally primed nonpregnant ewe will stimulate her to form a bond with an unfamiliar lamb within a few minutes. After this bonding process, the ewe will behave maternally to the bonding lamb and reject all other lambs.

The olfactory bulb appears to be a critical brain area responsible for developing a social memory for a lamb. OT release in the olfactory bulb during parturition is thought to synaptically recognize neurons in the mitral cell layer to selectively respond to the familiar lamb. In addition to OT, noradrenaline, acetylcholine, glutamate, and GABA levels increase following parturition or vaginocervical stimulation. It appears that OT modulates the release of other neurotransmitters, suggesting that the release of OT coordinates the changes in the olfactory bulb after parturition or vaginocervical stimulation.

Pair Bonding in Monogamous Prairie Voles

Like sheep, the monogamous prairie vole (*Microtus ochrogaster*) forms selective, enduring bonds. These bonds, however, are with their mates and can last the lifetime of the pair. Prairie voles are highly social and typically live in communal burrows occupied by a breeding pair and multiple generations of offspring. Laboratory studies suggest that mating facilitates pair bond formation, although mating is not strictly required. Because of its role in maternal bonding, it was hypothesized that OT may play a role in pair bonding in voles. In the laboratory, pair bonding is assessed using a partner preference paradigm. After a period of cohabitation, one of the pair is tethered to one chamber of a three-chambered testing arena. A novel animal of the same sex and stimulus value is tethered to the opposite chamber. The test animal is placed in the central chamber and is allowed to move freely through all three chambers. Typically, a prairie vole that has formed a pair bond will spend more than twice as much time in contact with the partner than with the stranger.

Infusions of OT in female prairie voles result in the development of a partner preference in the absence of mating. Likewise, mating-induced partner preferences are blocked by central infusion of an OTR antagonist in females. Similarly, central injections of AVP into the brain facilitate pair bond formation in the absence of mating and V1aR antagonist blocks pair bond formation in male prairie voles.

Unlike prairie voles, montane voles (*M. montanus*) are non-monogamous, relatively asocial, and do not typically form social bonds. Both species have similar levels and distributions of OT and AVP in the brain. However, infusions of either peptide do not stimulate affiliative behavior in montane voles. In contrast to the peptides, the distribution of OT and AVP receptors in the brain differs dramatically between these species, suggesting that receptor distribution may be responsible for the differences in behavior (**Figure 2**).

Prairie voles have high densities of OT receptor and V1aR in brain regions implicated in reward and reinforcement, such as the nucleus accumbens and ventral pallidum, respectively. In contrast, non-monogamous

Figure 2 Oxytocin receptor (a, b) and vasopressin 1a receptor (c, d) binding in the brains of monogamous prairie voles (a, c) and non-monogamous montane voles (b, d). Prairie voles have higher densities of oxytocin receptors in the nucleus accumbens (NAcc) than montane voles. Additionally, prairie voles have higher densities of vasopressin receptors in the ventral pallidum (VP) than do montane voles. CP, caudate putamen; LS, lateral septum; PFC, prefrontal cortex. Adapted from Young LJ and Wang Z (2004) The neurobiology of pair bonding. *Nature Neuroscience* 7: 1048–1054.

montane and meadow voles have low levels of receptors in these regions. Microinjection of OT receptor antagonist in the nucleus accumbens blocks pair bond formation in female prairie voles, whereas microinjection of V1aR antagonist into the ventral pallidum blocks pair bonding in male prairie voles. Artificially elevating V1aR levels in the ventral pallidum of the non-monogamous meadow vole (*M. pennsylvanius*) was found to enhance mating-induced partner preference formation in this species. Thus, it appears that differences in mating strategies in these species may be due in part to the species differences in OT receptor and V1aR expression patterns in the brain.

The involvement of the nucleus accumbens in pair bond formation suggests a role for the mesolimbic dopamine reward pathway in pair bond formation. Extracellular dopamine levels rise in the nucleus accumbens during mating. Infusion of dopamine D2-like receptor agonist and antagonist into the nucleus accumbens of prairie voles facilitates and blocks partner preference, respectively. However, simultaneous blockade of OT receptors in females prevents dopamine agonist-induced partner preference formation in females. This suggests that the OT and dopamine systems interact, resulting in pair bond formation.

Since OT and AVP are critically involved in social recognition processes and dopamine is important in reward conditioning, it has been proposed that pair bond formation results from the convergent activation of social recognition circuits (necessary for long-term memory of the mate) and the reward pathway. That is, simultaneous activation of both circuits during mating results in a conditioned association between the olfactory signature of the partner and the rewarding nature of mating, resulting in a conditioned partner preference (Figure 3).

Genetic studies suggest that individual differences in V1aR gene structure and expression in the brain contribute to individual differences in affiliative behavior. In the wild, not all male prairie voles form bonded pairs, and there are significant individual differences in brain V1aR patterns. Comparison of the V1aR gene structure between prairie and montane voles revealed a highly repetitive microsatellite element in the promoter of the gene which differed significantly between the species. Microsatellite elements are highly unstable and prone to mutation. There is significant individual variation in the length of the microsatellite among individual prairie voles. Interestingly, males with long alleles of the microsatellite have higher levels of V1aR expression in the olfactory bulb and lateral septum than do males with short alleles. In addition, males with longer microsatellites also display higher levels of paternal behavior and are more likely to form partner preferences than males with shorter microsatellites. These data suggest that variation in V1aR expression may underlie both individual and species differences in affiliative behavior in voles.

Figure 3 Proposed neural circuitry underlying pair bonding in prairie voles. Mating activates the ventral tegmental area (VTA), resulting in increased dopamine activity in the prefrontal cortex (PLC) and nucleus accumbens (NAcc). Concurrently, olfactory signals from the mate are transmitted via olfactory bulb to the medial nucleus of the amygdala (MeA). Mating also stimulates increased extracellular concentrations of oxytocin in the PFC and NAcc of females and vasopressin in the ventral pallidum (VP) of males. Vasopressin fibers in the lateral septum (LS) and VP originate from cell bodies in the MeA and bed nucleus of the stria terminalis (BST). Oxytocin projections to the NAcc and PFC most likely arise from cells in the hypothalamus (Hypo). The concurrent activation of the dopaminergic system and the oxytocin (in females) or arginine vasopressin (in males) system in the NAcc or VP potentially results in the development of a conditioned partner preference. The VP is a major output relay of the NAcc and modulates motor output in response to reinforcing stimuli via projects to the mediodorsal thalamus (MdTh) and cortical and mesencephalic motor nuclei. Adapted from Young LJ and Wang Z (2004) The neurobiology of pair bonding. *Nature Neuroscience* 7: 1048–1054.

Implications for Human Social Behavior

It is impossible to directly translate findings in animal models to human behavior. However, the animal studies discussed in this article suggest that it is possible that OT and AVP may also modulate human social behavior and that disregulation in these systems may contribute to the behavioral phenotypes observed in psychiatric disorders associated with disruptions in social behavior, such as autism. Findings from a study that used intranasal infusion of OT suggest that OT increases trust in humans. A separate brain imaging study demonstrated that intranasal OT infusion alters amygdala activity in response to viewing socially salient scenes. OT infusion also acts synergistically with the presence of a partner to decrease the cortisol stress response resulting from a public speaking task.

One study has reported that autistic children have significantly lower levels of plasma OT compared to age-matched normal subjects. Interestingly, nursery-reared rhesus monkeys (raised by humans instead of their mothers), which have severely disrupted social behaviors, have lower levels of OT in the cerebrospinal fluid (CSF) than monkeys reared by their mothers. In another primate model, the relatively asocial pigtail macaques also had significantly lower levels of OT in CSF than the more social bonnet monkeys. Notably, studies examining the therapeutic value of OT in autism have reported that intravenous OT infusions reduce repetitive behaviors and enhance social cognition in adults with autism, although these studies need to be replicated.

Several studies suggest that central AVP may modulate human social behavior as well. Intranasally administered AVP altered human facial responses (as measured by electromyograms) to normally neutral social stimuli in a sex-specific manner, suggesting that AVP might modulate the processing of social stimuli in humans similar to that observed in rodent models. Polymorphisms in microsatellites in the human V1aR gene have also been associated with variation in human social behavior as well as psychopathology. Specifically, three independent studies have reported associations between these polymorphisms and autism. Thus, as in prairie voles, genetic variability in the V1aR gene may contribute to individual differences in affiliative behavior in humans.

Conclusions

Affiliation results from a complex set of behaviors that involve many cognitive processes, each of which is regulated by many neuroendocrine factors, neurotransmitters, and brain circuits. We have made

significant progress in understanding the neural mechanisms underlying specific examples of affiliative behavior in animals and are just beginning to understand how these same mechanisms may modulate human behavior. The studies of social recognition, parental care, and social bonding discussed in this article reveal specific roles for neuropeptides (OT, AVP, and prolactin), steroids (estrogen and progesterone), and dopamine. However, it should be recognized that a multitude of other hormones and neurotransmitters are acting in concert with these systems to produce the complex set of events that ultimately lead to the development of social relationships which are critical for our own well-being.

Neuroethics

S J Bird, Wrentham, MA, USA

© 2009 Published by Elsevier Ltd.

Introduction

Neuroethics is a newly identified field at the intersection of neuroscience and ethics, the area of philosophy that deals with the study of standards of conduct and moral judgment. (Neuroscience intersects with other areas of philosophy as well, such as aesthetics, epistemology, metaphysics, and mind–body theory, but these are not directly relevant to neuroethics.) Neuroethics includes both the ethics of neuroscience and the neuroscience of ethics; that is, it is concerned with ethical issues uniquely or primarily associated with the practice or application of neuroscience and also the neurobiology of moral and ethical thinking and decision making (Figure 1).

History

The term neuroethics was initially introduced in 1993 in the context of treatment of young neurological patients and reintroduced almost a decade later in discussions of the application of technological advances in the area of neuroscience and the biological elements underlying ethical thoughts and behavior. However, many of the issues with which neuroethics is concerned have been the focus of philosophical thought for centuries. Attention to the ethical concerns associated with the application of neuroscience findings, and with the conduct of neuroscience research, has steadily increased during the past several decades. For example, debates about free will and determinism which were initially grounded in the role of the gods in controlling the lives of mere mortals evolved into a recognition and discussion of the strong influence of cultural factors and experience in behavioral decisions. These discussions were the forerunners of current debates about responsibility, self-control, and the neurobiological underpinnings of moral decision making.

In the twentieth century, discussions of ethics and neuroscience primarily centered around the application of neuroscience findings or techniques to address individual or societal concerns. For example, the actual and proposed use of psychosurgery to treat mental conditions and to control problematic behavior was and remains controversial. Since 1983, the Society for Neuroscience, the largest professional society of neuroscientists in the United States, has held an annual Social Issues Roundtable that has generally focused on the ethical, legal, and social implications of neuroscience research. These sessions have examined such topics as research into possible sex differences in the brain and the applications of that research, brain death, therapeutic and nontherapeutic use of cognitive enhancers, the use of fetal tissue to treat neurological diseases, neurotoxicity of food additives, and the role of neuroscience research into drug addiction in the development of health and public policy. Also in 1983, the US Office of Technology Assessment commissioned a report that included the potential societal impacts of neuroscience research. Among the topics covered were the implications of neuroscience findings for the criminal justice system, the workplace, and education.

Attention to neuroethics in research practice has primarily emphasized issues associated with the humane treatment of research subjects, especially laboratory animals. Debate pitting the scientific advances and societal benefits of animal experimentation against concerns about animal cruelty has raged since the early 1800s. This controversy was brought directly to neuroscience research in the 1980s, initially when police raided a laboratory in Silver Spring, Maryland, where neuroregeneration was being studied in primates and later as a result of highly publicized exposures of controversial practices in neuroscience research. In the United States, neuroscience research with laboratory animals, like animal experimentation in general, is regulated by the Department of Agriculture and the Department of Health and Human Services, primarily through required institutional animal care and use committees (IACUCs). The neuroscience community is actively engaged in discussing the ethical issues associated with animal experimentation in neuroscience.

Features of the Nervous System with Ethical Implications

The complexity of the nervous system, its plasticity, the dynamic, interactive quality of its elements, and the remarkable variation in structure and function from one individual to the next are qualities of the nervous system with important implications for neuroethics. Because there are more uniquely expressed genes and more types of cells in the nervous system than in the rest of the body, more interconnections throughout the nervous system (and connections with the immune, endocrine, and other physiological systems as well), and because dynamic interactive communication between and among cells can result in short-term and long-term changes in the elements of

the system, it can be difficult, if not impossible, to reliably predict short- and long-term effects of the manipulation of brain structure or function. Moreover, individual differences in neuroanatomy, physiology, and biochemistry defy easy generalization regarding the impact of various types of experience or interventions from one individual to the next.

Although there is great interest and appeal in applying neuroscience to address societal concerns, and technological advances provide ever more detailed information about molecular and cellular mechanisms underlying emotion, perception, cognitive function, and behavior, scientific understanding of brain structure and function continues to evolve. Although much is known, much remains to be discovered. The relevance and importance of these characteristics of the nervous system to ethical analysis become increasingly clear in the context of particular research practices and applications of research findings. They are fundamental to accuracy and reliability and therefore to the interpretation and appropriate application of neuroscience findings and techniques.

Figure 1 Neuroethics includes both the ethics of neuroscience and the neurobiology of ethics.

Structure of Neuroethics

Broadly speaking, there are three branches of neuroethics: (1) ethical issues that are uniquely or especially associated with the conduct of neuroscience research; (2) issues associated with the application of neuroscience research findings or technologies to human needs, interests, public policies, or societal concerns; and (3) the neurobiological aspects of ethical and moral thinking, judgment, decision making, and behavior (Figure 2).

Conduct of Neuroscience Research

In general, ethical issues associated with conducting neuroscience research are not unique to neuroscience and are the same as those encountered in any area of research in the natural and social sciences. They fall under the umbrella of research ethics, and especially the responsible conduct of research (RCR). The Office of Research Integrity in the Office of the Secretary of the US Department of Health and Human Services identifies the areas of RCR as follows:

- Data acquisition, management, sharing, and ownership
- Conflict of interest and commitment
- Human subjects
- Animal welfare
- Research misconduct
- Publication practices and responsible authorship
- Mentor and trainee responsibilities
- Peer review
- Collaborative science

Appropriate recognition for contributions to a research project, the responsibilities of authorship, and confidentiality and impartiality in the peer review process are a few of the many aspects of research

Figure 2 The three branches of neuroethics.

ethics that are not unique to neuroscience and are not, *per se*, part of neuroethics. However, some components of RCR, such as the humane treatment of research subjects and potential for bias in research, raise questions of particular relevance to neuroscience research.

Clinical research A core ethical principle central to research involving humans is respect for persons. It is reflected in the requirement that participation in a research study be a voluntary and informed decision, and that research subjects can discontinue their involvement in the study at any time. Whether one can make a truly informed decision to be a research subject is widely debated no matter what the nature of the research, but it is especially problematic when the mental capacity of a research subject is compromised, for example, a patient with dementia or schizophrenia. A patient with Alzheimer's disease who initially agrees to participate in an extended study of the efficacy of a particular treatment may lose the capacity to comprehend the broader value of the study as the disease progresses and his or her experience as a research subject becomes a series of confusing, painful encounters with clinical research staff. Although proxy or surrogate consent allows family members or other legal guardians to give consent for the patient, to some degree it inevitably undermines the notion of research participation as a fully informed choice. Even for fully functioning research participants, given the complexity, plasticity, and interconnectivity of the nervous system, research that involves psychoactive substances or other treatments that may directly affect brain function could impair the capacity to understand and evaluate the risks and benefits of participation and affect the participant's ongoing assessment of his or her desire to continue in the study.

Basic research Required for both the ethical and the scientific justification of the use of laboratory animals in research is that the work has the potential to reveal useful insights into biological structure and/or function that lay a foundation for the understanding and, ultimately, the treatment, prevention, and/or cure of disease, dysfunction, or injury. At the same time, it is expected that research can be carried out so that the animals will experience minimal or no pain, suffering, or distress. Any research with animals potentially raises ethical concerns: research that is redundant, poorly designed, of dubious merit, or that inflicts unnecessary or extreme suffering is ethically unacceptable. Whether the procedure involves maternal–pup separation, implementation of starvation or dietary manipulations, surgical interventions, or any other painful or stressful components, IACUCs, the research community, and ultimately the society which funds the research and in whose name the research is carried out must determine whether the potential benefits of the expected research findings outweigh the suffering borne by the research subjects. Given that suffering is a subjective experience, it is challenging if not impossible to carry out this calculus objectively or reliably.

Some areas of neuroscience research pose particular concerns. For example, when research focuses on mental conditions such as schizophrenia or elements of cognition such as intentionality, investigators must make assumptions about the similarity of brain function across species. The reliability of those assumptions and their implications for the understanding of human brain function and disease can be questioned. Moreover, when the focus of research is pain, anxiety, or other forms of stress, some degree of pain and/or stress are elements of the research. Paradoxically, the more like humans an animal is – that is, the more it possesses attributes such as intelligence, sensitivity to pain, emotional complexity, or other similar qualities – the more the research is informative but also ethically problematic if the justification for conducting the research in animals is that it is unethical to investigate the phenomenon in humans because the benefit does not outweigh the harm to the research subject.

Bias in research Attention to bias in the various components of research, from research design to data collection, selection, and interpretation and the reporting of study findings, is always an important aspect of research ethics. Bias in research design is of particular relevance and concern in neuroscience research, and thus an aspect of neuroethics, because of the extent, nature, and implications of findings in this field. Assumptions that underlie research questions are often not adequately investigated. Yet they are likely to reflect conscious or unconscious bias that arises from long-standing socially determined beliefs. For example, it is widely assumed that some differences in male and female behavior reflect anatomical and physiological differences in the brains of males and females. Although this may be true, it is not clear whether biological differences relevant to behavior result from the presence of different sex-related genes or molecules, from differences in the many external factors that shape interactions with others from birth, or from a combination of both. Whatever the basis of sex differences in behavior, the extent to which they are linked to biology and perceived as predetermined and immutable can have far-reaching ramifications for education, employment, health care, and other areas of social and public policy.

Application of Research Findings

Although neuroscience research findings have application in veterinary medicine (e.g., psychoactive medication to treat anxiety), in animal control (e.g., the design of slaughter houses), and in the development of more humane animal research methods, the literature in neuroethics has most commonly focused on the use of neuroscience findings or technology to address human needs, interests, and public policy issues and concerns. The ethical issues associated with the use of research findings are linked to the particular application: who uses the information, for what purpose (e.g., therapy and enhancement), and how it will be used (e.g., passively to monitor brain activity or actively to manipulate behavior). In addition, whether information is about the general population or about a particular individual, and whatever its intended application, its accuracy and reliability are always important considerations, as is accurate presentation of its limits and potential for misuse and abuse, because these considerations directly affect decisions about whether and how best to use the information.

Who, why, and how If individuals use research findings for their own purposes, to inform their own decisions about therapy, for example, or for self-understanding, ethical concerns are not the same as if the information is being used by a second or third party to decide how to interact with another individual (e.g., a patient or client) or to develop policies for a particular group (e.g., sex offenders or women students). For an individual, if the information is general and benign with noninvasive applications (e.g., mnemonic techniques for remembering names), the accuracy and reliability of the research findings are less critical than if the information may expose an individual to risk (e.g., research that suggests a particular dietary supplement is an effective sleep aid although it has the potential for inducing heart arrhythmias). When research findings provide information specific to a particular individual, the accuracy and reliability of the information can be critically important depending on the nature of the information and the purpose for which it is being gathered. For example, the reliability of predictions of a test for a debilitating hereditary neurological or mental illness is key. If test findings are perceived to be consistent markers for the disease (i.e., individuals with a positive test result inevitably get the disease), then the actual reliability and limits of the test (and the research on which the test is founded) are critically important if individuals are to make important medical and personal decisions (e.g., whether to have children) based on test results.

On the other hand, if the test is an indication of a predisposition for a mental illness, then additional ethical concerns arise. In particular, given the dynamic and interactive nature of the human mind, knowledge of the identification of a biological element that is neither necessary nor sufficient for a mental illness but, rather, indicates a predisposition for that condition can become a contributing factor in its own right and a self-fulfilling prophecy. Thus, ethical concerns regarding information about predispositions to disease are related not only to the accuracy and reliability of the test but also to the nature of the nervous system and the independent power of the information. In addition, given the continuing social stigma associated with mental illness, provision of test results to third parties, whether health insurance providers, employers, family members, or others, may also contribute to stress and the development, expression, and manifestation of disease. As a result, information about mental function poses risks as well as benefits because it is provided in a personal and social context with which it interacts. Technological advances can improve the accuracy of the information but may not have much impact on the contexts in which it is provided.

With increased understanding of brain chemistry, pharmacology, and physiology has come the development of invasive techniques such as pharmaceuticals, electroconvulsive shock therapy, stereotaxic surgery, and deep brain stimulation to address mental conditions. These therapeutic strategies are prescribed to treat an individual's self-report of dysfunction and, as with any treatment, raise issues of benefit versus risk, reversibility, patient expectations and informed decision making, and allocation of resources. However, because brain dysfunction and mental illness are often at the extreme ends of normal brain function, some therapeutic agents may be able to enhance normal function. For example, some treatments for Alzheimer's disease or other forms of dementia may be able to enhance normal cognitive function. The use of pharmaceuticals for artificial enhancement of performance, whether mental or physical, is highly controversial (e.g., the use of steroids or erythropoietin to enhance performance in sports). The potential development of cognitive and/or emotional enhancers to gain personal advantage not only changes the benefit versus risk analysis and alters discussions of the fair allocation of scarce resources but also raises issues of respect for both the self and others, fair competition, and informed decision making. Enhancement also raises questions regarding who is being enhanced, by whom, and for what purpose. Psychotherapeutic agents that modify brain chemistry to treat mental conditions

(e.g., anxiety, dementia, depression, and schizophrenia) are prescribed and are taken by individuals to modify brain function, mental activity, and behavior. Those who take these agents may report feeling 'more like themselves' or conversely 'not themselves.' This not only prompts the philosophically interesting question of how one defines and recognizes 'the self' but also raises ethical concerns regarding the extent to which peer and/or societal pressures may lead an individual to modify his or her mental processes, behavior, or other elements of the self in order to conform to the expectations of others or to internalized social norms.

When second-party practitioners (e.g., clinicians, lawyers, and educators) or third parties (e.g., corporations and government agencies) apply the results of neuroscience research to others, accuracy and reliability continue to be fundamental, but concerns about the purpose for applying the information or technology, and the way in which it is used, take on even greater significance. For example, the purpose may be to determine brain death, assess awareness, ascertain dangerousness, or evaluate the capacity to learn. An obvious clinical application is in assessing awareness in comatose patients or patients in a vegetative state. Currently, clinical evaluation depends on subjective interpretation of a patient's response to stimuli. Disturbingly, a number of studies have shown that a diminished response has commonly led clinicians to underestimate the degree of a severely disabled patient's awareness and to incorrectly diagnose a persistent vegetative state. Technological developments that make possible physically noninvasive access to brain activity seem to offer the possibility of an objective measure of awareness and potentially promise a clearer determination of brain death or more reliable prediction of recovery. At the same time, this raises questions about the relationship between brain activity and awareness and the extent to which brain activity can predict future loss or recovery of mental function, and therefore how the information will be used.

The possibility of monitoring the mental activity of others also holds the possibility of detecting deception or determining the intentions of others. This application challenges notions of individual integrity and privacy. In general, respect for the individual includes the right to privacy, and exceptions are allowed only when the health, safety, or welfare of that individual, or others, is threatened. A key consideration is whether the individual whose mental activity is being examined will benefit from the process. In addition, the extent of the invasion of privacy (and attendant harm to the principle of respect for persons and potential harm to that individual) is balanced against the seriousness and certainty of the harm or threat to be averted. A physician is likely to be willing to invade privacy to determine if a patient is suicidal. In the criminal justice system, the primary beneficiary may not be the individual examined. It is well established that eyewitness testimony is unreliable, and the potential for conflicting interests among experts as well as the concerns of a hostile or threatened witness can also call into question the reliability of courtroom testimony. Thus, if and when it is possible and in the putative interest of justice, authorities might seek to access directly the memories of a witness or an accused to determine what actually occurred. Similarly, they might seek access to the mental activity of a perpetrator in order to determine the individual's intentions.

The notion of monitoring the mental activity of others again raises questions regarding the actual and perceived correlation between brain activity and mental activity. This topic is dominated by presumption and uncertainty. Although the consensus of the neuroscience community is that, at least in humans, brain and mind are two sides of the same coin, there is considerable controversy and disagreement regarding the degree to which mental activity can be correlated with, identified as, and reduced to brain activity. The view that patterns of brain activity detectable with imaging technologies or by monitoring electrical changes can be identified with specific cognitive functions is not universally accepted. Yet the actual and perceived nature and reliability of this correlation is central to many of the ethical concerns associated with the application of scientific findings and technical developments in neuroscience.

Brain–computer interfaces Studies are currently exploring the possibilities of the brain–computer interface (BCI). Initially, BCIs have been designed to be therapeutic (e.g., to overcome physical limitations or visual deficits). Some are implanted (e.g., cochlear implants) and others respond to transcranial signals. Again, beyond the ethical concerns associated with any therapy, BCIs emphasize the importance of who is applying the technology and for what purpose. There are distinct and important differences between the BCI that makes the brain of a quadriplegic a 'transmitter' that can manipulate the external environment (e.g., move a cursor on a computer screen), a cochlear implant that makes the brain a 'receiver' for information about the outside world (and again thereby overcomes a physical limitation), and an implant that makes the brain a receiver in order to alter brain function in some other way (e.g., to treat obsessive–compulsive disorder).

Although manipulation and control of others are always ethically problematic because they violate the basic bioethical principle of respect for individuals

and their autonomy, two primary considerations are (1) the degree of invasiveness and (2) the extent to which the individual being controlled is aware of, and consents to, the control. Invasiveness need not be physical: education and subliminal suggestion can permeate one's thinking with long-term, widespread effect (e.g., educational programs that include evolutionary theory and/or creationism or that exclude acknowledgment of the Jewish holocaust and/or Chinese 'comfort women'). Moreover, the conscious intent of manipulation or control may well be in the eye of the beholder. Thus, education, although not physically invasive, is potentially manipulative; subliminal suggestion is not physically invasive but is designed to be manipulative; and psychoactive agents and BCIs may be more or less physically invasive and can be perceived as manipulative or not. Scientific and technological advances that reflect new or refined understanding of brain structure and function have the potential for making possible more specifically targeted monitoring and manipulation of individual or group perceptions and function, but the extent to which individuals are aware of and consent to the manipulation makes the ethical concerns akin to those raised by con artists, rabble rousers, propaganda, and deceptive advertising.

Neurobiology of Ethics

The third branch of neuroethics considers the neurobiological underpinnings of ethical thought and practice. This rich and complex area of study is contributing to an intellectual understanding of moral development, the cognitive and emotional elements of moral reasoning and decision making, and the mechanisms by which ethical decisions are expressed in behavior. How society understands notions of free will, moral agency, and responsibility will be influenced by the findings of neuroscience research, and of necessity, this understanding will reflect recognition of the limits of human capabilities.

For example, notions of responsibility require intentionality, and moral decision making consists of a number of elements, including (1) awareness of ethical problems, which consists of both perception and understanding; (2) analysis of a situation, which entails identification of ambiguities, development of alternative responses, and envisioning the implications of various courses of action; (3) evaluation of the advantages and disadvantages of the alternative responses; (4) deciding how to proceed; and (5) carrying out the action. A variety of factors affect these elements of decision making, such as education, intelligence, peer influence, and empathy. At the same time, a number of endogenous and exogenous biological factors are also known to influence one or more of the elements of decision making, ranging from reflexes, brain tumors, and hormones to neurotoxins and other psychoactive substances including those in food. In addition, current research is investigating a number of relevant topics, such as the biological basis of empathy, the impact of drugs of addiction on brain function such as emotional and motor control, and the behavioral effects of interactions between genetic makeup, environment, and experience.

Responsibility is often framed simplistically in terms of the presence or absence of free will (free will vs. determinism), despite both the fact that moral decision making is composed of a large number of stages, steps, and interacting elements (most of which cannot be readily dissected from each other) and the fact that a host of simple and complex biological and environmental factors influence these stages, steps, and elements through complicated, dynamic, and variable neurobiological mechanisms. Only some of these factors (e.g., education) are under the control of the individual. It is not clear how these findings can or should be used in judgments of moral and legal responsibility or culpability.

In addition, as with research in neuroscience in general, conscious and unconscious assumptions may introduce an inappropriate bias into research design, analysis, or reporting. For example, it is widely assumed that moral reasoning is a rational rather than emotional process. This assumes a potentially false dichotomy in brain processing. Thus, the ethical issues that are likely to be raised by future investigations of the neurobiological basis of ethics will be complex and dynamic like the nervous system.

Conclusion

During the past several decades, research in the neurosciences has expanded dramatically and the applications and implications of this research are becoming more apparent. Like other areas of science and technology, ethical values are both intentionally and unintentionally embedded in neuroscience. Neuroethics, like other areas of ethics in science and technology, is identifying and examining the practices and ethical, legal, and social impacts of the field. Unlike other areas of science and technology ethics, the dynamic, reflexive nature of the object of study of the neurosciences raises unique questions. Neuroscience research seeks to investigate, understand, and explain to scientists and nonscientists alike the nature of the structure and function of the nervous system and, by extension, higher brain function, cognition, and behavior. This inevitably introduces ethical issues that must

be recognized, acknowledged, and addressed as the field and the knowledge it creates continue to expand and evolve.

Neuroethological Perspective

K K Watson and M L Platt, Duke University, Durham, NC, USA

Introduction

The unifying goal of ethology, as well as of newer fields of behavioral ecology and sociobiology, is to provide an evolutionary explanation for behavior. This approach proposes that both natural and sexual selection favor those behaviors that maximize the reproductive success of individuals within the context of their physical and social environments. Ethologically, rewards can be considered proximate goals that, when acquired, tend to enhance survival and mating success. Similarly, avoiding punishment is a proximate goal that ultimately serves to augment the long-term likelihood of survival and reproduction. These definitions thus extend the traditional psychological and neurobiological notions of reward and punishment, which are typically defined by the quality of eliciting approach and avoidance, respectively. As detailed herein, the assumption of evolutionary adaptation within ethology, behavioral ecology, and sociobiology has promoted the development of mathematical models that formally define rewards and punishments within specific behavioral contexts. Such models suggest that full understanding of the neurobiology of reward and decision making will require consideration of naturally occurring behaviors in the specific ecological and social contexts in which they are normally expressed.

The Economics of Natural Behavior

In one of the first direct applications of economic modeling to animal foraging behavior, MacArthur and Pianka proposed in 1966 a model that defined criteria for the consumption or rejection of prey by a foraging animal. Using feeding efficiency as a proxy measure for evolutionary fitness, the benefits of consuming a particular prey type were modeled as the ratio of the energetic benefit afforded to the animal relative to the time costs of seeking and handling that prey type:

$$R = E/(T_h + T_s)$$

R is the net benefit gained by the predator for consuming a particular prey type, E is the amount of energy gained, T_h is the handling time, and T_s is the search time. The model is solved to maximize R, which determines the diet offering the greatest net energetic return and thus maximizing evolutionary success.

One prediction of this model is that the greater the abundance of higher quality foods, the less an animal's diet will consist of lower quality foods (the 'independence of inclusion from encounter' rule). In the 1970s, Goss-Custard found evidence in support of this prediction in his studies of redshank, small wading birds found in estuarine habitats in Great Britain. Redshanks feed on crustaceans and worms; crustaceans offer higher energetic returns relative to worms, which offer lower energetic returns. As predicted, the birds did not indiscriminately consume every worm or crustacean encountered; instead, they exclusively ate crustaceans when their density was high, but included worms in the diet when crustacean density declined. This result makes intuitive sense because the cost of eating worms includes 'missed opportunities' to search for and eat more nutritionally profitable crustaceans. When crustaceans are rare, however, it is more profitable to focus on small but abundant worms rather than wasting time searching for higher value foods.

The general prediction of the prey model – that inclusion of a particular food in the diet is independent of its encounter rate – has since been replicated in a variety of species, including birds, insects, fish, mammals, and even humans. However, as is often the case in economics, MacArthur and Pianka's simple model does not perfectly describe behavior in the real world. In Goss-Custard's study, as well as subsequent studies of different species using different methods, the animals did not display the steplike preference shift predicted by the prey model. Instead, foragers exhibited 'partial preferences' for different types of prey (e.g., preferring one type 75% of the time) when prey density changed. Such partial preferences might reflect the implementation of sampling behavior, which allows the animal to acquire improved information about the statistics of the local environment. Alternatively, partial preference could reflect sensory or memory-related cognitive limitations.

Early models, including MacArthur and Pianka's, described behavioral optimization in a generic sense, without regard to the specific physiological or cognitive constraints of a particular animal. Prediction of a precise outcome in an individual species, on the other hand, requires consideration of the specific set of physiological and environmental constraints relevant to that animal. For example, moose foraging for terrestrial and aquatic plants must satisfy both energetic needs and sodium requirements within the limitations

imposed by gut capacity. Terrestrial plants are richer in energy than aquatic plants are, and take up less room in the gut. However, aquatic plants contain more sodium than terrestrial plants do, and, because aquatic plants are buried under ice during the winter, moose must consume enough of them during the summer to satisfy their sodium requirements for the rest of the year. Belovsky developed a model of diet choice in moose, satisfying these constraints using linear programming. According to this model, if moose forage in a manner that maximizes energetic return while simultaneously satisfying sodium needs and rumen constraints, the model predicts a diet of 18% aquatic plants, in precise agreement with actual field observation data (Figure 1).

Early field studies using optimal foraging models, such as Goss-Custard's redshank study and Belovsky's moose study, demonstrated the strengths of the economic approach: formulation of models allows for clear and precise predictions that can be tested empirically, and provides a quantitative tool around which to organize explanations of behavior. Importantly for this discussion, such models make clear that defining rewards and punishments requires careful consideration of the behavioral and physiological capacities of a given species and the specific physical and social environments in which the species normally acts.

Neurobiology of Reward and Decision Making

Ultimately, the nervous systems of humans and other animals have evolved to promote behaviors that enhance fitness, such as acquiring food and shelter, attracting mates, avoiding predators, and prevailing over competitors. To achieve these goals, animal brains have become exquisitely specialized to attend to important features of the environment, extract their predictive value for success or failure, and then use this information to compute the evolutionarily optimal course of action. Traditionally, these brain mechanisms have been studied with regard to their roles in acquiring rewards and avoiding punishments.

As noted, rewards are traditionally defined as stimuli that elicit approach behavior, while punishments can be defined as stimuli that elicit avoidance. Recent studies have revealed elementary properties of the neural systems that process rewards and punishments as traditionally defined. Specifically, the circuit connecting midbrain dopamine neurons to the ventral striatum and prefrontal cortex appears to be crucial for processing information about rewards. For example, animals will work to receive current delivered via electrodes implanted in the dopaminergic ventral tegmental area (VTA) or medial forebrain bundle, which connects the VTA to the ventral striatum. In fact,

Figure 1 Optimal diet choice in moose (*Alces alces*). The daily ratio of aquatic plants to terrestrial plants consumed by moose must satisfy three constraints: the diet must meet energetic (blue line) and sodium requirements (red line), subject to digestive limitations (green line). Those ratios that meet these constraints are contained in the yellow shaded area. The vertex marked with an asterisk indicates the aquatic-to-terrestrial plant ratio that maximizes energetic intake while also satisfying all constraints. Adapted from Stephens PW and Krebs JR (1987) *Foraging Theory*, p. 120. Princeton, NJ: Princeton University Press. Photo courtesy of the National Park Service.

animals will preferentially work for such intracranial self-stimulation (ICSS), to the exclusion of acquiring food or mating opportunities, which are normally reinforcing.

Electrophysiological recordings from dopaminergic neurons show that these cells respond to primary rewards, such as food and water, as well as to conditioned stimuli that predict such rewards (Figure 2). Moreover, dopamine neuron responses scale with both reward magnitude and reward probability. Dopamine neurons do not, however, merely signal rewards and the stimuli that predict them. Current evidence suggests that phasic bursts by dopamine neurons may correspond to the reward prediction error term initially proposed in purely behavioral models of learning. According to this view, such phasic dopamine responses provide a mechanism for updating predicted valuation functions, which can be used both to learn about stimuli in the environment and to select profitable courses of action.

Figure 2 Reward-related responses by a single dopamine neuron recorded in a macaque monkey. (Top) When the animal is still learning the task, the fruit juice reward is unexpected, and the neuron responds at the time of reward delivery (R). (Center) After the monkey learns the relationship between a conditioned stimulus (such as a light or tone) and a reward, the neuron responds to the conditioned stimulus that predicts reward delivery (CS), but not to the reward itself. (Bottom) If the reward is omitted after the predictive stimulus, dopamine neuron activity is suppressed during the time of expected reward delivery. Each raster indicates the time of neuron spiking, and each row corresponds to a single trial for that neuron. The histograms summate the spikes over all the trials. Adapted from Schultz W, Dayan P, and Montague PR (1997) A neural substrate of prediction and reward. *Science* 275: 1593–1599.

These valuation functions can be thought of as the neural implementation of the optimization functions assumed to guide behavior in economic models of behavior developed in behavioral ecology and ethology.

Signals from the dopaminergic midbrain neurons influence processing within cortical decision-making areas, primarily in prefrontal and parietal cortex, that assign value to sensory stimuli and eventually transform that information into motor output. Platt and Glimcher probed the impact of expected value on sensorimotor processing in the lateral intraparietal area (LIP), a region of the brain previously linked to visual attention and motor preparation. In that study, monkeys were cued to shift gaze from a central light to one of two peripheral lights to receive a fruit juice reward. In separate blocks of trials, the authors varied the expected value of orienting to each light, either by varying reward size or by varying the probability of each cue onset. Platt and Glimcher found that LIP neurons signaled expected target value, the product of reward size, and saccade likelihood, prior to cue onset (Figure 3). In a second experiment, monkeys were permitted to choose freely between the two targets, and both neuronal activity in LIP and the probability of target choice were correlated with expected target value.

Sugrue, Corrado, and Newsome extended these observations by probing the dynamics of decision-related activity in LIP using a virtual foraging task. In this experiment, the rewards associated with each of two targets fluctuated over time. Under these conditions, monkeys tended to match the rate of choosing each target to its relative rate of reinforcement. Moreover, the responses of individual LIP neurons to a particular target corresponded to the relative rate of reward gained from choosing it on recent trials, with the greatest weight placed on the most recent trials. Together, these and other studies suggest that simple behavioral decisions may be computed by scaling neuronal responses associated with a particular stimulus or movement by its value, thus modifying the likelihood of reaching the threshold for eliciting a specific motor action.

Uncertainty and Decision Making

Early ethological models of behavior assumed that animals maintained complete knowledge of the environment and that reward contingencies were deterministic. In practice, however, uncertainty about environmental contingencies places strong constraints on behavior. The impact of uncertainty on choice has long been acknowledged in economics, which defines the spread of an outcome's known probability as risk. In the eighteenth century, Daniel Bernoulli proposed

Figure 3 Lateral intraparietal area neurons encode expected target value. (a) Neuronal firing is greater during trials when the expected reward is large (black line) than when the expected reward is small (gray line). Black and gray rasters indicate the time of individual spikes for large- and small-reward trials, respectively; each line of rasters corresponds to a single trial. Curves represent the summation of activity over all the trials. (b) Firing rate of a single lateral intraparietal area neuron increases linearly with reward size (left) and reward probability (right). Adapted from Platt ML and Glimcher PW (1999) Neural correlates of decision variables in parietal cortex. *Nature* 400(6741): 233–238.

that the expected values of monetary transactions, particularly risky financial ventures, differ from their corresponding subjective utilities (as determined by the economic agent). This idea, which would eventually revolutionize the field of economics, challenged the traditional notion that people value outcomes strictly according to their financial returns.

Initial economic models applied to animal behavior explicitly ignored variance in reward outcomes. For example, Charnov's marginal value theorem, devised to predict when a foraging animal should leave a particular food patch, was based purely on the average distribution of resources. Although this model described behavior in simple contexts fairly well, it failed to account for behavioral sensitivity to variability within patches even when the average value of each patch was identical.

In a seminal ethological study probing the impact of risk on decision making, Caraco observed the behavior of yellow-eyed juncos, a species of small bird. These birds were given the option of choosing a tray with a fixed number of millet seeds or a tray with a probabilistically varying number of seeds, with the same mean as the fixed option. Preferences depended on the ambient temperature. At 19 °C, juncos preferred the fixed option, but at 1 °C, they preferred the variable option. The proposed explanation for this switch from risk aversion to risk seeking is that, at the higher temperature, the rate of gain from the fixed option was sufficient to maintain the bird on a positive energy budget. At the lower temperature, however, energy expenditures were elevated, so the fixed option was no longer adequate to meet the animal's energy needs. When cold, the bird's best

chance for survival was to gamble on the risky option, since it might yield a higher rate of return, compared to the fixed option.

The relationship between energy budget and risk taking has been found to be generally true across a variety of animal species, including insects, fish, birds, and mammals. Moreover, this principle also describes human decisions in experiments using money as a reward. The convergence of behavioral results from animals and humans endorses the notion that studying risk-sensitive decision making in animals can illuminate the mechanisms underlying risk sensitivity in humans. These observations strongly suggest that sensitivity to risk is an evolutionarily ancient neural adaptation supporting adaptive decision making.

Neuroimaging studies in humans have revealed that preference for a risky option is associated with increases in neuronal activity in the ventral striatum and posterior parietal cortex. Moreover, choosing a risky option activates the dorsal striatum, precuneus, and premotor cortex. A recent electrophysiological study in monkeys probed how such risk-related activity might be translated into action. Monkeys were given a choice between juice rewards of fixed or variable sizes, with the same mean reward rate. Under these conditions, monkeys showed a strong preference for the risky option. Simultaneous recordings from single neurons in the posterior cingulate cortex, a region of the brain associated with spatial attention, visual orienting, and reward processing, revealed responses that were correlated with subjective preferences for the risky option. The foregoing discussion makes plain that the discrepancy between observable outcomes and subjective preferences in decision making under risk offers a powerful paradigm for investigating the neural mechanisms underlying adaptive decision making.

Social Rewards in Primates

In most neurobiological studies of decision making in nonhuman animals, food or water is delivered following performance of a particular action. Such direct and immediate reinforcers are typically referred to as primary rewards, and, as reviewed earlier, are associated with activation of midbrain dopamine neurons, as well as neurons in the ventral striatum and orbitofrontal cortex. In humans, a varied assortment of hedonically positive experiences can evoke activity in these regions, including eating chocolate, hearing pleasant music, or even reading a funny cartoon.

Although outcomes such as food consumption or the opportunity to mate clearly motivate behavior, abstract goals such as information gathering or social interaction can also motivate approach or orienting behavior in the absence of hedonic experience. For humans and other primates, in particular, many decisions are motivated by competitive and cooperative interactions with others in a social group. The adaptive significance of navigating a complex social environment explains why social stimuli and interactions, such as an attractive smiling face, a cooperative transaction, or the opportunity to punish a traitor, evoke activity in neural circuits that overlap with those activated by primary rewards. Physical features of the face, for example, provide information about genetic quality and thus can be useful in determining whether to pursue mating. In addition to attractiveness, people apparently also use information apparent in faces to assess the expected value of cooperation. Together, these observations implicate the operation of a neural system dedicated to linking social stimuli, such as faces, to the valuation functions guiding behavioral decision making.

Nonhuman primates also use social information to evaluate their behavioral options. For example, field studies of primate social behavior have revealed that monkeys preferentially invest in relationships with dominant individuals. Moreover, male primates often use visual cues to predict female mating receptivity. These observations suggest that primates maintain valuation functions for specific social and reproductive stimuli that guide behavior. Deaner, Khera, and Platt explored this hypothesis quantitatively in the laboratory using a pay-per-view task in which male rhesus macaques were given a choice between two targets. Orienting to one target yielded fruit juice but orienting to the other yielded fruit juice and the picture of a familiar monkey. By systematically changing the juice payoffs for each target and the pools of images revealed, the authors estimated the value of different types of social and reproductive stimuli in a liquid currency.

Their work revealed that male monkeys forego larger juice rewards to view female sexual signals or the faces of high-ranking males, but need overpayment to view the faces of low-ranking males (**Figure 4**). In contrast to the valuation functions governing target choice, the patterns of gaze associated with each class of image hint at the affective complexity associated with social stimuli. Specifically, monkeys looked at female sexual signals for longer times than they looked at either high-ranking or low-ranking male faces, perhaps reflecting differences in the hedonic qualities of these stimuli (**Figure 4**). Presumably, male monkeys value the opportunity to view the faces of high-ranking males not because they are hedonically pleasing, but rather because they are potentially threatening and thus highly relevant for guiding behavior. Thus, social stimuli and behaviors that are strongly motivating are not necessarily hedonically

Figure 4 Monkeys value social and reproductive information. (a) Example images shown to monkeys during a 'pay-per-view' task used to assess valuation of socially relevant visual images. (b) Mean normalized orienting values (left) and looking times (right) for various image classes. Orienting values are significantly higher for both the perinea (red bar) and high-status faces (blue bar), in contrast to either the low-status faces (green) or gray square (gray). Although the monkeys choose to orient more frequently to the high-status faces than the low-status faces, the lengths of time they gaze at either of these image classes are both shorter than the time they spend viewing the perinea. Adapted from Deaner RO, Khera AV, and Platt ML (2005) Monkeys pay per view: Adaptive valuation of social images by rhesus macaques. *Current Biology* 15: 543–548.

pleasing, and it is likely that they engage distinct neural circuitry – a hypothesis yet to be tested empirically.

Social Games

One of the results of the dialogue between biology and economics was the development of evolutionary game theory. As a conceptual framework, game theory can be used to describe the ways in which behavior is influenced by the behavior of other animals when they compete for limited resources, such as mates and food, in order to survive and reproduce. A classical game describes the interaction of two or more agents with conflicting interests, both trying to maximize some gain. Each game makes precise the number of agents involved, the actions available to those agents, and the payoff that will result from all possible interactions. In economics, the participants in the game identify the costs and benefits available to each player, and are generally expected to adopt a 'rational' behavioral strategy. Typically, these behavioral strategies comprise a probabilistic distribution of responses for all players, often called the Nash equilibrium, invulnerable to penetration by other behavioral strategies. In biological applications of game theory, the economic assumptions of self-interest and rationality are replaced by the evolutionary assumptions of Darwinian fitness and population stability.

Lee and colleagues explored frequency-dependent decision making in monkeys while recording from neurons in the dorsolateral prefrontal cortex (DLPFC). Monkeys played an analog of matching pennies against a computer opponent. In this game, the animal is rewarded for choosing the target not chosen

by the computer. By manipulating the algorithm governing the computer's choices, the experimenters were able to simulate social opponents implementing various strategies. When confronted with an opponent that tracked both the history of choices and the rewards received, monkeys' choice frequencies approached the optimal random solution. Neurons in the DLPFC were sensitive to the history of choices, rewards, and current movement plans. These signals could in theory be used to update the values of each alternative action, a computation necessary for the animal to choose optimally. Obviously, the ability to make such strategic changes in behavior would be highly favored in the natural social environment. However, the neural mechanisms underlying strategic interaction with other individuals, rather than a computer opponent, have just begun to be explored in humans using neuroimaging techniques, and have yet to be probed in animals.

Conclusion

Although still in the early stages, the union of ethology, economics, and neuroscience – the emerging field of neuroeconomics – offers a potentially powerful way to study the neural mechanisms underlying decision making and behavioral allocation. Just as in other animals, natural selection has shaped human behavior and its neural substrate. Thus, the behavior we display today may more strongly reflect the operation of a nervous system which evolved over eons to optimize hunting and gathering behavior in small groups, rather than being economically rational. These considerations predict that neuroethological studies will be crucial for understanding the neurobiology of reward and decision making in humans and other animals.

Neurofibromatosis Type 1

A Theos and B R Korf, University of Alabama at Birmingham, Birmingham, AL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The term phakomatoses is derived from the Greek root, *phakos*, meaning birthmark, and refers to a group of inherited disorders that affect the skin and nervous system. Neurofibromatosis 1 (NF1) is the most common phakomatoses, with an estimated prevalence of 1 in 3500 individuals worldwide. It is an autosomal dominant disorder with complete penetrance but highly variable expression, even among family members. NF1 is characterized by a propensity to develop benign tumors of the nerve sheath (neurofibromas) along with other benign and malignant tumors of a variety of neural and nonneural tissues. Other features of NF1 include hyperpigmented skin lesions, skeletal dysplasias, learning disabilities, structural cerebral abnormalities, and vascular anomalies. In 1990, the NF1 gene was cloned, and its protein product, neurofibromin, identified. The *NF1* gene functions as a tumor suppressor, which explains the susceptibility for individuals with NF1 to develop tumors; the pathogenesis of nontumor manifestations is not known.

NF1 Phenotype

Diagnostic Criteria

Clinical diagnostic criteria for NF1 were established at the National Institutes of Health (NIH) Consensus Development Conference on Neurofibromatoses in 1987 and the diagnosis of NF1 is still made on the basis of these criteria (Table 1). Radiographic studies and molecular genetic testing are not necessary to establish a diagnosis of NF1.

NF1 is a progressive disorder and the incidence of diagnostic clinical signs increases with age; therefore, a definitive diagnosis is not always possible in young children. The diagnosis of NF1 can be reliably established in only 70% of children by age 1, but increases to 97% by age 8 and 100% by age 20. Café-au-lait spots are the earliest feature and are present in 99% of infants with NF1. Skin-fold freckling is the next most common feature to appear and is present in 90% of children by age 7 and often confirms a suspected diagnosis of NF1 in a sporadically affected child. Iris hamartomas (Lisch nodules) are present in 70% of affected individuals by the age of 10 and are best viewed by slit lamp examination. Cutaneous neurofibromas do not start to appear until early adolescence and are present in almost all adults with NF1. In contrast, plexiform neurofibromas are often congenital, but may not be noticed until later in life and occur in 25–30% of affected individuals. The incidence of osseous lesions, particularly tibial dysplasia, and optic pathway gliomas is less common (2–3% and 15%, respectively), but if present are typically recognized in early childhood. Table 2 lists the likely age of onset of other clinical features and complications of NF1.

Tumors

NF1 is characterized by a propensity to develop benign and malignant tumors of a variety of neural and nonneural tissues. The hallmark tumor of NF1 is the neurofibroma, which arises from cells of the nerve sheath. Neurofibromas can arise anywhere along any nerve, from the dorsal root ganglion to the nerve ending. Cutaneous neurofibromas appear either as discrete soft pink or brown papules above the skin surface or as more subtle bluish lesions below the skin surface (Figure 1). The visibility and number of lesions accounts for much of their morbidity. Subcutaneous neurofibromas run along the course of the nerve and present as discrete, firm, often painful, nodules appreciable only by palpation. Plexiform neurofibromas involve multiple nerve fascicles, including multiple nerve branches, and can invade surrounding tissues. Involvement can be superficial or deep. Some plexiform neurofibromas can be seen on a surface examination, and manifest as ill-defined cord-like masses often with overlying hyperpigmentation, hypertrichosis, and/or increased vascular markings (Figure 2). Others that do not involve superficial tissues may not be apparent on clinical examination. Complications of plexiform neurofibromas include disfigurement, pain, signs, or symptoms related to compression of nerves or other vital structures, and malignant transformation.

Malignant peripheral nerve sheath tumors (MPNSTs) arise predominantly in preexisting plexiform neurofibromas; the lifetime risk in individuals with NF1 is 10%. Signs of malignancy are pain and sudden growth. The prognosis of MPNST is very poor and is due to the frequent delay in diagnosis, the infiltrative growth of these tumors, and a lack of response to traditional chemotherapy and radiation.

In addition to peripheral nerve sheath tumors, tumors of the central nervous system may occur in affected individuals. Optic pathway and brain stem gliomas are the most common intracranial

Table 1 NIH diagnostic criteria for NF1 (2 or more needed for definitive diagnosis)

Clinical criterion	Comments
Café-au-lait spots	≥6 larger than 5 mm before puberty or 15 mm after puberty; 10% of population has one café-au-lait spot
Skin fold freckling	Axilla, inguinal folds, neck, inframmary region; highly specific for NF1
Lisch nodules	≥2; best viewed on slit lamp examination; highly specific for NF1
Neurofibromas	≥2 dermal neurofibromas or one plexiform neurofibroma
Optic glioma	Bilateral lesions highly suggestive of NF1
Tibial or sphenoid wing dysplasia	With or without pseudoarthrosis
Affected 1st degree relative	Severity may vary widely among family members

Table 2 Clinical features and complications of NF1 and the typical age of onset

Age of onset (years)	*Clinical features and complications*
Congenital or infancy (0–2)	Café-au-lait spots, plexiform neurofibromas, macrocephaly, tibial or orbital dysplasia, pulmonic stenosis, aqueductal stenosis, hypotonia
Childhood (2–12)	Skin fold freckles, iris hamartomas, optic pathway gliomas, learning disabilities, ADHD,[a] scoliosis, precocious or delayed puberty, short stature, renal artery stenosis, JMML,[b] rhabdomyosarcoma, migraines, abdominal pain, vascular dysplasia
Adolescence and adulthood (>12)	Cutaneous neurofibromas, pheochromocytoma, MPNST,[c] hypertension, vascular dysplasia

[a]ADHD, attention-deficit/hyperactivity disorder.
[b]JMML, juvenile myelomonocytic leukemia.
[c]MPNST, malignant peripheral nerve sheath tumor.

Figure 1 Cutaneous neurofibromas: (a) discrete soft pink papules; (b) more subtle bluish lesions (indicated by arrows).

neoplasms. Optic pathway gliomas are low-grade pilocytic astrocytomas that occur in 15% of children with NF1. In NF1, these tumors are characterized by slow growth and a usually benign course. Signs and symptoms occur in approximately half of affected children and are a result of tumor growth with compression or invasion of contiguous structures. These symptomatic tumors present with visual abnormalities, most commonly decreased visual acuity, or hypothalamic dysfunction. Hypothalamic dysfunction most commonly presents as development of signs of puberty, including breast development and pubic hair, at an early age (5 years or less). Such precocious puberty is indicative of chiasmatic involvement. Brain stem gliomas behave much like optic gliomas and follow a relatively indolent course. Hydrocephalus and cranial neuropathies are complications of these tumors.

Other malignancies reported to occur at a higher frequency in the NF1 population include leukemia, particularly juvenile myelomonocytic leukemia (JMML), rhabdomyosarcoma, and pheochromocytoma. Malignancies are a major cause of premature death in patients with NF1.

Nontumor Manifestations

The NF1 phenotype also includes many nontumor manifestations. The most common of these are

Figure 2 Superficial plexiform neurofibroma with overlying hyperpigmentation and hypertrichosis.

hyperpigmented skin lesions, skeletal abnormalities, learning disabilities, structural cerebral abnormalities, and vascular anomalies. Café-au-lait spots and skin fold freckles are important diagnostic criteria but are of no medical significance.

Skeletal abnormalities range in severity and most commonly involve the sphenoid wing, vertebrae, and long bones. Potentially serious skeletal lesions include thinning of long bone cortices, particularly the tibia, which can lead to pathological fractures and pseudoarthrosis and dystrophic scoliosis, which can progress to paraplegia. Short stature is also common.

Learning disabilities are very common, occurring in more than one half of children with NF1. Learning disabilities are diverse and include a global decline in general intellectual functioning as evidenced by lower IQ scores compared to a control population, visuospatial and visuoperceptual deficits, difficulty with planning and abstract concept formation, lower expressive and receptive language skills, and deficits in attention (Table 3). One-third of children with NF1 meet the diagnostic criteria for attention-deficit/hyperactivity disorder (ADHD). Verbal and visual memory seem to be unaffected in NF1 children. The learning deficits are static and persist into adulthood, although compensatory mechanisms are developed and performance seems to improve.

Macrocephaly is frequent in children with NF1 and relates to a significantly larger brain size. The ratio of gray to white matter volume is different when compared to controls and accounts for the larger brain size. White matter volume is increased in the frontal lobe whereas gray matter volume is increased in the temporal, parietal, and occipital lobes. In addition, high signal intensities (unidentified bright objects or UBOs) have been noted on T2-weighted magnetic resonance imaging (MRI) scans in 60–70% of children with NF1. These abnormal signals are found most commonly in the basal ganglia, brain stem, and cerebellum. The pathogenesis of these signal abnormalities is unknown and they seem to disappear over time. There is conflicting evidence on whether or not the presence of UBOs correlates with cognitive deficits. These lesions do not cause focal defects and are not necessary to establish the diagnosis of NF1; therefore, routine imaging searching for these lesions is currently not recommended.

The vascular complications of NF1 are uncommon but are an important cause of premature death and consist of vasculopathy and hypertension. The vasculopathy causes arterial stenoses, due to proliferation of cells in the intima. Involvement of the renal arteries can lead to hypertension, which most often presents

Table 3 Types of cognitive deficits in NF1

Global cognitive deficits (6% are mentally retarded with an IQ[a] < 70)
Specific learning disabilities
Attention deficits and ADHD[b]
Executive deficits (planning and abstract concept formation)
Visuospatial deficits
Fine motor coordination deficits
Slowing of motor speed

[a]IQ, intelligence quotient.
[b]ADHD, attention-deficit/hyperactivity disorder.

in childhood or pregnancy. Cerebral artery stenosis can lead to strokes or to moya moya syndrome, where collateral vessels develop around the stenotic areas and appear as a 'puff of smoke' on cerebral angiogram. Arterial dissection and hemorrhage is another complication of the vascular involvement of NF1.

Genetics of NF1

Genetic Transmission

NF1 is a classical autosomal dominant single gene disorder with complete penetrance but variable expression. NF1 has a high rate of new mutations and one half of NF1 patients are a result of a *de novo* mutation of the *NF1* gene. Affected individuals have a 50% chance of passing this disorder to any of their offspring. Parents of a sporadically affected child have a low chance of having another affected child, barring the rare occurrence of germ line mosaicism.

Segmental NF1 and Mosaicism

Segmental NF1 refers to the confinement of typical features of NF1 to a localized region or segment of the body. Café-au-lait spots, skin fold freckling, and neurofibromas are the most common features, but iris hamartomas, plexiform neurofibromas, and skeletal abnormalities have been reported in segmental NF1. At least some cases of segmental NF1 are due to somatic mosaicism of the *NF1* gene. Mosaicism refers to the presence of two genetically distinct cell populations and results from mutations occurring during mitotic cell division in the embryo with subsequent clonal expansion of the affected somatic cells. If the mutation occurs early in embryonic development, germ cells can also be affected and that individual is at risk of passing generalized NF1 to any offspring. Individuals with generalized features of NF1 have also been shown to result from somatic mosaicism and this may explain the occurrence of a subset of patients with sporadic NF1. It is thought that these patients may display a milder phenotype. There is currently no easy way to identify if an individual with segmental NF1 or sporadic generalized NF1 has a somatic or germ line mosaicism for an *NF1* gene mutation.

NF1 Gene Mutations

The *NF1* gene is approximately 350 kb in size, maps to chromosome 17q11.2, and encodes a 2818-amino-acid protein product designated neurofibromin. The large size of the gene, the diverse types of mutations, and equal distribution of mutations along the gene has made mutation detection difficult and laborious. The highest detection rate of pathogenic mutations has been reported by Messiaen et al. Using a multistep mutation detection protocol, 95% of *NF1* gene mutations were detected in a cohort of patients with NF1. Pathogenic mutations in the *NF1* gene have been found in most of the 60 exons and comprise a wide diversity of mutation types. These include complete gene deletions, chromosome rearrangements that disrupt the gene, smaller deletions or insertions, stop mutations, amino acid substitutions, and splicing mutations. The latter are particularly prevalent given the large number of exons. The majority of *NF1* gene mutations result in premature termination of translation and a truncated protein product. Molecular genetic testing is available on a clinical basis for individuals who do not yet meet diagnostic criteria for NF1 and for prenatal testing in offspring. Identification of the *NF1* gene mutation does not alter management or predict severity or progression of NF1.

Genotype–Phenotype Correlations

Genotype–phenotype correlations have been difficult to establish due to the complexity of both the phenotype and the gene. Complete gene deletions, consisting of about 1.5 Mb, including the *NF1* gene and multiple contiguous genes, are associated with a severe presentation, including dysmorphic facial features, mental retardation, cardiac anomalies, a large neurofibroma burden, and a substantially higher lifetime risk of developing MPNST. Another distinct phenotype, familial spinal neurofibromatosis, characterized by café-au-lait spots, paucity of dermal neurofibromas, and numerous dumbbell-shaped neurofibromas along the spinal roots, may also be associated with a distinct mutational spectrum, with enrichment for amino acid substitutions or stop mutations near the 3′ end of the gene. It is possible that other genotype–phenotype correlations will emerge as a larger number of carefully phenotyped patients are studied.

Variable Expression

NF1 is known for its highly variable expression. Families with multiple affected individuals demonstrate a wide range in the presence and severity of phenotypic features and complications. A parent with a mild presentation can have a child with a severe presentation, and vice versa. Mechanisms of variable expressivity in NF1 include alleleic heterogeneity, modifying genes, somatic mosaicism, haploinsufficiency, environmental factors, and stochastic factors.

Alleleic heterogeneity plays at least some role, as noted above, though the full extent of phenotypic variability attributable to allelic heterogeneity is unknown. Modifying genes may play an important

role. Concordance studies with identical twins have shown correlation between some features (e.g., café-au-lait spots, neurofibromas) but not others (e.g., plexiform neurofibromas). Identification of genetic modifiers is an area of active study. Somatic mosaicism, as explained above, may account for some of the cases of sporadic NF1 and possibly milder phenotypic expression. Haploinsufficiency has been used to explain the occurrence of some nontumor features of NF1. To date, no environmental factors have been identified that alter the expression of NF1, although tumors often grow during times of hormonal change, such as puberty and pregnancy. Lastly, stochastic factors have been postulated as a mechanism to explain the often random progression of an individual's NF1 phenotype.

Pathophysiology of NF1

Function of Neurofibromin

Neurofibromin is expressed in a variety of cell types but is most abundant in cells of the peripheral and central nervous system. Neurofibromin shares sequence homology with members of the Ras GTPase-activating protein (GAP) family. This central GAP-related domain (GRD) is the only part of the protein whose function is known. Neurofibromin functions as a GAP protein and inactivates the intracellular signal transduction protein Ras by converting the active GTP-bound form into its inactive GDP-bound form. This in turn leads to the downregulation of Ras activity. Loss of neurofibromin activity increases Ras activity, which in turn promotes the transcription of a number of genes required for cell growth and proliferation.

NF1 Is a Tumor Suppressor Gene

Substantial evidence has accumulated that the *NF1* gene functions as a tumor suppressor and that this accounts for the propensity of tumor development in patients with NF1. Loss of heterozygosity (LOH) or mutation of both *NF1* alleles was initially demonstrated in some MPNSTs and subsequently in the Schwann cells of dermal neurofibromas. JMML cells in NF1 patients also have mutation of both *NF1* alleles. In addition, patients with JMML without NF1 may also have *NF1* mutations, activating mutations of Ras, or of the Ras activating gene PTPN11, suggesting that activation of the Ras pathway is critical to the development of JMML.

Mouse models have generated additional support for the tumor suppressor hypothesis. Mice rendered heterozygous for *Nf1*, the murine equivalent of the *NF1* gene, do not develop neurofibromas, although they eventually succumb to leukemias or sarcoma. Homozygously mutated mice die of cardiac anomalies *in utero*, but chimeras with homozygously mutated *Nf1* alleles survive and develop plexiform neurofibromas. More recently, conditional knockout mice have been created with one *Nf1* allele mutated in the germ line, and the other allele subject to mutation in developing Schwann cells. These animals develop neurofibromas, providing powerful support for the tumor suppressor hypothesis. There is also a mouse model for optic glioma, created by conditional knockout of the *Nf1* gene with an astrocyte-specific promoter.

The pathogenesis of nontumor manifestations of NF1 is not as well understood. Evidence suggests that the pigmentary disturbances and learning deficits do not result directly from a tumor suppressor mechanism. Melanocytes from café-au-lait spots have thus far been shown to be heterozygous for an *NF1* mutation. Similarly, mice that are heterozygous for an *Nf1* (Nf1 +/−) mutation have cognitive deficits, specifically visuospatial deficits. These learning deficits have been shown to be Ras dependent and reversible with the inhibition of Ras. It is not known whether homozygous *NF1* mutations occur within focal skeletal lesions.

Management of NF1

The mainstay of care in NF1 is anticipatory guidance, surveillance for treatable complications, and genetic counseling. Optimum management of NF1 involves a multidisciplinary approach.

Surveillance

Once the diagnosis of NF1 is confirmed by clinical criteria or is suspected, for instance in a young child with multiple café-au-lait spots without an affected parent, the patient should be evaluated on an annual (or more often, if indicated) basis, preferably by a physician familiar with NF1. The history should focus on symptoms associated with NF1, such as cognitive or psychomotor deficits, pain, visual complaints, change in bowel or bladder function, weakness, seizures, headaches, abdominal pain, and in children a thorough review of developmental history. The physical examination is directed at identifying potential medical complications of NF1, such as hypertension, scoliosis, ocular abnormalities, focal neurologic deficits, developmental disabilities, proptosis, short stature, macrocephaly, and signs of precocious puberty. Routine evaluations should include a yearly ophthalmologic evaluation in children under the age of 7, developmental assessment, and blood

pressure monitoring. Routine screening with computed tomography, magnetic resonance imaging, electroencephalogram, and visual evoked potentials is not advocated unless indicated by signs or symptoms detected on history or physical examination.

Treatment of Manifestations

Café-au-lait spots cause no medical problems but can be located in cosmetically sensitive areas. Lasers for pigmented lesions exist and have been used to lighten or remove café-au-lait spots with variable results.

Cutaneous neurofibromas can cause pruritus, pain, or cosmetic disfigurement. Surgical removal or other forms of destructive therapy (e.g., carbon dioxide laser) is the only available option for removing symptomatic lesions. Associated risks include scarring and the possibility of recurrence.

Plexiform neurofibromas can cause significant deformity as well as compression of nerves or other vital structures and erosion of bones. Surgical excision is the mainstay for symptomatic or progressive lesions, but due to the infiltrative nature of many of these tumors complete surgical excision is frequently not possible and recurrence is common. The use of ketotifen, a mast cell stabilizer, retinoic acid, interferon alpha, and thalidomide have been reported as potential treatments for progressive or symptomatic plexiform neurofibromas. No objective change in the volume of the tumors was reported, but a minority of patients treated with some of these agents experienced either symptomatic improvement or a slight decrease in the surface dimensions of the tumor. There are several ongoing clinical trials evaluating the use of other medical agents for the treatment of plexiform neurofibromas. Those under investigation include tipifarnib, a farnesyl protein transferase inhibitor, pirfenidone, an antifibrotic agent, pegylated interferon, and combination chemotherapy with methotrexate and vinblastine. Clinical trials for NF1 are listed on the Children's Tumor Foundation website.

Vigilance for malignant transformation into an MPNST is vital in patients with plexiform neurofibromas. The best clinical indicators of malignant transformation are persistent pain, sudden growth or swelling, and the onset of new neurological deficits. If present, an MRI with contrast should be obtained and the presence of inhomogeneous contrast enhancement is suggestive of malignancy. Fluorodeoxyglucose positron emission tomography (PET) has also shown promise in distinguishing benign from malignant lesions and deserves further study. A tissue biopsy is necessary for definitive diagnosis but false negatives can occur due to occurrence of MPNSTs in preexisting plexiform neurofibromas and sampling error.

MPNSTs have a poor prognosis with an estimated 5-year survival rate of less than 20%. Early diagnosis along with complete surgical excision portends the best prognosis. It is not clear that radiation or chemotherapy markedly improves outcome. There are ongoing clinical trials evaluating the use of other agents for MPNSTs.

Optic pathway gliomas occur in 15% of patients with NF1 and approximately half of affected individuals will develop signs or symptoms associated with their tumor, generally during the first decade. Asymptomatic children with known or suspected NF1 should have an annual ophthalmologic evaluation. If signs or symptoms of visual disturbance or neuroendocrine dysfunction are noted, an MRI is indicated. Symptomatic lesions should be followed more frequently with examination and imaging. Treatment is reserved for lesions that are symptomatic and progressive. Treatment options include surgical resection, radiation, and chemotherapy. Carboplatin in combination with vincristine has been reported for the treatment of progressive tumors, usually with a good outcome.

Learning disabilities are one of the most common features in children with NF1. Any child with NF1 suspected of having learning disabilities should be examined early and intervention begun promptly. Children with NF1 and ADHD have been shown to respond to stimulant medication with improved cognitive, academic, and social performance. Lovastatin, an HMG-CoA reductase inhibitor that also inhibits Ras, was shown to reverse the learning deficits in *Nf1*+/− mice and is currently being investigated in clinical trials in individuals with NF1 and learning disabilities.

Management of skeletal dysplasias has been symptomatic, with the tibial and orbital dysplasias proving to be the most problematic. Affected individuals should be referred to an experienced orthopedic surgeon. Prevention of fracture in children with long bone dysplasia is of paramount importance because the fractures tend to heal poorly and can result in pseudoarthrosis.

The importance of counseling the patient and family should not be underestimated. Education should include an explanation of the signs and symptoms of NF1, possible complications, the effects of puberty and pregnancy on certain features of NF1, and the importance of yearly evaluations to monitor for these complications. Individuals with NF1 should be provided genetic counseling regarding the 50% recurrence risk. Prenatal testing is available by linkage

analysis or direct mutational analysis if the mutation can be identified. It is not possible to predict severity in an individual based on family history or mutation identification.

Neurofibromatosis Type 1: Molecular and Cellular Biology

D H Viskochil and D A Stevenson, University of Utah, Salt Lake City, UT, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

As one of the most common heritable conditions, neurofibromatosis type 1 (NF1) displays a number of genetic principles that capture the molecular biology of human disease. Although a tremendous amount of knowledge has been gained since the gene was cloned, therapeutic options for the clinical presentations are limited. This article reviews the clinical aspects of NF1, details the molecular biology of the gene and its encoded product, neurofibromin, and concludes by examining the pathogenesis of this genetic condition.

NF1 is an autosomal dominant condition that afflicts approximately 1 in 3500 individuals worldwide. The physical deformities of Joseph Merrick, born in 1862 in England and documented in film and literature as *The Elephant Man*, due to affliction with a disfiguring disease causing tissue and vessel enlargements and grayish skin tone, were originally thought to be secondary to NF1. NF1 was thus termed in years past as the 'elephant man's disease.' This was an erroneous label, as further investigation showed that Joseph Merrick's physical deformities more closely resembled the features of Proteus syndrome, not NF1. Before the age of 20 years, individuals with NF1 typically develop cutaneous manifestations, neurofibromas, and café-au-lait spots. Approximately two-thirds of NF1 individuals will have only these cutaneous features. The remaining one-third will display a varied array of medical complications that affect multiple organ systems. Even though the condition was first described in the medical literature in the nineteenth century by Dr. von Recklinghausen, the biomedical characterization of the underlying defect was hindered by the variability of clinical expression and pleiotropy of NF1. NF1 captures many of the classical principles of human genetics, including expressivity, penetrance, pleiotropy, and sporadic occurrence.

A number of factors made this condition an early candidate for the 'reverse genetics' research approach, which applies molecular biological techniques to evaluate the potential function of a disease-causing protein by examination of its gene template. The prevalence of NF1, its straightforward clinical recognition, the availability of autosomal dominant pedigrees, and the minimal progress made through standard biochemical techniques all suggested feasibility of applying gene cloning by the mapping approach to the task of understanding the basic biology of the *NF1* gene product.

Clinical Aspects

Diagnostic Criteria

The diagnosis of NF1 is classically made on clinical grounds through a defined set of diagnostic criteria. Genomic and cDNA-based testing of the *NF1* gene is available clinically, but usually is not necessary for a clinical diagnosis in the majority of individuals. The typical clinical features generally enable practitioners to easily make the diagnosis in adults based on a simple physical examination. The diagnosis generally can be made in approximately 90% of NF1 individuals by the time they are 6–7 years old.

There are seven diagnostic features of NF1 that were developed in a consensus conference sponsored by the U.S. National Institutes of Health (NIH). In order to fulfill the diagnostic criteria for NF1, one must have two or more of the following features:

1. Six or more café-au-lait macules (1.5 cm or larger in postpubertal patients; 0.5 cm or larger in prepubertal patients).
2. Two or more neurofibromas or one or more plexiform neurofibromas.
3. Freckling in the axillary or groin region.
4. Optic pathway tumor.
5. Two or more Lisch nodules (benign hamartomas).
6. A distinctive osseous lesion (long bone dysplasia/pseudarthrosis or sphenoid wing dysplasia).
7. A first-degree relative with NF1.

Table 1 shows approximate percentages of NF1 individuals who have the typical features; the significant variation depends on the mode of ascertainment and the clinical setting of the evaluators. The Baylor study served a referral-based population, whereas the Southeast Wales study is a more population-based ascertainment. Other common manifestations of NF1, not included in the diagnostic criteria, include but are not limited to educational difficulty (40–60%), macrocephaly (38–45%), short stature (18–34%), scoliosis (10–30%), headache (22%), seizures (5–7%), neoplasms (5%), hemangiomas (5–10%), sensorineural hearing loss (5%), precocious puberty (4–5%), hypertension (4%), hydrocephalus (3–4%), and congenital heart disease (2–4%).

Table 1 Seven diagnostic criteria for neurofibromatosis type 1 and the prevalence of specific feature at the time of diagnosis according to two studies

Clinical feature	*Prevalence (%) in studies*	
	Baylor[a]	*SE Wales*[b]
Café-au-lait spots, >5 in number	99	85
>0.5 cm for prepubertal children	–	98
>1.5 cm for postpubertal adults	–	78
Neurofibromas: two of any type, or one plexiform	67	78
	–	35
Freckling in the axillary/inguinal regions	64	70
Optic nerve glioma	14	2
Two or more Lisch nodules (iris hamartomas)	84	85
Distinctive skeletal dysplasia	15	1
First-degree relative with NF1	47	30

[a]Study reported by Ricciardi (1992) involved 970 patients at a university-based clinic in a major city in the United States.
[b]Study reported by Huson and Hughes (1994) involved 135 patients ascertained through hospital admissions, relatives of probands, and general practitioners.

Café-au-lait spots Café-au-lait spots (pigmented macules resembling 'birthmarks') are the hallmark of this condition, and rightly so. Individuals without NF1 rarely have more than two birthmarks, whereas NF1 patients typically have more than five. These lesions are not pathological. Other disorders have café-au-lait spots as a feature, and since café-au-lait spots present as the first manifestation of NF1 without other clinical manifestations initially, other conditions need to be considered. A partial list of other syndromes that have café-au-lait spots or similar pigmentary findings includes Russell–Silver, Bloom, Noonan, Watson, LEOPARD, Sotos, Dubowitz, Klippel–Trenaunay–Weber, Proteus, and McCune–Albright syndromes.

Neurofibromas The presence of cutaneous neurofibromas is the other hallmark of NF1; these benign tumors generally comprise Schwann cells, extracellular matrix, fibroblasts, perineural cells, and mast cells. The neurofibromas typically appear after the development of the café-au-lait macules, beginning in late childhood and adolescence. Neurofibromas can remain under the skin or take on a pedunculated appearance, and they generally are not painful, though they are frequently noted to itch. Plexiform neurofibromas tend to be more aggressive, albeit nonmalignant, tumors that have a propensity to infiltrate surrounding tissue and cause pain. Plexiform neurofibromas can transform into malignant peripheral nerve sheath tumors. Particular attention to unexplained pain and rapid tumor growth will help identify patients with malignant peripheral nerve sheath tumors.

Intertriginous freckling Axillary and groin freckling (Crowe's sign) are common NF1-related findings not usually seen in the general population. Freckling patterns around the neck are also quite characteristic in the NF1 population.

Optic pathway tumors Optic nerve gliomas are low-grade tumors that arise anywhere along the optic nerve tract in the brain; approximately half of the tumors cause some symptoms, even though for unknown reasons they are much less aggressive than optic nerve gliomas are in individuals who do not have NF1. Optic pathway tumors often can be picked up by clinical exam by an experienced ophthalmologist (pale optic nerve) and then confirmed by magnetic resonance imaging (MRI) scan. These tumors affect approximately 15% of the NF1 population.

Lisch nodules Lisch nodules are harmless hamartomatous growths on the iris that are easily detected by ophthalmologic slit lamp exam; they serve as a reliable diagnostic marker for this condition.

Distinctive osseous lesion Helpful diagnostic signs also include the rare, NF1-specific skeletal dysplasias, which include sphenoid wing dysplasia and tibial pseudarthrosis. Other osseous findings include scoliosis, short stature (compared to familial background), bone cysts, and relative macrocephaly. Of NF1 individuals, approximately one-third have one or more orthopedic findings.

Long bone dysplasia is seen in approximately 5% of NF1 individuals and classically involves the tibia and fibula, although involvement of other long bones has been reported. The typical presentation is anterior lateral bowing leading to fracture and nonunion or pseudarthrosis. Tibial pseudarthrosis is strongly associated with NF1 – 50% of individuals with tibial pseudarthrosis have NF1. The bowing usually

presents before 4 years of age and fractures have been seen *in utero*. Approximately half of NF1 individuals with long bone bowing will experience a fracture before 2 years of age.

Both idiopathic and dystrophic forms of scoliosis are seen in individuals with NF1. The dystrophic form is usually a sharp, short-angle scoliosis. The nondystrophic form of scoliosis is more common in children with NF1, but dystrophic scoliosis is progressively debilitating and requires a more aggressive therapeutic approach.

Sphenoid wing dysplasia is a rare manifestation, usually unilateral and associated with a plexiform neurofibroma of the temporal-orbital region in about 50% of cases. Exophthalmosis is a rare complication that may require intervention, but the sphenoid wing dysplasia usually does not cause significant clinical complications or require therapeutic management.

Family history of NF1 Finally, the diagnostic criteria incorporate the well-documented dominant inheritance pattern in NF1: first-degree relatives with NF1 carry as much diagnostic weight as do multiple café-au-lait spots. The recognition that this condition is fully penetrant in older adolescents enables one to confidently provide reproductive risk counseling for families with members who have NF1.

Medical Complications

NF1 patients are prone to a number of medical complications that are quite varied, although one individual seldom is affected with more than one complication. They are also more likely to have a learning disability; approximately 40–50% of diagnosed patients have some form of learning disorder, which can be effectively managed if discovered early in a child's formative education. Short stature, macrocephaly, and hypertension are some of the more common complications. Seizures are also seen at a slightly increased frequency in NF1 individuals.

There is an association between NF1 and cancer, leading to a small but significantly increased relative risk to develop specific malignancies. Malignant peripheral nerve sheath tumors (MPNSTs), embryonal rhabdomyosarcomas, myelogenous leukemias, and pheochromocytomas are all found at a higher incidence in the NF1 population. Likewise, low-grade astrocytomas are relatively common in the NF1 population.

Although there is an increased incidence of intracranial tumors, controversy exists over the routine use of neuroimaging studies in NF1 individuals. Some groups perform an initial MRI upon diagnosis. Hyperintense T_2-weighted signals are commonly seen in NF1 individuals, but have unknown clinical consequences. Other groups advise against routine neuroimaging, as these and other incidental findings can cause anxiety when there is no clinical indication or subsequent approach to management, and therefore suggest relying on clinical symptoms to direct imaging protocol.

Genetic Principles and *NF1*

The clinical aspects of NF1 encompass many genetic principles, including Mendelian inheritance, variable expressivity, age-related penetrance, pleiotropy, mosaicism, and sporadic occurrence. Before we explore the molecular biology aspects that might explain the pathophysiology of NF1, it will be beneficial to review such principles in order to gain a better understanding of the clinical features of this condition.

Variable Expressivity

Variable expressivity of NF1 manifests in many ways, from the diagnostic criteria to the unpredictable multiple medical complications that arise. The presence of severe manifestations involving one organ system in one patient does not correlate with severity in other clinical aspects. For example, an NF1 patient who has more than 30 café-au-lait spots with a high degree of freckling may have few, small neurofibromas. Furthermore, as a medical complication, renal artery stenosis does not predict that an NF1 patient is more prone to other vasculopathies. It is difficult to explain the intrafamilial variability of this dominant disorder; affected siblings typically display remarkable differences in their clinical expression, as different as if they were not related. Historically, practitioners could not predict the natural progression of an individual's clinical course based on another family member's degree of involvement. However, larger sampling and more detailed clinical profiles of the NF1 population have revealed more similarity among first-degree relatives than had been appreciated, suggesting that other unlinked genetic loci play some role in the expression of NF1 features. The identification and characterization of such loci, coupled with knowledge of the *NF1* genotype, may lead to better prediction of the natural history of NF1 in any given individual.

Penetrance

Even though NF1 is 100% penetrant, there are a number of issues regarding the age-related penetrance of NF1 features, and perhaps the most important pertains to diagnosis. Typically, children present at an age less than 5 years with multiple café-au-lait spots as their

only feature, thus they do not fulfill the criteria for NF1. Axillary and groin freckling, and Lisch nodules, tend to arise by the age of 10 years, whereas neurofibromas are noticed sometime during adolescence. Thus there is a time period during which families must deal with the possibility of a diagnosis of NF1 while keeping in perspective the variability of clinical expression of NF1, which includes potential medical complications that are not part of the diagnostic criteria. For example, a child not fulfilling the diagnostic criteria may display learning disabilities prior to the onset of a second sign of NF1.

Some features of NF1, such as optic nerve glioma, sphenoid wing dysplasia, tibial pseudarthrosis, and plexiform neurofibroma, tend to be congenital and are thought to represent true malformations of embryological development. On the other hand, cutaneous neurofibromas that initially arise during adolescence will persist, and additional tumors tend to arise throughout the patient's lifetime in a progressive fashion. Additionally, women with NF1 may also experience an exacerbation of neurofibroma numbers and size during pregnancy. It is not understood how age and/or hormones alter the clinical expression of this condition, and one aspect of future research is to clearly delineate the natural history of NF1 in attempts to correlate it with the molecular biology discoveries.

Pleiotropy/Mosaicism/Mutation

Pleiotropy is a term used to describe the multiple organ systems affected by this condition: peripheral nervous system (neurofibromas), vasculature (renal arteries), brain (learning disabilities), endocrine (pheochromocytoma), skin (café-au-lait spots), and skeleton (dysplasias and scoliosis). Mosaicism also plays some role in NF1. There are a number of patients who have one or two NF1 manifestations occurring in regional parts of their body; this is termed 'segmental NF1.' Usually segmental cases of NF1 are restricted to cutaneous features, although solitary and deep plexiform neurofibromas have also been detected in individuals who do not fulfill the criteria of NF1. There has been one case of two affected offspring whose father had no clinical features of NF1, although approximately 10% of his sperm carried an identical disease-causing *NF1* mutation. The high mutation rate (1/10 000 gametes) involving the germ line, as determined by the number of *de novo* cases, suggests that multiple cells in normal individuals could conceivably carry nonmanifesting *NF1* mutations. Approximately half of patients who present to medical clinics have no family history of NF1, and, in sporadic individuals who have had testing to identify the chromosome that carries the disease-causing allele, it has been determined that in more than 90% of the cases the mutation arises in the paternal chromosome. The etiology of this observation has not been established: pedigree analysis does not support the hypothesis of parent-of-origin effects in NF1, selection against maternal oocytes with *NF1* mutations is not reflected in altered fertility or miscarriage rates, and paternal age effect is not apparent, as it is in the case of achondroplasia. As applicable to other aspects of NF1, the cloning and characterization of the *NF1* gene allow investigators to explore mechanisms that could explain the somewhat unusual genetic principles of NF1.

Molecular Biology of NF1

Gene Cloning

The *NF1* gene was identified by application of the paradigm of gene cloning by the mapping approach. As an autosomal dominant condition, genetic linkage analysis of combined pedigrees mapped *NF1* to the centromeric region of the long arm of chromosome 17, band 11.2. The identification of two NF1 patients who had balanced translocations provided researchers with the opportunity to pinpoint the *NF1* locus within this large region of chromosome 17 (see Figure 1). The *NF1* locus has turned out to be one of the most complex loci described. Screening various cDNA libraries with genomic DNA probes from the region encompassing the two *NF1* translocation breakpoints identified four genes: three small genes, *EVI2A*, *EVI2B*, and *OMGP*, mapping between the breakpoints, and *NF1*, a large gene that spans both breakpoints.

Gene Structure

NF1 spans approximately 335 kb of genomic DNA and is divided into 57 exons (see Figure 1). Three exons, 9A, 23A, and 48A, are alternatively spliced as insertion exons, but their respective expression pattern in various tissue has not been completely elucidated. Most cDNAs used in assembling the *NF1* coding sequence were isolated from fetal brain cDNA libraries; screening of other libraries yields few clones. A shorter *NF1* product with a poly(A) tail that terminates 14 bp downstream of a polyadenylation signal in intron 10C has also been identified from a placental cDNA library. Its role in the NF1 phenotype has not been examined, however.

NF1 contains two large introns greater than 40 kb, introns 1 and 27B. Intron 27B harbors the t(1;17) breakpoint, two short terminal repeats useful in linkage studies, and the three other genes that map

Figure 1 Physical map of the *NF1* gene. The genomic DNA is represented as a hatched bar. The cDNA is represented as a bar code, reflecting the sizes of each of the exons. The 5′-untranslated and first 30 codons are in the first exon, which maps just centromeric to a NotI site embedded in a CpG island. The stop codon is in exon 49 and is continuous with 3.5 kb of 3′-untranslated sequence that maps approximately 15 kb centromeric to a NotI site. The primary *NF1* transcript spans approximately 335 kb of genomic DNA. Translocation breakpoints map to introns 27B and 31.

between the translocation breakpoints. These genes are oriented in head-to-tail fashion, with the 3′ end of *OMGP* lying approximately 2.5 kb telomeric of the t (1;17) breakpoint and 20 kb centromeric of the 5′ end of *EVI2A*. Transcription of all three genes is in the orientation opposite to that of *NF1;* however, their influence on *NF1* expression has not been studied in detail. Intron–exon boundaries for *NF1* have been established, and assays are now available to amplify each exon independently, using genomic DNA as template.

The promoter region of *NF1* is embedded in a CpG island, and, similar to other 'housekeeping' genes, it does not harbor the typical regulatory TATA or CCAAT boxes. A number of DNA sequence motifs suggest binding sites for transcription factors, including SP1 and AP2, and, of note, there is a cyclic AMP response element. Functional studies with various *NF1* promoter sequences have not been reported, and therefore important motifs for *NF1* expression have yet to be elucidated.

The *NF1* mRNA encodes a peptide 2818 amino acids long, excluding the insertion exon-encoded segments of 10, 21, and 18 amino acids for exons 9A, 23A, and 48A, respectively. Exons 21–26 encode one domain lying between amino acids 1240 and 1430 that has approximately 30% homology to the catalytic domain of p120GAP, a protein that activates the intrinsic GTPase of p21Ras (see Figure 2). In addition to the shared catalytic domain, adjacent amino acid sequence extending in both directions from this core homologous region also has homology to two yeast proteins, IRA1 and IRA2, so named because they play an inhibitory role in the yeast RAS activation pathway. The 3′-untranslated region of *NF1* is 3500 bp (relatively long for a mammalian mRNA),

Figure 2 Schematic depicting regions of amino acid homology between yeast proteins IRA1 and IRA2, neurofibromin, and p120GAP. The p21Ras GTPase-activating catalytic domain is represented by stippling. IRA homology is depicted by hatching.

and the polyadenylation signal, lying 11 to 16 bases upstream of the poly(A) tail, is AGUAAA, instead of AUAAA, the typical sequence that most efficiently specifies polyadenylation.

Neurofibromin Function

The homology between a domain of the *NF1*-encoded peptide, neurofibromin, and the catalytic domain of p120GAP suggested that neurofibromin may also activate the GTPase of p21Ras. To prove this, the GAP-related domain of neurofibromin was expressed and shown to stimulate the GTPase activity of H-Ras, N-Ras, and yeast RAS1 and RAS2 *in vitro*. This observation clearly placed neurofibromin in the Ras signal transduction pathway, and it acts as a 'negative regulator' of p21Ras (see Figure 3). Even though p21Ras has been studied for many years, there is much still to be learned about the Ras signal transduction pathway, and, as more data accumulate,

Figure 3 Diagram depicting the potential roles of neurofibromin in the p21Ras signal transduction pathway. One potential role is the 'negative regulation' of p21Ras–GTP simply by stimulating the intrinsic GTPase of p21Ras. A second possibility is a 'positive effector' function, whereby interaction of neurofibromin with p21Ras could send a separate downstream signal independent of the Raf/MEK/MAPK pathway. Presently, a specific role for neurofibromin has not been elucidated. Sos1, Ras GTP exchange factor; MAP, mitogen-activated protein; MEK, MAP kinase.

the role of neurofibromin should be clarified. The GAP-related domain of neurofibromin comprises less than one-fifth of the entire peptide. Homology with the yeast IRA proteins suggests that the remainder of neurofibromin could play a significant role in modifying its interaction with p21Ras.

Gene Expression

NF1 expression has been evaluated at both the mRNA and protein levels. mRNA studies include both Northern analysis and reverse transcriptase (RT)-polymerase chain reaction (PCR), whereas protein studies include both immunohistochemistry and Western analysis using antibodies generated against various predicted peptide domains, and various *in vitro* p21Ras GTPase activation assays. When the most sensitive method of RT-PCR is used, *NF1* appears to be ubiquitously expressed in numerous adult tissues. However, the functional role that neurofibromin may play in different tissues is not so easy to demonstrate. Antibody studies do not demonstrate the same degree of expression. It is clear from Western analysis, however, that neurofibromin antibodies are not very sensitive, and the absence of staining may not reflect absence of neurofibromin activity in that tissue. Nevertheless, the highest levels of immunodetectable neurofibromin in adult rodents have been demonstrated in neurons and oligodendrocytes of the central nervous system, and in nonmyelinating Schwann cells in the peripheral nervous system.

In contrast to the limited immunodetection in adult tissue, neurofibromin is widely detected in numerous rodent embryonic tissues. *NF1* expression studies have not been performed in human embryos or fetuses, although the gene is presumed to be expressed in higher levels in developmental stages than in the adult, since the *NF1* cDNAs have been most readily isolated from fetal retina and fetal brain cDNA libraries. Functional assays for neurofibromin activity have shown that various tissues contain p21Ras GAP activity that is not due to p120GAP, which suggests the presence of neurofibromin-dependent p21Ras GTPase activation. However, these assays are dependent on the lipid inhibition of NF1–GAP activity in cell lysates, and the specificity of this assay for NF1–GAP has not been demonstrated as additional RasGAPs have been identified.

Pathophysiology of NF1

It is clear that mutations in the *NF*1 gene cause the phenotype that is clinically diagnosed as NF1. The mechanisms involved are not understood. Standard clinical management of NF1 presently involves

symptomatic treatment after medical complications have arisen, yet, until the basic biology relating to the pathogenesis of NF1 is unraveled, clinicians are powerless to rationally intervene in a proactive manner. Important considerations in delineating the processes leading to expression of the clinical features of NF1 include genotype–phenotype correlations, the role of neurofibromin in tumorigenesis, and the evaluation of animal models.

Genotype–Phenotype Relationships

The *NF1* mutational spectrum that enabled investigators to identify the *NF1* gene included multiple-exon deletions, interrupting translocation, a frame-shifting insertion, and both missense and nonsense base pair substitutions. Mutation screening has included analysis of both mRNA and DNA by various techniques, including single-strand conformational polymorphism, chemical cleavage of mismatches, size shift of PCR products, Southern analysis, and detection of two mRNA alleles as a check for mutations involving the transcriptional regulation. Once verified, *NF1* mutations can be deposited in a mutation database sponsored as a consortium by the Children's Tumor Foundation. One group screened 67 NF1 patients and found 10 recurrent mutations (approximately 3% of the germ line mutations). Mutations seem to be spread throughout the *NF1* gene, with few apparent 'hot spots' for mutation. Examples of exons with recurrent mutations previously reported include exons 4b, 7, 10a–10c, 13, 22, 23.2, 27a, 29, 31, 37, and 39.

Approximately two-thirds of NF1 patients have mutations resulting in truncated neurofibromin peptides. Notably, some mutations lead to stable mRNAs that can translate smaller peptides, including the GTPase-associated protein (GAP)-related domain (GRD). This implies that domains outside the *NF1* GRD are important either as modifiers of the interaction with p21Ras or as effectors. The observation that many *NF1* mutations are truncating has been extended to the application of screening techniques using transcriptional/translational systems that detect premature translational stops in PCR products from segments of *NF1* mRNA.

The evaluation of various *NF1* mutations with respect to the respective clinical expression of NF1 in each individual has not demonstrated a clear genotype–phenotype correlation. Different patterns of associations of some clinical features have been reported in NF1 families, but further investigation is needed. Whole-gene microdeletions in *NF1* have been associated with mental retardation, minor facial abnormalities, plexiform neurofibromas, and MPNSTs. The phenotype in patients with microdeletions that involve the entire *NF1* gene potentially have contributions from contiguous genes affecting this phenotype.

There appears to be some randomness to number and location of café-au-lait spots and neurofibromas, to the presence of multiple diagnostic features, and to the severity of medical complications. One possible explanation is simply the nature of stochastic processes, whereby the balance of signal transduction is altered as a result of variable levels of expression of both *NF1* and modifying genes involved in a complex biochemical pathway. Having a constitutional *NF1* mutant allele could conceivably lower the 'threshold' at which such seemingly random events could alter the normal signal. For example, one mechanism to explain the age-related penetrance of neurofibromas could be the random somatic mutation of either the normal *NF1* allele or other modifying loci resulting in 'loss of signal' within the cell, hence unregulated growth. This scenario fits the paradigm of a 'tumor suppressor' model, and there is some evidence supporting the role of *NF1* as a tumor suppressor in certain tissue.

The Role of *NF1* in Tumorigenesis

The association of cancer and NF1 was an important motivating factor in the cloning and characterization of the *NF1* gene. Since NF1 is a familial cancer predisposition syndrome, it was hoped that identifying the biochemical pathway involving the *NF1* gene product would provide researchers with insight into early genetic events in tumorigenesis.

The *NF1* mutations are generally inactivating. This would suggest that the cellular biochemical processes are operating with half of the normal amount of neurofibromin. If neurofibromin were acting as an enzyme, this would not be important, as evidenced by the many examples of recessive inheritance of disorders involving inborn errors of metabolism; however, the dominant inheritance pattern of *NF1* suggests that a critical level of neurofibromin is necessary to prevent the varied clinical expression of many features. The 'tumor suppressor' model would predict that any process that lowers the function of neurofibromin below the threshold of signal transduction would culminate in a resultant altered cellular phenotype (i.e., growth). One process to account for this is the loss of the normal allele, and there is accumulating evidence that many tumors associated with NF1 involve a deletion of the *NF1* locus as a 'second hit.'

The best evidence supporting the role of *NF1* as a tumor suppressor is the observation that the *NF1* allele inherited from the unaffected parent is deleted in the clonal expansion of myelogenous leukemia cells in NF1 patients whose other parent has NF1.

Presumably, the *NF1* allele inherited from the affected parent carries an inactivating mutation, and the subsequent somatic deletion of the normal allele in a bone marrow precursor cell allows unregulated cell replication. The identification of the 'second hit' in a MPNST from an NF1 patient, and the demonstration of loss of immunoprecipitable neurofibromin with concomitant altered p21Ras–GTP/p21Ras–GDP levels in an MPNST cell line derived from a different NF1 patient, also support the tumor suppressor function of neurofibromin. As compelling as these observations are, the accumulation of other somatic mutations, unrelated to *NF1,* may also play a role in the development of malignancies in NF1. The inactivation of the normal *NF1* allele may be necessary but not sufficient to initiate the process of tumorigenesis in NF1-related sarcomas.

The common tumors of NF1, neurofibromas and gliomas, do not conform to the model of tumor progression that is apparent with the malignant tumors. As benign growths, these tumors are very different from the relatively rare malignancies that fit the tumor suppressor role of *NF1*. Even though the benign tumors are unpredictable in timing and location of presentation, the gliomas and plexiform neurofibromas usually present in childhood, whereas cutaneous neurofibromas tend to arise during puberty and continue to present throughout adulthood. Unlike the case of benign colonic adenoma, whose paradigm comprises progression to adenocarcinoma in colon cancer via the accumulation of mutations in multiple genes, there is no definitive evidence demonstrating transformation of these benign NF1-associated tumors into malignancies. The multicellular composition of neurofibromas makes it difficult to identify specific genetic changes in these tumors, and the status of the 'normal' *NF1* allele in all cells within the tumors is difficult to ascertain. In some studies of human neurofibromas, a subpopulation of Schwann cells undergoes double inactivation of NF1, which then induces adjacent NF1 haploinsufficient cells of various lineages to participate in tumor progression. This paracrine action is also demonstrated in transgenic mouse models. Presently, there is no accepted therapy aimed at limiting either the numbers or continued growth of neurofibromas in afflicted individuals.

Animal Models for NF1

The amino acid homology between human, rodent, and chicken neurofibromin predicts that this protein plays a significant role in many species. However, there are no recognizable animal models depicting NF1 features that occur naturally in other species. Apparent neurofibromas are reported in multiple members of one bovine pedigree, and tumors that are similar to neurofibromas have been propagated in damsel fish via a presumed viral infection. In laboratory experiments, hamsters injected during pregnancy with *N*-nitroso-*N*-ethylurea have pups that develop sarcomas associated with large sensory nerves, and ecotropic viral insertions at the mouse *Nf1* locus result in myelogenous leukemias in one strain of mice. These models have yet to provide information applicable to human NF1. A more promising model for the evaluation of NF1, however, is found among transgenic mice.

Identification of the *NF1* gene enabled investigators to 'knock out' neurofibromin production in strains of mice, and both heterozygous and homozygous animals have been propagated. The homozygous mice die *in utero* no later than 14.5 days postconception, and death is tentatively attributed to cardiac dysfunction. Other features include overgrowth of the para- and prevertebral sympathetic ganglia, hypoplastic skeletal muscle, reduced number of renal glomeruli, and hepatocellular hypoplasia. The heterozygous mice do not display an NF1 phenotype; in age-related fashion, however, they have a higher incidence of malignancies, including lymphomas, adrenal tumors, myeloid leukemias, and one case of neurofibrosarcoma. Thus, heterozygous mice provide some insight into tumor progression, whereas homozygous mice yield information on the possible roles of neurofibromin in embryogenesis. Given the possibility that modifying genes likely play a role in the variability of clinical expression of human NF1, the genetic background of the transgenic mice may come to play a significant role in the establishment of the murine NF1 phenotype. Thus, crosses between different animal strains could provide important revelations in the future.

Conclusions

The ongoing research involving the basic biology of NF1 has become possible with the cloning and characterization of the gene. It is only by understanding the pathogenesis of NF1 that rational approaches to meaningful therapeutic intervention can be developed. The identification of proteins that interact with neurofibromin and/or modifying genes will further delineate the pathway involving neurofibromin. Little is known about the regulation of *NF1* gene expression in various cell types and the timing of its expression during embryogenesis. Knowledge of transcriptional factors important in *NF1* expression

could link the signaling pathways involving neurofibromin with other pathways, to provide a clearer understanding of cascade networks within a given cell type.

The identification of more *NF1* mutations in patients who have sound clinical information may reveal genotype–phenotype correlations previously overlooked for lack of disease phenotype. In conjunction with the identification of modifying loci, such information may enable practitioners to provide better counsel regarding the natural history for an individual with a specific genotype. Finally, knowledge of the pathogenesis of NF1 is prerequisite to the development of rational clinical management regimens for those afflicted with this disorder. It is hoped that areas of research touched upon here will provide the foundation for a more directed approach to the development of treatment protocols.

Neurofibromatosis Type 2

S R Plotkin, Massachusetts General Hospital, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Neurofibromatosis type 2 (NF2, MIM 101000) is an autosomal dominant neurogenetic disorder characterized by the presence of schwannomas, meningiomas, ependymomas, and ocular abnormalities. The first clinical description of NF2 dates to 1822 when the Scottish surgeon JH Wishart described a 21-year-old man with amblyopia and macrocephaly-who became deaf at age 19. At autopsy, multiple tumors arising from the skull base were identified. For many years, NF2 was confounded with the more common syndrome NF1 from which it derives its name. In the 1980s, these two disorders were finally differentiated when tumor studies and linkage analysis localized the genes to different chromosomes. The *NF2* gene was cloned in 1993 by two groups. As expected by Knudson's two-hit hypothesis, patients with NF2 have a germline mutation in the *NF2* gene and loss of the second allele in tumors. Subsequent studies on the NF2 protein have established its role in linking the cell membrane to the cytoskeleton, and progress on the nature of tumorigenesis continues. Transgenic mouse models of NF2 have advanced the understanding of NF2 and hold promise for accelerating the discovery of active drugs to treat NF2.

Epidemiology and Diagnostic Criteria

The current knowledge about the prevalence and incidence of NF2 comes from large population-based studies in the United Kingdom and Finland. In an early study, the birth incidence was estimated to be 1 in 40 000 with a prevalence of 0.86 per 100 000 persons. In a more recent study from the same group, the birth incidence was estimated to be 1 in 25 000 with a prevalence of 1.14 per 100 000 persons.

Clinical criteria for the diagnosis of NF2 were first formulated at the National Institutes of Health (NIH) Consensus Conference on NF1 and NF2 in 1987 and revised in 1991. Under NIH criteria, a diagnosis of NF2 is based on either (1) the presence of bilateral vestibular schwannomas or (2) a family history of NF2 and either a unilateral vestibular schwannoma or any two other tumors typically associated with NF2 (Table 1). Thus, only patients with bilateral vestibular schwannomas or a family history can qualify for a diagnosis under NIH criteria. Patients who lack these criteria but have multiple features associated with NF2 represent a diagnostic dilemma. For this reason, revised criteria were proposed by the Manchester group in 1992 and by the National Neurofibromatosis Foundation in 1997 (Table 1). The relative merits of these criteria continue to be debated by researchers.

Clinical Features

NF2 is characterized by the predisposition to develop multiple tumors, including schwannomas, meningiomas, and spinal cord gliomas. However, nontumor abnormalities such as cataracts and peripheral neuropathy are also common in NF2. The average age of onset of symptoms is between 17 and 21 years and typically precedes a formal diagnosis by 5–8 years. Signs of eighth nerve dysfunction (deafness, tinnitus, or imbalance) are the most common presenting symptoms in adults but occur in only a minority of pediatric patients. In younger patients, presenting signs include cranial nerve dysfunction, peripheral nerve dysfunction, myelopathy, seizures, skin tumors, café-au-lait macules, and juvenile cataracts (Table 2).

Tumor Manifestations of NF2

Schwannomas Vestibular schwannomas are the hallmark of NF2 and invariably develop in patients with the disorder (Figure 1). Schwannomas of nonvestibular cranial nerves and spinal nerves (Figure 2) are common. For example, in one series of 27 patients, 88% of 201 spinal tumors were consistent with schwannomas, with an average of 6.8 tumors per patient. In some NF2 patients, tiny nodular expansions of nerve fibers are present, most commonly in the cauda equina. For many years, it was debated whether these small nodules represented Schwann cell hyperplasia or an initial step in schwannoma formation. Loss of heterozygosity analysis and immunohistochemistry of these nodules confirmed the loss of both *NF2* alleles, suggesting they represented an early phase of tumorigenesis. Schwannomas in patients with NF2 are histologically benign. Rarely, malignant peripheral nerve sheath tumors occur in patients who have received radiation therapy.

Meningiomas About 50% of all patients with NF2 develop intracranial meningiomas (Figure 3) and 50% develop spinal meningiomas. In the previously mentioned series of 27 patients, 12% of 201 spinal tumors were consistent with meningiomas, with an average of 2.6 tumors per patient. Optic sheath meningiomas occur in 4–8% of patients with

Table 1 Clinical criteria for diagnosis of NF2

National Institutes of Health criteria
Bilateral vestibular schwannoma
or
First-degree family relative with NF2 and either unilateral VS or any one of the following: meningioma, schwannoma, glioma, neurofibroma, juvenile posterior subcapsular lens opacity

Manchester criteria
Bilateral vestibular schwannoma
or
First-degree family relative with NF2 and either unilateral VS or any two individual manifestations including meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lens opacity
or
Unilateral VS and any two individual manifestations including meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lens opacity
or
Multiple meningiomas ($\geq$2) and either unilateral VS or any two individual manifestations including schwannoma, glioma, neurofibroma, cataract

National Neurofibromatosis Foundation (Children's Tumor Foundation) criteria
Definite NF2
Bilateral vestibular schwannoma
or
First-degree family relative with NF2 and either unilateral VS at <30 years of age or any two of the following: meningioma, schwannoma, glioma, juvenile lens opacity
Presumptive or probable NF2
Unilateral VS <30 years of age and at least one of the following: meningioma, schwannoma, glioma, juvenile lens opacity
or
Multiple meningiomas and either unilateral VS <30 years of age or at least one of the following: schwannoma, glioma, juvenile lens opacity

Table 2 Prevalence of clinical findings in individuals with NF2

	All subjects	*Pediatric subjects*
Mean age at onset (years)	17–21	5.5–6.5
Cranial nerve schwannoma (%)	24–48	33–90
Intracranial meningiomas (%)	45–58	22–83
Spinal tumors (%)	26–90	75–78
Skin tumors (%)	64–68	56–92
>10 skin tumors (%)	10–15	
Optic sheath meningioma (%)	4–8	
Lens opacities (%)	38–81	36–75
Retinal hamartoma (%)	9	0–42
Astrocytoma (%)	2–16	0–24
Ependymoma (%)	3–6	11–25
Peripheral neuropathy (%)	2–6	0–42
Any CAL macules (%)	42–48	0–100
Lisch nodules (%)	3–4	0–22

NF2 and are a disproportionate cause of decreased visual acuity. Compression of the optic nerve can produce optic atrophy. Meningiomas associated with NF2 are almost universally benign histologically.

Spinal cord gliomas Spinal ependymomas and astrocytomas in patients with NF2 present as intramedullary spinal cord lesions and occur in up to 53% of patients. Two-thirds of patients with ependymomas have multiple tumors. The cervicomedullary junction or cervical spine is most commonly involved (63–82%), followed by the thoracic spine (36–44%). The brain and lumbar spine, common sites for sporadic tumors, are rarely involved. Radiographic evidence of tumor progression occurs in less than 10% of patients, and progressive neurologic dysfunction requiring surgical intervention occurs in 12–20% of patients.

Nontumor Manifestations of NF2

Ophthalmic abnormalities Lens opacities occur in 70–90% of patients with NF2. Only a minority of patients experience diminished visual acuity (20/40 or less) or increased sensitivity to glare. Surgical intervention for lens opacities is rarely necessary. Epiretinal membranes have been detected in 80% of patients undergoing comprehensive ophthalmologic testing and in 100% of eyes examined during autopsy. Pigment epithelial or retinal hamartomas are benign growths that are located in the peripapillary, macular, or peripheral retinal areas. These hamartomas are derivatives of glial, vascular, and/or melanocytic tissue within the retina and occur in up to 25% of patients with NF2. In a minority of patients, retinal or pigment epithelial hamartomas can cause decreased visual acuity, amblyopia, or strabismus in the affected eye. Epiretinal membranes and pigment epithelial/retinal hamartomas are associated with inactivation of chromosome 22 and loss of expression of merlin.

Neuromuscular abnormalities Peripheral neuropathy and monomelic atrophy have been reported in patients with NF2. Estimates of the prevalence of peripheral neuropathy vary from 1.3% to 47%, which likely reflects the technique and definitions used in the studies. Regardless, it is likely that this manifestation is underrecognized. MRI scans revealed no evidence of tumors that could explain the clinical or electrophyiological findings.

Focal amyotrophy has been documented in patients with NF2. Although the prevalence of this finding has not been firmly established, wasting of a single limb was noted in 4% of patients in a registry of NF2 patients in the United Kingdom. Detailed examination of four different patients by MRI and electrodiagnostic studies excluded compression of proximal nerves or roots by tumors as a cause. The etiology of focal amyotrophy in NF2 is not known but is thought to arise from neurofibromatous changes in peripheral nerves.

Figure 1 Contrast-enhanced MRI scans from a patient with NF2. The left vestibular schwannomas (arrows) noted in 2002 (a, axial T1 post-contrast image; b,coronal T1 post-contrast image) have enlarged in size by 2004 (c, axial T1 post-contrast image; d, coronal T1 post-contrast image).

Delineation of NF2 from NF1

Historically, patients with skin and spinal cord tumors were diagnosed with neurofibromatosis. The term 'central' neurofibromatosis was introduced to distinguish patients with tumors involving the eighth cranial nerves but not the skin from those with the more common 'peripheral' neurofibromatosis described by von Recklinhausen. Unfortunately, the distinction between central and peripheral neurofibromatosis was confounded by Harvey Cushing in 1917. Subsequently, NF2 was seen as a manifestation of von Recklinghausen's disease rather than as an independent entity. The disorders were conclusively separated in the 1980s when the genes were localized to different chromosomes.

In the clinic, patients with multiple nerve sheath tumors are recognized to have neurofibromatosis but the distinction between NF1 and NF2 is not always emphasized. A detailed history and physical examination (including the skin and eyes) can reliably distinguish between the two disorders in almost all patients. Occasionally, MRI scan of the brain (including the internal auditory canals) is required for diagnosis. Rarely, biopsy of a tumor is required. The main similarities and differences between NF1 and NF2 are shown in Table 3.

Molecular Genetics of NF2

Linkage Studies and Positional Cloning of *the NF2* Gene

The first clues to the location of the *NF2* gene came from tumor studies. Cytogenetic analysis of sporadic and NF2-related meningiomas revealed frequent deletions of chromosome 22. Subsequently, Seizinger et al. scanned sporadic and NF2-related vestibular schwannomas for chromosomal deletions using polymorphic DNA markers. They confirmed loss of heterozygosity for D22S1, suggesting that loss of genes on chromosome 22 was important for vestibular schwannoma formation. Subsequent linkage analysis of D22S1 in a large NF2 kindred established that the defect causing NF2 was located in the immediate vicinity of D22S1

on chromosome 22. Taken together, these tumor and linkage studies suggested that the *NF2* locus encoded for a tumor suppressor gene whose inactivation leads to tumor formation.

Figure 2 Sagittal T1 post-contrast MRI scan of the lumbar spine in a patient with NF2. Note innumerable tiny contrast-enhancing lesions (arrowheads) consistent with schwannoma tumorlets and larger contrast-enhancing lesions consistent with schwannomas (arrows).

The region of interest was narrowed to the interval between D22S212 and D22S32 using segregation studies in affected families and tumor deletion mapping. In 1993, two groups independently published the identity of the *NF2* gene. One group cloned the gene after delineating nonoverlapping germline deletions in two unrelated NF2 families. This group named the encoded protein 'merlin' (moezin, ezrin, radixin-like protein) to emphasize its relationship to various cytoskeletal proteins. The other group screened the region of interest for chromosome rearrangements by hybridization of single copy probes to DNA. This technique identified two probes that detected abnormal fragment sizes on two unrelated patients and the group named the protein 'schwannomin' to emphasize its role in suppression of schwannoma formation.

Table 3 Comparison of clinical features of NF1 and NF2[a]

	NF1	*NF2*
Mean age at diagnosis	**First decade**	**Third decade**
Vestibular schwannomas	**No**	**Yes**
Hearing loss	No	Yes
Nerve sheath tumors	Neurofibromas	Schwannomas
Glial tumors	Optic pathway gliomas	Spinal ependymomas
Meningiomas	No	Yes
Opthalmologic examination	**Lisch nodules**	**Cataracts, epiretinal membranes**
Skin tumors	**Many**	**Few**
Skin fold freckling	**Yes**	**No**
≥6 CAL macules	**Yes**	**No**

[a]Features that help distinguish between the two diseases are shown in bold.

Figure 3 Axial (a) and coronal (b) T1 post-contrast images from an cranial MRI of a patient with NF2. Note ventricular-enhancing lesions consistent with meningioma (arrow) and bilateral vertibular schwannomas (arrowheads).

NF2 Gene and Its Protein Product

The *NF2* gene is composed of 17 exons spanning 110 kb. The NF2 gene is highly conserved between species, including mouse, rat, pig, chicken, hamster, cow, turkey, and monkey. There are three alternative messenger RNA (mRNA) species (7, 4.4, and 2.6 kb) in humans due to variable length of the 3′ untranslated region. In mice, there is a single mRNA species of 4.5 kb. The predominant *NF2* gene product is a 595-amino-acid protein and is a member of the 4.1 family of cytoskeletal proteins that includes ezrin, radixin, and moesin (ERM proteins). The NF2 protein shares approximately 45–50% amino acid identity with these proteins and lacks an extended hydrophobic stretch associated with transmembrane proteins. Merlin is composed of an N-terminal four point one ezrin radixin moesin (FERM) domain that has 59–62% homology with moesin and radixin, an α-helix domain, and a C-terminal domain that has 40–42% homology for moesin and radixin. The moesin FERM domain is composed of three lobes that bind the C-terminal tail, thereby masking a large portion of the FERM domain surface. This intramolecular association plays a key role in regulation of ERM proteins. Although the C-terminal tail of merlin has important differences from the ERM proteins, the overall conservation of critical residues suggests that merlin is also regulated by FERM–tail domain interactions.

Tissue specificity Studies of mRNA using Northern blot and reverse-transcriptase polymerase chain reaction have revealed ubiquitous expression in human and mouse tissues. Similarly, immunoblotting has confirmed the widespread expression of merlin in all tissues. Attempts to localize mRNA and protein expression to specific cells within tissues using *in situ* hybridization and immunohistochemistry have produced conflicting results. mRNA expression is reliably seen within neurons of the brain and spinal cord and within epithelial cells of the developing lens. Protein expression is noted in neurons (particularly Purkinje cells of cerebellum and motor neurons of spinal cord), Schwann cells, and blood vessels. The inability to demonstrate mRNA and protein expression using *in situ* hybridization and immunohistochemistry in some tissues is likely due to the relatively low sensitivity of the techniques used in these studies.

Regulation and function of merlin Despite more than a decade of intense scientific investigation, the function of the merlin remains elusive. In part, this has been attributed to the technical difficulty in isolating and localizing the protein. Localization and functional studies suggest that merlin links membrane-associated proteins and the actin cytoskeleton, thereby acting as an interface with the extracellular environment. Merlin is regulated, in part, through phosphorylation of serine and threonine residues, which accounts for the two major isoforms seen by Western blotting. The best studied stimulus for merlin phosphorylation is activation of Rac1, which is mediated by p21-activated kinase and by protein kinase A. In addition, merlin has been shown to interact with many different proteins, such as magicin, N-WASP, and betaII-spectrin, but functional studies to confirm these findings have been lacking. Understanding the molecular basis of merlin's function remains one of the most pressing issues faced by the research community.

Merlin represents a novel class of tumor suppressor. Unlike p53 or retinoblastoma protein, merlin does not act directly on the cell cycle machinery but instead mediates and interprets signals from the extracellular milieu. The tumor suppressor function of merlin is manifested by its ability to maintain contact-dependent inhibition of proliferation. The mechanistic basis for contact inhibition is poorly understood and is the subject of intense investigation. Evidence suggests that merlin is involved in trafficking of growth factor receptors on the cell surface such as the epidermal growth factor receptor. This provides a plausible mechanism by which merlin could regulate cellular proliferation.

Model organisms Germline inactivation of both *NF2* alleles is embryonically lethal due to the absence of extraembryonic structures and failure of gastrulation. Germline inactivation of one *NF2* allele leads to a high incidence of malignant tumors such as osteosarcoma, lymphoma, lung adenocarcinoma, hepatocellular carcinoma, and fibrosarcoma, suggesting a broad role in tumorigenesis. Unfortunately, these transgenic mice do not develop tumors seen in human patients with NF2, which limits the use of these animals in clinically related studies. However, mice with targeted inactivation of *NF2* in Schwann cells do develop multiple Schwann cell tumors, and those with targeted inactivation in arachnoid cells develop tumors that resemble meningioma.

Tumor studies Merlin acts as a true tumor suppressor since loss of both copies of the gene results in tumor formation. In NF2, loss of the first copy occurs in the egg or sperm and usually involves a coding sequence mutation or deletion. Loss of the second copy occurs as a somatic event, often as loss of part or all of the *trans* chromosome. In sporadic tumors,

losses of both copies occur as somatic events. Molecularly, somatic events can be visualized as loss of heterozygosity of nearby polymorphic markers. Inactivation of the *NF2* gene can be detected in the vast majority of sporadic schwannoma, in 50–60% of sporadic meningiomas, and in a minority of sporadic ependymomas. *NF2* gene mutations have been found in unrelated tumors such as melanoma, malignant mesothelioma, thyroid carcinoma, and perineural cell tumors, suggesting a more general role for the protein in tumor suppression for certain cancers.

Mutational Analysis of the *NF2* Gene

All families with affected members in more than one generation show linkage to the *NF2* gene and there is no evidence for locus heterogeneity. Using exon scanning and single-strand conformation polymorphism, detection rates for germline mutation in patients with bilateral vestibular schwannomas vary between 40% and 66%. The presence of large deletions, mutations in promoter or intronic regions, and somatic mosaicism may explain the difficulty in identifying a causative mutation in all patients. Use of multiplex ligation-dependent probe amplification assays has improved the ability to detect deletions of one to a few exons. The vast majority of alternations are 'private' – unique to a family or individual. Nonsense and frameshift mutations are most common, followed by splice site and nontruncating mutations. CpG dinucleotides within CGA codons (in exons 2, 6, 8, and 11) represent mutation hot spots since C>T transitions result in a stop codon TGA through deamination of 5-methylcytosine. The majority of these mutations are predicted to truncate (nonsense or frameshift mutations) or shorten (splicing mutation) the gene product. Loss of function due to foreshortening of the C-terminus or instability of the protein product leads the tumor suppressor phenotype.

Mosaicism Mutations in the *NF2* gene have been detected in up to 70% of affected subjects. The detection rate for mutations is 20–30% lower for founders (i.e., patients without a family history of NF2). In part, the low rate of detection for mutations in sporadic cases is due to somatic mosaicism. Somatic mosaicism results from a mutation that occurs during postzygotic embryonic development. In these patients, only a subpopulation of cells carry the constitutional mutation and analysis of blood leukocytes is often unremarkable.

Indirect evidence suggests that mosaicism exerts a mitigating effect on the NF2 phenotype such that patients may experience a later time of onset and milder course of disease. Historically, a precise estimate of the rate of mosaicism in these patients has been difficult to establish. The most definitive numbers come from a study of 233 NF2 founders with bilateral vestibular schwannomas. In this study, the authors estimated the rate of mosaicism to be 16.7–24.8%. Recurrence risk to offspring of mosaic patients is significantly lower than the 50% expected rate for an autosomal dominant disorder and is probably on the order of 5–15%.

Genotype/phenotype correlations Genotype/phenotype correlations have been published by multiple groups. All studies are limited by the small number of patients with mutations identified. In a German study using number of tumors identified by MRI scan as a measure of disease severity, frameshift and nonsense mutations were associated with severe disease, whereas missense mutations were associated with mild disease. Splice site mutations were associated with both mild and severe phenotype, suggesting the possible importance of additional determinants such as stochastic, epigenetic, or environmental factors. In a US study, frameshift or nonsense mutations were associated with a younger age at onset and diagnosis and with a larger mean number of tumors than were splice site mutations. Interestingly, an association between nonsense mutations and retinal hamartomas and/or epiretinal membranes has been found. Finally, in a UK series, truncating mutations, compared with other mutations, were associated with an early age at onset and diagnosis, with symptomatic central nervous system tumors besides vestibular schwannomas, and with spinal tumors. Point mutations are rare in patients with NF2 and have been associated with mild, moderate, and severe disease. Genotype/phenotype correlations suggest that patients with mosaic disease and those with large deletions have a significantly reduced risk of developing cataracts compared to patients with classic NF2.

Detailed clinical studies of patients with NF2 suggest that phenotypic variability is smaller within families than between families. This is in contrast to patients with NF1, where there is significant variability within families. Mathematical modeling of intrafamilial correlation supports these clinical impressions. In a study of 390 patients from 153 families in the UK NF2 registry, age at onset of diagnosis, age at onset of hearing loss, and number of intracranial meningiomas were correlated within families. A significant intrafamiliar correlation was noted for age at onset (correlation coefficient, 0.35), age at onset of hearing loss (correlation coefficient, 0.51), and number of meningiomas (correlation coefficient, 0.29). This study supports the notion of familial homogeneity but also demonstrates the importance of other uncharacterized factors.

Future Directions

Our understanding of NF2 has significantly improved since the gene was cloned in 1993. The near future will witness an intense collaboration among basic scientists and clinicians. As scientists examine the role of merlin in contact-dependent inhibition of growth and generate animal models that recapitulate the human disease, clinicians will begin to mount clinical trials for NF2-related tumors. Advances in mutational analysis will lead to better family planning and more accurate presymptomatic diagnosis of family members. Finally, patients with NF2 will play an increasingly important role in expanding research support for NF2.

Introduction

The neurofibromatosis type 2 (NF2) tumor suppressor gene, *NF2*, was identified in 1993, and was variably named *Schwannomin* or *Merlin* by the two groups involved. The name *Schwannomin* was proposed because *NF2* is inactivated in schwannomas. *Merlin* was suggested as a name (and Merlin, for the protein) because of the homology of *NF2* to the ERM family of proteins (moesin, ezrin, and radixin). This dual nomenclature, both in the literature and at conferences, creates confusion and it would be preferable to use a single designation. Therefore, in an attempt to simplify matters, but also to recognize the valuable contributions of both research groups who first identified the gene, we suggest that the *NF2* gene/protein be called *Schmerlin*/Schmerlin.

Germ line mutation of one copy of *Schmerlin*, with somatic mutation of the remaining allele, results in the inherited syndrome, NF2. Patients frequently develop multiple tumors, with the severity determined by several factors, including the type of mutation in *Schmerlin* (see the section titled 'Genotype–phenotype correlation in NF2'). Early reports describing NF2 are difficult to find in the literature, as the condition was historically grouped together with neurofibromatosis type 1 (NF1; also termed von Recklinghausen's disease, or peripheral neurofibromatosis). However, it became clear during the late twentieth century that NF2 was a distinct clinical entity. The original descriptions of NF2 referred to the disease as central neurofibromatosis or bilateral acoustic neurofibromatosis, but over the past two decades the term 'NF2' has become almost universally accepted. Clinically, the hallmark of NF2 is the development of bilateral vestibular schwannoma (BVS) together with solitary or multiple meningiomas (and occasionally ependymomas). However, bilateral eighth-nerve tumors are not compulsory for a diagnosis of NF2. For example, a solitary vestibular schwannoma combined with a positive family history for NF2, or a solitary meningioma, is sufficient (see the section titled 'Epidemiology, clinical features, and diagnostic criteria').

Biallelic somatic mutations in *Schmerlin* predispose to the corresponding sporadic nervous system tumors commonly found in NF2, including schwannomas and meningiomas (and less commonly ependymomas). Somatic *Schmerlin* mutations are also found in malignant mesothelioma, but these tumors are not typically associated with NF2. *Schmerlin* is a tumor suppressor gene (TSG) and thus follows the 'two-hit' model of tumorigenesis. This model was first proposed by Knudson in his landmark paper on retinoblastoma in 1971. The 'first hit' is usually a protein-inactivating point mutation in a single somatic cell (point mutations comprise single nucleotide substitutions, leading to missense, nonsense, and splice-site alterations, and small insertions/deletions). A 'second hit' to knock out the remaining copy of the gene's locus is then required in order to give this cell a growth advantage, which eventually leads to tumorigenesis. This second hit is often monosomy 22 (loss of one entire copy of chromosome 22) or deletion of a large proportion of the chromosome. Monosomy 22 is usually the result of nondisjunction during mitosis in the cells containing the original point mutation. The term 'loss of heterozygosity' (LOH) describes the experimental findings in tumors that are missing one copy of a particular chromosomal region. Numerous groups have performed LOH studies in sporadic NF2-associated tumors (including meningiomas and schwannomas) and have shown a high frequency (usually 50–80%) of loss of one copy of chromosome 22. These high frequencies of LOH would suggest that inactivation of *Schmerlin* is a prerequisite for the development of these tumors.

The biological role of *Schmerlin* is not completely understood. Reports published soon after the identification of the gene demonstrated that it was located intracellularly at the plasma membrane and colocalized with elements of the actin cytoskeleton. It was believed that Schmerlin, like the other members of the ERM family, acts to stabilize the plasma membrane cytoskeleton junction. It is difficult to rationalize how this role alone results in inhibition of cell growth and proliferation. Subsequently, Schmerlin was found to interact with numerous intracellular components – for example, p21-activated kinase (Pak1) and phosphatidylinositol 3-kinase enhancer (PIKE) – many of which could conceivably be involved in tumor suppression. To date, a unifying tumor suppressor mechanism for the NF2 protein has not been conclusively demonstrated. However, several distinct lines of investigation are now under way and these are discussed in detail in the following section.

Epidemiology, Clinical Features, and Diagnostic Criteria

Mutations in *Schmerlin* occur frequently in human disease. It is helpful to divide clinical cases which

involve NF2 mutations into the two principal modes of presentation. Patients can either present with a sporadic NF2-associated tumor (schwannoma, meningioma, or ependymoma) which occurs as a result of biallelic somatic gene inactivation or, alternatively, patients have an inherited mutation and thus develop the full clinical syndrome of NF2. The prognosis for patients in the first group (a solitary meningioma or schwannoma) is usually very good, as often these tumors grow slowly and rarely display aggressive or malignant features. These patients do not have an inherited mutation and are thus very unlikely to develop further tumors. As already discussed, these sporadic tumors develop as the result of inactivation of both copies of *Schmerlin* in a single somatic cell, the first event usually being a point mutation and the second being loss of the remaining wild-type allele by deletion of the entire gene (complete or partial loss of chromosome 22, demonstrated by LOH studies). The prognosis for patients with NF2 is usually considerably worse than for patients with sporadic NF2-associated tumors. However, there are some rare exceptions to this rule and the prognosis for NF2 patients may be very variable. Some patients with NF2 have mild disease and only develop BVS at a late age and often lead relatively normal lives. The opposite end of the NF2 spectrum is severe disease in which multiple intracranial and intraspinal tumors cause symptoms at an early age, resulting in significant disability and death in the third or fourth decade. There are a number of factors which determine the clinical severity of NF2. These include the severity in other family members (see the section titled 'Genotype–phenotype correlation in NF2'), the location of tumors within the central nervous system (CNS; tumors in close proximity to sensitive structures will carry a poorer prognosis), the histological classification and growth rate of each tumor.

Constitutional (inherited) mutations of *Schmerlin* occur with a birth incidence of approximately one in every 25 000 to 40 000 individuals. In England, Wales, and the Republic of Ireland (with a combined population of more than 57 million people), there are approximately 700 000 births per year. Thus, between 18 and 28 people are born with NF2 in these countries each year. At first glance, it would therefore appear that *Schmerlin* mutations are not very common. However, sporadic mutations causing isolated solitary tumors are much more frequent. Sporadic meningiomas and schwannomas together constitute the second largest group of primary CNS neoplasms. The classical schwannoma described in NF2 is located on the vestibular branch of the eighth cranial nerve; such tumors are termed vestibular schwannomas (previously known as acoustic neuromas). Vestibular schwannomas occur in greater than 90% of NF2 patients, but NF2 patients account for only a small proportion (approximately 5%) of all vestibular schwannomas found in a given population. The incidence of sporadic unilateral vestibular schwannomas (UVSs) is approximately 1.4 per 100 000 individuals per year, and it is estimated that 1 in every 1000 people will be diagnosed with a vestibular schwannoma in their lifetime. Meningiomas (often multiple) are also found in patients with NF2 in frequencies greater than 50%. Again, their sporadic counterparts occur much more frequently in the general population. Sporadic meningiomas comprise 20–25% of all primary intracranial neoplasms in the United States, with an annual diagnostic incidence of 8 per 100 000. Moreover, asymptomatic meningiomas are believed to be 10 times more common, the majority of which are identified incidentally at autopsy.

The diagnostic criteria for NF2 are well established and have been previously documented. There have, however, been some slight modifications of these criteria in recent years. In most large series published to date, approximately 85–90% of patients develop BVS. A further 5% of NF2 cases develop a UVS. Thus, up to 95% of patients develop at least one vestibular schwannoma. Schwannomas at other sites (including other cranial nerves, within the spinal cord, and on peripheral nerves) are also very common, and are found in more than half of all patients in most studies. Approximately 60–70% of NF2 cases develop at least one meningioma (intracranial and spinal). More than half of all NF2 patients also develop posterior subcapsular lens opacities (PSLO). Ependymomas are seen in less than 5% of all NF2 patients. Less than 2% of NF2 patients have six or more café-au-lait macules, one of the diagnostic criteria for neurofibromatosis type 1 and sometimes a source of confusion between the two entities. The revised National Institutes of Health (NIH) diagnostic criteria for NF2 (published in 1991) are as follows: a patient has NF2 if there is evidence of BVS or if a patient has a first-degree relative with NF2 and evidence of a UVS or any one of meningioma, schwannoma, glioma, neurofibroma, or PSLO. The Manchester criteria involve further subdivisions, in an attempt to pick up more cases. A patient has NF2 if they have (1) BVS, (2) a first-degree relative with NF2 and UVS or any two of meningioma, schwannoma, glioma, neurofibroma, or PSLO, (3) UVS and any two of meningioma, schwannoma, glioma, neurofibroma, or PSLO, or (4) multiple meningiomas (two or more) and UVS or any two of schwannoma, glioma, neurofibroma, or PSLO. A recent report suggests that neither set of diagnostic criteria is sufficient and still further refined criteria are needed.

Identification of the NF2 Gene

The NF2 gene was originally localized to chromosome 22 employing cytogenetic studies in sporadic NF2-associated tumors (predominantly meningiomas). Confirmation of this localization came in 1987 from genetic linkage studies in NF2 families. A number of studies further refined the localization to 22q12.2, and concluded that NF2 appeared to be a genetically homogeneous disease. *Schmerlin* was cloned simultaneously by two groups in 1993 and found to be mutated in NF2 patients and in the majority of sporadic meningiomas and schwannomas. It comprises 17 exons and codes for a protein of 595 amino acids. The protein is closely related to the ERM proteins ezrin, radixin, and moesin. There are no hotspots for mutation in *Schmerlin* in NF2 patients, in sporadic meningiomas, or in schwannomas. Furthermore, all possible types of mutations (missense, nonsense, frameshift, splice-site, and various deletions/insertions) are found. Interestingly, mutations have not been found in exon 16 or 17, suggesting that these regions are not necessary for *Schmerlin* to perform as a tumor suppressor.

There is now overwhelming evidence that *Schmerlin* behaves as a TSG. Furthermore, it is becoming clear that it is the principal TSG for sporadic meningiomas and schwannomas. This is analogous to the retinoblastoma TSG for retinoblastoma and many other cancer predisposition genes. This is not to say that *Schmerlin* is the only gene required for meningioma and schwannoma development. Mutations in other, as yet, unknown genes are necessary before these tumors develop. One such candidate is the tumor protein p53 suppressor gene (*TP53*), which has recently been shown to act synergistically with the *Schmerlin* gene (in conditional NF2 mutant mice) in the development of malignant tumors of neural crest origin. Furthermore, mutation/loss of *Schmerlin* is probably an early event in tumor development, with aberrations of genes on other chromosomes resulting in a more aggressive phenotype. One such candidate gene is *DAL-1/4.1B* (approved symbol, *EPB41L3*), which is located on chromosome 18. A recent study of sporadic meningiomas has shown LOH at the *DAL-1/4.1B* locus in approximately one-fifth of the tumors studied (practically all of which also had LOH at the *Schmerlin* locus on chromosome 22). These findings would support a secondary progressive role of *DAL-1/4.1B* in meningioma tumorigenesis.

Evidence to support a TSG role for *Schmerlin* comes from various quarters. First, inactivating mutations in *Schmerlin* are found in the majority of NF2 patients and in the sporadic tumors associated with NF2 (including meningiomas, schwannomas, and ependymomas). Second, mice with targeted inactivation of *Schmerlin* specifically in Schwann cells develop schwannomas (the commonest tumors found in NF2) and Schwann cell hyperplasia. Third, mice heterozygous for an NF2 mutation develop numerous malignant tumors, including osteosarcomas at high frequency, and fibrosarcoma and hepatocellular carcinoma at a lower frequency. There is also a growing body of evidence from cell biology experiments that *Schmerlin* functions normally as a negative regulator of cell growth and proliferation (see the section titled 'Biological role of the NF2 protein'). Loss of function experiments, in a number of different biological systems, appear to confirm these results.

Genotype–Phenotype Correlation in NF2

Initial descriptions of NF2 showed that the severity of disease was relatively preserved within individual families. Affected members from the same family generally tended to develop symptoms of the disease around the same age, and had a similar rate of progression with equivalent disability and similar numbers of tumors. Therefore, it became clear clinically at a very early stage that a strong genotype–phenotype correlation existed for NF2. This was in stark contrast to neurofibromatosis type 1, in which there is often marked variation with regard to severity of disease within a given family. It is only since the identification of *Schmerlin* that it has been possible to provide the molecular evidence for a clear correlation. NF2 has been historically divided into severe (Wishart) and mild (Gardner) disease. However, it is now apparent that a more refined system is needed. A milder NF2 phenotype (with a later age of onset and fewer tumors) is associated with missense mutations, certain splice-site mutations, and certain large deletions. In addition, mosaics for any particular type of mutation tend to display a milder phenotype. One could further hypothesize that mosaics harboring missense and splice-site mutations should have an even milder phenotype, although this would require a very large series of patients to confirm. Severe disease is usually caused by protein-truncating alterations (such as frameshifts and nonsense mutations). A number of studies have shown that individuals with splice-site mutations in exons 1–5 of *Schmerlin* had more severe disease than did those with splice-site mutations in exons 11–15. Phenotype–genotype correlations have now been documented for overall disease severity, for vestibular schwannomas, for cataracts, and for noneighth cranial nerve tumors (including intracranial meningiomas, spinal tumors, and peripheral nerve tumors). However, there are exceptions to this rule and even in monozygotic twins the clinical course may not be identical.

Mosaicism and Schwannomatosis

Mosaicism for NF2 mutations is a relatively common occurrence. These patients often appear to have a relatively mild phenotype or may just present with multiple schwannomas or meningiomas, either diffusely or in a specific anatomical distribution (single limb, defined segment of the spinal cord, etc.). The common understanding of mosaicism is that there is a mutation in a proportion of cells or tissue types in a particular individual. The mutation is not present in either gamete from the individual's parents, but it occurred during early development of the embryo. The number and location of tumors are dependant on precisely when the mutation occurred. Patients may have very mild disease, whereby a small proportion of Schwann cells or meningeal cells are harboring a single copy of mutated *Schmerlin*. Alternatively, patients may present with clinically typical NF2, but fail to show a constitutional *Schmerlin* mutation in circulating peripheral white blood cells, and also do not have a family history of the disease.

Schwannomatosis is the term used to describe the disease in patients who develop multiple schwannomas in the absence of BVS, the hallmark of NF2. There is an ongoing debate as to whether schwannomatosis is a form of NF2 mosaicism or whether it is a distinct genetic entity. There have been studies to suggest that secondary loci on chromosome 22 are involved, and that both *Schmerlin* and this secondary gene are necessary for the development of this separate disease. The data to support this argument are, however, not convincing, and we would suggest that schwannomatosis is an unusual presentation of mosaicism for NF2.

Biological Role of the NF2 Protein

The exact role of Schmerlin in tumorigenesis is not clear. However, there are some very interesting clues as to the possible mechanisms whereby loss of NF2 function may promote uncontrolled growth and proliferation. Various cytoskeletal and signaling proteins which interact with and bind to the NF2 protein have been identified and are being closely characterized. The principal candidates are described in the following discussion.

The Pak1 protein has been shown to be inhibited by Schmerlin and this has been suggested as a mechanism for tumor suppression. Pak1 belongs to a subgroup of serine/threonine kinases (the group 1 Paks) that are known to be downstream effectors of Rac/cdc42. Pak1 function is required for activation of stress-activated protein kinases by cdc42 and Rac1, as well as for transformation by activated forms of these GTPases. Furthermore, activated forms of Pak1 induce rapid formation of membrane ruffles and focal complexes. Pak1 is essential for both Ras transformation and neurofibromatosis type 1. The proposed mechanism by which Pak1 may be involved in tumorigenesis is as follows: Schmerlin normally functions to inhibit Pak1 and therefore downregulates Rac/cdc42. This in turn would result in inhibition of Ras-induced malignant transformation. Cell culture experiments have demonstrated that mutated Schmerlin, which lacks the Pak1-inhibiting domain, fails to suppress Ras transformation. Thus, Paks are probably bifunctional proteins, affecting both gene transcription (through a kinase cascade) and actin dynamics (via an unknown mechanism). Recently, it has been demonstrated that the NF2 protein is normally involved in arresting cell growth at the G1 phase, with decreased expression of cyclin D1, inhibition of cyclin-dependent kinase 4 (CDK4) activity, and dephosphorylation of the retinoblastoma protein, pRB.

A second candidate pathway for Schmerlin-mediated tumor suppression is via the related FERM (four-point-one, ezrin, radixin, moesin) domain protein, named 'Expanded.' In *Drosophila*, Schmerlin and Expanded are components of the Hippo signaling pathway (a system which is believed to play a role in tumor suppression). In this system, both Schmerlin and Expanded are necessary for proliferation arrest and apoptosis in developing imaginal discs. Thus, this new signaling pathway appears to restrict cell proliferation in differentiating epithelia. The Schmerlin/Expanded proteins control the activation of the Hippo/Salvador kinase complex, which in turn activates the Warts/Mats kinase complex. Warts/Mats kinase phosphorylates and inhibits Yorkie, a transcriptional activator that positively regulates cell growth and proliferation. A further associated possible mechanism of Schmerlin/Expanded tumor suppression, again in *Drosophila*, involves regulating the abundance, localization, and turnover of certain cell surface receptors. One report suggests that misregulation of these processes may be a key component in tumorigenesis. Further studies will be necessary to prove these hypotheses.

There have been a number of reports describing an interaction between Schmerlin and PIKE. PIKE is a brain-specific GTPase that binds to phosphatidylinositol 3-kinase (PI3K) and stimulates its lipid kinase activity. PIKE exists as three isoforms: PIKE-S (short form), PIKE-L (long form), and PIKE-A. PIKE-S and PIKE-L result from differential splicing whereas PIKE-A results from the use of a second transcription initiation site. Schmerlin binds to PIKE-L and abolishes its stimulatory effect on PI3K. PI3K is a lipid kinase that generates phosphatidylinositol 3,4,5-trisphosphate (PI(3,4,5)P3), a second messenger that is

essential for the translocation of Akt to the plasma membrane, where it is phosphorylated and activated. The PI3K/Akt pathway is fundamentally involved in several key cellular functions and plays a central role in cell proliferation. There are numerous examples of alterations in the PI3K/Akt pathway in a variety of human cancers. The implications of Schmerlin interaction with this pathway for tumor suppressor function are thus quite significant.

The interaction of the NF2 protein with hepatocyte growth factor-regulated tyrosine kinase substrate (HRS) is also intriguing. The NF2 protein binds (via its C-terminal end) to HRS. It has been suggested that this interaction may facilitate its ability to function as a tumor suppressor. Experiments in schwannoma cell lines have shown that both the NF2 protein and HRS inhibit activation of signal transducers and activators of transcription (STATs). Moreover, rat schwannoma cell lines experiments have demonstrated that HRS can reduce the amount of total and active epidermal growth factor receptor (EGFR). Therefore, a potential direct consequence of Schmerlin inactivation may be the downregulation of EGFR.

Numerous other cellular proteins/systems have been shown to interact/influence Schmerlin. These include CD44, BII-spectrin, SCHIP-1, HE110, NHE-RF, eukaryotic initiation factor 3 (eIF3c), and BI-integrin. Moreover, Schmerlin co-localizes and interacts with adherens junction components in cell culture experiments. Knocking out Schmerlin in this environment results in an inability to undergo contact-dependent growth arrest, and to form stable cadherin-containing adhesion junctions. Again, this may be an important mechanism whereby tumor suppressor function is inactivated.

The study of animal models often provides valuable clues as to the function of specific proteins in humans. A variety of mouse models have been developed in an attempt to further elucidate the molecular biology of Schmerlin. Heterozygous NF2 mutant mice develop various neoplasms which show inactivation of the wild-type copy of *Schmerlin* (in keeping with its function as a TSG). However, these mice do not develop the characteristic tumors seen in human NF2. Furthermore, homozygous NF2 mutant mice (homozygous *Schmerlin* knockouts) are embryonic lethal and are therefore unhelpful as a model for human disease. In an attempt to overcome the deficiencies of the heterozygous and homozygous NF2 mutant mice, conditional mutant mice were generated which have restricted homozygous *Schmerlin* mutations in predominantly Schwann cell populations. These 'conditional' (Schwann cell) NF2 knockout mice show many similarities with human NF2 disease – for example, Schwann cell hyperplasia, Schwann cell tumors, cataracts, and cerebral calcification. They do not, however, develop vestibular schwannomas or meningiomas, two of the hallmark features of NF2. The conditional knockout mice have already provided important details regarding certain domains within *Schmerlin* (exon 2) and insight into how its protein product may function in cell migration and differentiation. Conditional NF2 knockout mice do aid in the understanding of the molecular mechanisms involved. However, one needs to be cautious about extrapolating the findings in rodents to human disease.

Conclusions

The neurofibromatoses are a complex group of genetic diseases which have been the principal research subject of numerous independent groups for more than three decades. This has resulted in the accumulation of a vast array of information during this period. A novel phase in molecular biology is now beginning which will characterize how genetic alterations in *Schmerlin* result in the disruption of the regulation of different proteins and signaling pathways, culminating in tumor formation. The biological interactions that have recently been elucidated may prove even more exciting than the findings of the last century. Judging by the pace of publications during the past 6 years, it may not be long before therapeutic strategies for NF2 and its tumors become a reality.

Neurofilaments in Neuronal Function

Introduction to Neurofilaments

A neuron is composed of the neuronal cell body (perikaryon) and several processes (dendrites and axon), of which the axon is usually the longest one. The axon is comparable to an electrical wire that the neuronal cell body extends to other neurons or muscles to transmit its signal. Assembled neurofilaments are an essential part of the cytoarchitecture of mature axons and are particularly important in establishing the diameter of the largest axons, where they are the most abundant structural component. The first description of this fibrous axonal network dates back to the late nineteenth century, when newly developed silver staining methods allowed anatomists to visualize so-called neurofibrils within axons. Neurofilaments form a very dense network of discontinuous, cablelike filaments (oriented along the axon) which are interconnected by small extensions. This reversibly cross-linked meshwork of structural elements provides mechanical stability to the axon (Figure 1).

Structure of the Neurofilament Proteins

The subunits of neurofilaments belong to one of five classes of proteins and assemble into long protein polymers named intermediate filaments. There are more than 50 different kinds of these proteins in humans. Intermediate filaments are involved in cell architecture of most eukaryotic cells. The name 'intermediate' derives from the diameter of the assembled filaments (8–10 nm), which distinguishes them from the two other major structural polymers of the cytoskeleton, the actin microfilaments (6 nm) and the microtubules (24 nm). In a large myelinated axon, the neurofilaments make up the bulk of the intra-axonal volume, with long polymers interlinked to each other and to the thicker and structurally more rigid microtubules, which are outnumbered (by 10- to 30-fold) by neurofilaments. The actin microfilaments form a spiderweb-like structure underneath the axonal membrane. Both neurofilaments and microtubules are aligned in the same orientation along the axon, and all three cytoskeletal structures (actin microfilaments, neurofilaments, and microtubules) are interconnected by a separate family of proteins, the plakins, to produce a reversibly cross-linked filament meshwork that proves a flexible, deformable array that provides mechanical strength.

Neurofilaments are obligate heteropolymers requiring their smallest subunit, neurofilament light (NF-L; 60 kDa), and the two large subunits, neurofilament medium (NF-M; 90 kDa) and neurofilament heavy (NF-H; 115 kDa). Like all other intermediate filament subunits, the molecular structure of each of the three neurofilament subunits contains a central helical rod domain of approximately 310 amino acids and a subtype-specific globular domain at the head. The rod domain is highly hydrophobic and can form stable coiled-coil dimers with two protein subunits wrapped around each other within the rod domain, forming an initial assembly unit around 50 nm in length. The actual neurofilament is built up by assembling the coiled-coil dimers and then aligning both longitudinally and laterally in a staggered fashion, ultimately to form a ropelike structure 10 nm in diameter and of indeterminate length. NF-M and NF-H are unique among the intermediate filament subunits in that each contains an extended tail domain (about 400 and 600 amino acids long, respectively) which protrudes from the axis of the assembled filament. The NF-M and NF-H tail domains protrude up to 80 nm from the assembled filaments and interact with neighboring neurofilaments and microtubules (Figure 1). The stoichiometry of the neurofilament subunit composition varies but is approximately 5:3:1 for NF-L:NF-M:NF-H.

Peripherin and α-internexin represent two additional components of neuronal intermediate filaments present in a subset of neurons. They share the structural features of intermediate filament subunits, and both can co-assemble with neurofilaments. In the mature nervous system, peripherin is expressed predominantly in small-caliber sensory neurons of the peripheral nervous system and also to some extent in motor neurons of the central nervous system (CNS). α-Internexin is a component of certain types of CNS neurons, mainly the cerebellar granule cells.

Function of Neurofilaments

In the human nervous system, the largest neurons and the ones with the longest axons are the lumbar spinal cord motor neurons, which mainly innervate the leg muscles. There are thousands of these motor neurons, each with a cell body around 50 μm in diameter and each extending a single axon to its target muscle. These are the most asymmetric cells in nature, with axons in humans up to a meter in length (the full length of the leg), but even the largest have a maximal

Figure 1 Neurofilaments are the major component of the cytoskeleton of large myelinated axons. (a) Schematic representation of the structural features of a human spinal cord motor neuron innervating muscle with the myelinating Schwann cells along the axon. The neurofilament network is represented by black lines, with the cross-linking neurofilament tail domains in red. The enlargement shows that the tail domains of the neurofilaments are heavily phosphorylated (black circles) in the internodes (large axonal caliber), whereas at the Node of Ranvier they are not (small axonal caliber). (b) Neurofilaments in the axon. Quick-freeze deep-etch view of the axonal cytoskeleton from a large myelinated axon, showing the neurofilament network. Arrowheads point to cross-bridges between the 10-nm-diameter neurofilaments, and arrows point to the single microtubule in the field. M, mitochondria. Scale bar = 100 nm. Reproduced from Hirokawa N (1982) Cross-linker system between neurofilaments, microtubules, and membranous organelles in frog axons revealed by the quick-freeze, deep-etching method. *Journal of Cell Biology* 94(1): 129–142, by copyright permission of The Rockefeller University Press.

axonal diameter (14 μm in humans) that is only 1/70 000th of their length. A real-life example of these cell dimensions is a soccer ball (with a diameter of 22 cm) as the cell body and a tube 6 cm in diameter extending over the length of 44 soccer fields, each 100 m long, as its axon. A large motor axon is more than 2000 times the volume of its cell body.

Neurofilaments are central determinants in generating normal axonal diameters. Mature axonal caliber is of importance for normal neuronal function because the speed of transmission of the electrical signal along the axon (the nerve conduction velocity) is directly proportional to the diameter (the bigger the diameter, the faster the speed). Complete loss of neurofilaments caused by loss of the major neurofilament subunit NF-L (either by gene deletion or by mutation that precludes synthesis of NF-L) blocks growth in axonal diameter that normally is contemporaneous with myelination. In mice, loss of neurofilaments is asymptomatic, but in larger animals (as seen in the quiver quail), absence of neurofilaments and reduced conduction velocity are accompanied by constant quivering and behavioral abnormalities.

The extensive, multiphosphorylated tail domains of NF-M and NF-H subunits (in human with 43 or 44 sites on NF-H and at least seven sites on NF-M) have, for a long time, been proposed to mediate neurofilament-dependent growth of axonal diameter that takes place within myelinated axonal segments. Although it has been proposed that space-filling properties of neurofilaments are achieved by electrostatic repulsion between these highly charged domains on adjacent neurofilaments, this is not the case. Deletion of the entire NF-H tail domain has little effect on radial growth, with organization of the remaining neurofilament array largely unaffected. Removal of the NF-M tail, on the other hand, dramatically limits acquisition of correct axonal diameter, producing a

50% reduction of caliber (fourfold reduction in overall axonal volume) and concomitant lower nerve conduction velocities. Replacement by transplantation of normal Schwann cells with mutant ones that are unable to produce myelin blocks this growth in diameter, but only within the unmyelinated segment, precluding neurofilament tail phosphorylation in the transplanted axonal region, whereas in the neighboring nerve regions with normal myelination, caliber and phosphorylation state remain normal. Thus, growth in diameter is limited to myelinated portions of the axon, evidence supporting the current model that correct diameter is achieved through an 'outside-in' signal generated by the enwrapping myelinating Schwann cells (Figure 1).

The Involvement of Neurofilaments in Neurodegenerative Diseases

Abnormal assembly and/or accumulations of neurofilaments are thought to be involved in the pathology of several human neurodegenerative diseases, including amyotrophic lateral sclerosis (ALS), infantile spinal muscular atrophy, and hereditary sensory-motor neuropathy. This is especially so in ALS (known familiarly in the United States as Lou Gehrig's disease), the most prominent human adult motor neuron disease. ALS is typically fatal, with onset between 50 and 60 years of age and complete paralysis within 1–5 years after onset, mainly resulting from premature death of upper (brain) and lower (spinal cord) motor neurons, especially the subset with the largest axons and the highest neurofilament contents. Aberrant neurofilament accumulations both in the neuronal cell bodies and in axons are a major pathological hallmark in both sporadic and familial ALS cases (Figure 2).

Figure 2 Accumulations of neurofilaments in motor neurons in the spinal cord of a patient with amyotrophic lateral sclerosis. Most of the perinuclear area is occupied by abnormal aggregates of 10 nm neurofilaments. Scale bar = 40 μm. Reproduced with permission from Hirano A (1988) *Color Atlas of Pathology of the Nervous System*, 2nd edn. Tokyo: Igaku-Shoin Medical Press, with permission from Igaku-Shoin Ltd.

Disorganized Neurofilament Arrays as a Cause for Motor Neuron Disease

Altered neurofilament organization can be a primary cause of motor neuron disease. Expression of a mutant NF-L subunit whose incorporation into neurofilaments disrupts their continued assembly provokes an aggressive, fatal, early onset motor neuron disease producing paralysis caused by massive neurodegeneration and death of motor neurons. Even increased synthesis of normal NF-L or NF-H subunits has been shown to produce abnormal accumulations of neurofilaments in motor neuron cell bodies and proximal axons, accompanied by motor neuron dysfunction and atrophy of the target muscles, very similar to the pathological signs of ALS.

Mutations in Neurofilament Genes Linked to Human Motor Neuron Diseases

Genetic evidence in humans has suggested mutations in neurofilament genes as contributors or direct causes for human motor neuron diseases. The most compelling evidence comes from missense mutations in the *NF-L* gene that are strongly associated with human Charcot-Marie-Tooth Disease Type 2E (CMT2E). CMT2E is a milder motor neuron disease than ALS, with an earlier onset and a slower progression and typified by muscle weakness and (depending on the severity) partial paralysis. With respect to ALS, several mutations have been found in the tail domain of the *NF-H* gene in a small group of sporadic ALS patients but not in control individuals. A large-scale sequencing of DNAs from ALS and control individuals has demonstrated that neurofilament mutations are not a significant primary cause of ALS, albeit they may be risk factors for ALS. These findings suggest, but fall short of proving, linkage of neurofilament sequence variants as contributors to human disease.

Peripherin is another intermediate filament subunit of mature motor neurons, and an abnormal version of it has also been suggested to be involved in ALS. Peripherin is normally encoded by two differentially spliced mRNAs transcribed from the same gene and encoding proteins with slightly different molecular weights (58 and 56 kDa). An aberrantly spliced form that generates a 61 kDa protein and that is both assembly incompetent and toxic *in vitro* in neuronal cells has been detected in motor neurons of a few human ALS patients and in ALS mouse models, suggesting a linkage of aberrantly spliced peripherin and human motor neuron disease.

Axonal Neurofilaments as Determinants of Neurodegeneration in ALS

Most incidences of ALS are sporadic, that is, they are without evidence for a genetic origin. Approximately 10% of ALS is inherited in an autosomal dominant manner, and a proportion of those are caused by missense mutations in the gene encoding the ubiquitously expressed Cu/Zn-superoxide dismutase 1 (SOD1). Mice that accumulate such mutations develop a fatal-progressive motor neuron disease comparable to ALS in humans, accompanied by massive motor neuron death and paralysis. As in ALS in humans, it is specifically the largest motor neurons with the biggest axons and highest neurofilament content that are most affected.

Neurofilament accumulations in spinal motor neurons are prominent hallmarks of all ALS disease forms, including mutant SOD1-induced ALS, both in humans and in transgenic mouse models. Elimination of assembled neurofilaments from axons (by deleting NF-L) or trapping most neurofilaments in motor neuron cell bodies (by overexpressing NF-H) both greatly slow ALS-like disease. Although the disease-modifying effect of altering neurofilament content could be achieved through increased accumulation of neurofilaments in the neuronal cell bodies or their removal from axons, removal of the NF-M and NF-H tail domains (by gene replacement in mice) provides a comparable benefit without altering axonal neurofilament content. This outcome eliminates the possibility that the phosphorylation site-rich tail domains of NF-M and NF-H can serve as phosphorylation sinks for buffering a detrimental mutant SOD1-induced hyperactivation of kinases, including cyclin-dependent kinase 5. Thus, neurofilaments are a modifier of ALS caused by mutant SOD1, probably through their influence on slowing transport of other cargoes transported along the axon.

Conclusion

Neurofilaments are essential for establishing a flexible, deformable, reversibly cross-linked array that supports growth in axonal diameter. Absence of neurofilaments reduces conduction velocity, resulting in behavioral abnormalities. Changes or dysregulations of the neuronal neurofilament network can induce pathological signs of neurodegeneration and even neuronal death. Certain human neurodegenerative diseases, such as CMT2E, are directly caused by mutations in a neurofilament gene. Other human neurodegenerative diseases, such as the motor neuron disease ALS, show pathological neurofilament accumulations, although mutations in any of the three neurofilament genes represent disease modifiers rather than direct causes. Changes in the neurofilament network can strongly influence the ALS disease course.

Until very recently, it was thought that the adult brain was incapable of generating new neurons or having neurons added to its complex circuitry. However, the development of new techniques has resulted in a major increase in research demonstrating that the adult central nervous system (CNS) contains neural progenitors, precursors, and stem cells that are capable of generating new neurons, astroglia, and oligodendroglia. It has also been shown that neurogenesis constitutively occurs in two specific regions of the adult mammalian brain (olfactory bulb and hippocampal dentate gyrus), and that a significant number of multipotent neural precursors, or 'stem cells,' reside in many parts of the adult CNS. While challenging previous dogma that no new neurons are born in the adult mammalian CNS, these findings bring with them future possibilities for the development of novel neural repair strategies.

A substantial body of research regarding constitutively occurring neurogenesis provides insight into the potential for and limitations of neuronal replacement therapies based on manipulation of neural precursors. Recent work has partially elucidated the normal behavior of endogenous adult precursors, including their ability to migrate to select brain regions, differentiate into neurons, integrate into normal neural circuitry, and, finally, functionally integrate into the adult brain. Research is also beginning to identify and describe molecular and activity-related controls over constitutively occurring neurogenesis.

Defining Neural Stem Cells, Progenitors, and Precursors

Rigorously defined, adult CNS stem cells exhibit three cardinal features: (1) self-renewal, with the theoretically unlimited ability to produce progeny indistinguishable from themselves; (2) they are proliferative, continuing to undergo mitosis (although perhaps with quite long cell cycles); and (3) they are multipotent for the different neuroectodermal lineages of the CNS, including the multitude of different neuronal and glial subtypes. Multipotent progenitors of the adult brain are proliferative cells with only limited self-renewal that can differentiate into at least two different cell lineages (multipotency). Lineage-specific precursors or progenitors are cells with restriction to one distinct lineage (e.g., neuronal, astroglial, or oligodendroglial). Together, CNS stem cells and all precursor/progenitor types are, broadly defined, 'precursors.' We favor reserving the term stem cell as rigorously defined previously and using 'precursor' or 'progenitor' for most forms of multipotent or lineage-restricted mitotic cells. We use 'precursor cell' as a generic term encompassing both stem and progenitor cells.

Adult neurogenesis comprises all the events of neuronal development, beginning with the division of a precursor cell and ending with the survival of a mature, integrated, functioning new neuron. Neurogenesis is sometimes incorrectly used only in the sense of 'precursor cell proliferation,' but this definition clearly falls short. Precursor cell proliferation is not predictive of net neurogenesis. True neuronal integration depends on many complex variables and progressive events.

Even in the absence of a fully detailed molecular characterization, neural precursor cells of the adult brain clearly possess features that justify a view of these cells as extremely promising for the goals of CNS cellular repair. They are undifferentiated, often highly mobile cells, relatively resistant to hypoxia and other injury, proliferatively active, and able to produce mature neurons and glia. The most critical caveat, however, is that precursor cells in both the developing and the adult mammalian brain are heterogeneous, and although all of these criteria might apply in many cases, it is not clear how many of the sometimes site-specific and condition-specific observations in neural precursor biology can be broadly generalized and how many reflect particulars of a certain brain region or a certain condition.

Although the identity of 'true' CNS stem cells is unknown, limiting some conclusions, the heterogeneity of neural precursor cells is also an important aspect of the promise of such cells. Their variable specialization and differentiation competence provides great promise for future clinical applications. The idea that 'one cell fits all' might turn out to be as unrealistic as it is unnecessary. Adult neural precursors with partial fate restriction may, in some cases, allow for more efficient production of desired cell types. The brain may provide the environmental determinants for the different forms and sequelae of adult neurogenesis and gliogenesis, and it may powerfully enable and direct specific lineage development.

*These authors contributed equally to this work.

The Discovery of Constitutively Occurring Adult Mammalian Neurogenesis

Ramon y Cajal has been widely quoted as writing that "in the adult centres the nerve paths are something fixed, ended and immutable. Everything may die, nothing may be regenerated." The lack of recovery from CNS injury and neurodegenerative disease in the adult mammalian CNS is in marked contrast to the enormous regenerative potential of the CNS in non-mammalian vertebrates. Indeed, the consensus in the field for some time was that neurogenesis does not occur in the adult mammalian brain. Joseph Altman was the first to use techniques sensitive enough to detect the ongoing cell division that occurs in the adult brain. Using tritiated thymidine as a mitotic label, he published evidence that neurogenesis constitutively occurs in the mammalian hippocampus and olfactory bulb. These results were later replicated using tritiated thymidine labeling followed by electron microscopy. However, the absence of neuron-specific immunocytochemical markers at the time resulted in identification of putatively newborn neurons being made on purely morphological criteria. These limitations led to a widespread lack of acceptance of these results and made research in the field difficult.

The field of adult neurogenesis was rekindled in 1992 with demonstrations that precursor cells isolated from the forebrain can differentiate into neurons *in vitro*. These results, and technical advances such as the development of immunocytochemical reagents that could more easily and accurately identify the phenotype of various neural cells, led to an explosion of research in the field. Normally occurring neurogenesis in the subventricular zone (SVZ)/olfactory bulb and the dentate gyrus has now been well characterized in the adult CNS.

Neurogenic versus Nonneurogenic Regions in the Adult Brain

Neurogenesis constitutively occurs only in the olfactory bulb and the dentate gyrus of the hippocampus. In the olfactory system, precursor cells reside in the anterior aspect of the SVZ (sometimes also called the subependymal zone) in the walls of the lateral ventricles, migrate via 'chain migration' through a structure surrounding the remnants of the olfactory ventricle (the rostral migratory stream (RMS)) into the olfactory bulb, and differentiate into granule or periglomerular interneurons. In the dentate gyrus of the hippocampus, precursor cells are found in the subgranular zone (SGZ). Here, new hippocampal granule cell neurons are produced. These two brain regions are thus referred to as 'neurogenic regions.' As discussed later in more detail, a report of extremely low-level constitutive neurogenesis in the normal neocortex has been disputed on important methodological grounds, leaving this reported result quite controversial. In addition, the same group later modified its interpretation by stating that the existence of these neurons was only transient. There have also been reports of extremely low-level constitutive adult neurogenesis in the amygdala, area cornu ammonis field1 (CA1) of the hippocampus, the dorsal vagal complex of the adult brain stem, the spinal cord, the substantia nigra, and the hypothalamus, although some of these results have been disputed. Overall, these isolated data remain controversial, but not because the possibility of extremely low-level neurogenesis occurring in essentially nonneurogenic regions is remote. Instead, isolated reports of such a phenomenon have not sufficiently overcome many of the important methodological issues mentioned previously.

Transplantation studies support the principle of defining neurogenic and nonneurogenic regions, and they provide evidence about the role of the microenvironment in influencing the potential of neural precursors. If precursor cells are transplanted into neurogenic regions, they can differentiate into neurons in a region-specific manner. SVZ precursor cells generate hippocampal neurons when transplanted into the hippocampus, and SGZ precursor cells generate olfactory interneurons after transplantation into the RMS. When implanted outside the neurogenic regions, both types of precursor cells generate only glia. These data further support the interpretation that neurogenesis is dependent on a permissive microenvironment rather than on the regionally different properties of precursor cells. Local microenvironmental influences on the behavior of precursors and their ability to differentiate into neurons support the argument that it will be critical for the goal of neuronal repopulation to understand the cellular and molecular controls over cell type-specific precursor cell differentiation in the adult CNS.

It came as a surprise to many in the field that neurogenic regions are defined by the neurogenic permissiveness of the local microenvironment rather than by the presence of neural precursor cells. Neural precursor cells have been found in a large number of brain regions, including white matter tracts. It is possible that the entire brain contains neural precursor cells (albeit at very low density), just as it contains partially restricted glial precursors that act as progenitor cells. These widely distributed neural precursor cells do not seem to differ fundamentally from one another, although they are far from homogeneous, with notably different growth kinetics and likely at

least partially restricted differentiation potential. Their function outside the classical neurogenic regions is not known (e.g., whether evolutionary remnants or occasionally activated in certain circumstances), nor is their relation to the precursor cells of the neurogenic regions. For example, neural precursor cells from the spinal cord behave *in vitro* much like their counterparts from the SGZ and SVZ, and they are multipotent after implantation into the hippocampus, producing granule cell neurons, but only generate glial cells *in situ* or when transplanted back to their original site in the spinal cord. *In vivo*, no adult neurogenesis can be found in the rodent spinal cord. In summary, the extent of neurogenesis in a region is a function of the local microenvironment on precursor cells with (varying) neurogenic potential and differentiation restriction.

Therefore, there is an important conceptual distinction between neurogenic and nonneurogenic regions, but it might turn out that this distinction reflects complex molecular and functional states rather than a fixed cellular environment. Can nonneurogenic regions be molecularly modified to promote neurogenesis? Could this change in neurogenic permissiveness be induced under certain pathological conditions? There are strong natural precedents in other vertebrate systems, such as the avian telencephalon and the olfactory epithelium, for the concept that selective neuronal death can alter the differentiation of precursors, thereby inducing or increasing neurogenesis. Although not yet proved, it is hypothesized that this change in neurogenesis occurs via alterations in the local molecular microenvironment and intercellular interactions with partner glial and interneuron populations that resemble conditions seen during nervous system development and in adult neurogenic regions.

Several groups have demonstrated the induction of modest levels of neurogenesis in normally nonneurogenic regions in response to selective neuronal death or degeneration. As described in more detail later, we found that endogenous multipotent precursors normally located in the adult brain can be induced to differentiate into neurons in the normally nonneurogenic adult mammalian neocortex – a result extended to corticospinal motor neurons. Other groups have reported similar and complementary results in a normally nonneurogenic region of the hippocampus and in the striatum, confirming and further supporting this direction of research. These reports of seemingly regenerative neurogenesis in the vicinity of targeted cortical neuron degeneration and cerebral ischemia suggest that the lack of normal neurogenic permissiveness in these regions is not unalterable. The controversial examples of reportedly extremely low-level constitutive neurogenesis outside the classical neurogenic regions might also support this possibility, potentially as 'leakage' from normally tightly inhibited systems. Precursor cells resident in nonneurogenic regions appear at least partially competent to respond to either instructive neurogenic signals or release from inhibition to induce them to develop into new, potentially function-restoring neurons.

The vast majority of studies investigating potential neurogenesis in the neocortex of the well-studied rodent brain do not report normally occurring adult cortical neurogenesis. Rigorous studies employing serial-section analysis and three-dimensional confocal reconstruction demonstrate a complete absence of constitutively occurring neurogenesis in the murine neocortex. These experiments provide evidence that satellite glial cells, closely apposed to neurons in normal neocortex, could be mistakenly interpreted as adult-born neurons when, in fact, a newborn glial cell overlies a preexistent neuronal nucleus. However, a few studies report low-level, constitutively occurring neurogenesis in specific regions of the neocortex of adult primates and in the visual cortex of adult rat. In one such study, neurogenesis of two or three new neurons per cubic millimeter was reported in prefrontal, inferior temporal, and posterior parietal cortex of the adult macaque (in one case, after likely damage from prior electrophysiological recordings in the same regions) but not in striate cortex, which was interpreted by the authors as being due to the fact that this is a simpler primary sensory area. These authors later reported that these cells are transient and do not survive. In contrast, other reports analyzed with more rigorous methods, as noted previously, have been unable to reproduce these findings and report a complete absence of constitutive cortical neurogenesis in both rodents and primates. There exists a single report of neurogenesis in the visual cortex of the adult rat, but this study used tritiated thymidine and purely morphological cell type identification, and it has not been confirmed by any other group (the satellite glia issue casts substantial doubt on this study performed prior to confocal microscopy availability). Work using ^{14}C counts from human tissue, based on the peri-1960 aboveground nuclear testing contamination of the atmosphere, confirms the absence of any substantial adult neocortical neurogenesis. It seems highly unlikely that even very low-level neurogenesis occurs normally in the neocortex of any mammals (and most data indicate none in rodents or primates), but further examination of the potential for constitutive neurogenesis in what are considered normally nonneurogenic regions will be required.

The situation in the literature is far from clear, but it is important to remain critical and cautious in interpretation. After all, the brain does regenerate poorly. Although some of the newer results fundamentally change our view on the possibility of pathology-induced neuroplasticity, it should not be forgotten that there is little evidence that neurogenesis outside normally neurogenic regions by itself significantly contributes to brain repair. Attempts toward endogenous repair will almost certainly require exogenous activation and/or release of inhibition of the processes involved, control over directed subtype differentiation, and support of both neuron survival and axon outgrowth and pathfinding. Restorative neurobiology focusing on these approaches aims at activating the potential that lies in precursor cells in the neurogenic and nonneurogenic regions of the adult brain.

Induction of Neurogenesis in Nonneurogenic Regions of the Adult Brain

Induced neurogenesis in nonneurogenic regions can be envisioned in two basic forms: (1) Local parenchymal precursor cells might be activated to generate new neurons upon a stimulus associated either with a pathological event or with a set of directed molecular and/or genetic interventions, or (2) precursor cells from normally neurogenic regions (e.g., the SVZ) might respond to either type of stimulus and migrate into the perenchyma. There are already examples for both possibilities.

The first evidence that regenerative neurogenesis is possible was reported by our lab for the neocortex; this work served as a 'proof of concept' for the induction of adult mammalian neurogenesis. Work by our lab and other groups has extended this general concept importantly in new directions – in the striatum, hippocampus, hypothalamus, and corticospinal system. Whereas multipotent precursors are concentrated in the anterior SVZ and the dentate gyrus, they can be found in lower densities in several other regions of the adult brain. As discussed previously, these precursors have broad potential; they can differentiate into astroglia, oligodendroglia, and neurons; receive afferents; and extend axons to their targets, given an appropriate *in vitro* or *in vivo* environment. Prior results demonstrated that cortex undergoing targeted apoptotic degeneration could direct multipotent precursors to integrate into adult cortical microcircuitry. The population specificity of neuronal death was found to be essential, allowing for maintenance of local circuitry and survival of surrounding cells that alter gene expression to direct precursors to their final location. These properties of endogenous multipotent precursors led us to investigate the fate of these precursors in an adult cortical environment manipulated in a manner previously demonstrated to support neurogenesis.

We found that endogenous multipotent precursors could be induced to differentiate into neurons in the adult mouse neocortex, without transplantation. These experiments induced synchronous apoptotic degeneration of corticothalamic projection neurons and examined the fates of newborn cells within cortex using markers of progressive neuronal differentiation. The results demonstrated that endogenous neural precursors (mostly from the SVZ and possibly some from the parenchyma of the cortex) could be induced *in situ* to differentiate into cortical neurons, survive for many months, and form appropriate long-distance connections in the adult mammalian brain. These results indicated that the normal absence of constitutive cortical neurogenesis does not reflect an intrinsic limitation of the endogenous neural precursors' potential but more likely results from a lack of appropriate microenvironmental signals necessary for neuronal differentiation or survival. Elucidation of these signals could enable CNS repair.

Other groups have reported similar and complementary results in hippocampus and striatum, confirming and further supporting this direction of research. Nakatomi and colleagues used an *in vivo* ischemia model by which it was found that repopulation of neurons in the CA1 region of the hippocampus is possible following the elimination of CA1 neurons. It was found that the overwhelming majority of adult-born neurons repopulating the damaged CA1 region originated from a proliferative response in the posterior periventricle, and that this proliferative response could be augmented by infusion of high levels of epidermal growth factor (EGF) and fibroblast growth factor-2 (FGF-2), dramatically increasing the number of neurons able to migrate into and repopulate the damaged CA1 region. Although the levels of EGF and FGF-2 substantially exceeded those reasonable for human application, these experiments serve as a proof of principle for enhancement of an endogenous neurogenic response. We demonstrated induction of low-level neurogenesis of corticospinal motor neurons, with progressive extension of axons into the cervical spinal cord over 3 or 4 months. Flier and colleagues found that ciliary neurotrophic factor (CNTF) seemingly supports the survival of a very small number of new neurons of the hypothalamus involved in energy balance, rescuing them from what appears to be normal death following a possibly very low level of constitutive but abortive neurogenesis. Ultimately, a considerable and critical challenge will be to assess true functional integration of recruited adult-born neurons.

Taken together, these results demonstrate that endogenous neural precursors can be induced to differentiate into CNS neurons in a region-specific manner and at least partially replace neuronal populations that do not normally undergo neurogenesis. It appears that these results are generalizable to at least several classes of projection neurons, including the clinically relevant striatal medium spiny neurons and corticospinal motor neurons. Microenvironmental factors, importantly including signaling from local interneuron populations that normally interact during the development of their partner projection neuron populations, appear capable of supporting and instructing the neuronal differentiation and axon extension of adult-born neurons derived from endogenous precursors.

Conclusions and Future Prospects

Following the demonstration of the existence of neurogenesis in discrete regions of the adult mammalian CNS, a vast amount has been learned about the function of and controls over this set of processes. New knowledge is emerging regarding the lineage-specific differentiation of specific neuronal subtypes, particularly spinal motor neurons and corticospinal motor neurons and other forebrain projection neuron populations. Looking forward, it might be possible to induce the cellular repopulation of the diseased brain and spinal cord via specific activation and differentiation of endogenous neural precursors along desired neuronal or glial lineages. Even if multipotent precursors are not located in large numbers outside of normally neurogenic regions of the brain, it might be feasible to induce them to proliferate and differentiate from small populations that are more widely distributed throughout the neuraxis. There is accumulating evidence that endogenous neural precursors are regionally and even locally quite heterogeneous, and that subsets of partially fate-restricted precursors might exist local to regions in which neuronal replacement is desired. Such precursors might offer advantages in directing lineage-specific differentiation for cellular repair. However, this field is just at the beginning of understanding the complex interplay between neural precursors' potential and signals in their local microenvironment; much can be learned about precursor heterogeneity and how to take advantage of what may be partial cell type restriction, permissive and instructive developmental signals, and modulation of specific aspects of neuronal differentiation and survival. Progress during the past decade has been great, and the coming decades promise to offer significant insight into potential strategies for directed CNS repair.

Neurogenesis in the Intact Adult Brain

G Kempermann, Max Delbrück Center for Molecular Medicine (MDC) Berlin-Buch, Berlin, Germany

© 2009 Elsevier Ltd. All rights reserved.

Adult neurogenesis is the development of new neurons from resident neural precursor cells in the adult brain. The term 'adult neurogenesis' encompasses the entire process of neuronal development from the division of the precursor cell to the existence of a functionally integrated new neuron. Adult neurogenesis is rare and locally restricted in mammals but frequent and widespread in lower vertebrates; it seems that over the course of evolution with increasing brain complexity adult neurogenesis became more and more limited. Quantitatively, most adult neurogenesis occurs relatively early in life, but adult neurogenesis persists lifelong on a very low level. There is no evidence that adult neurogenesis would primarily contribute to a neuronal turnover in that it would replace damage or lost neurons. Rather, the new neurons are added to the persisting networks.

In mammals, physiological adult neurogenesis appears to be restricted to two canonical neurogenic regions, the dentate gyrus of the hippocampus and the olfactory bulb (**Figure 1**). Adult hippocampal neurogenesis generates new excitatory granule cells, the principal cells of the dentate gyrus, whose axons form the mossy fiber tract to hippocampal subregion CA3. Adult olfactory neurogenesis produces two types of interneurons in the granule cell layer and the periglomerular regions of the olfactory bulb.

Adult neurogenesis in other brain regions, most notably the neocortex, remains controversial, and if it exists will range on a minute scale. Initial reports about the production of large numbers of cortical neurons were not confirmed by others. In contrast, the question of whether small numbers of cortical interneurons, primarily in the deep cortical layers, might be generated in adulthood is more difficult to prove or disprove. In addition, under particular circumstances (e.g., in the face of locally limited pathology), regenerative or targeted neurogenesis in physiologically nonneurogenic regions seems to be possible. Such exceptions might question a rigid conceptual distinction between neurogenic and nonneurogenic regions. For most practical purposes, the distinction, however, is valid. In contrast to the nonneurogenic areas, the canonical neurogenic regions contain a morphologically distinct neurogenic or stem cell niche that provides a microenvironment permissive for precursor cell function and neuronal development. The niche consists of the precursor cells and their progeny, supporting cells, immune cells, vasculature, and a specialized extracellular matrix, whose exact composition is still unknown. The structure of the precursor cell niches of the adult brain resemble similar niches, for example, in bone marrow, testes, and olfactory epithelium.

Precursor cells can also be found outside the neurogenic regions, albeit at very low density. No structural evidence of a niche is found in these regions and physiologically no (or extremely limited) neurogenesis appears to take place. The function of precursor cells outside the neurogenic regions is unknown. It is also not clear how homogenous the population of neural precursor cells in the adult brain is. Concepts of neuroanatomists like Wilhelm His, Alfred Schaper, and Wilder Penfield, who proposed the existence of a 'spongioblast' in the brain parenchyma, are thereby revived. Currently, the best candidates for the parenchymal precursor cells outside the neurogenic regions are slowly proliferative cells expressing the proteoglycan NG2. The neurogenic precursor cells in the hippocampus and olfactory system, in contrast, are NG2-negative but express markers including nestin, doublecortin, brain lipid binding protein, glial fibriallary acidic protein, Sox2, and others, but neither sensitivity nor specificity are sufficiently clear.

Meaning and relevance of markers that are associated with neurogenesis in the neurogenic regions (nestin, doublecortin, calretinin, etc.) are not known for the nonneurogenic regions. The presence of these markers alone should not be taken as evidence of a neurogenic potential or even ongoing neurogenesis.

Adult neurogenesis also takes place in the olfactory epithelium (as part of the peripheral nervous system), where olfactory receptor neurons are continuously replaced from local precursor cells.

History

Adult hippocampal neurogenesis was first described by Joseph Altman, then at the Massachusetts Institute of Technology, in the early 1960s. Altman also described postnatal neurogenesis in the olfactory bulb in 1969. The response by the scientific community was skeptic, largely for methodological reasons but also because of the fact that no stem cell population was known in the brain and the origin of new neurons thus remained speculative. In the 1980s, Fernando Nottebohm and colleagues described adult neurogenesis in those brain nuclei of canary birds that are responsible for song learning. These studies provided the first link between adult neurogenesis

Figure 1 Adult neurogenesis occurs in two canonical neurogenic regions: the olfactory system and the hippocampus.

and behavior. After the discovery of neural stem cells in the adult mammalian brain in 1992, research on adult neurogenesis gained momentum. The isolation of stem and progenitor cells in the olfactory system was first reported by Brent Reynolds and Sam Weiss. Stem cells in the adult hippocampus followed in 1995 with the work of Theo D Palmer, Jasodarah Ray, and Fred H Gage. In the early 1990s, Elizabeth Could and co-workers reported that corticosteroids negatively affect adult neurogenesis. In 1997 and 1998, Fred H Gage's group showed that environmental enrichment and physical exercise positively influence adult hippocampal neurogenesis. The occurrence of adult neurogenesis in the human dentate gyrus was confirmed in 1998 by Eriksson and colleagues.

Adult Hippocampal Neurogenesis

The precursor cells driving adult hippocampal neurogenesis reside in the subgranular zone (SGZ) of the adult dentate gyrus. An astrocyte-like stem cell with radial morphology (type 1 cell) gives rise to highly proliferative intermediate progenitor cells (type 2 cells) and lineage-determined neuroblast-like cells (type 3 cells) that exit from the cell cycle and go through an immature postmitotic stage. During this stage, which coincides with the transient expression of calretinin, the new neurons fully extend their neurites and go through a phase of increased synaptic plasticity. The distinction of the cell types by numbers is preliminary and should one day be exchanged to a functional nomenclature.

Regulation of adult neurogenesis mainly occurs in two stages, an expansion phase on the level of the precursor cells and a phase of selective survival on a postmitotic stage. A transient expression of doublecortin lasts from the type 2 cell level to the calretinin phase. Doublecortin has become a surrogate marker of adult neurogenesis that is even used for quantification. The equalization of doublecortin expression with hippocampal neurogenesis, however, is not without problems because doublecortin expression ends before the cells are fully integrated. The newly generated cells receive first input through GABAergic synapses, which are excitatory. This input is involved in the induction of full maturation. The new cells receive glutamatergic input within days to weeks and go through a transient phase of increased synaptic plasticity (i.e., a lowered threshold for the induction of long-term potentiation). After approximately 7 weeks, the cells have become largely indistinguishable from the older granule cells and remain stably integrated into the network.

Adult Olfactory Neurogenesis

The precursor cells for adult olfactory neurogenesis are found in the subventricular zone (SVZ) of the lateral ventricle. The stem cell of this region has a cilia-bearing process touching the ventricular surface between the ependymal cells. The exact relationship between these stem cells (B cells) and the ependymal cells (E cells) is not clear; in particular, it remains controversial whether under certain conditions ependymal cells can act as stem cells. Undoubtedly, however, the astrocyte-like B cells do serve as stem cells and give rise to highly proliferative progenitor cells (C cells) that generate migratory neuroblasts (A cells). The A cells migrate in a specialized form of migration, homonymic chain migration, through the rostral migratory stream (RMS) to the core of the olfactory bulb, where they change for a radial migratory pattern and reach the granule cell layer and the glomerular and periglomerular regions. Precursor cells with a neurogenic potential can be isolated not only from the SVZ but also from the RMS and the olfactory bulb. All new neurons in the olfactory bulb are inhibitory interneurons and thus GABAergic. A subset of new periglomerular neurons co-expresses dopamine as neurotransmitter. Maturation of the new cells is delayed until they have reached their final position. The new cells in the granular layer express calretinin. The exact lineage relationship between the different types of new olfactory bulb neurons is not clear.

Regulation

Regulation of adult neurogenesis mainly falls into two categories. Numerous relatively nonspecific stimuli can affect the proliferation of precursor cells. Acutely this increase can lead to an increase in net neurogenesis, but this does not necessarily have to be the case. For many factors, the question of whether a particular stimulus has long-term effects on net neurogenesis has not yet been specifically addressed. Many of the nonspecific stimuli are associated with 'activity,' and many examples of pathology (ischemia, trauma, etc.) can upregulate neurogenesis. Other stimuli such as stress and inflammation downregulate precursor cell proliferation and neurogenesis. For many such regulators, complex dose–response relationships might exist so that generalization is difficult. Age can be considered a strong negative regulator early in life but apparently loses this strong impact, because with increasing age adult neurogenesis settles at a very low level.

Stimuli that appear to be of more specific relevance to the hippocampus or the olfactory system act on the selective survival of the new cells. Under physiological conditions, these stimuli tend to be associated with the function of the hippocampus (memory, learning, etc.) or the olfactory system (olfaction). Genetical studies indicate that regulation on the survival and differentiation level has a larger quantitative (and presumably qualitative) impact on the control of adult neurogenesis than the regulation of cell proliferation.

On a mechanistic level, regulation involves several neurotransmitter systems that provide input to the SGZ and SVZ. For the SGZ, the research focus has been on the GABAergic, the serotonergic, and the glutamatergic system. High levels of glucocorticoids acutely suppress neurogenesis. Presumably because the expression of corticosteroid receptor expression changes in the course of neuronal development in the adult, the net effect under prolonged exposure to glucocorticoids is complex. Many situations with elevated levels of glucocorticoids are thus associated with increased levels of neurogenesis. The details of this regulation are unknown. The role of other hormone systems is even more ambiguous.

Growth factors and neurotrophic factors, most notably fibroblast growth factor 2 (FGF2) and epidermal growth factor (EGF), strongly affect adult neurogenesis in a complex way. Insulin-like growth factor 1 (IGF1) and vascular endothelial growth factor (VEGF) have been discussed as centrally involved in the activity-dependent regulation of adult neurogenesis. Brain-derived neurotrophic factor (BDNF) is widely proposed to play a major role in controlling adult neurogenesis but experimental evidence supporting this assumption so far remains limited.

Among the short-range-acting signaling molecules with effects on adult neurogenesis contributions of the ephrins, bone morphogenic proteins (BMPs) and

the Wnt system have been described. More are likely to follow. It is assumed that the general and intrinsic developmental principles regulating neuronal development in the adult more or less recapitulate the processes prevalent in the fetus. Extrinsic and activity-dependent regulation, in contrast, are likely to set adult neurogenesis apart from fetal neurogenesis. In addition, differences between the two neurogenic regions might exist with regard to the contribution of individual regulatory factors.

Function

The fact that adult neurogenesis is the exception and not the rule has raised the question of why dentate gyrus and olfactory bulb in contrast to all other brain regions not only accommodate the integration of new neurons but actually call for it in a function-dependent manner. In both systems, adult neurogenesis does not add bulk numbers of new neurons. Rather, the contribution of adult neurogenesis might be qualitative and allow a possibly subtle modification of the existing neuronal network. In the hippocampus, adult neurogenesis allows the activity-dependent optimization of the mossy fiber connection between the dentate gyrus and CA3. Integration is triggered during a phase of increased synaptic plasticity and leads to a cumulative adaptation of the network to a level of complexity and novelty. Alternative hypotheses that mostly suggest a transient functional contribution of the immature neurons in the sense of a direct contribution to memory formation are questioned by the lacking evidence for substantial neuronal turnover and the scarcity of new neurons. Mechanistically, it has been proposed that the new neurons help the hippocampal network to avoid catastrophic interference in the dentate gyrus, that is, the destruction of codings for older information by incoming new information.

Similarly, adult olfactory neurogenesis has been brought into connection with novelty detection, here the coding of novel odors. It seems that new neurons are more sensitive to novel odors and might help to adjust the network to the processing of a new range of olfactory stimuli.

A general principle might be that adult neurogenesis is used in bottleneck situations, where the insertion of new neurons is strategic and allows the incremental optimization of a network that in general tends to remain as lean as possible. Networks in nonneurogenic areas might not exist under this priority of size limitation.

Medical Relevance

Adult neurogenesis might be of medical relevance either because a failure of adult neurogenesis might contribute to brain disease or because a reactive increase in adult neurogenesis might be part of endogenous regenerative attempts. A role for adult neurogenesis in brain pathology, among others, is discussed for temporal lobe epilepsy, major depression, and dementias. In temporal lobe epilepsy, cell proliferation is massively increased, many new neurons are found in ectopic locations, and aberrant projections from the new neurons might support the chronification of the disease. In the context of major depression, a reduction in hippocampal volume has been noted (that is, however, much larger to be explained by a lacking contribution of adult neurogenesis) and all antidepressants have been found to increase adult hippocampal neurogenesis. As the most extreme position in the context, it has been suggested that antidepressants might even require neurogenesis for their action. Dementias might at least partly be explained by a reduction in the contribution that new neurons make to hippocampal function – a concept that is complicated by the fact that the functional relevance of adult neurogenesis itself is not yet fully understood. As yet, no similar concrete links to pathology have been proposed for neurogenesis in the olfactory bulb.

Numerous pathological stimuli, most notably trauma and ischemia, induce the proliferation of precursor cells and in many cases net adult neurogenesis. These effects appear to be indirect because they are found even in the absence of direct damage to the dentate gyrus or SVZ. In addition, after middle cerebral artery occlusion in rats, precursor cells migrated from the SVZ into the striatum and differentiated into local neurons. The massive infusion of growth factors supported the replacement of ischemic CA1 neurons by SVZ precursor cells. Phototoxically induced circumscript cell death in the cortex also led to the replacement of neurons.

Envisioned therapeutic strategies that are based on the transplantation of neurons that have been generated from neural precursor cells benefit from the knowledge accumulating from research on adult neurogenesis, because here nature exemplifies how neuronal development is possible under the conditions of the otherwise nonneurogenic adult brain.

Medical relevance also depends on the occurrence of adult neurogenesis in humans. Adult hippocampal neurogenesis has been demonstrated for humans and nonhuman primates. There is evidence for neurogenesis in the adult olfactory bulb of nonhuman primates but not yet unambiguously of humans. Precursor cells, however, have been isolated from ventricle biopsies and resection specimens from the adult human hippocampus, as well as postmortem brain tissue of infants.

Hormone Structure, Biosynthesis, and Secretion

Peptide and Prohormone Structure and Processing

Vasopressin (VP) and oxytocin (OT) are nine-amino-acid peptides that differ from each other by only two amino acids (Figure 1). Each includes a disulfide ring formed between cysteine residues. They are synthesized as part of larger prohormone molecules (Figure 1). Following translation, the prohormone molecule undergoes initial glycosylation in the endoplasmic reticulum and is packaged into large (150–200 nm) secretory granules in the Golgi complex. During transport of these secretory granules to the axon terminal in the neurohypophysis, the prohormone molecule is enzymatically cleaved into the peptide, its associated neurophysin, and, in the case of VP, a C-terminus glycopeptide molecule. Secretion of the hormones occurs by calcium-dependent exocytosis induced by depolarization of the axon terminal. During exocytosis, the contents of the secretory granule are discharged into the extracellular fluid surrounding the nerve terminal and diffuse into the surrounding capillaries for distribution by the bloodstream to distant target organs. Although neurophysin and the glycopeptide (as well as VP and OT) are detectable in the blood, no hormonal action of these molecules has been identified.

Genes and mRNA

VP and OT are produced only by mammals, but they differ by one amino acid from the closely related peptide, vasotocin, which is produced in nonmammalian vertebrates. The genes for VP and OT evolved from the vasotocin gene by a gene duplication event. In all species studied, the two genes are linked on the same chromosome in opposite transcriptional directions. The intergenic sequence is important for regulation of gene expression. Each gene is composed of three exons. Exon 1 codes for the N-terminal portion of the preprohormone molecule that includes the signal peptide that directs the molecule from the ribosome to the endoplasmic reticulum, the VP or OT peptide, and the N-terminal portion of the neurophysin molecule. Exon 2 codes the central component of neurophysin and shows a high degree of homology between VP and OT. Exon 3 codes the C-terminal portion of neurophysin and, in the case of VP, the glycopeptide. Mutations in the VP gene with resultant loss of VP production result in neurogenic diabetes insipidus (DI). A rat with a single base deletion that disrupts the translation stop codon for VP mRNA was discovered in Brattleboro, Vermont, in 1962. This animal exhibits polydipsia and polyuria, the hallmark symptoms of VP deficiency, and it has been a very useful animal model for studying VP secretion and action. Multiple mutations in the human gene have also been identified in families with hereditary neurogenic DI. These mutations generally lead to abnormalities in folding or packaging of the prohormone.

Structure of the Neurohypophyseal System

Hypothalamic Nuclei (Supraoptic/Paraventricular/Accessory)

VP and OT are synthesized by neurons localized in the supraoptic (SON) and paraventricular nuclei (PVN) of the hypothalamus as well as in several small groups of accessory magnocellular neurons (Figures 2 and 3). The axons from these neurons form the hypothalamo-neurohypophyseal tract (Figure 3(c)) and terminate in the posterior lobe of the pituitary or neurohypophysis. Due to dilution of the hormones in the blood prior to their delivery to their target tissues, they must be synthesized and released in large quantities and this is reflected by the large size of the VP and OT neurons (25–30 μm in diameter). The hormones are synthesized in the cell bodies of these 'magnocellular' neurons and the secretory granules are transported by fast axonal transport to the nerve terminal in posterior pituitary. Large clusters of secretory vesicles are visible as Herring bodies (5–15 μm) in the nerve terminals (Figure 4(a)). These contain large stores of hormone sufficient, in the case of VP in the rat posterior pituitary, to maintain hormone release for 5–7 days of water deprivation.

Although all mammals, including humans, have a mix of VP and OT neurons in both the PVN and the SON, within each nucleus the VP and OT neurons cluster in specific regions. In rat SON, OT neurons predominate in the dorsal, lateral, and rostral regions of the nucleus, and in many species a large cluster of magnocellular VP neurons in the lateral wing characterizes the PVN (Figure 3). Although in most cases VP and OT are produced in separate neurons, many neurons can synthesize both peptides, and under conditions of enhanced hormone release, co-localization of

Figure 1 The peptide and prohormone structures of the mammalian neurohypophyseal hormones vasopressin (VP) and oxytocin (OT). They are similar to the nonmammalian hormone vasotocin in that all three are nine-amino-acid peptides with a disulfide ring differing only by the amino acids in positions 3 and 8 (asterisk). Position 3 is Ile in vasotocin and oxytocin but Phe in vasopressin, whereas position 8 is Arg in vasotocin and vasopressin but Leu in oxytocin. An exception is the pig family, in which vasopressin has Lys at position 8. The prohormones for VP and OT both include the peptide sequence at the N-terminus followed by neurophysin. After packaging into the secretory granule, the prohormone is cleaved at the positions indicated by the vertical bars.

Figure 2 Diagram of the hypothalamo-neurohypophyseal system in the rat brain. The rat brain is cut away at the level of the optic chiasm to show the location of the SON and PVN. On the right side is shown the axonal projections from the magnocellular VP and OT neurons to the neurohypophysis. On the left side is shown the axonal projections from the parvocellular VP/corticotropin neurons in the PVN to the portal vessels in the median eminence that carry hormones to the anterior pituitary (not shown). Note that these latter axon terminals are visible in the external zone of the median eminence in **Figure 3(c)**. the peptides increases (Figure 3(b)). Both VP and OT are also synthesized in small (parvocellular) neurons located in PVN and, in the case of VP, other brain regions, such as the suprachiasmatic nucleus of the hypothalamus and the medial amygdala. These parvocellular neurons project to regions of the brain other than the neurohypophysis and are not involved in producing VP and OT for release

Figure 3 Location of optic tract (OT) and VP neurons and the hypothalamo-neurohypophyseal tract in coronal sections of rat brain. Glial/Neuronal Interactions

The VP and OT neurons are closely associated with glial cells, and plastic changes in the neuronal/glial relationship associated with physiological stimulation of VP and OT release have been well documented in both SON and the neurohypophysis. A ventral glial lamina separates the SON from the ventral surface of the brain. This region contains the cell bodies of astrocytes that under basal conditions send long processes dorsally into SON, separating adjacent

neurons from each other and wrapping around the dendrites. During lactation or following dehydration (e.g., increased OT and VP secretion, respectively), the glial processes withdraw, allowing increased apposition of somatic membranes and formation of multiple synapses between dendrites. These conditions allow for enhanced neuronal activity by removing inhibitory agents released by glia as well as enhancing the potential for synchronous activation of neurons by afferents synapsing on multiple dendrites. The astrocytes in the posterior pituitary (called pituicytes) demonstrate similar plasticity. Under conditions stimulating hormone release, withdrawal of pituicyte processes is observed, resulting in increased exposure of the nerve terminals to the basal lamina of the perivascular space. This morphological change improves access of released hormone to the capillaries and may remove inhibitory agents such as taurine released by the pituicytes.

Regulation of Hormone Secretion

Vasopressin

Due to its vasoconstrictive actions on peripheral vessels, and its ability to cause water reabsorption from the renal filtrate, VP directly modifies the osmolality of the extracellular fluid (ECF) as well as blood volume and pressure. These parameters in turn regulate its secretion from the neurohypophysis.

Osmotic regulation VP release is exquisitely sensitive to changes in osmolality of the plasma or ECF. A 1% increase in osmolality increases plasma VP to a level sufficient to elicit detectable antidiuresis. This is the result of an elaborate series of osmoreceptive elements strategically situated to monitor ECF osmolality at different sites in the body. Osmoreceptive elements are located in the mesenteric and hepatic portal vasculature. These receptors monitor osmolality of the blood draining the intestine and provide an early indication of water, electrolyte, and nutrient intake. Osmoreceptors are also located in several regions of the brain that lack a blood–brain barrier (i.e., subfornical organ (SFO) and organum vasculosum of lamina terminalis (OVLT)). These receptors are positioned to monitor plasma osmolality unaffected by transport limitations of the blood–brain barrier. Finally, the magnocellular neurons of the SON and PVN are also osmosensitive, providing a final site for regulation of VP secretion by osmolality.

In 1947, Verney postulated the existence of 'osmoreceptors.' His pioneering work and subsequent studies by many others have led to the consensus that neurons in the SON and PVN as well as in the OVLT and SFO function as osmoreceptors by monitoring changes in their cell volume induced by fluctuations in the concentration of nonpermeable solutes (e.g., Na^+ and sucrose, but not urea) in the surrounding ECF. Stretch-inactivated, nonselective ion channels have been functionally demonstrated in these regions and shown to underlie the osmosensitivity of SON and OVLT neurons. Modulation of these channels by angiotensin II, cholecystokinin, and neurotensin underlies the ability of these neuropeptides to modulate osmotic regulation of VP secretion. These channels also contribute to the observation that increases in ECF Na^+ can induce VP release independent of changes in ECF osmolality because the permeability of these channels to Na^+ is enhanced by increases in ECF Na^+. The ability of gadolinium to block these channels suggested that they are mechanosensitive ion channels, and evidence that an N-terminal variant of the Trpv1 channel is expressed in SON neurons and is required for osmosensation suggests a molecular identity of the osmosensor.

Although the magnocellular neurons are osmoreceptive, several additional mechanisms contribute to the ability of the intact organism to tightly regulate ECF osmolality. First, excitatory afferents from osmosensitive neurons in the SFO and OVLT innervate the magnocellular neurons, enhancing their endogenous responses to changes in osmolality. Second, similarly, afferents carrying information from the peripheral osmosensors also influence VP release. Third, taurine release from astrocytes in SON may be regulated by cell volume-sensitive mechanisms. Taurine released by glial cells under hypotonic conditions activates inhibitory glycine receptors on magnocellular neurons and thus may contribute to inhibition of VP and OT neurons. Fourth, the withdrawal of astrocytic processes during hypertonicity removes this inhibitory influence and increases exposure of the neurons to excitatory neurotransmitters from osmosensitive afferents. Finally, additional sodium sensors may participate as well. SON neurons have been shown to express Na_x, a sodium channel that is sensitive to the ECF sodium concentration. This channel is also expressed in SFO and OVLT, and mice deficient in the gene ingest greater quantities of salt.

Pressure/volume regulation As a potent vasoconstrictor agent, VP is important for preventing decreases in blood pressure, and as a potent antidiuretic agent, it is important for maintaining blood volume. Thus, it is appropriate that information about blood pressure and volume are important regulators of VP secretion. Although larger percentage decreases in blood pressure or volume are required to achieve comparable increases in plasma VP compared to increases in

Figure 5 Comparison of the VP response to decreases in blood pressure or volume versus increases in plasma osmolality. VP release is linearly related to increases in osmotic pressure once a threshold is exceeded while it is exponentially stimulated by decreases in blood volume or pressure. Thus, it is more sensitive to changes in osmolality (e.g., a smaller percentage change from baseline is required to induce detectable increase in plasma VP) but greater overall increases in plasma VP are induced by decreases in blood pressure or volume. The arrow indicates that the osmotic relationship is displaced to the left in the presence of hypovolemia/hypotension such that VP release in response to osmotic stimulation is enhanced. Based on original data published in Dunn FL, Brennan TJ, Nelson AE, and Robertson GL (1973) The role of blood osmolality and volume in regulating vasopressin secretion in the rat. *Journal of Clinical Investigation* 52: 3212–3219, and modified with permission from Baylis PH (1987) Osmoregulation and control of vasopressin secretion in healthy humans. *American Journal of Physiology* 253: R671–R678.

osmolality, decreases in blood pressure result in much greater increases in plasma VP (Figure 5).

Arterial blood pressure is monitored by stretch receptors in the carotid sinus and blood volume is monitored by stretch receptors in the atria and pulmonary vessels. This information is transmitted to neurons in the nucleus tractus solitarius of the brain stem via cranial nerves IX and X (glossopharyngeal and vagus, respectively) and in turn to the SON and PVN via multisynaptic pathways. The A1 catecholamine pathway is activated in response to a decrease in blood pressure or volume. This pathway directly innervates the SON and PVN, and it uses ATP, norepinephrine, and neuropeptide Y as excitatory neurotransmitters. Increases in blood pressure activate a different and only partially characterized pathway involving the parabrachial nucleus and the diagonal band of Broca, with ultimate inhibition of VP neurons by GABAergic neurons located in the perinuclear zone adjacent to SON.

Other physiological regulators A large number of hormones and cytokines alter VP release. Since many peripherally generated hormones or cytokines cannot cross the blood–brain barrier, these agents may act indirectly by activating receptors on circumventricular organs (e.g., angiotensin II and interleukin-1 and -6). In contrast, specific transport mechanisms allow insulin to access receptors in the brain, and the lipid-soluble steroid hormones can freely permeate the blood–brain barrier. The VP neurons express insulin, estrogen, and, during chronic hyponatremia, glucocorticoid receptors. Understanding of the role of these agents in regulating VP release is incomplete, but insulin may facilitate glucose uptake by the VP neurons since glucose becomes an effective osmotic agent for stimulation of VP release in the insulin deficiency of uncontrolled diabetes mellitus.

Electrophysiology of VP neurons The pioneering observations of Harris and Douglas revealed that Ca^{2+}-dependent, stimulus-secretion coupling in the neurohypophysis resembled that observed at the neuromuscular junction. Electrophysiological studies later affirmed that it is the pattern and rate of action potential activity originating in SON and PVN neurons that is the primary determinant for peripheral VP and OT release. Action potentials propagate toward and depolarize neurohypophyseal terminals, increasing Ca^{2+} influx through voltage-gated channels to trigger the exocytosis of hormone-containing vesicles near fenestrated capillaries. A common theme for both cell types is that the patterns of electrical activity adopted lead to efficient hormone release.

Hypotension, hypovolemia, and hyperosmolality all trigger an electrical response from VP neurons referred to as phasic bursting (Figure 6). With even moderate stimulation, such as 6 h of dehydration, the majority of VP neurons adopt this pattern. Further stimulation of phasic neurons increases firing rate within the burst, and often bursts lengthen. VP neurons fire asynchronously, leading to smooth increases in VP release.

The efficiency (hormone release per action potential) of phasic bursting for VP release can be directly demonstrated using the action potential distribution of recorded bursts to time electrical stimulation of neurohypophysial axons. Phasic bursting stimuli at the same mean frequency as continuous trains release far more VP, with a maximal efficiency of ~13 Hz. This rate corresponds to that achieved within VP bursts during stimulation. Over extended periods, efficiency is related to both the high frequency of discharge at the beginning of each burst (facilitation) and recovery from fatigue during interburst intervals. Recovery during interburst intervals maximizes Ca^{2+} uptake into the terminals for successive bursts.

Although activity is instigated and modified by peripheral signals promoting VP release, phasic bursting is

Figure 6 Phasic bursting VP neuron. (a) Whole cell recording of a phasically bursting VP neuron recorded from a rat hypothalamic slice *in vitro*. The firing pattern is similar to that observed *in vivo*. Each burst of action potentials rides on a plateau potential (white dotted line) and is preceded by a slow depolarization (arrows). Black dotted line indicates the hyperpolarization of the membrane potential following each burst. (b) Rate meter histogram of the fire rate of the neuron shown in (a). The peak firing rate (solid black vertical line) occurs near burst onset. (c) The spike depolarizing afterpotential (DAP) of a VP neuron. (Left) The DAP following a single spike. (Right) After two spikes, the DAP summates and underlies a burst as the plateau potential. Adapted from Roper P, Callaway J, and Armstrong W (2004) Burst initiation and termination in phasic vasopressin cells of the rat supraoptic nucleus: A combined mathematical, electrical, and calcium fluorescence study. *Journal of Neuroscience* 24(20): 4818–4831.

an intrinsic, voltage-dependent property of the VP neuron. Thus, synaptic or osmotic stimuli must bring the VP neuron to a membrane potential of −60 to −50 mV before bursting can commence. With this depolarization, the Ca^{2+} influx from voltage-gated Ca^{2+} channels opened by action potentials triggers a Ca^{2+}- and voltage-dependent depolarizing afterpotential (DAP) (Figure 6(c)). The DAP summates with repetitive firing to form a plateau potential on which a long (10–60 s) burst discharge is maintained. The current underlying the DAP may result from either the reduction in a resting K^+ conductance or an increased conductance through nonselective cationic channels. SON neurons contain many other conductances that shape the activity of the burst, the best studied of which are voltage-gated Ca^{2+} currents; Ca^{2+}-dependent K^+ currents, which gate firing rate and shape burst length; voltage-gated K^+ currents, which influence firing rate and spike width; and a hyperpolarization activated, nonselective cation current (I_H) that contributes to plateau level.

VP neurons also synthesize the opiate peptide dynorphin and package it within VP dense core vesicles. Both dynorphin and VP are released locally (i.e., from the soma or dendrites) during neuronal activity, and both modify burst parameters through feedback. Dynorphin acts on kappa opioid receptors on VP neurons and serves to terminate bursts by direct inhibition of the DAP/plateau potential. VP gates burst firing rate through unknown mechanisms. VP receptors V1a and possibly V1b (or related variant) are located on the membrane of VP neurons, and their activation increases $[Ca^{2+}]_i$ and modulates VP neuronal activity. The action of VP depends on the neuron's current activity and serves to reinforce the most efficient firing rate for VP release.

Oxytocin

OT causes contraction of smooth muscle in the uterus and mammary glands, resulting in expulsion of the fetus during birth and milk ejection during lactation. Its release from the neurohypophysis is regulated by nerve impulses initiated by stretch of the cervix during parturition and suckling of the nipples by the infant. It also participates in fluid and electrolyte homeostasis, ejaculation, and possibly appetite regulation in males and nonpregnant or nonlactating females.

Pregnancy and parturition During pregnancy, both uterine and hypothalamic mechanisms participate in preventing premature, OT-induced, uterine contractions. Several of these mechanisms are driven by the high circulating concentrations of pregnancy-associated hormones, including estrogen, progesterone, and relaxin. Just prior to parturition, this brake on OT stimulation of uterine contractions is reversed by the regression of progesterone and relaxin secretion. In the uterus, progesterone withdrawal during late pregnancy allows estrogen to rapidly induce upregulation of OT receptor expression and tissue responsiveness. In the hypothalamus, progesterone is converted to allopregnanalone, which acts on $GABA_A$ receptors to potentiate GABAergic inhibition of OT neurons. Progesterone withdrawal at the end of pregnancy reduces this inhibitory influence on OT secretion. Progesterone-independent, opioid inhibitory mechanisms also restrain OT release during pregnancy. The site and source of this opioid inhibition remain to be completely delineated, but multiple mechanisms may participate. Activation of kappa opioid receptors on OT nerve terminals in the neurohypophysis suppresses activity-induced OT release, and activation of either mu or kappa opioid receptors inhibits the firing of OT neurons. Neurohypophyseal opioid inhibition is upregulated in midpregnancy and then downregulated near parturition. This change may reflect relaxin secretion by the corpus luteum because relaxin stimulates opioid release from the adrenal gland, which in turn can access the OT nerve in the neurohypophysis to inhibit activity-induced OT release. Activation of opioid receptors in the hypothalamus may reflect autorelease of enkephalin and/or dynorphin by the OT neurons, release of beta-endorphin by afferents from the arcuate nucleus, and/or release of enkephalin by brain stem afferents.

At parturition, stretch of the cervix activates vagal and spinal afferents to the NTS in the brain stem. In turn, the A_2 noradrenergic neurons in NTS as well as non-noradrenergic NTS neurons activate the OT neurons, inducing high-frequency bursts of action potentials that efficiently release OT. Since active OT receptors are present in the uterus at this stage of pregnancy, OT release sets up a positive feedback situation called the Ferguson reflex, in which cervical stretch stimulates OT release, which in turn stimulates uterine contraction and results in additional cervical stimulation.

Norepinephrine excites OT neurons via activation of α_1 noradrenergic receptors. Since 60% of the brain stem neurons activated during parturition are noradrenergic, this is undoubtedly an important component of the system. However, other neurotransmitters (perhaps including cotransmitters and/or neuropeptides in the catecholamine neurons such as ATP) can take over in the absence of norepinephrine since α_1 adrenergic antagonists injected into SON do not delay or impede spontaneous parturition.

Suckling OT is essential for successful lactation because milk secreted by the mammary glands must be pushed into the duct system by contraction of the smooth muscles surrounding the mammary glands. This process is called milk 'let-down' or ejection and is induced by OT. The pups of OT-deficient mice die of malnutrition because milk is not available in the mammary ducts for suckling. Suckling in turn induces OT secretion from the neurohypophysis by activating spinal afferents that synapse on noradrenergic neurons in the NTS. Suckling increases norepinephrine release in SON, and disruption of hypothalamic noradrenergic transmission prevents systemic OT release during lactation. Additional neurotransmitters required for suckling-induced OT release include histamine and glutamate. Both of these agents may be important mediators of noradrenergic stimulation. Histaminergic innervation of the OT neurons arises from the tuberomammillary nucleus. Histamine alters the sensitivity of SON neurons to norepinephrine, and blockade of H1 histamine receptors prevents suckling-induced release of OT. Glutamatergic afferents to the OT neurons include the osmoreceptive pathways described previously as well as local glutamatergic neurons in the perinuclear regions surrounding SON. Central blockade of either glutamate (AMPA) receptors or α_1 adrenergic receptors blocks milk ejection, but the precise location of antagonist actions is unknown. Norepinephrine has been shown to activate magnocellular neurons directly as well as via presynaptic actions on glutamatergic terminals. Thus, glutamate may relay suckling-induced noradrenergic signals to the OT neurons.

Milk let-down can also occur in response to the sight, sound, and/or smell of the infant. It is likely that this effect reflects innervation of the OT neurons by afferents from the amygdala and olfactory bulb. Reciprocal oxytocinergic innervation of these brain regions has been implicated in development of maternal behaviors required for successful nurturing of the young.

Homeostatic regulation of OT release In addition to the specialized reflexes that result in bolus release of OT during parturition and suckling, OT is released with VP in response to hypertonicity and hypovolemia. Thus, the pathways described previously for osmotic and hemodynamic regulation of VP secretion also innervate the magnocellular OT neurons in SON and PVN. This is physiologically relevant because OT

induces natriuresis (renal sodium excretion) and therefore contributes to maintenance of fluid and electrolyte homeostasis. The natriuretic action of OT reflects both direct actions of OT on the kidney and its ability to stimulate release of atrial natriuretic peptide from the heart. During pregnancy, relaxin activates osmosensitive neurons in SFO and OVLT. This, in conjunction with high circulating estrogen, is thought to result in resetting of the threshold for osmotic stimulation of thirst as well as VP and OT secretion. The resultant increase in OT-induced natriuresis and VP-induced water retention contributes to the plasma volume expansion required to meet the increased vascular needs of the fetus.

OT release is also stimulated by peripheral administration of cholecystokinin (CCK) or CCK released by gastric distension. This action of peripheral CCK is mediated via activation of brain stem pathways perhaps involving the A_2 noradrenergic pathways and is highly selective for the OT neurons. It has been used as a tool for experimental identification of OT neurons but may also be indicative of a role for OT in appetite regulation.

During pregnancy, OT secretion is relatively insensitive to the homeostatic signals (e.g., osmolality and gastric distention) that stimulate its secretion in males and in nonpregnant females. During lactation, the system is able to respond effectively to both types of signals due to the difference in the response pattern: Homeostatic signals increase the firing rate of OT neurons but maintain a relatively uniform firing frequency which induces a sustained elevation in OT secretion, whereas suckling evokes synchronized, high-frequency burst activity inducing the bolus pulses of OT secretion required for milk ejection.

Ejaculation Plasma OT is increased during sexual arousal and orgasm in both men and women. In males, OT contracts the reproductive tracts, which appears to aid in sperm release and transport. The central pathways for this stimulus for OT release have not been fully elucidated, although it is known that electrical stimulation of the rat dorsal penile nerve excites PVN and SON OT cells, and penile erection is attenuated by lesions of the catecholaminergic inputs to the hypothalamus.

Electrophysiology of OT neurons OT neurons show two different modes of enhanced activity, depending on the stimulus. In response to many of the same stimuli releasing VP (e.g., hypotension and hyperosmolality), OT release is associated with a continuous firing pattern of OT neurons, the rate of which reflects stimulus intensity. To these sustained stimuli related to fluid balance, OT's capacity as a natriuretic agent may be more relevant than its actions on smooth muscle.

In most mammalian species, OT release during suckling is episodic, and it is during lactation in the rat that OT neuronal activity has been most intensely studied. In response to suckling, OT neurons fire in a bursting mode that is quite different from the phasic bursting of VP neurons (Figure 7). First, OT bursts are synchronous across OT neurons in the PVN and SON, and this firing pattern leads to pulsatile OT release that maximizes discrete milk ejections at the mammary gland. Second, OT bursts are much shorter and more intense than those of VP neurons, firing for ~4 s at rates averaging 50 Hz. Third, the interburst intervals are long, from 5 to 15 min. These intervals are relatively constant within a period of suckling.

Figure 7 OT neurons firing during lactation. The top trace shows the intramammary pressure changes associated with synchronous bursts of OT neurons in a lactating female rat, and beneath this are two sets of traces for neuronal firing recorded extracellularly – one cell from the PVN and one from a simultaneously recorded SON neuron. For each neuron, the rate meter (in Hz) and a pen recording registering each action potential are shown. The numbers associated with the rate meters indicate the number of spikes in a milk-ejection burst. The numbers at the bottom of the figure indicate the delay in minutes since the previous burst. Adapted from Richard P, Moos F, and Freund-Mercier M-J (1988) Bursting activity in oxytocin cells. In: Leng G (ed.) *Pulsatility in Neuroendocrine Systems*, pp. 75–97. Boca Raton, FL: CRC Press.

The bolus release of OT strongly increases intramammary pressure, signaling to the attached pups that milk is being extruded, and thereby stimulating a stereotypic 'stretch reflex' as each pup sucks vigorously to remove milk. Although recording studies are uncommon, bursting can appear during parturition, when OT promotes uterine contraction. However, these bursts may be triggered by irregular periods of cervical dilation, a strong afferent stimulus for OT release.

Studies *in vivo* and *in vitro* suggest that excitatory glutamatergic input is critical for milk ejection and thus burst firing. As mentioned previously, blockade of AMPA receptors blocks milk ejection *in vivo*. *In vitro*, OT cell bursting reminiscent of that observed during milk ejection is facilitated by OT, an effect that is totally dependent on glutamatergic excitatory neurotransmission.

Of great interest is the role that OT plays in regulating its own release. OT neurons possess OT receptors such as those found in the myoepithelium of mammary gland and in uterine smooth muscle. These receptors sense somatodendritically released OT within the SON and PVN in response to suckling. This local release recruits additional neurons into the synchronous burst discharges and increases burst amplitude. Blockade of brain OT receptors severely disrupts milk ejection, decreasing burst amplitude and frequency. Although these autoreceptors are undoubtedly important, the level at which OT produces these effects is not known. The autoreceptors are linked to increases in intracellular Ca^{2+} through internal stores. However, although activation of OT receptors on other neuronal types (e.g., vagal motor neurons) results in membrane depolarization through a persistent Na^{+} current, such an action has yet to be identified in the SON and PVN. This action is G-protein coupled but independent of intracellular Ca^{2+} mobilization, and it may work through cAMP and phospholipase C second messengers. *In vitro* studies further suggest that OT modulates excitatory inputs to OT neurons since OT applications can increase the frequency of bursts driven by volleys of excitatory postsynaptic potentials as well as burst amplitude. Presynaptic inhibitory actions of OT have also been described, but data suggest these may be mediated through OT-induced cannabinoid release subsequent to autoreceptor activation on SON and PVN neurons.

Introduction

Neuroimaging is the discipline that deals with the *in vivo* depiction of anatomy and function of the central nervous system (CNS) in health and disease. The term 'neuroimaging' is more comprehensive than the older term of neuroradiology; although in the past, neuroimaging was considered the domain of radiologists with a specific interest in the nervous system, the participants in this rapidly changing field now come from diverse backgrounds. Contributors exist in all areas in the neurosciences, including basic scientists, neurologists, neurosurgeons, psychologists, psychiatrists, physicists, chemists, and clinicians in radiology and nuclear medicine. It is important to realize that neuroimaging is a dynamic and evolving field. The developments that have occurred in the past decade could not have been predicted when the first edition of this Encyclopedia was published, and we can expect that in the future some of what we currently regard as essential elements of neuroimaging will be surpassed.

In 1895, a year after Roentgen discovered the X-ray and thus the medical specialty of radiology, the penetrating ability of this new ray was used to localize bullets in the calvarium. It therefore indirectly provided the first insights into the morphology of the living brain. However, the skull, vertebral column, and theca remained formidable barriers to direct visualization of the brain and spinal cord for over 75 years. Instead, the anatomy of the CNS was inferred from indirect observations, such as bony erosion on plain skull radiograph, displacement and distortion of the ventricular system (via pneumoencephalography) and the arteries and veins (via angiography), and the outline of the spinal cord (via myelography). Confirmation of the neuroscientists' diagnosis during life was only possible at neuropathologic examination of the brain or spinal cord after death. It was not until 1972 when Hounsfield introduced X-ray computed tomography (CT) that a true representation of the brain itself was realized. CT revolutionized the neurosciences, because for the first time a noninvasive modality could demonstrate the ventricular system, separate gray from white matter, outline the deep nuclei, and recognize pathologic changes in the cerebral parenchyma. CT was remarkable not just for its ability to display anatomic detail, but more generally, because it introduced the fundamentally new technique of 'true' tomography – the imaging of slices – through mathematic reconstruction of data obtained from multiple projections. Computers enabled this advance and also aided the development of the other major three-dimensional imaging modalities in neuroimaging – emission computed tomography (ECT) in its two forms (positron emission tomography [PET] and single photon emission computed tomography [SPECT]) and magnetic resonance (MR) imaging. Although these modalities provide different imaging data, they have the common unifying thread of a computed mathematic reconstruction of the final image (Figure 1).

The basis of all reconstruction techniques is the synthesis of a three-dimensional image from a series of two-dimensional images (projections) taken at various angles around the subject. Thus although the image value of each small volume element within the object cannot usually be determined directly, it can be computed by making a series of measurements at many angles with detectors placed outside the patient. In CT, for example, a slab of tissue is penetrated by a narrow X-ray beam, which is itself composed of photons, that originates from a large number of angles. Antipodal detectors record the multiple transmissions so that an array of point-by-point relative absorption coefficients can be calculated and techniques such as filtered back projection and Fourier analysis are used to make the computation. In MR imaging a somewhat different approach is used, as gradients of the magnetic field permit a more direct evaluation of the Fourier coefficient of each volume element; however, Fourier techniques are still used to reconstruct the full image. Regardless of the algorithm, the reconstructed image is a quantitative measure of some property of the tissue. In CT, the tissue property is the X-ray attenuation coefficient. PET and SPECT techniques measure the tissue concentration of a radioisotope (tracer) in raw counts or nanocuries (nCi) per milliliter after the tracer has been injected into the patient in trace quantities and for MR imaging the property being measured is the transverse magnetization density.

Computed Tomography

A CT scanner measures the linear attenuation or reduction in the X-ray beam as the beam passes

Figure 1 Sequence of events in neuroimaging.

Figure 2 Relationship of X-ray beam, the plane of tissue imaged, and the subject in computed tomography.

through the body (Figure 2) X-ray attenuation is made up of two physical components: (1) Compton scattering, which depends on electron density, and (2) photoelectric absorption, which depends on atomic number and density. Collimators (devices for producing a beam of parallel X-rays) are used to reduce the amount of scattered photons. The unit of X-ray attenuation coefficient is the Hounsfield unit and it is defined as 1/1000 of the attenuation coefficient of water, assuming the same X-ray energy. The intensity of each exiting X-ray beam is measured and transformed into an electronic signal that is then quantified, digitized, reconstructed, and displayed. To a first approximation, a CT scan may be thought of a density image. Limitations of CT include the associated patient radiation exposure, because X-rays are ionizing radiation, artifacts caused by beam hardening, patient motion and partial volume effects, and inferior anatomic detail for gray and white matter when compared with MR imaging. Beam hardening occurs particularly in regions adjacent to thick dense bone such as the skull base or in the oropharynx caused by dental fillings. It occurs because average energy of the exiting X-ray is greater than that entering the patient as a result of absorption of the lower energy X-ray beam by bone. Artifacts induced by beam hardening render the interpretation of structures in the middle and posterior cranial fossae problematic. Helical or spiral CT involves translation of the patient through the scanning gantry while the X-ray source rotates simultaneously so that continuous data acquisition exists throughout the volume of interest and has now become the standard in most medical imaging departments (Figure 3). The X-ray traces a helix, akin to a spiral staircase, on the patient's surface. Spiral CT has distinct advantages in whole-body scanning, where respiratory misregistration artifacts are minimized and the overlapping image planes offer the potential for true three-dimensional image displays. In the brain the newer multi-slice tomographs reduce movement artifacts because of shorter acquisition times and allow for dynamic data acquisition (CT angiography) and three-dimensional data reconstruction.

Cerebral CT is still widely used for day-to-day management of patients with neurologic and neurosurgical conditions. It can rapidly identify cerebral edema/atrophy, hydrocephalus, cerebral infarction, mass lesions, and extravasated blood from sub-arachnoid and intra-cerebral hemorrhage. The integrity blood–brain barrier (BBB) is evaluated after the intravenous injection of iodinated contrast media. Although the patterns of enhancement that are associated with tumors, cerebral infarction, infection, and inflammation differ slightly, CT contrast enhancement is relatively nonspecific. However, CT is without peer in the evaluation of the bony skull. Further, in the acute stroke setting, the wider availability of helical CT

Figure 3 Helical computed tomography shows relationship between patient translation (purple arrow) and simultaneous movement of X-ray source (red arrow).

has enabled the acute assessment of patency of the major cerebral vessels – the extracranial and intracranial carotid, distal vertebral, basilar, and proximal middle cerebral arteries – through dynamic data acquisition after the rapid intravenous injection of contrast (CT angiography). However, to a great extent, if MR imaging is available, it is the method of choice used by neuroscience clinicians because of its superior depiction of anatomy and physiology in the supra- and infratentorial compartments, its ability to evaluate the integrity of the BBB with para-magnetic contrast agents, and its lack of ionizing radiation.

Emission Computed Tomography

Emission computed tomography (i.e., PET, SPECT) is the term for functional imaging methods that use injected radioisotopes and combine the principles of the tracer kinetic method and tomographic image reconstruction. In the tracer method, a radiolabeled, biologically active compound (the tracer) is injected into a subject in minute or tracer quantities. The tracer then participates in, without perturbing, a biochemical process. The tomography or scanner detects the tissue concentration of the tracer. A mathematic model can then be derived to describe the kinetics of the process, and in some instances it is possible to convert the raw counts to a unit of physiologic function such as the cerebral metabolic rate for glucose or cerebral blood flow. A number of fundamental differences exist between PET and SPECT. The instrumentation and also the radioisotopes that are used differ. Table 1 lists a number of common PET and SPECT tracers, the half-lives of the radioisotopes, and the biologic parameters that can be measured. The list is not exhaustive but noteworthy in that the radioactive isotopes of some of the most important elements in biology happen to be positron emitters (^{15}O, ^{13}N, ^{11}C). These PET isotopes have very short half-lives and are produced in cyclotrons, which generally means that for all but ^{18}F the cyclotron must be in close proximity to the PET scanner. SPECT isotopes are much longer lived and may be transported long distances. Most commonly used SPECT radioisotopes are produced in reactors, but ^{123}I, ^{68}Ga, and ^{201}Tl are produced by cyclotrons.

In PET the unstable positron emitters decay to a stable state by emitting a positron (positive electron) from the nucleus. The positron travels a small distance (1–2 mm) in tissue before colliding with a surrounding electron and annihilation takes place. The masses of the positron and electron are converted to energy in the form of two high-energy photons or gamma rays that are emitted 180 degrees apart (Figure 4). The simultaneous production of annihilation photons in opposite directions and their coincident detection by the PET scanner are the fundamental bases for the localization of the positron emitter in tissue. The PET scanner has multiple rings of detectors that are composed of inorganic crystals (e.g., bismuth germanate), which scintillate when struck by a photon. The detectors are connected to photomultiplier tubes and the light energy is converted into a digital signal to provide a three-dimensional distribution of the tracer. The physics of PET allow the measurement of scattered and attenuated photons

Table 1 Some PET and SPECT radiotracers in the neurosciences

Technique	*Radiotracer/neuroreceptor ligand*	*Radioisotope/half-life*	*Biologic parameter/receptor*
PET			
	[^{18}F]fluorodeoxyglucose (FDG)	^{18}F ~ 108 min	Glucose metabolism
	[^{18}F]-6-flurodopa		Dopamine
	[^{11}C]-methionine	^{11}C / 20 min	Amino acid uptake
	[^{11}C]-raclopride		Dopamine
	[^{11}C]-nomifensine		Catecholamine re-uptake
	[^{11}C]-flumazenil		Central benzodiazepine
	[^{11}C]-PK 11195		Peripheral benzodiazepine
	^{15}O-water	^{15}O/~ 2 min	Cerebral blood flow
SPECT			
	99 m Tc-hexamethyl propylene amine oxime (HMPAO)	99 mTc / 6 h	Cerebral blood flow
	^{201}Thallium	^{201}T1 / 73.1 h	+ analog-cellularity
		^{133}Xe xt-raise: 3.0pt'	Cerebral blood flow
	^{123}I-iodoamphetamine (IMP)	^{123}I ~ 13 h	Cerebral blood flow
	^{123}I-methyl tyrosine (IMT)		Amino acid transport
	^{123}I-iodoamphetamine (IMP)		Cerebral blood flow
	^{123}I-QNB		Muscarinic cholinergic
	^{123}I-iodobenzamide (IBZM)		Dopamine
	^{123}I-iomazenil		Central benzodiazepine
	^{123}I-iododexetimide (IDEX)		Muscarinic cholinergic

Figure 4 (a) Depiction of positron emission and co-incidence detection in positron emission tomography (PET). (b) Steps in image production in PET. Center panel shows line of response used to produce image.

so that quantitative measurement of a particular physiologic process is possible. In SPECT, single photons are detected by rotating gamma cameras with a single large crystal detector (Figure 5). Multi-detector gamma cameras (double- and triple-headed cameras) have enabled improved resolution through the detection of a greater proportion of unscattered photons. However, scatter and attenuation correction are not routine in SPECT, which limits the provision of quantitative data. Instead, ratios of regional counts within a study are used to compare data. The resolution in PET is also superior to that in SPECT. The latest generation PET scanners have resolution in the order of 2–3 mm full-width at half-maximum (FWHM), whereas for triple-headed SPECT cameras, resolution approximates 8–10 mm FWHM compared with 14–17 mm FWHM for single-head systems and 7–8 mm FWHM for ring-detector imaging devices, similar to PET scanners. However, these devices are not widely available. Resolution is determined by a number of factors, including (1) the type of detectors, (2) the distance a positron (for PET) travels in tissue before annihilation, (3) random and scatter coincidences, and (4) reconstruction algorithms. In an exciting new development, a new and more efficient detector crystal called lutetium oxyorthosilicate (LSO) with a shorter fluorescence time has been incorporated into PET scanners. This detector material has significantly shortened the acquisition time for neurologic PET scans, but in addition it has been placed in PET scanners that have been coupled to CT scanners, so called PET-CT. These devices are now replacing stand-alone PET scanners as the norm for clinical PET devices. They offer the added advantage of perfectly registered anatomic (CT) and functional (PET) data. The CT scanners are helical devices that

Figure 5 (a) Depiction of single-photon emission and detection in single-photon emission computed tomography (SPECT). (b) Steps in image production in SPECT. Center panel shows line of response used to produce image.

provide the means of attenuation correction for the PET, as well as the anatomic information. These combined devices offer advantages for selective PET receptor experiments. It is anticipated that the next generation of PET scanners will approach the theoretic finite in plane spatial resolution in PET of less than 2 mm.

Overall, PET has proved more fruitful than SPECT in the neurosciences by virtue of its superior resolution and ability to quantify *in vivo* biochemical processes. PET has been used in the evaluation of cerebral blood flow, blood volume, oxygen use and metabolism, glucose metabolism, amino acid transport, and metabolism and protein synthesis. Neuroreceptor ligands for the dopaminergic, opiate, benzodiazepine, cholinergic, and serotonergic systems have been developed and used in humans. In recent years much effort has been directed to brain mapping with ^{15}O-water, where localization of cerebral function is deduced from changes in local cerebral blood flow that are induced by the presentation of a paradigm (e.g., a complex image) to a normal subject. In some instances these data have confirmed findings in nonhuman primates, but in other instances these data have provided unique insights into the functioning of the brain. In the clinical arena the most commonly used PET isotope is FDG (see Table 1), and through the evaluation of cerebral glucose metabolism PET is used to localize epileptic foci in patients with refractory epilepsy, separate low-grade from high-grade brain tumors, differentiate the effects of treatment from recurrent tumor, and distinguish Alzheimer's disease from other types of dementia and neurodegenerative conditions (such as multiple system atrophy, corticobasal degeneration, Huntington's disease, acquired immunodeficiency syndrome (AIDS), dementia, and progressive supranuclear palsy). A reduction in parietal lobe glucose metabolism has been described in individuals at high risk for developing familial dementia before the onset of symptoms. In this scenario, PET will provide a method to both identify those at risk and evaluate new therapies in the dementias. Early observations also indicate that PET neuroreceptor studies will assist us in the management of extrapyramidal disorders such as Parkinson's disease, other neurodegenerative conditions including dementia, and the refractory epilepsies.

Magnetic Resonance Imaging

The nuclear magnetic resonance phenomenon was originally described in 1946. It results from the magnetic properties of some atomic nuclei, particularly the hydrogen nuclei in water molecules. Hydrogen nuclei in the body behave like tiny bar magnets when placed in a strong magnetic field. Just as bar magnets with north and south poles align themselves with the external magnetic field, so too do the hydrogen nuclei in the body when placed in the strong magnetic field of an MR scanner. This orientation can be perturbed by the application of electromagnetic energy in the form of radiofrequency (RF) pulses. An RF pulse applied at right angles to the static field around a subject changes the orientation of the nuclear spins of the hydrogen molecules and increases their energy state. When the field is turned off, the nuclei return to their original state with the emission of energy at the same frequency as that of the applied RF (resonance or Larmor frequency) pulses. The Larmor frequency varies significantly from element to element and even for different isotopes of the same element. The emitted radiofrequency signal can be detected in a receiver coil placed around the subject's head. The frequency of the signal depends upon the strength of the magnetic field, the physicochemical properties of the tissue, and the manipulation of the applied RF pulses. By varying the strength of the field spatially, the resulting signal reflects the magnetization of water molecules at each point in space, and with proper spatial encoding these signals can be reconstructed to yield images with high contrast and spatial resolution and orientated in axial, coronal, or sagittal planes.

Many factors affect the MR image: excited proton density, the longitudinal (spin-lattice) relaxation time T1, the transverse (spin-spin) relaxation time T2, diffusion, and flow. Differences in tissue relaxation times are the main determinants of image contrast. Therefore *a priori* knowledge of the relaxation behavior of different tissues is important in the selection of the proper RF pulse sequence for optimal images production. RF pulses, which tilt the nuclear spins 90 degrees or 180 degrees, may be injected at various times, with various sequences and frequencies. The terms *TE-echo time*, TR-repetition time, and T1-inversion time are used to indicate some of these parameters. In addition, the signal-to-noise ratio is favorably affected by the field strength and surface coils. It was apparent, very early in the development of MR imaging, that the image quality surpassed that of CT (Figure 6). MR imaging was able to demonstrate small structures such as the substantia nigra, the red nucleus and, in selected cases, the various thalamic nuclei separated by strips of myelin. In the spinal cord, the H-shaped central distribution of gray matter was delineated. Pathologic lesions were also much more easily identified, because they are often characterized by long T1 and T2. In multiple sclerosis, MR imaging provided a marked increase in

Figure 6 Patient study. Thirty-five-year-old woman with multiple sclerosis and massive plaque of demyelination in corpus callosum imaged with computed tomography and magnetic resonance (MR) imaging. MR images demonstrate superior anatomic definition but also the inability to separate edema from inflammation on T2-weighted and proton density images.

sensitivity for identifying plaques of demyelination and insights into the activity of the disease by the demonstration of rapid appearance and disappearance of asymptomatic plaques. Mass lesions with their associated edema were easily shown, and the natural history of small cavernous hemangiomas was documented. Examination of the spinal cord was simpler – tumors, syrinxes, cord compression from discs and tumors, and atrophy, as well as congenital abnormalities such as tethered cord were easily

recognized. Imaging the posterior and middle cranial fossae was easier because of the absence of beam-hardening artifacts.

However, although MR imaging offered greater sensitivity when compared with CT, it had poor specificity. Tumors, cerebral infarctions, some hematomas, foci of demyelination, and regions of edema all gave similar signals on T2-weighted images. Therefore, in an effort to improve this deficiency together with a desire to explore and push the technology to its limits, a bewildering number of advances have been made in the past few years. There have been improvements in (1) instrumentation: surface coils and high magnetic field strength (4.0 Tesla) devices; (2) software: new pulse sequences/protocols with acronyms such as FLASH, FLAIR, MPRAGE, magnetization transfer ratios, transverse magnetization decay; (3) contrast media; (4) pulse sequences to image blood flow and hence MR angiography (MRA); and (5) MR techniques known as functional MR imaging. However, before we discuss functional MR imaging methods, it is important to mention that MRA, although it has not yet replaced digital subtraction angiography for the assessment of the intracranial and extracranial arterial and venous circulation, is a useful clinical adjunct and can provide valuable information for clinical management.

Functional Magnetic Resonance Imaging

Functional MR imaging refers to techniques that provide data about aspects of metabolism, be it tissue metabolite concentrations, perfusion/diffusion, and blood flow rather than pure anatomy (which forms the basis of routine clinical MR imaging). The term encompasses MR spectroscopy and those techniques that rely on the change in blood oxygenation levels to provide an indirect image of neuronal activity that is referred to in some circles as *functional MR imaging* (fMRI). This is an exciting area of development, because it means that functional data, formerly the exclusive domain of PET and SPECT, can now be obtained with MR scanners without the associated ionizing radiation.

In magnetic resonance spectroscopy (MRS), signals are obtained from nuclei that are constituents of molecules other than water. These signals are generated by nonradioactive nuclei that are parts of other solutes or metabolites, but these signals are much weaker than the signals arising from water. The solutes that produce them occur in concentrations of 0.5 mM. Non-water ^{1}H, ^{31}P, and ^{13}C are the most important nuclei in MRS. The signals are analyzed and the radio frequencies emitted by the sample of interest appear as peaks on a plot of signal intensity against signal frequency, thus producing an NMR spectrum. The horizontal or frequency axes are normalized to the frequency of a strong signal of known origin and the location of peaks are given as parts per million (ppm) relative to the known signal (Figure 7). The signal strength (the vertical axis) is proportional to a number of factors, including the number of nuclei in the tissue volume being studied. Signals from different isotopes are distinguishable, because they occur at different frequencies in any given magnetic field, nuclear signals from different solutes can also be separated from one another by the property of chemical shift. 'Chemical shift' refers to the fact that within a molecule containing magnetic nuclei, the electron clouds in the chemical bonds surrounding the nuclei change the local magnetic field so that nuclei of the same species spin at different frequencies.

Figure 7 ^{1}H-magnetic resonance spectroscopy imaging spectra show distribution of metabolites (in ppm) from a slab of tissue.

The influence of these weak signals is that (1) MRS has poorer sensitivity and resolution when compared with clinical MR imaging, (2) some solutes cannot be measured with MRS (e.g., virtually all neurotransmitters with the exception of glutamate, glutamine, and GABA are beyond detection). Further, molecular motion is required for a solute to be detected with MRS, and most macromolecules (myelin, proteins, nucleosides, phospholipids) are inaccessible because of their limited mobility. Both ^{31}P and ^{1}H-MRS have been used in the neurosciences, but only the application of ^{1}H-MRS (or proton-MRS), which has an inherently stronger signal, better resolution, and greater sensitivity than ^{31}P, is discussed here. In proton-MRS, four metabolites are of interest: (1) *N*-acetyl-aspartate (NAA), (2) choline-containing compounds (Cho), (3) creatine-containing compounds (Cre), and (4) lactate (Lac) (Table 2). Initial ^{1}H-MRS studies involved acquisition of data from single voxels of varying sizes, so effectively only a small region of the brain could be sampled at once. Gradient-based phase-encoding techniques allowed the simultaneous acquisition of data from multiple voxels in a single tissue slab; therefore, instead of interpreting an NMR spectrum, an image of the topographic distribution of metabolites, or spectroscopic imaging, was produced. Further pulse sequence enhancements led to the development of multi-slice spectroscopic imaging (Figure 8).

Preliminary data suggest that ^{1}H-MRS imaging can be used for the grading of brain tumors, the detection of malignant degeneration in low-grade tumors, the localization of seizure foci in refractory epilepsy, the evaluation of the dementias, and the differentiation of cerebral abscesses from other enhancing lesions. However, proton MRS has some limitations. It places more stringent demands upon the quality and strength of the magnetic field than does clinical imaging. Clinical imaging can be performed quite satisfactorily at 0.5 Tesla (T), but stronger fields are needed for MRS. Most current MRS work is performed at 1.5 to 2.0 T, but increasingly 3.0 and 4.0 T devices that provide better metabolite delineation are being used. Good magnetic field homogeneity is critical for MRS, and poor field homogeneity manifests as difficulty in resolving signals from one another and from noise. Most current MR scanners are sold with spectroscopy capabilities; although this capability is for single voxel examinations, proton spectroscopic imaging should be available on clinical MR scanners within a few years.

'fMRI' refers to a number of methods where gradient-recalled echo (GRE) techniques and sub-second echoplanar imaging (EPI) are used to identify aspects of physiologic function in the nervous system. For instance, these MR techniques can identify diffusion of water in the ischemic brain and neuronal activity in normal subjects akin to the ^{15}O-water activation methodologies used with PET. The advantage of these techniques in the experimental setting is that no ionizing radiation is involved; therefore, experiments can be repeated indefinitely in the one subject; the high spatial resolution of MR can be used so that no need exists for subsequent registration of the functional data to anatomy, because it is already provided by the MR scan.

'Diffusion MR imaging' refers to the ability of MR to detect and measure water diffusion in tissue and hence information about tissue composition, microstructure, and architectural organization. A term such as the apparent diffusion coefficient (ADC) is used to describe diffusion in complex media such as the brain and is defined as the ratio of mean-squared displacement and the diffusion time. Diffusion-weighted images (DWIs) are obtained by incorporating diffusion gradient pulses within a conventional MR sequence. A variation of this technique to allow for the measurement of diffusion in tissues oriented in a variety of direction such as cerebral white matter is called diffusion tensor imaging. The major clinical application of DWI at present is in the evaluation of hyperacute (minutes to hours after the ictus) cerebral ischemia. It can separate acute ischemia from old

Table 2 Metabolites seen with ^{1}H-MRS at TE 272 ms

Metabolite	*Frequency (ppm)*	*Site and function*
N-acetyl-aspartate (NAA)	2.02	Neuronal; possible storage form of aspartate; possibly involved in lipid synthesis and regulation of protein synthesis
Choline (Cho)	3.20	Cytosol; includes phosphorylcholine, glycerophosphoryl choline, and choline; components of phospholipid metabolism; role in cell membrane turnover
Creatine (Cre)	3.93, 3.04	Cytosol; reserves of high- and low-energy phosphates and used for cellular synthetic and transport functions
Lactate (Lac)	1.33	Cytosol; terminal metabolite of glycolysis and initial substrate for mitochondrial tricarboxylic acid cycle

infarction but also identify regions of ischemia that are not yet apparent on conventional T2-weighted images that offers tremendous potential for active intervention to limit the extent of cerebral infarction. fMRI techniques are based on the magnetic difference between deoxyhemoglobin and oxyhemoglobin and the small increase in signal intensity, which has been ascribed to a local change in blood oxygenation that results from neuronal activity. During neuronal activity an increase takes place in local cerebral blood flow and metabolism, a local decrease in the amount of deoxyhemoglobin, and an increase in signal intensity. Although other factors exist, such as inflow, effects from draining venules, hematocrit, oxygenation saturation, and cerebral blood volume (which may also contribute to the signal change a number of comparative studies with ^{15}O-PET), they suggest that both techniques image the same process. Increasingly fMRI is being used in the clinical context to localize eloquent cortex adjacent to brain lesions to help guide the neurosurgeon.

Figure 8 Single slice from ^{1}H-magnetic resonance spectroscopy imaging study in patient with a brain tumor. Individual images indicate maps of metabolite distribution in the one slice plus the anatomic magnetic resonance and positron emission tomography (PET) images of glucose metabolism.

Summary

The advances in neuroimaging in the past decade could not have been predicted in the late 1980s, and major strides will also be made in the next few years. Apart from the rapid pace of technologic developments there has also been the realization that many of the current imaging methods are complementary. Although MR imaging is the single most versatile modality, PET, SPECT, and CT still provide important unique data that are indispensable to the neurosciences for research and patient management. Just as algorithms exist to merge and use these data (Figure 9), contributions to neuroimaging come

Figure 9 Twelve-year-old boy with refractory frontal lobe epilepsy. Volume rendered magnetic resonance (MR), positron emission tomography (PET), and fused magnetic resonance spectroscopy (MRS)-PET data. Images show a large area of reduced glucose metabolism in region of mesial frontal and dorsolateral prefrontal cortex that is responsible for seizure generation. Minimal change seen in MR image. In addition, crossed cerebellar hypometabolism (PET) and atrophy (MR) from the longstanding frontal lobe heterotopia are seen.

from diverse investigators. PET and CT are being combined in the clinical setting; in the author's opinion, continued collaboration across the imaging specialties will increase our understanding of the nervous system and improve the care of those afflicted with neurologic disorders. The PET-CT and the PET-MR animal scanners provide a window to the next phase of imaging development where unique functional and anatomic datasets are obtained simultaneously.

The Immune-Neuroendocrine System: The Evolutionary Perspective

The immune system, consisting of innate and adaptive branches, acts to recognize and cope with a variety of stressors, including physical, emotional, chemical, and biological agents. The evolutionary perspective indicates that this system is a part of a larger network involving the neuroendocrine circuit, termed the immune-neuroendocrine suprasystem, which is able to integrate immunity, stress response, and inflammation. The major characteristic is that this suprasystem is conserved with variations and increased complexity, from invertebrates to vertebrates, and a pool of well-known molecules (pro-opiomelanocortin-derived peptides, cytokines, biogenic amines, glucocorticoids, and nitric oxide) are used for intra- and intersystem communication. The main cellular actor of this network is the macrophage, which produces all of the previously mentioned mediators.

In a number of low eukaryotes, such as yeast and worm, the ability to cope with stressors is provided by a defense network including superoxide dismutase and catalase (free radical scavenger enzymes), heat shock proteins and other chaperones, DNA repair genes, and intracellular signaling molecules (e.g., H-RAS). A study on *Caenorhabditis elegans*, a favorite model for the genetic investigation of the physiology and developmental biology of multicellular organisms, showed that the resistance to pathogen is mediated by a Toll/interleukin-1 receptor domain adaptor protein and a conserved p38 mitogen-activated protein kinase family (PMK)-1 pathway. Moreover, this circuit is involved in mediating resistance to osmotic stress, in addition to mediating immune signaling.

In invertebrates (mollusks, insects, and annelids), immune and neuroendocrine functions are performed by a cell type called immunocyte, the ancestor of macrophage, that can be considered an 'immune-mobile brain.' This phagocyting cell expresses molecules such as adrenocorticotropin hormone (ACTH), corticotropin-releasing hormone (CRH), interleukin-like IL-1α, -1β, -2, and -6, and tumor necrosis factor (TNF)-α that are able to affect migration and increase phagocyte activity against pathogens. Moreover, immunocytes express a NO synthase-like molecule producing NO, which provokes the clumping of bacteria around them and their subsequent killing. Pathogen recognition in *Drosophila melanogaster* is mediated by different molecules, including a member of the immunoglobulin superfamily which is diversified by alternate splicing. This molecule is called Dscam, the homolog of Down syndrome cell adhesion molecule, and its isoforms are expressed in immune tissues as membrane and soluble proteins.

During evolution, the old molecular and cellular effectors merged with the new sophisticated recognition system, the adaptive clonotypical immunity, to face the increasing complexity of the organisms, which required a more sophisticated type of circuitry and recognition. Specialized function for the defense of the organism occurred in jawed fish, in which the thymus, the B and T lymphocytes, and the major histocompatibility complex (MHC) appeared in order to improve recognition of external molecules, on the one hand, and avoid self-destruction, on the other hand. The thymus, a neuroendocrine organ, was built up with cellular and molecular components present in invertebrates, and it is able to perform a local immune and stress response. Accordingly, the appearance of a new organ such as the thymus can be envisaged as an example of tinkering – that is, the combinatorial reutilization of preexisting materials, a strategy largely used in evolution.

In mammalian, immune and neuroendocrine responses are bidirectionally regulated through more specialized tissues and organs, where neuropeptides and cytokines represent the signaling molecules responsible for chemical information. In particular, in the central nervous system (CNS), the hypothalamus integrates information from physical (e.g., trauma and infection) and emotional stimuli (e.g., bereavement) and, in response to stress, releases CRH from the paraventricular nucleus, which acts on the pituitary gland to induce the release of ACTH to stimulate the adrenal gland and the production of glucocorticoids (cortisol) and dehydroepiandrosterone (DHEA) from the cortex. The adrenal gland is also regulated by the sympathetic nervous system, secreting catecholamines in response to acetylcholine release from the fibers innervating adrenal medulla. Catecholamines and glucocorticoids mediate the 'fight-or-flight' response to stress but at the same time induce suppression of the majority of immune functions. The principal mechanism of glucocorticoids is the downregulation of pro-inflammatory cytokine synthesis and the inhibition of enzymes such as cyclooxegenase-2 (COX-2). Moreover, they affect cell-mediated immune function,

suppressing natural killer (NK) cell cytotoxicity and neutrophil chemotaxis. By contrast, DHEA is primarily immune enhancing and counterbalances the potentially detrimental effect of long-term stimulation of the hypothalamic–pituitary–adrenal (HPA) gland axis. In particular, DHEA improves NK cell number and cytotoxicity and induces superoxide generation in neutrophils. As an example of this connection between the CNS and the immune system, we studied the effect of an emotional stimuli, such as bereavement, on the immune system and found functional alterations of immune parameters, such as responsiveness of peripheral blood lymphocytes to mitogens. In particular, despite a normal number of circulating lymphocyte subsets, the functional activity of NK cells was markedly reduced. Moreover, changes in the intracellular concentration of β-endorphin in peripheral blood mononuclear cells correlated with anxiety and depression scores. Other distress-generating events (e.g., divorce, caring for a relative affected by Alzheimer's disease, and unemployment) are associated with alterations in both cellular and humoral immune response and enhanced risk of developing infectious disease.

Evidence also supports the idea that information can flow from the immune system to the CNS – for example, the innervation of the immune system and organs, the production of neuropeptides by cells of the immune system, and the presence of receptors for both cytokines, as well as neurotransmitters on immune and CNS cells. An example of such communication is that, upon peritoneal infection with bacteria, resident macrophages produce IL-1, which acts on the vagus nerve to cause behavioral changes and illness symptoms, and on hypothalamus and pituitary gland to produce CRH and ACTH. Additionally, lymphocytes produce β-endorphin to modulate pain sensations, acting on peripheral sensory nerves. Moreover, evidence from our laboratory indicates that a pure immunological stimulus is able to impact on the brain inducing neuroendocrine changes and to modify cognitive performance. Indeed, healthy volunteers were vaccinated against hepatitis B and tested during a 6-month period on a simple reaction times task and the Stroop task. Although we did not find improvement in the general efficiency of the CNS as indexed by simple task reaction, when we considered higher cognitive function (Stroop task), the performance of vaccinated subjects was faster and more accurate. Additionally, these effects were not acute, being evident 4 weeks after antigenic stimulation, and they persisted even after 25 weeks.

Thus, the available data in the literature suggest that a bidirectional circuitry is present between the immune–endocrine and the nervous system, where both systems continuously alert and inform each other.

Immunosenescence

The aging of the immune system (immunosenescence) is a recent phenomenon related to the linear improvement in survival and life span not predicted by evolutionary force. Indeed, the immune system has probably been selected to serve individuals living until reproduction, as supported by the thymic ontogenesis and involution. Nowadays, the immune system supports the soma of individuals living 80–120 years; during this increased life span, elderly people have to cope with long-lasting antigenic burden (clinical and subclinical infection, as well as continuous exposure to other types of antigens), which causes a chronic activation of the immune system. In order to adapt to and counteract the effect of chronic stress, the immune system undergoes reshaping and remodeling, in which some parameters decrease with age while others increase or remain unchanged. The adaptive immunity is the most affected by aging, being characterized by expanded clones of memory and effector T cells, mostly prominent in $CD8^+$ and specific for viral antigens. In particular, we showed that Epstein–Barr virus (EBV) and cytomegalovirus (CMV) infections are responsible for the expansion of memory $CD8^+$ T cell clones specific for a limited number of viral peptide epitopes which accumulate in the immune system of older people, thus filling the 'immunological space.' We have shown that $CD4^+$ T cells are also affected by viral chronic infections such as CMV. Indeed, when cells from CMV^+ $CD4^+$ T cell are stimulated *in vitro* with specific peptides of the CMV, they produce seven or eight times more inflammatory cytokines such as interferon-γ (IFN-γ) and TNF-α, thus contributing to the inflammatory status present in elderly people. Moreover, aging is associated with a shrinkage of T cell repertoire and a decrease in thymic emigrant T cells and virgin T cells. The result is the filling of the immunological space (the physical space in which all possible interactions among immune cells and/or cell subsets must occur) with indolent cells with memory markers which could exert a suppressor/negative effect on other bystander T cells, including the few naive (virgin or antigen-nonexperienced) cells. Considering the innate immunity, different studies have shown that age-associated alterations are also present in this branch of immunity, but overall it is well preserved. Our attention was particularly focused on NK cells, macrophages, and cytokine circuits. NK cells are large granular lymphocytes expressing

surface markers such as CD16 and CD56 and lacking the CD3 T cell receptor. They display two alternative mechanisms of cytotoxicity activity: the MHC unrestricted cytotoxicity against neoplastic and virus-infected cells and antibody-dependent cell-mediated cytotoxicity. In elderly people, an increase in the absolute and relative number of NK cells, with a mature phenotype ($CD56^{dim}$), is seen, with no variation in their killing activity as a whole, despite the presence of subtle impairment of killing activity on a per cell basis. Moreover, a feedback loop between NK cells and macrophages has been described. Since NK cells secrete factors such as IFN-γ which activate macrophages to eliminate pathogens, some of the age-associated macrophage dysfunctions may be secondary to alteration in cytokine production of NK cells. Additionally, an age-related reduction in hydrogen peroxide and nitric oxide synthesis by macrophage has been described, paralleled by an induction of suppressive substances (e.g., prostaglandin E) which have an inhibitory effect on dendritic cells, the main antigen presenting cells. *In vitro* studies on cytokine production by peripheral mononuclear cells from healthy young and aged subjects identified a complex scenario. Significant increases in levels of IL-6, TNF-α, and IL-1β were found in mitogen-stimulated cultures from aged donors despite a similar amount of cytokines in unstimulated cultures from young and aged subjects. Moreover, chemokines such as MCP-1 and RANTES, soluble TNF-α receptor I and II, and IL-1 receptor antagonist increased in the elderly. For one of the most important proinflammatory cytokines, IL-6, synthesis in macrophage cells is controlled by the CRH–DHEA circuit. Whereas production of cortisol remains constant or even increases with age, levels of DHEA decrease gradually from the third decade, reaching levels that are only 10–20% of their maximum by the eight decade; aged-related decrease of DHEA correlates with IL-6 overproduction. The elderly thus gradually approach a status of relative glucocorticoid excess with age, with a potential negative impact on baseline immune function and an exaggerated response to stressors. The correlation between DHEA and IL-6 has been reported in several studies. In particular, it has been demonstrated that in normal subjects, serum IL-6 levels increased with age, whereas serum DHEA concentrations decreased. Furthermore, serum IL-6 levels were inversely correlated with serum DHEA levels. In addition, in *in vitro* experiments, DHEA inhibited the lipopolysaccharide-stimulated IL-6 production from monocytes and peripheral blood mononucleated cells, even in a narrow concentration range.

Inflamm-Aging

As previously described, the major consequence of chronic exposure to antigenic stress is the progressive activation of macrophages and related cells in most organs and tissues of the body, leading to a progressive chronic, low-grade proinflammatory status which is the principal characteristic of the aging process. We called this phenomenon 'inflamm-aging,' and we postulated that it contributes substantially to the pathogenesis of all major age-related diseases, such as cardiovascular diseases, diabetes type 2, dementia, and cancer, and also to complex pathological conditions very common and characteristic of elderly people, such as frailty and sarcopenia. Thus, directly or indirectly, inflamm-aging is a major determinant of morbidity and mortality in the elderly. However, inflammatory status *per se* is compatible with extreme longevity in good health, and paradoxically proinflammatory characteristics have been documented in healthy centenarians, suggesting that inflammation is a physiologic phenomenon and a beneficial response to cope with chronic stressors. We also found evidence that centenarians activate a strong and effective anti-inflammatory response mediated by cytokines such as IL-10 and T cell transforming growth factor-β capable of counteracting their inflammatory status. Moreover, the rate at which the threshold of proinflammatory status is reached and over which disease/disabilities emerge and the individual's ability to adapt to stressors can be considered a complex trait with high interindividual variability and a strong genetic component. We propose that the persistence over time of inflammatory stimuli, such as CMV chronic infection, represents the biological background favoring susceptibility to a variety of diseases. The absence of robust gene variants and/or the presence of frail gene variants is necessary to develop overt organ-specific, age-related disease. We predicted that the concomitant presence of high inflammatory status and inherited variants of frailty genes or the absence of robust genes can explain why some individuals, but not others, are more susceptible to certain types of age-related disorders.

Inflammation and the Neuroendocrine System

Major Depression

The proinflammatory status in elderly people is associated with several inflammatory-based pathologies, such us cardiovascular disease, sarcopenia, and Alzheimer's disease. Moreover, studies suggest that proinflammatory cytokines play an important role

in the pathophysiology of major depression. This psychiatric disorder, at a neurobiological level, is associated with alterations in neurotransmitter function involving serotonin, norepinephrine, and dopamine. Hypersecretion of CRH and alteration of its regulation by glucocorticoids are also described. Regarding the emerging role of the immunological pathway in major depression, several studies have shown that patients with this pathology, who are otherwise medically healthy, have increased serum and plasma concentrations of IL-6 and/or C-reactive protein and elevated IL-1β and TNF-α in peripheral blood and cerebrospinal fluid. Additionally, increased levels of chemokines and adhesion molecules, such as E-selectin, have been described. A positive correlation between plasma concentrations of various inflammatory mediators and depressive symptom severity has been reported. Finally, a nascent literature suggests that functional allelic variants of genes for IL-1β and TNF-α increase the risk for depression and are associated with reduced responsiveness to antidepressant therapy.

Given the primary factors that are associated with the pathophysiology of depression, it is likely that peripherally released inflammatory cytokines can access the brain. Because of the large size of cytokines and their resultant inability to readily penetrate the blood–brain barrier, attention has focused on routes by which they access the brain, including through leaks in the blood–brain barrier, the binding to specific transport, or the activation of vagal afferent fibers which transmit cytokine signals to specific brain nuclei. Once in the brain, there is a CNS cytokine network made up of cells that not only produce cytokines and express cytokine receptors but also amplify cytokine signals, which in turn can have profound effects on neurotransmitter and CRH function, as well as behavior. These cytokine-induced behavioral changes are associated with alterations in the metabolism of serotonin and dopamine in brain regions essential for the regulation of emotion and psychomotor function. Moreover, these cytokines induce the activation of the HPA axis hormone, as well as CRH in both the hypothalamus and the amygdala, regions that have an important role in fear and anxiety. Finally, NF-κB induction in the brain may also contribute to alterations in neuronal growth and survival, especially through the induction of nitric oxide production and, ultimately, oxidative stress. The discovery that depression shares common features with inflammation and stress system activation led to a novel perspective to treatment. Indeed, patients with a history of nonresponse to antidepressants have been found to exhibit increased plasma concentration of IL-6 compared to treatment-responsive patients. Moreover, antidepressants may only address select symptoms (e.g., depressed mood and anxiety), whereas others are relatively unaffected. Thus, inhibition of proinflammatory cytokine signaling represents a viable strategy for the treatment of depression, especially in patients with evidence of increased inflammatory activity who might be less likely to respond to convectional agents.

Anorexia Nervosa

Prolonged elevation of proinflammatory cytokines may induce a cascade of biochemical effects in the CNS, involving secretion of neurotransmitters, neuropeptides, neurohormones, and peripheral hormones, which may be etiopathogenetic for the development of anorexia nervosa. Indeed, in experimental animal models, IL-1β, IL-6, and TNF-α introduced directly in the CNS induced anorexia, fatigue, apathy, depressed mood, and impaired secretion of catecholamines, serotonin, and HPA axis hormones. Although there are no reports regarding the cerebrospinal fluid concentration of such cytokines in patients affected by anorexia nervosa, we performed a study on a group of anorectic subjects (restricted and bingeing–purging) measuring plasma concentrations of IL-1β, IL-6, TNF-α, and their soluble receptors. Surprisingly, we found that the concentrations of the three cytokines were normal in our patients, as well as the concentrations of the TNF-α soluble receptors. Interestingly, the levels of the IL-6 soluble receptor were lower than normal in our patients. Since there was a positive correlation between the levels of cytokine and its soluble receptors, the low level of receptors contrasts with the normal levels of IL-6. The biological significance of the soluble IL-6 receptor is not clear, but an impairment of the proinflammatory cytokine pathway might be involved in the development of anorexia nervosa.

Alzheimer's Disease

One of the most important age-associated pathologies is Alzheimer's disease (AD), a heterogeneous and progressive neurodegenerative form of dementia. Neuropathological hallmarks of AD are neuronal and synapsis loss, extracellular β-amyloid deposition (neuritic/senile plaques), and intracellular deposition of hyperphosphorylated tau-based paired helical filaments in hippocampus, temporal and frontal cortex. Inflammation clearly occurs in this pathologically vulnerable region of the AD brain, where the principal proinflammatory stimuli are highly insoluble Aβ42 and Aβ40. Indeed, these peptides are recognized by astrocytes and microglia, which in turn produce many cytokines such as IL-1, IL-6, and TNF-α. In particular, TNF-α acts as a proapoptotic agent,

which contributes to neuronal loss in AD. Moreover, the senile plaques are potent activators of the complement cascade; during this process, small fragments, known as anaphylotoxins, are produced and stimulate inflammation. Chemokines and acute phase proteins are also co-localized as secondary components in neuritic plaques and are overproduced in brain of the AD patient. Other important mediators of inflammation in AD are prostaglandins, a group of fatty acids derived from the precursor arachidonic acid, with COX catalyzing the initial step. Both the constitutive COX-1 and the inducible COX-2 mRNA, as well as their protein products, are upregulated in affected brain areas. COX-1 is mainly expressed in microglia, whereas COX-2 is abundantly expressed in pyramidal neurons and seems to play a role in synaptic plasticity. Epidemiological studies have shown that levels of proinflammatory mediators, particularly cytokines such as IL-6, IL-10, and TNF-α, in blood and brain may be under genetic control and the risk of AD is influenced by several polymorphisms in the noncoding region of these genes. Thus, the overall chances of an individual developing AD might be profoundly affected by a susceptible proinflammatory profile, reflecting the combined influence of inheriting multiple high-risk alleles. The identification of such a profile might in the future lead to strategies for therapeutic intervention in the very early stages of the disorders. Indeed, one possible strategy to suppress inflammatory response would be the administration of nonsteroidal anti-inflammatory drugs (NSAIDs). Epidemiological investigations indicate that the use of NSAIDs decreases the risk of AD by approximately 50% and delay the onset of AD by 5–7 years. (R)-flurbiprofen, the R enantiomer of racemic flurbiprofen, is under license for the potential treatment of AD, modulating the gamma secretase and the production of Aβ42. Indeed, in a murine model of AD, it lowered the level of this toxic peptide, and chronic administration reduced brain amyloid pathology and prevented defects in learning and memory. In a phase II clinical trial in AD, patients demonstrated a benefit in cognitive and behavioral performance. Two pivotal phase III clinical trials in AD are under way.

Frailty Syndrome

Another aged-related disorder, involving innate immunity and inflammation, is frailty and sarcopenia. Frailty has been defined as a decline in lean body mass and decreased muscle strength, endurance, balance, and walking performance, accompanied by a high risk of disability, falls, hospitalization, and mortality. This syndrome reflects a profound metabolic imbalance due to overproduction of catabolic cytokines (likely TNF-α) and the diminished availability of anabolic hormones such as insulin-like growth factor-1 (IGF-1), resulting from aging and the presence of associated chronic conditions. Sarcopenia, the loss of muscle mass and strength that occurs with normal aging, is a central part of the frailty syndrome, probably due the decline of neural, hormonal, and environmental trophic signals to muscle. The most

Figure 1 The central role of the macrophage in stress response, inflammation, and age-related diseases. The immune and neuroendocrine systems share common mediators to exchange information and they are affected by different stressors. The macrophage is the most important actor in integrating information, and its chronic activation in aging supports the development of inflammatory diseases.

important endogenous cause may be the irreversible age-related loss of α-motor units in the central nervous system. TNF-α has effects that may contribute directly to sarcopenia, including increased basal energy expenditure, and anorexia, and it is associated with wasting/cachexia in chronic inflammation disorders. In the CNS, TNF-α can drive neuronal apoptosis, as previously described for AD. The role of IL-6 in sarcopenia is not clear, even though the effect of IL-6 in the regulation of IGF-1 action has been widely documented. To better understand the involvement of this circuit in this complex condition, we evaluated the relationship of plasma concentrations of IGF-1 and IL-6 with muscle function in apopulation-based sample of elderly people. We found that higher IL-6 and lower IGF-1 plasma levels are associated with lower muscle strength and power, suggesting a multifactorial relationship between these two mediators. Thus, insulin resistance in the elderly and loss of insulin anabolic action on muscle are factors favoring the onset and progression of this pathology.

Conclusion

In this article, we discussed the most important link between the immune system and the neuroendocrinal circuit. These three systems form a complex network, conserved during evolution, in which cytokines and neuropeptides are the mediators. The most important actor which regulates this network is the macrophage, a very ancestral cell that is able to integrate immunity, stress response, and inflammation (**Figure 1**). Aging is characterized by a proinflammatory status which supports the most important aged-related pathologies.

Successes and Challenges of Modern Neuroscience

The foundations of neuroinformatics as a new multidisciplinary field of science were laid in the late 1980s as advances in both neuroscience and information science made their incorporation possible. Relating the complex structures and functions of the nervous system requires coordination among diverse domains of knowledge, integration across multiple levels of investigation, and fusion of seemingly disparate technical approaches, from molecules to behavior. The challenge of neuroinformatics is to provide a unified computational information framework to enable, facilitate, and foster such an enterprise. In practice, major advances in our understanding of the brain require the development and application of suitable electronic tools to handle, represent, transform, analyze, and synthesize digital neuroscience data. In turn, such a challenge is the key solution to preventing, diagnosing, and treating brain diseases.

Neuroinformatics is still in its infancy, and it may be premature to attempt a historical perspective on a field in evolving and dynamic development. In this article, we present an overview of the status of neuroinformatics mostly by means of focused examples. We first state the main areas of neuroinformatics research in broad terms. Next, we describe some of the principal institutional initiative and resources, exemplifying both organizations and funding programs. We then offer several examples of ongoing efforts. This selection is not meant to (and could not possibly) provide a comprehensive account of current neuroinformatics; on the contrary, we wish to illustrate the diversity and breadth of this rapidly growing branch of science. To offer a sense of the depth involved in these programs, we present one specific case our own laboratory is contributing. Finally, we close by venturing a forecast of the future research landscape after the full maturation and blossoming of neuroinformatics.

By its own nature, much neuroinformatics content exists on the World Wide Web and in fact mostly consists of its very online presence. It is, thus, impossible (and would be counterproductive) for this review to be devoid of direct references to uniform resource locators (URLs) corresponding to the described information; we therefore include an extensive list of websites. Internet content evolves dynamically, and a static text such as this can provide only a temporary snapshot of journalistic value, destined to age quickly. The same applies to the illustrations, which are all derived from material accessed in April 2007.

Neuroinformatics: Premise and Promise

Neuroscience studies all aspects of the nervous system and its development to understand the biological principles of the mind and behavior. Modern neuroscience encompasses many diverse areas of investigation: from the brain's shape and cellular structure (neuroanatomy) to molecular manipulations and chemical composition (neurochemistry) and from bioelectrical plasticity and circuit dynamics (neurophysiology) to the personal and social organization of cognitive systems (psychology). Heterogeneous and complex results of such specialized domains require proper integration and analysis. How can firing patterns enable slow, inaccurate computational elements (synapses and nerve processes) to perform fast and accurate computation (logical reasoning)? Questions such as this call for the application of proper mathematical methods, computational models, analytical tools, and numerical simulations.

Completion of the Human Genome Project has clearly evidenced the usefulness of structured databases in biomedical researches. However, compared to genome sequences, neuroscience data are generally more interconnected, detailed, and multidimensional. Naturally, such complexity makes neuroscience data very difficult to deal with. These same challenging features, however, make the application of theoretical and computational models to neuroscience data particularly effective and powerful.

Neuroinformatics efforts can be broadly ascribed to four frontiers:

- Defining consistent knowledge environments and constructing web-based information management systems.
- Promoting and enabling data sharing and providing network-accessible, interoperable databases.
- Developing analysis, visualization, and simulation tools for and across all major neuroscience data types.
- Implementing accurate computational models for subcellular components, neurons, networks, and neuromorphic artifacts.

It is important to stress that informatics tools are already commonly and widely employed in neuroscience and that increasing data complexity requires correspondingly more sophisticated tools. In neuroimaging, the only available approach to the study of the intact human brain in both physiological and pathological conditions, for example, information technology plays crucial roles in all stages of data manipulation. Informatics resources are used to design the experiments; control imaging instruments; minimize noise; reconstruct 3D images; quantify, analyze, and compare the results; and organize, store, query, retrieve, and share the data.

Complementary to the technological aspects lies the social facet of neuroinformatics. One of the main goals is to create an optimal environment for researchers to collaborate, communicate more effectively, and share their data. Neuroinformatics brings together investigators from a wide variety of basic and clinical disciplines, along with computational scientists and engineers. Despite a common interest in understanding brain development and function, such diverse cultural backgrounds make a productive dialog one of the most critical elements for the acceptance of common standards.

Institutional Resources and Initiatives

The US National Institutes of Health (NIH) formally established the Human Brain Project (HBP) in 1993 to develop and support the new science of neuroinformatics (Figure 1(a)). All approaches and technologies under this initiative were to be generalizable, scalable, extensible, and interoperable. The success of the HBP is evidenced by the range of digital resources it supported, from molecular biology to functional magnetic resonance imaging (fMRI) databases (Figure 1(b)). The HBP was also instrumental in nurturing the growth of the neuroinformatics community through annual public research conferences, regular meetings of the funded principal investigators, and sponsored satellite symposia and social gatherings at major scientific events. Several of the resources and initiatives described in this section, as well as the projects and databases exemplified in the next section, resulted directly or indirectly from the HBP.

The Society for Neuroscience (SfN), the largest worldwide scientific organization devoted to studying the nervous system, assembled the Brain Information Group (BIG) in 2003. One of the BIG recommendations was to establish and maintain an active role in informing the neuroscience community about available digital tools and resources. The SfN established a standing Neuroinformatics Committee and, recognizing the growing importance and number of electronic archives and repositories, launched the Neuroscience Database Gateway (NDG). The NDG provides a one-stop resource for neuroscientists, increasing awareness of and facilitating access

Figure 1 Institutional resources: (a) National Institute for Mental Health (NIMH) Neuroinformatics: Human Brain Project; (b) Human Brain Project database (HBPDB) at Yale; (c) Society for Neuroscience (SfN) Neuroscience Database Gateway (NDG). Collated from material available in April 2007.

to free tools and available databases (Figure 1(c)). In early 2007, the NDG listed more than 175 entries, including databases of experimental data, knowledge bases, software tools for neuroscience, bioinformatics resources, and providers of research materials. Other online indices include Neuroguide, Neuroinf.org, and the Internet Analysis Tools Registry.

The NIH Blueprint for Neuroscience Research was established in 2004 to develop new tools, resources, and training opportunities to facilitate discovery in brain science. One of the first projects sponsored under the Blueprint was the Neuroscience Information Framework (NIF), which was endorsed by the SfN as an expansion and continuation of the NDG. The goal of NIF is to integrate, provide access to, and facilitate the utilization of neuroinformatics resources. In addition to the partnership of five academic institutions (California Institute of Technology; George Mason University; University of California at San Diego; Yale University; and the Weill Medical College of Cornell University, which is leading the project), the NIF consortium relies on a network of nine additional sites as volunteer consultants and collaborators. The project NeuroMorpho.org, highlighted as a case example in a later section, is part of the NIF program.

In 2000, the Biomedical Information Science and Technology Initiative Consortium (BISTIC) was established at NIH as the focus for making optimal use of computer science and technology in biology and medicine. The BISTIC is composed of senior-level representatives from NIH centers and institutes as well as from other federal agencies concerned with bioinformatics and computational applications. Notable initiatives in this regard are also constituted by the National Centers for Biomedical Computing (NCBC), created to build the computational infrastructure of biomedical computing, and the Biomedical Informatics Research Network (BIRN), established by the NIH Center for Research Resources (NCRR). A geographically distributed virtual community of shared resources, BIRN, aims to enhance communication and promote collaboration across research disciplines.

Two NIH institutes, the Institute of Mental Health and the Institute of Neurological Disorders and Stroke, jointly sponsored the Neuroimaging Informatics Technology Initiative (NIfTI) to provide coordinated and targeted service, training, and research to speed the development and enhance the use of informatics tools related to neuroimaging. Among the practical results of NIfTI is the standardization of imaging file formats (under the same name), which was adopted by academia and the corporate world alike.

The International Neuroinformatics Coordinating Facility (INCF) was formed in 2005 on the recommendations of the Organisation for Economic Cooperation and Development (OECD) Mega Science Forum Working Group on Biological Informatics (1999) and the OECD Global Science Forum Working Group on Neuroinformatics (2002). Endorsed by 17 countries (Australia, Canada, China, the Czech Republic, Denmark, Finland, France, Germany, India, Italy, Japan, the Netherlands, Norway, Sweden, Switzerland, the United Kingdom and the United States), as well as by the European Commission, the INCF aims to coordinate key networking activities and to provide services and tools for identifying, analyzing, and drawing on knowledge from main neuroscience information resources all around the world.

Finally, the journal *Neuroinformatics*, now in its fifth year of publication, is the first scientific periodical dedicated entirely to the information science infrastructure of neuroscience.

A Sampler of Individual Projects and Databases

Neuroscience occupies a major and growing position in many general bioinformatics resources, including (but not limited to) genetic sequence databases, protein structure repositories, metabolic and regulatory networks, and microrray and expression pattern archives. Several bioinformatics developments, however, are dedicated entirely to or explicitly emphasize brain science. For instance, neuromolecular efforts to investigate the biochemical basis of neurological disorders have a relatively long-standing online presence, such as Neuromuscular information on ion channels, transmitters, receptors, and related diseases; the Ligand-Gated Ion Channel Database of nucleic and proteic sequences of channel subunits; and the Inherited Peripheral Neuropathies Mutation Database, which was made public in May 1999. A few selected examples of mature neuroinformatics resources in other domains are collected here.

The National Institute of Neurological Disorders and Stroke (NINDS) sponsors the Gene Expression Nervous System Atlas (GENSAT) for genetic mappings of the mouse central nervous system in different stages of development. Data in GENSAT are generated using radiolabeled riboprobes, *in situ* hybridization, and transgenic mouse techniques. In a similar vein, the Allen Institute developed the Brain Atlas as a freely available scientific resource to provide expression maps of the approximately 20 000 genes in the mouse brain (Figure 2(a)). After the completion of the sequencing of the mouse genome, and through the systematic automation of high-throughput techniques to probe gene expression, the goal of creating a detailed cellular-resolution, genomewide map of gene expression in the mouse brain was achieved.

The HBP sponsored several projects in related scientific domains, three of which we mention here. The Mouse Brain Library (MBL), a database of brains and high-resolution images from many genetically characterized rodent strains, aims to systematically map and characterize the key genes for the architecture of the mammalian central nervous system (Figure 3(a)). BrainMaps.org is an online high-resolution digital brain atlas implementing interactive zoomable technology (virtual microscope). Queriable and retrievable data include complete sets of scanned images from serial sections of both primate and non-primate brains (Figure 3(b)). BrainInfo helps identify brain structures and related information (Figure 3(c)) based on three distinct knowledge bases that provide the index to, relations among, and location of brain regions in the primate brain (NeuroNames, the Template Atlas, and NeuroMaps, respectively). Other knowledge bases include CoCoDat, a microcircuitry database with bibliographic references and parameter values from published experimental reports, and Textpresso, an NIF project to extract and process information from the neuroscience literature.

One of the efforts aimed at integrating disparate information at the molecular, cellular, and system level, the Blue Brain Project (BBP) was jointly established in 2005 by IBM and the Ecoles Polytechniques Fédérales de Lausanne in Switzerland (Figure 2(b)). By using the Blue Gene supercomputer, the BBP uses a strategy of reverse engineering the brain by modeling more details than ever before attempted, ultimately with large-scale bottom-up simulations. In particular, the BBP is directed at creating a microcircuit of the neocortical column, with accurate biological properties

(including membrane biophysics and synaptic connectivity) of individual neurons from the mammalian brain classified based on their morphology, electrophysiology, and gene expression. A longer-standing effort funded by the HBP, SenseLab consists of a collection of six databases supporting experimental and theoretical research on membrane properties and the olfactory pathway. For example, NeuronDB provides information regarding voltage-gated conductances and neurotransmitter receptors, whereas ModelDB collects computational neuroscience models which users can search and reuse. Mature simulation environments for individual neurons, their subcellular components and biochemical reactions or neural networks, and systems-level models include NEURON, GENESIS, and PDP++.

The HBP funded several neuroimaging projects. The International Consortium for Brain Mapping (ICBM), formed in 1993, is composed of four core research sites – the University of California at Los Angeles, Montreal Neurologic Institute, University of Texas at San Antonio, and the Institute of Medicine of Juelich/Heinrich Heine University (Germany) – with data acquisition sites from Asia and Europe also contributing. The main ICBM goal is the continued development of probabilistic reference systems for the human brain (Figure 3(d)). ICBM built and expanded neuroinformatics tools for data sharing and to map structural and functional anatomy both macroscopically (*in vivo*) and microscopically (post-mortem). An allied resource, the Alzheimer's Disease Neuroimaging Initiative (ADNI), was started in 2004 to define the rate of progress of mild cognitive impairment and improve the current methods for clinical and treatment trials in Alzheimer's disease by building a large neuroimaging database.

Another important neuroimaging project is the Functional Magnetic Resonance Imaging Data Center (fMRI-DC), started in 1999 with grants from the National Science Foundation (NSF) and the

Figure 4 NeuroMorpho.org: (a) home page; (b) browse all cells screen; (c) search by metadata screen; (d) search by morphometry screen.

W. M. Keck Foundation. The fMRI-DC archive serves as a public repository for data from studies published in the peer-reviewed literature. Uniquely in the brain sciences, the *Journal of Cognitive Neuroscience*, one of the leading venues for scientific reports based on fMRI, mandates that the data underlying manuscripts accepted for publication be made available for deposition in the fMRI-DC. The establishment of similar policies in other domains of biology (e.g., protein structures and gene sequences) has greatly benefited the explosive success of bioinformatics, and these standards also apply to other fields of science such as physics (e.g., astronomical and particle collision experiments).

NeuroMorpho.org: Opportunities and Solutions for Cellular Structure

NeuroMorpho.org is one of the projects piloted within the NIF (Figure 4(a)). A centrally curated web-based inventory of digitally reconstructed neurons, NeuroMorpho.org, aims at densely archiving and organizing all publicly available 3D reconstructions of neuronal morphology. This effort started in 2006 with contributions from over two dozen labs and is continuously updated. Dendritic and axonal arborizations influence neuronal integration and excitability and therefore overall brain activity. Morphological studies and neuronal reconstructions are increasingly popular, both for quantitative modeling of neuronal electrophysiology or network dynamics and in response to advances in genetic and physiological studies, providing a rapidly expanding pool of knowledge. Management of this exploding flow of information requires appropriate informatics tools, and effective data sharing is indispensable. In this sense, NeuroMorpho.org has significant promise both as a new resource and as a tool, which could become a model for other neuroscience data types. Archival in NeuroMorpho.org protects hard-earned

valuable data files from being lost without leveraging their full scientific and educational potential. The provided morphometric and stereological measures also enable a cascade of anatomical analyses and cellular classifications.

With over 1000 entries, NeuroMorpho.org is to date the largest online collection of digital reconstructions in cellular neuroscience. Data sets were gathered by mining available public databases and by direct peer-to-peer requests to researchers willing to share their data. Neurons are included from different species and strains, ages and developmental stages, experimental protocols, brain regions, and so on, thus providing a one-stop resource for neuronal morphology regardless of the individual investigator's interest (Figure 4(b)). Such diversity could foster comparative studies between neurons, for example, in various brain areas or animals or reconstructed from different histological and microscopic techniques. Users also gain the opportunity to familiarize themselves with the works and approaches of other researchers.

Data in NeuroMorpho.org are extensively annotated to allow efficient browsing and searching (Figure 4(c)). Fast navigation through a rich data selection has important scientific consequences; for example, it aids computational modelers in determining and accessing the most appropriate morphological data available to implement more accurate and precise biophysical simulations of neural activity and function. Morphometric parameters (including arbor size, branching angles, tree topology, and fractal dimension) are also precomputed to facilitate stereological studies, and the investigation of the structure–activity relationship or the effect of morphology on electrophysiology and plasticity (Figure 4(d)).

Each data file is classified with respect to brain regions and cell types based on the corresponding scientific report. NeuroMorpho.org adopts three hierarchical levels for brain region, starting with the main area (e.g., the neocortex, hippocampus, and cerebellum), further refining an intermediate level (the somatosensory vs. prefrontal cortex, CA3 vs. CA1, etc.), and finishing with the detailed cytoarchitectonic layer (such as layers I–VI or alveus through lacunosum-moleculare). Cell types are similarly divided into principal neurons and interneurons, then organized into common types (pyramidal, granule, stellate, basket, chandelier, etc.), and finally categorized into more specialized subtypes as described in the corresponding scientific reports. Reconstructions are also accompanied by useful information extracted from the articles' Materials and Methods (or equivalent) sections, including the species, strain, age, sex, weight, and development of the animal; reconstruction method; slicing thickness and direction; staining; imaging magnification and objective type; experiment protocol; and other experimental details. A PubMed link is also provided to enable users to look for other specifications and to identify all co-authors contributing to the reconstruction files.

In addition to a 2D image of the cell, NeuroMorpho.org renders neurons growing and revolving as a dynamic 3D display. A user-friendly neuron viewer has been integrated, allowing interactive visualization and manipulation of the reconstruction file (zooming, panning, turning, etc.) as well as conversion to common electrophysiology simulation environments such as NEURON and GENESIS. Users can download both the source reconstruction files (as provided by the original contributors) and a standardized integrity-checked and -corrected version in a common nonproprietary format. All conversion changes as well as notes of recognized residual irregularities are listed in additional log files, also optionally bundled for data retrieval.

With the expected future improvement of algorithms for automated reconstruction, the number of available digital morphologies will rapidly increase, exacerbating the need for central curation and ease of access. An important advantage of NeuroMorpho.org is its simplification of the data-sharing process, whereby any researchers willing to make their files available can simply send them to the database administrator without any technical hardship or storage-space investment while maintaining (and in fact gaining) recognition and full credit for their work.

The Future: Explosive Potential of Digital Neuroscience

Databases, visualization and analysis tools, and simulation environments have already impacted all fields of brain science, from molecular to cognitive, in both basic research and clinical applications. Computational skills have become an essential component of the neuroscientist's expertise. Nevertheless, neuroinformatics is still in its early stages. Ongoing progress, which will mature in the near future, includes the development of formal neuroinformatics vocabulary and effective neurontologies, that is, data models defining and interrelating neuronal concepts to maximize communication and interoperability. Technical advances will lead to the fall of the current social barrier to open and pervasive data sharing.

What will the typical neuroscience investigation of tomorrow look like? A massive amount of available data will be accompanied by powerful computational tools for analysis, integration, and modeling. In this scenario, the complexity of neuroscience will be an

opportunity for discovery and an asset for invention. Brain researchers will be able to design and execute sophisticated experiments at a computer terminal, developing, testing, and refining hypotheses, mechanisms, and theories. The ability to bridge diverse subdomains of neuroscience, transcending techniques and integrating heterogeneous data types, will become more important than specialized wet-bench expertise in one or few instruments and protocols. Neuroscientists will be one step closer to the direct acquisition, manipulation, and creation of knowledge.

Of course, neuroinformatics will never substitute for, but will, rather, integrate, experimental neuroscience. Primary data will continue to be needed, and newly synthesized or isolated chemicals will have to be tested *in vivo*. Neuroinformatics will certainly aid in the design of molecules and primary experiments alike, and the extracted data will, in turn, fuel and stimulate further neuroinformatics progress. In the life science, bioinformatics has already grown to occupy a prominent role in the spectrum of biological approaches. In neuroscience, the same complexity that constitutes a challenge today will lead to a future in which the vast majority of research will be carried out on archived, rather than primary, data.

Introduction

Schizophrenia is a devastating mental illness, usually striking individuals in their late teens or early twenties. It is characterized by a significant change in normal perception, with affected individuals suffering from hallucinations (most commonly auditory but sometimes affecting other sensory modalities), delusions (fixed false beliefs, often concerning elaborate plots in which the sufferer is being persecuted or that their actions are being controlled by an external entity), and impairment of cognitive ability, as well as the so-called negative symptoms of apathy, avolition, loss of emotional reactivity, and withdrawal from social contact. These symptoms are termed 'psychotic,' being qualitatively different from normal experience (cf. neurotic symptoms). Until the 1950s, no effective treatments for schizophrenia existed. The discovery that the drug chlorpromazine was effective in reducing the psychotic symptoms of schizophrenia heralded the start of a new era in the management of patients with the illness.

Chlorpromazine was not originally developed as an antipsychotic. It was first marketed as an antiemetic in the early 1950s. It's effects, leading to sedation without anesthesia, were first noted by the surgeon Henri Laborit. When given to patients with schizophrenia, as well as causing mild sedation, chlorpromazine also led to reductions in hallucinations and delusions, allowing individuals to become more able to function on a normal level. Following treatment with chlorpromazine, patients who previously had to be housed in mental institutions were able to move out into less restrictive settings.

The success of chlorpromazine in treating schizophrenia led to a huge interest in finding other drugs with a similar action against psychotic symptoms. Between 1952 and the mid-1970s, more than 40 first-generation antipsychotics (FGAs) had been developed, but it was some time before the specific mechanism of action of antipsychotic drugs began to emerge.

Antipsychotic Affinity for the Dopamine Receptor

In the mid-1970s, it was discovered that all drugs with antipsychotic effects shared the common property of high affinity for the dopamine D2 receptors (including D_2, D_3, and D_4 subtypes), and that, furthermore, the affinity of the drugs for the D2 receptors directly correlated with clinical potency (i.e., the higher their affinity for dopamine D2 receptors, the lower the dose of drug was required to have a clinical effect).

One consequence of this, thought to be unavoidable, was that all antipsychotic drugs led to extrapyramidal (Parkinsonian) side effects (EPSEs). The primary deficit in Parkinson's disease is a loss of dopamine in the striatum (caudate/putamen; see Figure 1). Antipsychotic drugs mirrored this effect by blocking dopamine receptors in the striatum. As a result, patients with schizophrenia, despite partial resolution of their psychotic symptoms, were often left with severe problems with abnormal movements, shuffling gait, and reduced facial expression. Furthermore, antipsychotic drugs were not helpful to all patients, with approximately one-third showing no improvement in symptoms despite treatment. Many psychiatrists concluded that patients who did not respond well to antipsychotic treatment might be taking insufficient doses of antipsychotic drug, causing a therapeutic occupancy of dopamine D2 receptors in the brain. As a result, patients who did not respond to antipsychotic drugs were often prescribed very high doses, with severe EPSEs as a common outcome. This practice was not universal, however, and some suggested that very high doses of antipsychotic drugs might not be the best method for tackling treatment-resistance.

Studies of Antipsychotic Action in Living Patients

The development and use of single-photon emission tomography (SPET) and positron emission tomography (PET) as research tools in psychiatry led to a reevaluation of the role of D2 receptors in antipsychotic drug action. SPET and PET are two methods by which neuroreceptor density can be measured in living humans. Both SPET and PET work by measuring the regional distribution of an injected radioactive tracer (radioligand) in the body. If the radioligand has been designed to bind to specific neuroreceptors, the regional density of these receptors can then be estimated.

Patients with schizophrenia who were good or poor responders to antipsychotic drugs were scanned using labeled (*S*)-*N*-[(1-ethyl-2-pyrrolidinyl)]methyl-2-hydroxy-3-iodo-6-methoxybenzamide ([^{123}I]IBZM), a SPET ligand for striatal D2 receptors, and [^{18}F] *N*-methylspiroperidol, the equivalent PET ligand.

Figure 1 Transverse section of one hemisphere of human brain showing three main subregions of striatum: caudate nucleus (nucleus caudatus), putamen, and globus pallidus (pallidum). Reproduced from *Grays Anatomy of the Human Body*, 20th edn. (1918).

No difference was found, in terms of striatal D2 receptor occupancy, between patients with a good or a poor clinical response to antispychotic treatment. Indeed, some patients who had not responded to antipsychotic treatment had close to 100% occupancy of striatal dopamine receptors. This suggested that striatal occupancy was not sufficient to explain antipsychotic response in all cases. It was also found that that 90% striatal dopamine receptor occupancy could be obtained at very low doses of FGAs. This meant that there was no logical reason to continue giving treatment-resistant patients very high doses of FGAs, since the same receptor occupancy could be obtained with lower doses, causing less severe EPSEs, and leading to a real benefit in the quality of life for such patients.

More recently, there have been studies of patients who were good responders to FGAs, or patients with first-episode schizophrenia (who generally show a good initial response to antipsychotic drugs). These studies found that greater striatal dopamine D2 receptor occupancy by FGAs predicted a better response to antispychotic treatment. This suggests that there is a subset of patients with schizophrenia in whom striatal dopamine D2 receptor occupancy is an important aspect of antipsychotic efficacy. It should be noted, however, that striatal D2 occupancy in these patients might simply be a marker for dopamine receptor occupancy in other parts of the brain.

Second-Generation Antipsychotics

Further progress in antipsychotic development after chlorpromazine did not occur until the reintroduction of clozapine in the early 1990s. Clozapine was first marketed in the 1970s but was withdrawn from widespread use because it led to a serious reduction in white cells (agranulocytosis) in a small proportion of patients, which caused several deaths. Despite this, several psychiatrists in Europe continued using it in patients who did not develop agranulocytosis, as it appeared to have greater efficacy than did other antipsychotic drugs, and furthermore, it did not have as much propensity to cause EPSEs. In 1988, Kane and colleagues performed a double-blind study of clozapine compared to chlorpromazine in treatment-resistant patients with schizophrenia. These patients had been treated with other existing antipsychotic drugs and had shown no significant response. In the study, one-third of these patients showed a marked response to clozapine and did not develop EPSEs. As a result of this study, clozapine was reintroduced as

an antipsychotic drug, with compulsory blood monitoring requirements. It was found that if patients had regular blood monitoring, and were permitted only to continue on clozapine while their white blood cell count remained within a healthy range, the risk due to agranulocytosis could be virtually eliminated.

Following on from the success of clozapine, a number of 'second-generation' antipsychotic drugs (SGAs) were developed. These sought to emulate the enhanced efficacy of clozapine in treatment-resistant patients, and also to minimize the extrapyramidal side effects traditionally associated with FGA treatment. In general, they were successful in having lower EPSE potiential, compared to FGAs, but none had the same enhanced efficacy in treatment resistance as seen with clozapine, with most sharing equal clinical effectiveness with the FGAs. Because of their lower propensity to cause EPSEs as compared to FGAs, the SGAs have also been termed 'atypical' antipsychotics. Recently there has been evidence from meta-analysis of available literature that some SGAs may have improved efficacy compared to FGAs, although clozapine was still found to be superior to any other available antipsychotic drug.

Mechanisms of Atypicality

The development of the SGAs led to interest in how they might obtain their beneficial antipsychotic effect without EPSEs. Initial studies used SPET and PET to try to answer this question. Pilowsky and colleagues studied striatal occupancy of dopamine D2 receptors by clozapine using [^{123}I]IBZM SPET to compare dopamine D2 receptor binding in patients treated with clozapine and patients treated with FGAs. Farde and colleagues performed the same study using [^{18}F]raclopride (a PET ligand for striatal D2 receptors). Both groups found that clozapine achieved an antipsychotic effect with a much lower occupancy of striatal dopamine D2 receptors than seen with FGAs. This unexpected result conflicted with conventional wisdom that striatal dopamine receptor occupancy was required for antipsychotic efficacy, although it gave some explanation as to why clozapine had lower propensity than FGAs did to cause EPSEs. This led to speculation as to what the mechanism of antipsychotic action of SGAs might be, and how they might avoid EPSEs.

5HT2A Occupancy

The finding that many SGAs shared the characteristic of a high affinity for 5-hydroxytryptamine (serotonin) 2A (5HT2A) receptors led to speculation that the ratio between 5HT2A and dopamine D2 receptor occupancy could be a key feature leading to lower propensity to EPSEs. Initial PET and SPET studies confirmed that many SGAs showed very high 5HT2A receptor occupancy at all doses. A later analysis revealed that SGAs could induce EPSEs with striatal D2 receptor occupancies greater than 78%, suggesting that it was the lower striatal D2 occupancy by SGAs, rather than any interaction with 5HT2A receptors, that was the cause of their lower EPSE potential. The fact that amisulpride, an SGA with no affinity for the 5HT2A receptor, also had low EPSE potential further suggested that 5HT2A receptor occupancy was not necessary for an atypical antipsychotic profile.

Extrastriatal Selectivity

Due to low D2 receptor densities in regions outside the striatum, it was not possible, with the first PET and SPET D2 receptor ligands, to determine whether SGA occupancy of extrastriatal dopamine receptors differed from their striatal occupancy, although it was hypothesized that dopamine D2 receptor occupancy in limbic regions of the cortex (temporal lobes) could be more important in antipsychotic action than was blockade of striatal dopamine D2 receptors. It was not until the development of high-affinity ligands for D2 receptor that this question could be addressed. The first SPET study comparing clozapine with haloperidol binding in striatal and temporal cortex revealed that clozapine appeared to preferentially bind cortical over striatal D2 receptors, while haloperidol showed equal occupancy of both cortical and striatal D2 receptors (**Figure 2**). Subsequent studies examined the binding characteristics of other SGAs and found that other SGAs, including olanzapine, quetiapine, risperidone, amisulpride, and sertindole, appeared to share the property of cortical over striatal D2 receptor selectivity, while FGAs did not show any preferential occupancy (**Figure 3**). Importantly, drugs with modest affinity for dopamine D2 receptors exhibited this effect more robustly across their whole dose range, where atypical drugs with higher affinity for D2 receptors (e.g., risperidone, amisulpride) displayed dose-dependent limbic selectivity. There is a nonreplication of these data in the literature and full *in vivo* PET or SPET confirmation awaits further study. Nevertheless, regionally selective dopaminergic action of atypical antipsychotic drugs is supported by both electrophysiological and animal studies, and the finding fits well with the theory that cortical, rather than striatal, dopamine receptors are the primary site for antipsychotic efficacy.

Intrastriatal Selectivity

The striatum has roles beyond its involvement in motor function. It may be divided into three distinct

Figure 2 Average percent occupancy of striatum and temporal cortex in patients with schizophrenia treated with first-generation antipsychotic (FGA) drugs, quetiapine (QUET), olanzapine (OLANZ), clozapine (CLOZ), low-dose risperidone (RIS < 3 mg) and amisulpride (AMI).

functions, which are approximately defined by anatomical boundaries. The ventral parts of the caudate and putamen are limbic in function, being involved in emotional processing and salience. The caudate nucleus (particularly the anterior and lateral portions) is involved in associative learning, and the dorsomedial caudate and putmen are involved in the integration of motor function. These functional distinctions can be observed in the differences in symptomatology in two neurological conditions affecting different striatal regions. Parkinson's disease primarily affects the putamen, and individuals with the disease have a marked difficulty in initiating movements, as well as having the classic tremor and masklike facies that accompany the illness. Huntington's disease, on the other hand, shows greater deterioration of the caudate nucleus and affected individuals have more pronounced problems with associative learning than do persons with Parkinson's disease. Stone and colleagues studied the occupancy of two pharmacologically distinct SGAs in substriatal regions and found that both showed preferential occupancy of head of caudate nucleus over striatum (Figure 3). This finding has been replicated by Grunder and colleagues, who reported similar caudate selectivity of clozapine and amisulpride. Intrastriatal selectivity, although a relatively recent discovery, may also contribute toward the lack of EPSEs propensity in SGAs. Further work is required to confirm this finding in other SGAs and to determine whether FGAs also show caudate selectivity.

How Might Atypical Drugs Show Extrastriatal and Intrastriatal Selectivity?

Kapur and Seeman noted that the strongest single predictor of a drug's status as an SGA was a high dissociation constant (k_{off}). They hypothesized that, in regions where there was low competition for receptors by endogenous dopamine (such as cortical brain regions), drugs with a low k_{off} would bind readily. In striatal brain regions, where the highest levels of dopamine in the brain are found, they suggested that SGAs would not bind so readily, as they would compete poorly with endogenous dopamine. They hypothesized that this would lead SGAs to show preferential binding to cortical brain regions over the striatum. It is interesting to note that, within the striatum, anterolateral caudate and ventral regions are reported to have lower dopamine concentrations than are found in the putamen, suggesting that SGAs would preferentially bind to caudate over putamen, as has been shown using SPET and PET.

Dopamine Abnormalities in Schizophrenia

Because of the striking relationship between antipsychotic drug dopamine D2 receptor affinity and clinical potency, it was hypothesized that the major neurochemical abnormality in schizophrenia might be an elevation in dopamine transmission. Postmortem studies appeared to support this hypothesis, with the demonstration of elevated dopamine D2 receptor density in striatum in patients with chronic schizophrenia. These findings were potentially confounded by the long-term use of antipsychotic medication, which may have altered dopamine receptor expression. The development of PET and SPET allowed the study of dopamine D2 receptor density in unmedicated living patients with schizophrenia. The first study appeared to support the hypothesis of elevated D2 receptor density in the striatum in patients with schizophrenia, but the methodology of this study was

Figure 3 Occupancy map of dopamine D2 receptors for patients with schizophrenia treated with amisulpride (Ami) and low-dose risperidone (Risp). Lighter colors represent greater antipsychotic drug occupancy of dopamine receptors. An outline of the striatum has been overlaid and heads of caudate (C) and putamen (P) have been labeled. Both amisulpride and risperidone appear to preferentially bind to dopamine D2 receptors in head of caudate over head of putamen. Reproduced from Stone JM, Bressan RA, Erlandsson K, et al. (2005) Non-uniform blockade of intrastriatal D2/D3 receptors by risperidone and amisulpride. *Psychopharmacology (Berlin)* 180(4): 664–669, with kind permission of Springer Science and Business Media.

criticized. Later studies generally failed to show any difference in D2 receptor density in patients with schizophrenia and in controls. Two recent meta-analyses suggest that there may be a small elevation in D2 receptor density in schizophrenia, although there is significant overlap with controls.

The basically negative finding with regard to striatal dopamine D2 receptors in schizophrenia led groups to look for other evidence of dopamine dysregulation in the illness. Laruelle and colleagues used IBZM SPET to study dopamine release following amphetamine administration. Since endogenous dopamine displaces the binding of IBZM, it was possible to estimate the magnitude of dopamine release by comparing IBZM binding before and after amphetamine was given. Patients with schizophrenia were found to have increased dopamine release following amphetamine challenge compared to healthy controls. In subsequent studies, it was found that this dopamine release correlated with increase in positive psychotic symptoms.

Recent studies have extended analysis of dopamine receptors to regions outside the striatum. These have reported either low or normal D2 receptor density in patients compared to controls. Correlations between dopamine receptor binding and psychotic symptoms have also been found. Symptoms were found to correlate directly with D2 receptor binding in frontal cortex, and to correlate negatively with D2 receptor binding in temporal cortex and thalamus, suggesting that extrastriatal dopamine receptors may play an important modulatory role in psychotic symptom formation.

Negative Symptoms

Although positive psychotic symptoms of schizophrenia (hallucinations, delusions, disorders in flow of thought) generally show a response to antipsychotic drug treatment, the so-called negative symptoms (avolition, apathy, emotional blunting, self-neglect) do not appear so amenable to treatment. Some studies have shown that negative symptoms improve, to a certain extent, in line with positive symptoms, but others have not found any effect of conventional antipsychotic drugs on negative symptoms and, in most cases, there appear to be residual negative symptoms that are refractory to current drug treatment.

There are several theories about the basis for negative symptoms in schizophrenia, but the generally accepted theory is that they relate to hypofunction of the frontal cortex that is found in schizophrenia. There is some evidence that this frontal hypofunction may be driven by a reduction in dopaminergic transmission (compared to the elevation of striatal dopamine transmission found following amphetamine administration in patients with schizophrenia). Since antipsychotic drugs act primarily as dopamine antagonists, it can be seen that they would be expected to worsen negative symptoms. In fact, it has been shown that although patients with schizophrenia suffer an exacerbation of positive symptoms when taking amphetamine, their negative symptoms may even improve, possibly due to increased frontal dopamine release, with amphetamine.

Dopamine-Stabilizing Drugs

The newest development in currently available antipsychotic drugs in schizophrenia is the release of first 'dopamine-stabilizing' antipsychotic, aripiprazole. Aripiprazole has a very high affinity for the dopamine D2 receptor but, in contrast to other antipsychotic drugs, which are inverse agonists at the dopamine D2 receptor, aripiprazole is considered a weak partial agonist. The theory behind the use of partial agonists for the dopamine receptor as antipsychotic drugs is that they should be able to treat both positive and negative symptoms, by reducing activation of dopamine receptors where endogenous dopamine levels are high (through competition for the binding site), with the aim of treating positive symptoms, and increasing activation of dopamine receptors where dopamine levels are low (through intrinsic agonist activity), theoretically improving negative symptoms. So far, aripiprazole is the only partial dopamine D2 agonist that has been marketed as an antipsychotic drug. Other partial agonists showed initial antipsychotic efficacy, which was lost after repeated dosing, and recent work suggests that aripiprazole shows functional selectivity at the D2 receptor, with different levels of agonism depending on the signaling pathway activated, rather than acting as a simple partial agonist. Disappointingly, aripiprazole has not proved to be markedly more effective than other antipsychotic drugs are, but an extensive study on its effects in patients with severe negative symptoms has yet to be performed.

The Future of Antipsychotic Treatment in Schizophrenia

Recently, the search for effective antipsychotic drugs has extended beyond the dopamine system. The finding that drugs blocking the *N*-methyl-D-aspartate (NMDA) system, such as ketamine and phencyclidine (PCP), induce symptoms closely resembling those in schizophrenia (including both positive and negative symptoms) led to the suggestion that NMDA receptor function could be abnormal in schizophrenia. Drugs aiming to enhance NMDA receptor function, given in tandem with SGAs or FGAs, have generally shown modest improvements in negative symptoms, with little effect on reducing positive psychotic symptoms.

Acetylcholine transmission at the muscarinic receptor has also been implicated as being abnormal in schizophrenia. A SPET study of unmedicated first-episode patients with schizophrenia found a significant decline in binding to muscarinic receptors compared to healthy controls. Furthermore, both clozapine and its main active metabolite, *N*-desmethylclozapine, are partial agonists with very high affinity for M1 and M4 muscarinic receptors. Muscarinic partial agonists have also shown some promise as potential antipsychotic agents in preclinical studies.

Last, there has been interest in developing drugs acting at non-D_2 subtypes of the dopamine receptor. D1 receptor agonists have been suggested as being helpful for treating cognitive deficits and negative symptoms in schizophrenia, and preferential antagonists at the D_3 dopamine receptor subtype have been put forward as potential antipsychotic agents with fewer side effects compared to drugs with greater affinity for the D_2 subtype.

Conclusions

Despite recent research suggesting novel targets for antipsychotic drugs, D2 receptor antagonism remains an essential aspect of any medication for schizophrenic symptoms. Little progress in terms of antipsychotic efficacy has been made since the discovery of chlorpromazine, although SGAs have a much lower propensity to cause EPSEs than do FGAs. Clozapine still remains the most effective antipsychotic available, but the basis for its therapeutic superiority remains an enigma. Unraveling its actions will provide leads for novel therapies, with the hope of more effective, less toxic treatments for schizophrenia.

Neuroligin Genes and Structures

Individual neuroligins have extremely high sequence conservation across mammalian species (~99%), whereas the amino acid identity among individual neuroligins within the family is approximately 52% (Figure 1). Their globular, esterase domain has the highest sequence conservation (~72%) and the intracellular domain the lowest (~31%). Neuroligins are also related to a series of tactin proteins found in *Drosophila*: neurotactin, gliotactin, and glutactin.

Structurally, neuroligins contain four distinctive domains: (1) an N-linked glycosylated dimeric extracellular domain of approximately 630 amino acids; this domain belongs to the α,β-hydrolase fold and, as such, is homologous to many serine hydrolases, such as the cholinesterases; (2) a heavily O-linked glycosylated stalk region of approximately 50 amino acids that resembles a bottlebrush-like structure and links the above globular domain to the membrane; (3) a single transmembrane span; and (4) a cytoplasmic domain lacking a defined structure with a known fold but containing a PDZ recognition domain enabling interaction with scaffolding proteins on the intracellular side of the membrane. Neuroligin binds to the PDZ domain of several scaffolding proteins, including PSD95, SAP102, S-SCAM, Magi1 and -3, Shank1 and -3, Pick1, and GOPC. A dendritic-targeting motif is present in the cytoplasmic domain of neuroligin-1, distinct from the classical PDZ recognition motif.

With the four previously discussed domains, neuroligins have the capacity to serve as a heterophilic adhesion protein to dock and anchor proteins localized within the synaptic gap and, in turn, link with scaffolding molecules on the intracellular side of the cell membrane. The primary identified partner extending from the presynaptic membrane, neurexin, also has its synaptic recognition domain connected through an extendable stalk through the membrane, where its PDZ recognition domain interacts with PDZ motif proteins in the cytoplasm of the nerve ending.

The structure of the dimeric extracellular domain of the neuroligin molecule has been described at intermediate resolution through a combination of homology modeling with the crystal structures of the cholinesterases, low-angle X-ray and neutron scattering, and hydrodynamic analyses (Figures 2 and 3). The core structure is the neuroligin dimer stabilized through a four-helix bundle characteristic of many α,β-hydrolase fold proteins. Whereas hydrodynamic data indicate a 2:2 stoichiometry for the neuroligin–neurexin association, small-angle scattering studies establish the two neurexin sites to be on opposite sides of the long axis of the dimer near the neuroligin subunit interface. The O-glycosylated, linking sequence is also detected, extending tangentially from the dimer structure. The site of neurexin association appears distinct from the active center gorge of the cholinesterases, revealing that the adhesion and catalytic functions of the α,β-hydrolase fold proteins take place in discrete domains (Figure 3).

Recognition of the Neurexins

The neuroligin–neurexin system has built in a hierarchy for the molecular recognition code originating in the biosynthesis and processing steps. Neuroligin possesses as many as five genes (neuroligin-1 to -5), and whereas neuroligin-1, with its two alternative splice inserts (A and B), can encode for four splice variants, neuroligins-2 to -5 only show alternative splicing at position A (Figure 1). Neuroligins, encoded by the different genes and splice variants of neuroligin-1, show a differential affinity for the neurexins. Although the β-neurexins possess a higher affinity for the neuroligins, it has been shown that α-neurexin exhibits significant and graded interactions with the neuroligins. Finally, glycosylation and its processing also affect neuroligin affinity for neurexin in a negative manner. One of the influential glycosylation sites in neuroligin-1 is on an alternatively spliced region B. Given that both neuroligin and neurexin are encoded by multiple, alternatively spliced genes and they may be differentially expressed in various tissues, a complex code likely exists for the maintenance and formation of synapses. Moreover, it has been shown that neuroligin-1, -3, and -4 are associated with excitatory amino acid synapses in the central nervous system (CNS), whereas neuroligin-2 is associated with inhibitory synapses.

Neuroligins in Development and Disease

The importance of neuroligin in the formation and development of synapses was dramatically demonstrated in cell-based studies in which both neuroligins and neurexins presented on the surface of nonneuronal cells induced the formation of functional pre- and postsynaptic components involving partnering neuronal cells. Ultrastructure and electrophysiology show transfected neuroligin and neurexin appearing at the synaptic gap in a functional synapse. Further *in vitro*

Figure 1 Schematic representation of the domain organization of the mammalian neuroligins 1–4. The leader peptide is absent in the mature protein. N and O, consensus sequences for N- and O-linked glycosylation sites, respectively. For neuroligin-1, disulfide bonds were assigned, and glycosylation sites were identified by mass spectrometry. A fifth neuroligin has been described and located on the Y chromosome rather than the X chromosome for NL4. NL4 and NL5 have close sequence identity.

Figure 2 Ribbon representation of dimeric neuroligin-1 homology model. The structural model of the extracellular domain of the neuroligin-1 was generated using the crystal structure of mouse acetylcholinesterase as a template. Two monomeric neuroligin-1s are connected at the center of the image through a four-helix bundle typical of the α,β-hydrolase fold proteins. In the side view, the O-linked glycosylation region would extend toward the bottom of the page as visualized in **Figure 3**. The arrow indicates the direction and degree of rotation.

studies, using overexpression and knockdown of neuroligins, suggest that these molecules control the balance of inhibitory/excitatory synapses in the CNS. *In vitro* work has shown that the binding between the scaffolding protein PSD-95 and neuroligin can modulate the release probability of synaptic vesicles in a retrograde manner, suggesting a role for β-neurexin as a presynaptic mediator. *In vivo* studies have demonstrated that individual neuroligin knockout mice survive and are fertile, whereas the *NL1*, *NL2*, and *NL3* triple knockout mice die soon after birth because of respiratory failure. Ultrastructure of the synapses of these animals appears normal, but marked functional defects in synaptic transmission have been noted. This study indicates that neuroligins are necessary for synapse stabilization and maturation but not for the initial formation of synaptic contacts.

Genetic investigations have revealed a linkage in twin sets and siblings between the incidence of the autism spectral disorders and mutations in the neuroligin gene. Although the frequency of neuroligin polymorphism in the overall autistic population is low, this key finding, substantiated by an increasing number of studies, points to adhesion proteins or their associating partners (neurexin-1 and Shank-3) as being linked to the autism spectral disorders. Although some mutations result in a truncated and inactive protein, other nonsynonymous coding region single nucleotide polymorphisms give rise to neuroligins that are deficient in association properties or processing after biosynthesis. Mutants of the neuroligin-3 gene with defective processing, when transfected into mammalian cells, give rise to abnormal expression, trafficking, and localization as evidenced by altered patterns of clustering of the neuroligin. Hence, a cellular phenotype can be defined based on cell culture studies of the modified neuroligin.

Neuroligin in the Peripheral Nervous System and Secretory Tissues

In addition to their expression in the CNS, neuroligins are found in several other peripheral tissues such as the uterus, in which neuroligin-2 expression appears to be under the influence of both estrogens and progesterone, and in heart, liver, skeletal muscle, and pancreas, indicating that different neuroligins may have discrete functions in neurosecretory cells in the central and peripheral nervous systems.

Conclusions

Neuroligins are a family of closely related gene products of highly conserved sequences between species. Their extracellular domain utilizes a α,β-hydrolase fold similar to acetylcholinesterase. In the CNS, they

are found on postsynaptic surfaces and interact in a selective manner in synaptic space with presynaptic α and β neurexins. Their C-terminal recognition domains associate with several PDZ-containing synaptic proteins. *In vivo*, the neuroligins seem to be necessary for maintaining synapse integrity. Mutations in various neuroligin and neurexin genes appear to be linked to the autistic spectral disorders and mental retardation.

Neuromodulation

Introduction

The role of the nervous system is to control the body. This involves responding to sensory information from outside of the body and acting on information about internal drives or states. There is a tendency to think of information flow within the nervous system as an integration of excitatory and inhibitory input. However, the information processing performed by the nervous system is much more subtle and multifaceted.

Unfortunately, descriptions of complex phenomena tend to be reduced to simple dichotomies. In the case of information flow in the nervous system, the dichotomy is often presented as neurotransmission versus neuromodulation, where neurotransmission is taken to mean classical synaptic transmission (excitatory postsynaptic potentials and inhibitory postsynaptic potentials) and neuromodulation is everything else. Neuromodulation can also be defined as the alteration of cellular or synaptic properties by a neuron or a substance released by neurons. Thus, neuromodulatory actions do not necessarily convey excitation or inhibition, but they can lead to a change in the excitability of a neuron or a change in the strength of a synapse. In this way, neuromodulatory actions can be contingent upon the activity of the neurons being modulated. Neuromodulation can cause neurons and synapses to undergo state changes, effectively switching into a different processing mode.

It is useful to distinguish neuromodulation from homosynaptic plasticity such as frequency facilitation, synaptic depression, posttetannic potentiation (PTP), and long-term potentiation (LTP). In homosynaptic plasticity, the properties of a neuron or a synapse are altered by its own pattern of activity. This is different, in principle, from neuromodulation, which is the alteration of cellular and synaptic properties through the activity of another neuron and can thus be called heterosynaptic plasticity. Whereas homosynaptic plasticity changes how a neuron integrates information over time based solely on its own history, neuromodulation or heterosynaptic plasticity is imposed upon a neuron and, although it can depend on a neuron's own pattern of activity, provides new information to a neuron.

Neuromodulation is produced through a variety of mechanisms and plays diverse roles in information processing, from sensory adaptation to motor pattern selection and learning. Understanding the basics of neuromodulation is essential for understanding how the nervous system produces behavior.

Mechanisms of Neuromodulation

One of the primary mechanisms of neuromodulation is activation of G-protein-coupled receptors (GPCRs). GPCRs are membrane-bound neurotransmitter receptors that do not form ion channel pores; instead, they are linked via G-proteins to important intracellular signaling pathways. The association between neuromodulation and GPCRs is so strong that the two concepts have become practically synonymous. However, neuromodulation also occurs through other mechanisms that also produce changes in cellular and synaptic properties. These include influx of Ca^{2+} through ligand-gated ion channels and activation of intracellular receptors by membrane-permeable messengers such as nitric oxide (NO).

Most neurotransmitters act at both ligand-gated ion channels and GPCRs. Moreover, most postsynaptic membranes express a combination of ligand-gated ion channels and GPCR receptors. From this, several important conclusions can be drawn. First, neuromodulatory transmitters are not a specific chemical subgroup; nearly all neurotransmitters can have neuromodulatory effects. Second, neuromodulation is not particularly distinct from classic inhibitory/excitatory actions; both processes are likely to occur in parallel at most synapses. Finally, neuromodulation is not a 'rare' or 'specialized' form of neural communication; it is very common in the nervous system. In fact, the GPCRs of the endocannabinoid system are expressed at densities near the ligand-gated $GABA_A$ receptors that mediate most classical inhibition. In this light, it is a mistake to think of neuromodulation as secondary to neurotransmission; neuromodulation is a fundamental means by which information is processed in the nervous system.

The activation of G-proteins by GPCRs produces effects either through direct interactions of G-protein subunits with membrane proteins or by regulation of an enzyme that generates a second messenger. Several enzyme–second messenger systems have been identified, including, most notably, adenylyl cyclase–cAMP and phospholipase C–IP3/DAG. The second messengers can have direct actions on ion channels

or they can activate an effector enzyme such as a kinase or a phosphatase. For example, cAMP activates cyclic nucleotide-gated (CNG) channels and the enzyme protein kinase A. Similarly, IP3 gates IP3 receptors, which allow Ca^{2+} to enter the cytoplasm from intracellular stores. The elevation of intracellular Ca^{2+} together with DAG activates protein kinase C. Phosphorylation by kinases or dephosphorylation by phosphatases changes the conformation of proteins such as ion channels and thereby changes properties such as gating kinetics.

Neuromodulatory actions can also be mediated by other second messenger – effector systems that abound in neurons. For example, endocannabinoids and gaseous messengers such as NO evoke neuromodulatory actions. These messengers are cell-permeable metabolic by-products, not vesicularly released substances. As such, they do not act at anatomically defined synaptic contacts; rather, they can diffuse from the point of release. This type of local broadcast of a signal has been called volume transmission, in contrast to point-to-point transmission at defined synaptic contacts.

Neuromodulation of Neuronal Properties

Regardless of whether neuromodulation occurs via GPCR activation or another mechanism, the end result is an alteration of neural function. There are three possible targets: neuronal properties, presynaptic release, or postsynaptic responsiveness (Figure 1). The site of action implies a particular type of neuromodulatory effect with its own implications for signal processing.

The primary mechanism by which neuromodulation alters neural properties is through the modification of ion channel function and expression. This is a powerful target of action because the passive and active properties of a neuron are determined largely by the relative densities of ion channels expressed and their functional properties. By altering ion channel function, neuromodulators can shape the complex and highly nonlinear passive and active properties of a neuron (Table 1).

To understand the role that neuromodulation of ion channels can play in shaping neuronal properties, consider a simple Hodgkin–Huxley-style neuron that has just two types of channels: a voltage-gated sodium conductance (G_{Na}) and a delayed rectifier potassium conductance (G_K) (Figure 2). If neuromodulatory

Figure 1 Neuromodulatory inputs (arrows) acting at G-protein-coupled receptors can affect neurons at three distinct sites. (a) Neuronal properties can be affected by changes in the properties of membrane ion channels. (b) Synaptic release can be affected by changes in the properties of synaptic release proteins. (c) Synaptic responses can be affected by changes in neurotransmitter receptors.

inputs alter the maximal conductance of G_K, the properties of the neuron will vary tremendously. For example, if the neuron is tonically active at rest (Figure 2 (b)), then decreasing G_K will increase the spontaneous firing rate of the neuron (Figure 2(a)), and increasing G_K can cause the neuron to become silent at rest (Figure 2(c)). Thus, neuromodulation of one type of ion channel in this simple example changes the neuron's basal firing properties.

Neuromodulation of ion channel properties can do more than alter a neuron's tonic firing properties. Changes can also occur in the way a neuron integrates synaptic input, the location of action potential initiation, the speed and shape of the action potential, and the success of action potential propagation. One type of modulatory change that has attracted particular interest is the regulation of firing mode. For example, neuromodulation of ion channel properties can shift a neuron from tonic activity into an oscillatory state, in which it fires rhythmic bursts of action potentials. Alternatively, neuromodulation can regulate membrane potential bistability. Bistable neurons exhibit two stable states: a quiescent state below threshold and an active state above threshold in which a long-lasting plateau potential is produced. Neuromodulation can shift neurons between these states and/or change the probability of shifting between these states. The regulation of firing mode indicates that neuromodulation can exert significant influence on a neural circuit even in the absence of ongoing synaptic input.

Although ion channel function serves as an important target for neuromodulation, neural properties can also be altered by changes in neural morphology. This type of change may be particularly important for expressing modulatory changes at long timescales.

Figure 2 The firing properties of a simple Hodgkin–Huxley model neuron change by altering the maximal potassium conductance. The conductance was varied by multiplying the number of potassium channels by 0.5 (a), 1.0 (b), or 2.0 (c). With the potassium conductance halved (a), the neuron exhibits a higher rate of spontaneous firing. When the conductance is doubled (c), the neuron is not spontaneously active but responds to injected current (bottom trace). Stimulation produced using http://www.afodor.net/HHModel.htm.

Neuromodulation of Synaptic Properties

Neuromodulation not only affects the firing properties of neurons but can affect the synaptic properties of neurons as well (Table 2). This can occur through presynaptic modulation of release (Figure 1(b)) or postsynaptic sensitivity (Figure 1(c)).

On the presynaptic side, a number of modulatory targets are available. One common mode of action is again the modification of ion channel function. For example, increasing the maximal conductance of voltage-gated Ca^{2+} channels increases the Ca^{2+} influx for each action potential and thereby increases synaptic strength. If the targeted ion channels are localized to synaptic regions, this type of neuromodulation can occur independently of changes in neuronal firing properties. In addition to ion channels, presynaptic terminals expose a number of additional targets for neuromodulation. For example, changes in the extrusion of Ca^{2+} from intracellular stores affect synaptic release. Also, phosphorylation of proteins related to the synaptic release mechanism alters the amount of neurotransmitter released in response to Ca^{2+} influx.

Table 2 Partial list of synaptic properties that are subject to neuromodulation

Synaptic strength
Synaptic depression
Synaptic facilitation
Synaptic plasticity
Voltage sensitivity
Ion selectivity

Postsynaptic modification is also an important aspect of neuromodulation (**Figure 1(c)**). As on the presynaptic side, a diversity of targets are available for regulation. For example, phosphorylation of neurotransmitter receptors can alter their conductances or even their rates of desensitization, thereby affecting synaptic strength. Altering the relative contributions of different postsynaptic receptors can also have important implications for the information conveyed by a synapse. For example, at glutamatergic synapses, neuromodulatory changes that enhance the role of NMDA receptors over AMPA/kainate receptors will change the extent of Ca^{2+} influx into the synapse.

Finally, neuromodulation can also produce more global changes in synapse structure and function. This includes changes in synapse morphology, changes in spine morphology, and/or changes in the total number of synaptic contacts between neurons. These changes can serve to either increase or decrease the synaptic coupling between neurons.

Regardless of the site of synaptic change, it is important to consider that neuromodulation can result in more than a simple alteration in synaptic efficacy (stronger or weaker synapse): It can extend to a change in synaptic dynamics. For example, homosynaptic depression is a decrease of synaptic strength with the repeated activation of a synapse. Similarly, homosynaptic facilitation is a frequency-dependent increase in synaptic strength. Neuromodulatory actions can change the rates of depression and facilitation at synapses, allowing synaptic dynamics as well as strength to vary.

Neuromodulation can also change the susceptibility of a synapse to other forms of plasticity. This is known as metaplasticity. Neuromodulation can raise or lower the threshold for inducing several forms of synaptic plasticity, including PTP to LTP and long-term depression (LTD). Because LTP and LTD are believed to be particularly important for learning and memory, it seems that modulatory metaplasticity may be an important regulator of these processes. Specifically, neuromodulatory inputs may act as a gate for permitting synaptic changes that result in learning and memory.

By analogy with metaplasticity, neuromodulatory actions can be changed by neuromodulation, a situation that has been termed metamodulation. In some cases, one neuromodulatory action gates another. In other cases, it has been shown that neuromodulatory inputs converge on the same target, producing nonlinear summation of actions. The modulation of a modulation may play an important role in the control of neural circuits.

Time Course of Neuromodulation

Neuromodulation was traditionally thought of as having a gain-setting function, producing a static alteration in neural or synaptic function. It is now becoming clear, however, that neuromodulation is highly dynamic, operating on multiple timescales ranging from milliseconds to days.

Part of the early perception of neuromodulation as a static process probably stemmed from limitations in methodology. It is often difficult to selectively activate neuromodulatory neurons and record from appropriate targets, so neuromodulation is typically studied by direct application of a neuromodulatory substance. This static application tends to produce static effects, reflecting more on the mode of application than on the true nature of neuromodulation.

A clearer view of the dynamic nature of neuromodulation comes from studies in which it has been possible to directly evoke neuromodulatory action via selective activation of neuromodulatory neurons. In these cases, it has been shown that modulation can have a very rapid onset and decay, sometimes lasting only a few seconds. Moreover, a single modulator can evoke multiple processes operating on different timescales. This produces a highly dynamic pattern of neuronal and synaptic change.

The recognition that neuromodulation can occur on multiple timescales raises the question of how the time course of modulation is controlled. One important parameter seems to be the pattern of exposure to the modulator. Specifically, short pulses of the modulator can activate different intracellular pathways than a sustained exposure, leading to very different patterns of expression over time.

Another important aspect of the time course of modulation is the mechanism of action. Unlike the fast excitatory/inhibitory actions of neurotransmitters, neuromodulatory actions occur primarily via activation of GPCRs, which activate intracellular signaling cascades. Thus, neuromodulatory actions can greatly outlast the presence of the modulatory neurotransmitter. In fact, neuromodulation can have extremely long-lasting effects on neural function. In these cases, it seems that the primary target of modification is the transcriptional machinery of the neuron, enabling relatively permanent changes in neural and synaptic function. Thus, neuromodulators can act over a tremendous array of timescales, sometimes with multiple processes having different time constants.

The Complexity of Neuromodulation

From this overview, it should be clear that neuromodulation can alter nearly every aspect of neuronal and synaptic function. Moreover, these alterations can be highly dynamic, involving parallel signaling pathways operating over vastly different timescales. Unfortunately, the situation becomes even more

complicated once it is considered that neuromodulation never occurs within a vacuum but, rather, as part of the function of a complex and dynamic neural network.

One consequence is that neuromodulatory effects will have complex reverberations both at the direct sites of modulation and throughout the network. For example, in the mollusk *Aplysia californica*, serotonin produces neuromodulation that alters the function of voltage-gated potassium channels in some sensory neurons. The primary effect of this modulation is a narrowing of the action potential. Spike narrowing alters the active properties of the sensory neurons, making it possible to fire action potentials more rapidly. In addition, narrower spikes reduce synaptic release by limiting the duration of Ca^{2+} influx during each action potential. The decrease in initial release also slows the depression that occurs during a sustained activation, thus altering synaptic dynamics. Presumably, alterations in sensory neuron synaptic dynamics alter the ability to activate postsynaptic targets, but predicting exactly how faster, smaller, less depressing excitatory postsynaptic potential trains will influence postsynaptic activity is clearly quite challenging. This is especially true given that serotonin has several parallel effects on *Aplysia* sensory neurons.

Sources of Neuromodulation

In the mammalian brain, there are nuclei that are known to provide diffuse neuromodulatory input to other areas of the brain. Serotonergic axons arising from neurons in the raphe nuclei project to other brain areas. It is thought that practically every neuron in the brain receives some serotonergic input. Similarly, dopamine projects to other areas of the brain from the substantia nigra and the ventral tegmental area. Noradrenergic fibers originate in the locus coeruleus. Cholinergic axons originate in the basal forebrain region. Thus, these neuromodulatory substances arise from neurons whose cell bodies are clustered in discrete nuclei and project to diverse areas of the nervous system. Clearly, these neurons are extrinsic to the local circuits that they affect; thus, they are considered extrinsic neuromodulation.

Neuromodulation does not arise only from brain nuclei. Sensory input can also evoke neuromodulatory actions. This was noted with respect to muscle receptors in the crab stomatogastric nervous system. Neuromodulation is also present within sensory structures such as the retina. For example, some dopaminergic interplexiform neurons modulate the strength of electrical coupling between horizontal cells in the retina.

In contrast to extrinsic neuromodulation, neurons intrinsic to a local circuit can also exert neuromodulatory actions on other neurons within that circuit. For example, in the central pattern generator (CPG) for swimming in the mollusk *Tritonia*, some serotonergic neurons are rhythmically active and necessary for producing the swim motor pattern. They also alter the strength of synapses made by other members of the swim CPG. Thus, these neurons represent an example of intrinsic neuromodulation, in which the neuromodulatory elements are part of the local circuit. There are many examples in which neurons evoke neuromodulatory actions in addition to their classical neurotransmitting actions. It is likely that it will turn out to be a rule rather than an exception that neurons alter the properties of other neurons at the same time that they convey excitation or inhibition.

Functions of Neuromodulation

Neuromodulation has been implicated in a variety of functions at all levels of the nervous system. By changing cellular and synaptic properties, neuromodulation can adjust the gain of sensory input to the nervous system, the activity of interneurons, the output of motor neurons, and even the responses of muscles. Neuromodulation therefore provides the nervous system with the ability to extend the dynamic range of neurons and effectors as well as change the state of operation of systems.

The dynamic range of sensory neurons (i.e., the range of input values that elicit linear changes in the response) can be adjusted through neuromodulatory mechanisms. This can contribute to sensory adaptation or it can be used for dynamic filtering of sensory input. In central circuits, the receptive field properties of neurons can be adjusted by neuromodulation. For example, serotonin alters the sound frequency selectivity of auditory-responsive neurons in the inferior colliculus of echolocating bats.

For neuromuscular systems, neuromodulation can adjust the amplitude of contraction as well as the relaxation rates of muscles. This can alter how muscles respond to motor neuron input. For example, if the time constant of relaxation of a muscle is longer than the interval between motor neuron bursts, then contractions will summate. Increasing the muscle relaxation rate will allow the muscle to follow the motor neuron input with discrete contractions. Neuromodulation of amplitude and relaxation rate plays a role in the control of feeding movements in the mollusk *Aplysia*.

Neural circuits process information or generate activity based on the properties of their component

neurons and synapses. Since neuromodulation can change neuronal and synaptic properties, it can change how neural circuits process information or generate activity. In this way, neuromodulation can cause an ensemble of neurons to produce different patterns of activity. In motor systems, this results in the generation of different movements by the same motor circuitry.

A classic example of the ability of neuromodulation to alter the generation of motor activity comes from the stomatogastric ganglion of lobsters and crabs. This small ganglion contains just 30 neurons that comprise two semiautonomous CPG circuits, which control the rhythmic movements of the animal's foregut. The synapses among these neuronal circuits comprise an anatomically defined neural network. The motor patterns produced by this neural network depend on the neuromodulatory input that the ganglion receives; neuromodulatory inputs to the stomatogastric ganglion cause neurons to change their phase relations and their levels of activity and even switch their participation from one CPG to another. Thus, neuromodulatory inputs cause this anatomically defined network of neurons to be configured into different functional networks, which correspond to different modes of activity.

Homeostasis and Neuromodulation

The ability of neuromodulation to change cellular properties and thereby cause neural circuits to produce different outputs implies that the nervous system might be infinitely flexible. However, this does not appear to be the case. The anatomical pattern of synaptic connectivity constrains the neurons in a neural circuit to a limited range of possible firing patterns. Furthermore, not all combinations of ion channel properties result in adaptive cellular properties. For example, if potassium conductance overwhelms sodium conductance, then the neuron will not be able to fire an action potential, which would clearly be outside of the range of functionally relevant states.

Neurons have homeostatic corrective mechanisms that keep their cellular and synaptic properties within a functional range that is appropriate for each type of neuron. Thus, if the firing rate of a neuron decreases, the neuron will compensate by downregulating potassium channels or upregulating excitatory inputs.

The function of neuromodulation must be viewed within the context of homeostatic regulation. That is, neuromodulation does not determine cellular and synaptic properties; it merely perturbs them temporarily from their current state. In the presence of persistent neuromodulation, a neuron may homeostatically adapt to restore its basal properties. In this way, neuromodulation expands the dynamic range of neurons by allowing their properties to be up- and downregulated.

Neuromodulation and the Evolution of Behavior

Neural circuits, under the control of neuromodulation, can be multifunctional. Therefore, it follows that a mechanism underlying the evolution of species-specific behavior could involve alterations of neuromodulation. There is evidence that this has occurred. For example, in the stomatogastric system of decapod crustaceans, there are species differences in the neuromodulatory inputs even though the basic interconnectivity of the CPG circuits remains conserved across species.

Changes in the expression of GPCRs can alter the function of neuronal circuits. This can have far-reaching effects for the behavior of the animal. For example, it has been found that pair bonding by male prairie voles with their female partners is dependent on vasopressin receptor activation in the nucleus accumbens. However, the closely related montane voles lack these vasopressin receptors in that area of the brain and do not exhibit pair bonding. Thus, evolution of a complex social behavior may have involved a shift in the localization of neuropeptide receptors.

Summary

Neuromodulation plays an important, if underappreciated, role in information processing by the nervous system. By changing neuronal and synaptic properties, neuromodulatory actions reconfigure neuronal circuits and enable a wider variety of sensory responses and motor patterns to be produced by neural circuits. Without neuromodulation, the nervous system would act more like a hardwired device. Neuromodulatory actions bring the brain to life by endowing neural circuits with tremendous flexibility. Any mechanistic theory of how the brain produces behavior must take into account neuromodulatory signaling.

Neuromodulation of Calcium Channels

A Lee, Emory University School of Medicine, Atlanta, GA, USA

Introduction

Voltage-gated (Ca_v) Ca^{2+} channels play dual roles in controlling membrane excitability and activating Ca^{2+} signaling events in neurons. Ca_v channels contribute a depolarizing inward current, which influences the generation and duration of action potentials in some neurons. Ca_v channels also act as transduction elements, converting depolarizing stimuli into intracellular Ca^{2+} signals that activate gene transcription, protein phosphorylation, and neurotransmitter release. Therefore, factors that modulate Ca_v channel properties can powerfully influence cellular processes governing the proper development and function of the nervous system.

Multiple mechanisms have been identified that directly or indirectly adjust various parameters of neuronal Ca_v function. These include neurotransmitters acting through G-protein-coupled receptors, alternative splicing of the pore-forming Ca_v α_1 subunit, and direct interactions between Ca_v channels and various neuronal proteins. Neuromodulators can increase or inhibit the ability of Ca_v channels to open, close, or inactivate in response to membrane depolarization. They can also alter the localization or targeting of Ca_v channels to the plasma membrane and to discrete pre- or postsynaptic microdomains of neurons. The detailed molecular characterization of Ca_v channels has allowed the identification and analysis of factors that modulate Ca_v channels. Due to the relatively recent identification of the molecular sequences for Ca_v3 channels, considerably greater progress has been made to date in understanding the regulatory influences for Ca_v1 and Ca_v2 and the physiological consequences of these forms of modulation in the nervous system.

Neurotransmitter Modulation of Ca_v2 Channels

Mechanisms of G-Protein Modulation

$Ca_v2.2$ channels (which conduct N-type currents) and $Ca_v2.1$ channels (which conduct P/Q-type currents) are inhibited by neurotransmitters such as norepinephrine and γ-aminobutyric acid (GABA), which are agonists for receptors coupled to heterotrimeric G-proteins. Ca_v2 channels are largely expressed in presynaptic nerve terminals, where they mediate Ca^{2+} signals that trigger neurotransmitter release. G-protein-dependent inhibition of Ca_v2 is blocked by pertussis toxin, which inactivates $G\alpha_i$ and $G\alpha_o$, and can occur via two mechanisms.

Voltage-dependent G-protein inhibition Ca_v2 channel inhibition by G-proteins can occur by a voltage-dependent pathway, where inhibition is strong at negative, but not at very positive, membrane potential, such as during intense neuronal activity. This mechanism is fast (milliseconds) and membrane delimited in that it does not require the generation of second messengers: receptor activation causes G-protein $\beta\gamma$ subunits to dissociate from $G\alpha$ subunits and bind directly to the Ca_v2 α_1 subunit ($\alpha_1 2.2$). In electrophysiological recordings, voltage-dependent G-protein inhibition manifests as (1) slowing of Ca_v activation kinetics during sustained depolarizations, (2) depolarizing shift in activation voltage, and (3) relief of current inhibition (facilitation) by strong depolarizing prepulses. $G\beta\gamma$ binds to sites in the cytoplasmic N- and C-terminal domains of $\alpha_1 2.2$, and to two sites in the loop connecting domains I and II (Figure 1). These interactions coordinate conformational changes that cause channels to be 'reluctant' to open. Strong depolarization relieves the inhibitory conformations favored by $G\beta\gamma$, restoring channels to a 'willing' mode of opening. Inhibition by the membrane-delimited pathway is generally more prominent for $Ca_v2.2$ than for $Ca_v2.1$ and allows for rapid presynaptic inhibition by neuromodulators.

Voltage-independent G-protein inhibition A second route by which G-proteins inhibit Ca_v2 does not depend on membrane potential and can involve cytosolic second messengers. As a consequence, this voltage-independent inhibition is relatively slow (seconds) and can result from multiple mechanisms. In sympathetic neurons, $Ca_v2.2$ channels are inhibited by agonists of M1 muscarinic acetylcholine receptors, which are linked via $G\alpha_{q/11}$ to the activation of phospholipase $C\beta$. This enzyme hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_2) to the second messengers inositol 1,4,5-trisphosphate and diacylglycerol. PIP_2 depletion can itself cause slow, voltage-independent suppression of $Ca_v2.2$ in neurons and also $Ca_v2.1$ expressed in *Xenopus* oocytes. As has been shown for other ion channels, PIP_2 can interact directly with the $Ca_v2.1$ α_1 subunit ($\alpha_1 2.1$) and support channel activity, which would be reversed upon PIP_2 depletion by the $G\alpha_{q/11}$ pathway. However, phosphoinositide hydrolysis can liberate arachidonic acid, which has also been

	Modulator	Effect on Ca$_v$2

Figure 1 G-protein modulation of Ca$_v$2 channels. (Top) Schematic of Ca$_v$2 α subunit with Gβγ binding sites indicated. Factors supporting and opposing G-protein inhibition are shown as solid and dotted arrows, respectively. Regulators of G-protein signaling (RGS) proteins, protein kinase C (PKC), and syntaxin 1A affect voltage-dependent inhibition (black), while tyrosine kinases (TK) and phosphatidylinositol 4,5-bisphosphate/arachidonic acid (PIP$_2$/AA) are involved in voltage-independent pathways (red). PKC also affects soluble *N*-ethylmaleimide-sensitive attachment factor receptor (SNARE) binding to the synaptic protein interaction (synprint) site (blue dashed arrow). (Bottom) Major factors influencing voltage-dependent and voltage-independent G-protein regulation of Ca$_v$2.

implicated in the slow inhibition of Ca$_v$2.2. Therefore, voltage-independent inhibition of Ca$_v$2 channels via Gα$_{q/11}$ signaling is complex and may involve multiple lipid mediators.

A second mechanism for voltage-independent Ca$_v$2 inhibition occurs on a longer timescale (minutes) and is mediated by receptors coupled to Gα$_{i/o}$. Activation of these receptors by GABA promotes phosphorylation of α$_1$2.2 by tyrosine kinases and/or removal of the channel from the plasma membrane. The latter mechanism can involve direct receptor/Ca^{2+} channel interactions and internalization of the entire G-protein-coupled receptor/Ca$_v$2.2 complex. Ca$_v$2.2 channel internalization may allow for short-term desensitization and subsequent resensitization of activity-dependent presynaptic Ca^{2+} signals.

Modulators of G-Protein Inhibition

Ca$_v$2 inhibition by G-proteins can be controlled by a number of regulatory factors: proteins that are regulators of G-protein signaling (RGS), synaptic proteins, protein kinase C, and Ca$_v$2 α$_1$ splice variation.

RGS proteins RGS proteins cause ~100-fold stimulation of the GTPase activity of Gα, which promotes reassociation with Gβγ and restoration of the inactive G-protein heterotrimer. By limiting levels of active Gβγ, RGS proteins can terminate voltage-dependent inhibition of Ca$_v$2 channels. However, RGS proteins can also act through direct interactions with α$_1$2.2 to reverse voltage-independent modulation by G-proteins. For example, the GABA-B receptor-dependent phosphorylation of a tyrosine residue in the domain II–III linker initially promotes voltage-independent Ca$_v$2.2 inhibition that is eventually reversed by recruitment of RGS12 to this site (Figure 1). Greater than 20 RGS family members have been identified; they show specificity not only in how they turn off G-protein inhibition, but also in which G-protein signaling pathways are affected. Therefore, RGS proteins may

significantly influence the level and specificity of Ca_v2 channel inhibition by G-protein-coupled receptors.

Synaptic proteins $Ca_v2.1$ and $Ca_v2.2$ interact directly with soluble *N*-ethylmaleimide-sensitive factor (NSF)-attachment factor receptor (SNARE) proteins involved in the exocytotic release of neurotransmitter from presynaptic nerve terminals. SNAREs, which include syntaxin 1 and SNAP-25, interact with the synaptic vesicle Ca^{2+}-binding protein, synaptotagmin, during exocytosis. Biochemical studies indicate that SNAREs bind to a synaptic protein interaction ('synprint') site in the domain II–III linker of $Ca_v2\alpha_1$ (Figure 1). These interactions are generally thought to facilitate coupling between presynaptic Ca^{2+} entry and the neurotransmitter release machinery, but can also directly regulate the gating and G-protein modulation of Ca_v2 channels.

Syntaxin 1A is a membrane-associated protein that limits the functional availability of $Ca_v2.2$ by causing a decrease in channel expression levels and a hyperpolarizing shift in the steady-state inactivation curve. The effects on inactivation can be reversed by botulinum toxin C1, which cleaves syntaxin 1 close to its membrane anchor. In presynaptic nerve terminals, botulinum toxin C1 also prevents Ca_v2 inhibition by G-proteins. Biochemical studies indicate that syntaxin 1A binds to G-protein β subunits. When co-expressed with $Ca_v2.2$ in mammalian cells, syntaxin 1A facilitates tonic voltage-dependent G-protein inhibition of $Ca_v2.2$, perhaps by recruiting $G\beta$ into the channel complex. The syntaxin 1B isoform, which is ~80% identical to syntaxin 1A but is encoded by a separate gene, binds $\alpha_1 2.2$ and $G\beta$, but does not support G-protein modulation. This difference may arise from conformational distinctions in how syntaxin 1B versus syntaxin 1A interacts with $\alpha_1 2.2$ and/or $G\beta$. Variations in syntaxin 1A and syntaxin 1B expression, which occur between neurons and during development, may therefore determine the extent to which neuronal $Ca_v2.2$ channels are tonically regulated by G-proteins.

Protein kinase C Receptors coupled to $G\alpha_q$ activate protein kinase C (PKC), which can antagonize G-protein inhibition of $Ca_v2.2$. When activated pharmacologically by phorbol esters, PKC phosphorylates a threonine residue located in the $G\beta\gamma$ binding site of the $\alpha_1 2.2$ loop I–II linker (Figure 1), which opposes voltage-dependent inhibition by $G\beta\gamma$. PKC can also phosphorylate multiple sites in the synprint region of the $\alpha_1 2.2$ loop II–III linker. Phosphorylation of specific residues inhibits the ability of syntaxin 1A to cause negative shifts in $Ca_v2.2$ steady-state inactivation but not effects of syntaxin 1A on tonic G-protein regulation. Complex regulation of $Ca_v2.2$ channels by protein kinase C and $G\beta\gamma$ may permit dynamic control of presynaptic Ca^{2+} signals by 'cross-talk' of receptors coupled to functionally distinct G-proteins.

Ca_v2 α_1 splice variation Ca_v α_1-subunit genes are composed of multiple exons. Variable inclusion of particular exon sequences or exclusion of intron sequences during pre-mRNA processing can directly affect voltage-dependent Ca_v2 inhibition by $G\beta\gamma$. An $\alpha_1 2.1b$ variant containing a valine insertion in one of the two $G\beta\gamma$ binding sites in domain I–II linker shows stronger but slower inhibition by agonists of the μ-opioid G-protein-coupled receptor, compared to channels with $\alpha_{1A\text{-}a}$, which lacks the valine insertion. Expression of $\alpha_1 2.1b$ in some nerve terminals may therefore alter the efficiency with which Ca^{2+}-induced neurotransmitter release is presynaptically suppressed by $G_{i/o}$-linked receptors.

Cell-type-specific alternative splicing can also alter voltage-independent G-protein regulation of Ca_v2 channels. An $\alpha_1 2.2$ variant containing the alternatively spliced C-terminal exon 37a is mainly expressed in pain-transmitting nociceptive neurons that synapse in the dorsal horn of the spinal cord. Inclusion of exon 37a maintains voltage-dependent G-protein inhibition, but also strengthens voltage-independent inhibition by opiates and GABA, which depends on phosphorylation of a unique tyrosine residue in the alternatively spliced region (Figure 1). Since high-frequency stimulation relieves voltage-dependent inhibition of $Ca_v2.2$ by G-proteins, $\alpha_1 2.2$ variants containing exon 37a may allow for maintained suppression of presynaptic $Ca_v2.2$ channels and neurotransmission even during periods of heightened neuronal activity. This mechanism may be important for the analgesic effects of neurotransmitters and drugs on pain transmission in the spinal cord.

Neurotransmitter Modulation of Ca_v1 Channels

Ca_v1 (L-type) channels are also subject to modulation by G-protein-coupled receptor agonists (Figure 2). $Ca_v1.2$ channels are strongly potentiated by activation of β-adrenergic receptors coupled to G_s proteins. Initially characterized in the heart, this regulation involves a signal transduction pathway resulting in phosphorylation of the $Ca_v1.2$ α_1 subunit ($\alpha_1 1.2$) by cAMP-dependent protein kinase, which increases the duration and frequency of channel openings. Facilitation of $Ca_v1.2$ Ca^{2+} signals in response to β-adrenergic receptor agonists also occurs in individual dendritic spines of hippocampal neurons, suggesting that β receptors, $Ca_v1.2$, and signaling components must be highly

	GPCR	Effect on Ca_v1 currents
$Ca_v1.2$	β-Adrenergic	Facilitation
$Ca_v1.3$	D1 dopamine M1 Ach	Inhibition
	5HT serotonin	Facilitation

Figure 2 G-protein modulation of Ca_v1 channels. Major G-protein-coupled receptor (GPCR) regulatory pathways for $Ca_v1.2$ and $Ca_v1.3$. Increases in cAMP caused by β-adrenergic receptor activation promote $\alpha_1 1.2$ phosphorylation by cAMP-dependent protein kinase A (PKA), which is recruited to the channel by A-kinase anchoring proteins (AKAPs). The resulting facilitation of $Ca_v1.2$ is reversed by $\alpha_1 1.2$ dephosphorylation via associated protein phosphatase 2A (PP2A). $Ca_v1.3$ channels are potentiated by serotonin (5-hydroxytryptamine, 5HT) receptors and inhibited by dopamine (D2) and muscarinic acetylcholine (M1) receptors. The latter effect requires targeting of $Ca_v1.3$ to postsynaptic sites via the scaffolding protein, Shank, which binds to the $\alpha_1 1.3$ C-terminus.

compartmentalized. Biochemical studies confirmed the existence of an entire signaling complex (β-adrenergic receptor, $Ca_v1.2$, G_s-protein, adenylyl cyclase, cAMP-dependent protein kinase) that allows for rapid and localized signaling from receptor to Ca^{2+} channel. Efficient modulation of postsynaptic $Ca_v1.2$ channels may be required for the central role of these channels in Ca^{2+}-dependent synaptic plasticity.

Although expressed at lower levels than $Ca_v1.2$ in the nervous system, $Ca_v1.3$ is a second class of L-type channel that is regulated by G-protein-coupled receptors. $Ca_v1.3$ channels activate in a more negative voltage range than do $Ca_v1.2$ channels and therefore can facilitate attainment of action potential thresholds and regulate neuronal firing patterns. In spinal motoneurons and interneurons, $Ca_v1.3$ channels contribute to plateau potentials important for bistability and plasticity of postsynaptic depolarizations. $Ca_v1.3$ currents in these neurons are facilitated in response to activation of $G\alpha_q$-linked serotonin or metabotropic glutamate receptors that promote intracellular Ca^{2+} release. $Ca_v1.3$ facilitation is Ca^{2+} dependent in that it is blocked with high intracellular concentrations of Ca^{2+} chelators such as ethylene glycol tetraacetic acid (EGTA), and serves to modify the excitability and selective recruitment of motoneurons for the coordinated control of muscles during movement.

$Ca_v1.3$ channels are also inhibited by neurotransmitters such as dopamine and acetylcholine. In the striatum, $Ca_v1.3$ Ca^{2+} currents promote glutamatergic receptor-driven 'upstates' in medium spiny neurons, which are characterized by increased excitability. Activation of dopamine receptors and muscarinic acetylcholine receptors suppresses these upstate transitions by inhibiting $Ca_v1.3$. This inhibition requires a sequence in the distal C-terminal domain of the $Ca_v1.3$ α_1 subunit ($\alpha_1 1.3$), which is a consensus site for binding postsynaptic density-95 (PSD-95)/discs/large/zona occludens-1 (PDZ) domains, which are protein interaction modules present in a large variety of proteins. $Ca_v1.3$ channels interact with postsynaptic PDZ proteins, which act as molecular scaffolds and target these channels to particular synapses in medium spiny neurons, where they can be modulated by dopamine or

acetylcholine receptors. Thus, the formation of receptor/Ca^{2+} channel complexes is an important means for maintaining the specificity and efficiency of $Ca_v1.3$ channel regulation by neuromodulators (Figure 2).

Neurotransmitter Modulation of Ca_v3 Channels

Ca_v3 (T-type) channels are subject to both inhibitory and stimulatory regulation by neurotransmitters, peptides, and hormones acting through G-protein-coupled receptors. Ca_v3 channels are activated more negative voltages than are Ca_v1 and Ca_v2 channels, and are important for action potential bursting, transmission of noxious stimuli, and hormone secretion. There is considerable heterogeneity in how different Ca_v3 channels ($Ca_v3.1$–$Ca_v3.3$) respond to various stimuli and their underlying molecular mechanisms. $Ca_v3.2$ channels are inhibited by G_i-linked receptors in a membrane-delimited pathway mediated by direct binding of $G\beta\gamma$ to sites in the domain II–III linker. This effect differs from voltage-dependent inhibition of Ca_v2 channels in that it does not involve positive shifts in activation voltage or reversal by strong depolarizations. The II–III linker of $Ca_v3.1$ α_1 ($\alpha_1 3.1$) cannot bind $G\beta\gamma$ and therefore does not support similar G-protein inhibition of $Ca_v3.1$. The II–III linker of $Ca_v3.2$ α_1 ($\alpha_1 3.2$) is also the locus for the direct tethering and stimulatory effects of calmodulin-dependent protein kinase II, and so may coordinate modulatory cross-talk between receptors coupled to G_q and G_i.

Ca^{2+}-Dependent Modulation of Ca_v Channels

Although Ca_v channels readily conduct both Ca^{2+} and Ba^{2+} ions, L-type and P/Q-type Ca^{2+} currents decay (inactivate) strikingly faster than do Ba^{2+} currents. This process, Ca^{2+}-dependent inactivation, efficiently prevents Ca^{2+} overloads and refines activity-dependent Ca^{2+} signals in excitable cells. In cardiac myocytes, Ca^{2+}-dependent inactivation of $Ca_v1.2$ helps terminate action potentials and is surprisingly insensitive to high intracellular concentrations of Ca^{2+} chelators such as EGTA or 1,2-bis (*o*-aminophenoxy)ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid (BAPTA). This latter result indicates that Ca^{2+}-dependent inactivation for $Ca_v1.2$ depends on very rapid, local increases in Ca^{2+} either in or near the channel pore.

Ca^{2+}-dependent inactivation was long considered specific for L-type currents, in part because most whole-cell patch clamp recordings employed high concentrations of EGTA or BAPTA (5–10 mM) in the intracellular recording solution, levels which are permissive for Ca^{2+}-dependent inactivation of L-type currents. However, with EGTA reduced to 0.5 mM, Ca^{2+}-dependent inactivation for $Ca_v2.1$ channels is robust, similar to presynaptic P/Q-type currents at the calyx of Held, a giant synapse in the brain stem. During trains of depolarizations, P/Q-type Ca^{2+} currents inactivate faster than Ba^{2+} currents do and undergo an initial increase (Ca^{2+}-dependent facilitation) prior to onset of Ca^{2+}-dependent inactivation. The latter, but not the former, is prevented by high intracellular concentrations of EGTA (10 mM), indicating a difference in the Ca^{2+} sensitivities of the two processes. Given that P/Q-type Ca^{2+} currents mediate neurotransmitter release at many central synapses, this dual feedback regulation may permit activity-dependent sharpening of presynaptic Ca^{2+} signals underlying synaptic plasticity. With low concentrations of EGTA (0.5 mM), Ca^{2+}-dependent inactivation also characterizes $Ca_v2.2$ and $Ca_v2.3$. Therefore, Ca_v2 channels are generally distinguished from Ca_v1 in showing Ca^{2+} feedback regulation that is sensitive to the Ca^{2+} buffering conditions of the cell.

Calmodulin as a Ca_v Channel Subunit

Ca^{2+} feedback for Ca_v1 and Ca_v2 involves the ubiquitous Ca^{2+}-binding protein calmodulin. For $Ca_v1.2$, calmodulin binds to a consensus site (IQ domain) in the C-terminal domain of $\alpha_1 1.2$ (Figure 3). Ca^{2+} ions permeating the channel bind EF-hand motifs (composed of two helixes, E and F) in the N- and C-terminal lobes of calmodulin, causing conformational changes that favor inactivation. Ba^{2+} ions bind poorly to calmodulin, and so cannot support rapid inactivation for Ca_v Ba^{2+} currents. Calmodulin interactions with the $\alpha_1 1.2$ IQ domain are functionally complex: mutation of the initial isoleucine to glutamate abolishes Ca^{2+}-dependent inactivation, but when substituted with alanine reveals Ca^{2+}-dependent facilitation, which is normally masked by intense Ca^{2+}-dependent inactivation for $Ca_v1.2$ in recombinant systems. Structural and functional studies demonstrate that positive and negative Ca^{2+} feedback depend on the N- and C-terminal lobes of calmodulin, respectively, which make contacts with different residues in the IQ domain. Among Ca_v1 channels, the IQ domain and other sequences (pre-IQ and EF-hand motifs; Figure 3) required for Ca^{2+}-dependent inactivation are nearly identical, illustrating the essential nature of these determinants for Ca_v function.

In the C-terminal domain of the $\alpha_1 2.1$, calmodulin interacts with a less well-conserved IQ domain and a second site (calmodulin binding domain; CBD), both of which are required for Ca^{2+} feedback (Figure 4). Calmodulin mutants unable to bind Ca^{2+} at the

Modulator	Ca^{2+}-dependent inactivation	Ca^{2+}-dependent facilitation	Voltage-dependent activation
CaM	↑	↑	–
CaBP1	↓↓	↑	–
Caldendrin	↓	–	–
CaMKII	–	↑	↑ ($Ca_v1.3$)

Figure 3 Ca^{2+}-dependent modulation of Ca_v1. (Top) Schematic of Ca_v1 α subunit, showing binding sites for calmodulin (CaM), a Ca^{2+}-binding protein subfamily (CaBP1), and caldendrin, and calmodulin-dependent kinase II (CaMKII) phosphorylation sites (EF, calcium-binding motif composed of two helixes, E and F; the IQ domain is a consensus site). (Bottom) Effects of Ca^{2+} signaling proteins on Ca_v1 function. Positive (↑) and negative (↓) effects on Ca^{2+}-dependent inactivation, facilitation, and voltage-dependent activation are indicated.

N-terminal EF-hands cannot transduce Ca^{2+}-dependent inactivation, while C-terminal EF-hands are more critical for Ca^{2+}-dependent facilitation. Since the C-terminal lobe of calmodulin binds Ca^{2+} with higher affinity than does the N-terminal lobe, the calmodulin lobe dependence of Ca^{2+}-dependent facilitation and inactivation may underlie the distinct lobe sensitivities to Ca^{2+} buffering, and the increased Ca^{2+}-buffer sensitivity of Ca^{2+}-dependent inactivation for $Ca_v2.1$, compared to $Ca_v1.2$.

Calmodulin-Like Ca^{2+}-Binding Proteins as Ca_v Modulators

Calmodulin is but one member of a large family of EF-hand Ca^{2+}-binding proteins (CaBPs), some of which are expressed mainly in neurons. Like calmodulin, these CaBPs possess four EF-hand Ca^{2+} binding sites, at least one of which is nonfunctional. CaBPs are similar enough to displace calmodulin from binding sites in the Ca_v α_1 subunit, but different enough to confer distinct forms of regulation.

CaBP regulation of $Ca_v2.1$ channels CaBP1 represents a subfamily of CaBPs highly expressed in the brain and retina and is co-localized to some extent with presynaptic $Ca_v2.1$ channels. Like calmodulin, CaBP1 binds to the CBD of $\alpha_12.1$, but does not support Ca^{2+}-dependent facilitation and causes intense inactivation independent of Ca^{2+} (Figure 4). $Ca_v2.1$ also can interact with other CaBPs, such as neuronal Ca^{2+} sensor-1 (NCS-1), which has inhibitory effects on P/Q-type current amplitude in *Xenopus* oocytes and adrenal chromaffin cells. However, injection of purified NCS-1 protein into presynaptic nerve terminals at the calyx of Held synapse promotes facilitation of P/Q-type currents, and activity-dependent facilitation P/Q-type currents at this synapse can be prevented by injection of NCS-1-inhibitor peptides. Therefore, the effects of NCS-1 on $Ca_v2.1$ may depend on the cellular and subcellular context in which they are co-expressed. A third CaBP that modulates $Ca_v2.1$ is visinin-like protein-2 (VILIP-2), which is highly expressed in the neocortex and hippocampus and undergoes Ca^{2+}-dependent association with the plasma membrane in neurons and other cell types. When cotransfected with $Ca_v2.1$ in mammalian cells, VILIP-2 does not affect Ca^{2+}-dependent facilitation, but inhibits Ca^{2+}-dependent inactivation. These effects of VILIP-2 may involve displacement of calmodulin from the CBD, although both the CBD and IQ-like domain of $\alpha_12.1$ are required for the association of VILIP-2 with the channel. How

Modulator	Ca^{2+}-dependent inactivation	Ca^{2+}-dependent facilitation
CaM	↑	↑
CaBP1	↑	↓
VILIP-2	↓	–
NCS-1	–	↑

Figure 4 Ca^{2+}-dependent modulation of $Ca_v2.1$. $\alpha_1 2.1$ binding sites for calmodulin (CaM), a Ca^{2+} binding protein subfamily (CaBP1), and visinin-like protein-2 (VILIP-2), and potentially neuronal Ca^{2+} sensor-1 (NCS-1), and positive (↑) and negative (↓) effects on Ca^{2+}-dependent inactivation and facilitation are indicated.

VILIP-2 and CaBP1 can have such opposing effects on $Ca_v2.1$ function is not entirely clear, but may involve structural distinctions between the two CaBPs and/or how they interact with $Ca_v2.1$. The remarkably divergent actions of CaBPs on $Ca_v2.1$ may increase the range of presynaptic P/Q-type Ca^{2+} signals, thus contributing to heterogeneous forms of short-term plasticity at different synapses.

CaBP regulation of Ca_v1 channels Ca_v1 channels are also differentially regulated by CaBPs. Unlike its inhibitory effects on $Ca_v2.1$, CaBP1 prolongs $Ca_v1.2$ Ca^{2+} currents and completely abolishes calmodulin-dependent Ca^{2+}-dependent inactivation. The opposing actions of calmodulin and CaBP1 on $Ca_v1.2$ depend on differences in how the two interact with the channel. CaBP1 binds to the IQ-domain as well as to a site in the N-terminal domain of the $\alpha_1 1.2$ (Figure 3). Deletion of the N-terminal site prevents the effects of CaBP1 but not calmodulin on $Ca_v1.2$ inactivation. In contrast, IQ-EE substitutions in the IQ-domain prevent calmodulin-dependent inactivation, but partially spare the effects of CaBP1. Interestingly, a CaBP1 variant, caldendrin, causes more modest suppression of $Ca_v1.2$ Ca^{2+}-dependent inactivation than CaBP1 through interactions solely with the IQ-domain, and not with the N-terminal site in $\alpha_1 1.2$. CaBP1 and caldendrin associate and co-localize with $Ca_v1.2$ in somatodendritic domains of neurons, and so may help fine-tune and boost postsynaptic $Ca_v2.1$ Ca^{2+} signals that regulate gene transcription and neuronal excitability.

Calmodulin-Dependent Protein Kinase II Regulation of Ca_v1 Channels

Ca^{2+} binding to calmodulin causes autophosphorylation of the calmodulin-stimulated protein kinase, CaM kinase II, which can also promote Ca^{2+}-dependent facilitation of Ca_v1 (Figure 3). CaM kinase II binds to and phosphorylates both $\alpha_1 1.2$ and the auxiliary Ca_v β subunit, both of which cause Ca^{2+}-dependent facilitation during repetitive stimuli. Although characterized mainly for cardiac $Ca_v1.2$ channels, that neuronal $Ca_v1.2$ channels undergo a similar form of regulation is supported by the prevalence of CaM kinase II and $Ca_v1.2$ channels at postsynaptic sites in the brain. Such interactions may be important for boosting activity-dependent postsynaptic Ca^{2+} signals that trigger long-term changes in synaptic efficacy.

For $Ca_v1.3$, CaM kinase II causes a distinct form of facilitation that relies on intracellular Ca^{2+} release rather than Ca^{2+} influx. Insulin-like growth factor-1 (IGF-1) promotes neuronal survival and dendritic arborization in part by potentiating Ca_v1 channel activity. IGF-1 binds to a receptor tyrosine kinase, which causes Ca^{2+} release from intracellular stores by activation of the phospholipase Cγ signaling pathway. Activated CaM kinase II phosphorylates a serine residue in the EF-hand sequence in the C-terminal domain of $\alpha_1 1.3$, which causes faster activation kinetics and a negative shift in activation voltage for $Ca_v1.3$ expressed in a neuronal cell line. Since the serine that is phosphorylated by CaM kinase II in $\alpha_1 1.3$ is absent in $\alpha_1 1.2$, these effects of CaM kinase II may differentiate $Ca_v1.2$ and $Ca_v1.3$ modulation by IGF-1 and the respective roles of these L-type channels in Ca^{2+} signaling events required for neuronal development.

Conclusions

Due to their importance in controlling Ca^{2+} entry in neurons, Ca_v channels are subject to numerous and diverse forms of modulation. The intrinsic biophysical properties of Ca_v channels characterized in recombinant systems may therefore not be representative of how these channels behave in neurons. Characterizing the dynamic regulation of Ca_v channels by neurotransmitters, protein interactions, and alternative

splicing will further illuminate how Ca_v channels help orchestrate the normal development, function, and plasticity of the nervous system.

Neuromodulation of Sodium Channels

W A Catterall, University of Washington, Seattle, WA, USA

Introduction

Neuromodulation of electrical excitability and synaptic transmission is the fundamental basis for many aspects of learning, memory, and physiological regulation. Synaptic plasticity allows regulation of the input–output relationships of individual synapses in response to their level of activity and other influences. Long-term potentiation of synaptic transmission at glutamatergic synapses on central neurons is the most well-studied example of this type of regulation. In addition to this synapse-specific form of plasticity, there is increasing evidence of the importance of cellular plasticity, a form of plasticity that modifies the input–output relationships of the entire neuron. One can imagine many different mechanisms by which the input–output relationships of a neuron could be modified, but neuromodulation of voltage-gated Na^+ channels is one of the simplest. Voltage-gated Na^+ channels are responsible for the initiation and propagation of action potentials in neurons. Because generation of action potentials is the final common pathway for neural output, Na^+ channels are ideally positioned to serve as an important point of regulation of neuronal signal integration and transduction.

Na^+ Channel Protein Phosphorylation and Dephosphorylation

Na^+ channel proteins in mammalian brain consist of an α subunit of approximately 260 kDa in association with one or two auxiliary subunits of 33–36 kDa (β_1–β_4; Figure 1). Early biochemical studies of purified brain Na^+ channels showed that the α subunits are exceptionally good substrates for phosphorylation by cAMP-dependent protein kinase A (PKA). In contrast, no phosphorylation of the β_1 or β_2 subunits was detected. Na^+ channels were rapidly phosphorylated on multiple sites following activation of PKA or protein kinase C (PKC) in synaptosomes, and measurements of neurotoxin-activated Na^+ influx showed that cAMP-dependent phosphorylation is correlated with a reduction of approximately 26% in the maximum neurotoxin-activated Na^+ conductance. Therefore, by this *in vitro* biochemical measurement of Na^+ channel function, cAMP-dependent phosphorylation of the α subunit is correlated with a reduction in activity of brain Na^+ channels.

Na^+ channels in intact brain neurons in cell culture are rapidly phosphorylated by PKA on at least four sites, which are located in the large intracellular loop connecting domains I and II of the α subunits (Figure 1). This complex pattern of phosphorylation of sites in $L_{I–II}$ is responsible for the reduction of Na^+ channel activity by activation of the cAMP pathway.

Purified brain Na^+ channels are dephosphorylated by multiple phosphoprotein phosphatases. The calcium-regulated phosphatase calcineurin is more effective than the catalytic subunits of phosphatase 1 or phosphatase 2A in dephosphorylating purified Na^+ channels, and it is as efficient in dephosphorylating Na^+ channels as in dephosphorylating its known substrates. Purification of Na^+ channel phosphatases from brain also demonstrated the importance of calcineurin and phosphatase 2A in Na^+ channel dephosphorylation. Thus, biochemical experiments provide clear evidence for both second messenger-regulated phosphorylation and dephosphorylation of Na^+ channels in brain neurons.

Functional Modulation of Cloned and Expressed Na^+ Channels

Functional modulation of voltage-gated Na^+ channels by PKC- and PKA-dependent phosphorylation has been observed for cloned $Na_v1.2$ channels expressed in mammalian cells and in *Xenopus* oocytes. Activation of PKC with phorbol esters or diacylglycerols such as 1-oleoyl-2-acetyl-*sn*-glycerol (OAG) reduces peak Na^+ currents and slows the time course of inactivation (Figure 2). The observed effects of diacylglycerol activators of PKC are directly attributable to PKC activity because they were blocked by specific inhibitors and mimicked by application of purified rat brain PKC to the cytoplasmic surface of the channel in excised membrane patches.

Activation of PKA also modulates the Na^+ current mediated by cloned $Na_v1.2$ channels expressed in *Xenopus* oocytes and in cultured mammalian cells. In both cell types, peak Na^+ current is reduced 25–40% without change in the kinetics or voltage dependence of activation or fast inactivation (Figure 2). PKA-dependent inhibition has also been reported for $Na_v1.1$ channels expressed in *Xenopus* oocytes. This is not surprising since $L_{I–II}$ of $Na_v1.1$ contains five consensus PKA phosphorylation sites in similar positions to those described for $Na_v1.2$.

Sites of Neuromodulation by PKA and PKC

The molecular mechanism underlying the regulation of $Na_v1.2$ channels by PKC and PKA is complex and

Figure 1 Neurotransmitter pathways that modulate Na^+ channels in hippocampal neurons. (Middle) The Na^+ channel α, β_1, and β_2 subunits are illustrated as transmembrane folding diagrams. Sites of PKA phosphorylation are indicated by the letter P blue circles. Sites of PKC phosphorylation are indicated by the letter P in yellow diamonds. (Left) The pathway for modulation of Na^+ channels by dopamine is illustrated. Dopamine binds to D1-like receptors (D_1R), which activate G_s and adenylyl cyclase (AC). The increase in cAMP activates PKA. PKA tethered to AKAP-15 phosphorylates the Na^+ channel on four sites in $L_{I–II}$ (serines 573, 610, 623, and 687). Two of these sites have been shown to be required for maximal PKA modulation of Na^+ channels: serine 573 and serine 687. (Right) The pathway for modulation by acetylcholine is illustrated. Acetylcholine binds to muscarinic receptors, which activate G_q and phospholipase C (PLC). The increase in diacylglycerol (DAG) activates protein kinase C, which phosphorylates Na^+ channels on serine 1506 in the inactivation gate and serines 554, 573, and 576 in $L_{I–II}$.

Figure 2 Regulation of Na^+ currents by PKA and PKC. (PKA) Macroscopic Na^+ currents in an excised membrane patch from a cell transfected with $Na_v1.2a$ under control conditions, after addition of ATP, and, finally, after addition of PKA in the presence of ATP. Note the reduction in peak Na^+ current without change in the kinetics of the current. (PKC) Whole cell Na^+ currents in a cell transfected with $Na_v1.2a$ before and after activation of PKC with oleylacetylglycerol (OAG). Note the reduction in peak Na^+ current and slowing of inactivation.

involves phosphorylation at multiple sites on the α subunit, as identified using a combination of biochemistry, mutagenesis, and electrophysiology. PKA-mediated reduction in peak Na^+ current at typical resting membrane potentials of −70 to −80 mV is primarily mediated by phosphorylation at a single consensus phosphorylation site centered at serine 573 in $L_{I–II}$ of $Na_v1.2$ channels (Figure 1).

The dual effects of PKC activation – reduction of peak Na^+ current and slowing of fast inactivation – are mediated by PKC-dependent phosphorylation of multiple sites on the α subunit. Reduction of the rate of inactivation requires phosphorylation of serine 1506 in the intracellular loop connecting homologous domains III and IV (Figure 1). Effects on fast inactivation due to phosphorylation of this site are expected since this region of the channel is proposed to be the inactivation gate. PKC-mediated reduction in peak Na^+ current requires additional phosphorylation of $L_{I–II}$ at serine residues 554 and 573 (Figure 1). However, a double mutation in which both of these serine residues have been converted to alanine does not completely prevent PKC-mediated reduction in peak Na^+ current amplitude, suggesting the existence of one or more additional PKC phosphorylation sites. The involvement of serine 573 in PKC-mediated reduction of peak current is interesting since this is an important PKA phosphorylation site, raising the possibility of dual kinase regulation at a single site.

Membrane Potential-Dependent, Convergent Regulation by PKA and PKC

Surprisingly, PKA-dependent reduction of peak Na^+ currents requires concomitant activation of PKC and phosphorylation of serine 1506 on the cytoplasmic

linker connecting homologous domains III and IV. PKA-dependent modulation of $Na_v1.2$ channels is voltage dependent in the range of −110 to −70 mV. At a holding potential of −110 mV, little effect of PKA is observed on Na^+ channels expressed in non-neuronal cells. Modulation at this negative membrane potential was recovered following concurrent activation of PKC. At more positive membrane potentials, the requirement for PKC activation is progressively reduced and substantial PKA modulation is observed at the holding potential of −75 mV without PKC activation. The voltage dependence of these effects of PKA phosphorylation provides an additional element of specificity and sensitivity to modulation of brain Na^+ channels. Evidently, the Na^+ channel is a point of convergence of regulation by membrane potential and neurotransmitter receptors acting through second messengers, PKA, and PKC.

Enhancement of the regulatory effects of PKA on $Na_v1.2$ channels by PKC requires both PKC- and PKA-dependent phosphorylation at additional sites on the α subunit. The increase in strength of the PKA modulation results in part from recruitment of regulation by PKA-dependent phosphorylation at serine 687 (Figure 1). No PKA-dependent modulation was observed for mutant S573A under control conditions. However, PKA modulation was recovered for this mutant during concurrent PKC activation, suggesting that PKA phosphorylation may be recruited at one or more additional sites in these circumstances. Systematic mutagenesis of PKA phosphorylation sites in $L_{I–II}$ revealed the requirement for PKA phosphorylation at serine 687. A double mutation at positions 573 and 687 (SS573/687AA) eliminated the effect of concurrent PKC activation at both the permissive and the nonpermissive membrane potentials. The potentiating effects of PKC were blocked in the presence of the PKA inhibitor peptide, demonstrating the requirement for PKA for phosphorylation of this site.

How does PKC activation recruit regulation by PKA-dependent phosphorylation at serine 687? Systematic mutation of known phosphorylation sites showed that PKC must also phosphorylate serine 576 in $L_{I–II}$ in order to enhance modulation by PKA (Figure 1). A single mutation at this position (S576A) eliminates the effects of concurrent PKC activation on PKA modulation of $Na_v1.2a$ channels at all membrane potentials tested. Thus, maximal modulation of $Na_v1.2a$ channels by PKA requires phosphorylation at three distinct sites – serine residues 573, 576, and 687 – and concurrent activation of both PKC and PKA. One possible explanation for this synergistic regulation is that PKC-dependent phosphorylation of serine 576 might bring about a conformational change in $L_{I–II}$ that increases the accessibility of serine 687 to PKA. This type of convergent regulation provides a novel mechanism by which information from multiple signaling pathways may be integrated depending on the state of the cell and its prior history of electrical activity.

Enhancement of Slow Inactivation by Protein Phosphorylation

In addition to their well-known fast inactivation process, which acts on the timescale of milliseconds and involves the fast inactivation gate in the intracellular loop connecting domains III and IV, Na^+ channels enter a distinct slow-inactivated state upon depolarization for hundreds of milliseconds to seconds. Recovery from this slow-inactivated state is also very slow, requiring seconds at a repolarized membrane potential for completion. Slow inactivation therefore makes Na^+ channels unavailable for activation by depolarizing stimuli, and this intrinsic, voltage-dependent slow-inactivation process of Na^+ channels is known to modulate the threshold and firing pattern of brain neurons.

Analysis of single channel recordings indicated that neither the single channel currents nor the number of available Na^+ channels are altered by PKA. Instead, the decrease in peak current results from an increase in null sweeps during which no Na^+ channel openings are observed after depolarization, consistent with slow inactivation. Studies show that the biophysical mechanism underlying this form of modulation is indeed slow inactivation. The voltage dependence and kinetics of reduction of Na^+ current by activation of PKA and PKC correlate quantitatively with the kinetics and voltage dependence of slow inactivation. Similarly, the kinetics of recovery from slow inactivation are precisely correlated with the kinetics of recovery from inhibition by PKA and PKC phosphorylation. Moreover, mutations of Na^+ channels that specifically impair slow inactivation also prevent the reduction of Na^+ current caused by activation of PKA and PKC in transfected nonneuronal cells expressing $Na_v1.2$ channels. Together, these results provide strong support for the conclusion that modulation of Na^+ channels by PKA and PKC is caused by enhancement of the intrinsic slow inactivation process.

The functional impact of enhanced slow inactivation on the firing properties of a cortical pyramidal cell is illustrated in Figure 3. Under control conditions, depolarization by steady injection of inward current into the cell produces trains of action potentials faithfully. In contrast, after activation of serotonin receptors ($5\text{-}HT_{2a/c}$) with the agonist 2,5-dimethyloxy-4-iodoamphetamine HCl (DOI; 10 μM), stronger depolarizing stimuli produce trains of action potentials

Figure 3 Change in firing properties of prefrontal cortical neurons accompanying neuromodulation of Na^+ channels. Action current recordings obtained under current clamp in the whole cell configuration from single prefrontal cortical neurons in slices of mouse brain. Repetitive stimulation of control neurons with depolarizing current yielded continuous trains of spikes, whereas spike failures were observed for neurons treated with DOI (10 μM) to activate serotonin receptors and PKC signaling. From Carr DB, Day M, Cantrell AR et al. (2003) Transmitter modulation of slow, activity-dependent alterations in sodium channel availability endows neurons with a novel form of cellular plasticity. *Neuron* 39: 793–806.

that terminate due to depolarization block. This block of firing occurs because the treated neurons have progressively fewer Na^+ channels that are available to sustain firing as the train continues at more depolarized potentials due to enhanced slow inactivation during the train. In this way, phosphorylation of Na^+ channels controls the input–output relationships of neurons.

Modulation of Na^+ Channels in Neurons

How widepsread is this complex regulation of Na^+ channel activity in neurons? This critical question has been analyzed in cultured brain neurons and in acutely dissociated neurons from hippocampus, striatum, cerebral cortex, and dorsal root ganglion.

Modulation of Na^+ channels by direct activation of PKA and PKC is observed in primary cultures of embryonic rat brain neurons, as in transfected cells. Activation of PKC reduces peak Na^+ current and slows inactivation, whereas activation of PKA decreases Na^+ channel activity without change in kinetics.

Acetylcholine, serotonin, and dopamine regulate the functional properties of the voltage-gated Na^+ channel in brain neurons via activation of PKC and PKA, respectively (Figure 1), and one can anticipate that other neurotransmitters that activate these kinases will have similar effects. Activation of muscarinic acetylcholine receptors coupled to phospholipase C exerts a PKC-dependent inhibitory effect on Na^+ current in acutely isolated hippocampal pyramidal neurons. Both peak transient and persistent Na^+ currents are reduced without significant change in the voltage dependence of activation or fast inactivation (Figure 2). The rate of inactivation is also appreciably slowed. These effects of muscarinic stimulation require the activation of PKC because they were eliminated in the presence of the PKC specific inhibitor $PKCI_{19–36}$ and were mimicked by the extracellular application of the membrane permeant PKC activator OAG.

The hippocampus receives dopaminergic innervation from the mesocorticolimbic dopamine system. The effects of dopamine are mediated by a family of five G-protein-coupled dopamine receptors that are broadly classified as D1-like (D1 and D5) or D2-like (D2–D4) based on pharmacology and coupling to intracellular second-messenger systems. Activation of D1-like dopamine receptors, which couple to the activation of adenylyl cyclase, decreases Na^+ current in acutely isolated hippocampal pyramidal neurons without altering the voltage dependence or kinetics of activation or fast inactivation. These effects require PKA activity because they were eliminated in the presence of the specific PKA inhibitor $PKAI_{5–24}$ and were mimicked by a PKA activator. Na^+ channels in transfected cells as for (Figure 2). D1/PKA modulation in hippocampal neurons is voltage dependent in the range of −110 to −70 mV and is enhanced by concurrent activation of PKC at all membrane potentials tested. Thus, Na^+ channels in hippocampal pyramidal neurons are modulated via a voltage-dependent, convergent mechanism by neurotransmitter activation of the PKA- and PKC-signaling pathways as predicted from studies of transfected cells.

Dopamine-mediated regulation of neuronal excitability is also critically important in the neostriatum, in which the dopaminergic projection from the substantia nigra controls the firing of neostriatal neurons, and loss of this regulatory system results in the movement disorders associated with Parkinson's disease. Activation of D1-like dopamine receptors on medium spiny neostriatal neurons inhibits peak Na^+ current in a reversible, dose-dependent manner without significant effects on voltage- and time-dependent properties of the current. Persistent Na^+ current is also inhibited. This effect requires activation of PKA since it is mimicked by intracellular loading of PKA and prevented in the presence of a PKA inhibitor peptide, $PKAI_{5–24}$. Conversely, activation of D2 receptors, which are coupled to the inhibition of adenylyl cyclase and consequent reduction of PKA activity, increases the amplitude of Na^+ current in medium spiny neurons.

Phosphorylation-dependent neuromodulation of voltage-gated Na^+ channels has been demonstrated in neocortical neurons as well. Activation of D1-like dopamine receptors reduces peak Na^+ currents without a change in kinetics or voltage dependence of activation or fast inactivation in dissociated cortical neurons under voltage clamp. This effect is mimicked by cAMP analogs, implicating the PKA pathway. Activation of D1 receptors had a smaller effect on the persistent Na^+ current (I_{NaP}) remaining after fast inactivation. As in hippocampal neurons, muscarinic receptor activation in rat neocortical neurons inhibited the transient and persistent Na^+ currents evoked by slow depolarizing voltage ramps or by long depolarizing voltage steps. In cortical neurons, persistent Na^+ current is active near critical subthreshold voltages where other ionic currents are small, and modulation of its functional properties is thought to contribute to synaptic integration, regulation of intrinsic firing patterns, and active back-propagation of action potentials from the soma into the dendrites.

Sensory neurons express multiple Na^+ channel isoforms, including $Na_v1.8$ and $Na_v1.9$, which mediate slowly gated Na^+ currents that are tetrodotoxin (TTX) resistant. Neuromodulation of TTX-resistant Na^+ current (TTX-R I_{Na}) in small-diameter, nociceptor-like rat sensory neurons is mediated by proinflammatory, hyperalgesic agents, including serotonin, prostaglandin E_2 (PGE_2), and adenosine. These agents increase the amplitude of the TTX-resistant Na^+ current, accompanied by a negative shift in the voltage dependence of activation and increase in the rates of activation, deactivation, and inactivation. Direct activation of adenylyl cyclase or PKA mimicked the effects of PGE_2 and intracellular perfusion with a PKA inhibitor blocked the effects of PGE_2, demonstrating the requirement for PKA in this form of Na^+ channel modulation. Mutation of consensus PKA phosphorylation sites in $L_{I–II}$ greatly reduced PKA modulation compared to wild-type channels, leading to the conclusion that the major substrates involved in PKA modulation of the TTX-resistant channel are located in $L_{I–II}$ as for $Na_v1.2$. PKC plays a permissive role in the PGE_2-mediated modulation of TTX-resistant Na^+ current, similar to that reported for dopamine modulation of Na^+ channels in hippocampal neurons. However, in contrast to $Na_v1.2$ channels, activation of either PKA or PKC increases peak TTX-resistant Na^+ current. PKA-mediated modulation of TTX-resistant Na^+ current was partially attenuated by inhibition of PKC, suggesting a requirement for PKC in the PGE_2-mediated modulation of TTX-resistant Na^+ current. The sites at which PKC exerts its effects on TTX-resistant Na^+ current are unknown. However, it is intriguing that PKA and PKC act synergistically to increase the activity of $Na_v1.8$ channels, at least in part through phosphorylation of sites in $L_{I–II}$, whereas the same two kinases reduce the activity of $Na_v1.1$ and $Na_v1.2$ channels by a similar, synergistic mechanism based on phosphorylation of sites in $L_{I–II}$. Evidently, the molecular mechanisms of regulation of these different channel types by protein phosphorylation are similar but the effects on channel activity are opposite.

Role of Kinase Anchoring in Na^+ Channel Modulation in Neurons

Specificity and speed of kinase signaling are often achieved through association with anchoring or adaptor proteins that target kinases to subcellular organelles or to specific substrates via protein–protein interactions. PKA is localized by protein–protein interactions between the regulatory (R) subunit dimer of PKA and A-kinase anchoring proteins (AKAPs), a family of functionally related proteins defined by their ability to bind R subunits of PKA and target PKA to specific compartments or substrates. AKAPs contain an amphipathic helix that inserts into a hydrophobic pocket in the R subunit dimer. Consistent with this theme, modulation of the Na^+ channel by dopamine receptors in hippocampal neurons requires targeted localization of PKA near the channel via AKAP15 (Figure 1), which was characterized initially in studies of calcium channel modulation. This novel 81-amino acid AKAP has an N-terminal lipid anchor for membrane targeting, an amphipathic helix for PKA binding, followed by a site for interaction with Na^+ channels via a modified leucine zipper motif. PKA, AKAP15, and the Na^+ channel therefore form a signaling complex that controls channel activity. The site of binding of AKAP15 on the Na^+ channel is located at the beginning of the large intracellular loop connecting domains I and II ($L_{I–II}$), which also contains the sites of PKA phosphorylation and regulation (Figure 1). Thus, AKAP15 targets PKA to the Na^+ channel near its substrate sites.

Functional Consequences of Na^+ Channel Modulation

Neuromodulation of Na^+ channels by protein phosphorylation is implicated in diverse aspects of control of firing properties of neurons in the brain and sensory ganglia. Several examples are described next.

Neostriatal neurons can function in two states with different input–output relationships, designated upstate and downstate. For a cell at rest (approximately-85 mV) or in the downstate, Na^+ channels are largely

inactive. D1-mediated inhibition of peak Na^+ current via PKA-dependent phosphorylation increases the threshold for action potential firing and favors the downstate. Consistent with this mechanism, dopamine acting at D1 receptors inhibits action potential firing of neostriatal neurons. D2-mediated augmentation of whole-cell Na^+ current via inhibition of cAMP synthesis speeds depolarization and increases the rate of entry into the upstate. The reciprocal effects of these dopamine receptors on Na^+ channels contribute to the stability of the downstate and upstate of striatal neurons and to the transitions between them.

The nucleus accumbens is a primary site mediating reward behavior, and it is thought to be directly involved in reinforcing and addictive behaviors in response to drug use. Cocaine exerts its pharmacological effects by inhibition of dopamine-reuptake transporters, thereby increasing the extracellular concentration of dopamine in the vicinity of dopamine-responsive neurons. Na^+ currents of medium spiny neurons in the nucleus accumbens are inhibited by dopamine acting through D1 receptors, as in other striatal neurons. Remarkably, chronic (2-week) treatment with cocaine sensitizes these neurons to the effects of dopamine and causes a marked decrease in Na^+ currents that persists for 3 days after drug withdrawal. These results demonstrate a temporal correlation between persistent inhibition of Na^+ currents and the acute withdrawal effects of anhedonia and craving that accompany cessation of cocaine treatment. Neuromodulation of Na^+ channels via the dopamine/PKA pathway may be critically involved in the complex behavioral responses to chronic treatment with drugs of abuse.

The effects of dopamine released from the mesocorticolimbic system in the hippocampus are primarily inhibitory, resulting in elevation of spike threshold, slower firing rates, and, in some cases, membrane hyperpolarization. Although it is believed that these effects are primarily a consequence of activation of slow Ca^{2+}-dependent K^+ channels, they may actually be mediated by a concerted action of the transmitter on several ion channels, including voltage-gated Na^+ channels. The inhibitory effects of activation of D1-like receptors are consistent with a role for modulation of Na^+ currents as a contributing factor to the inhibitory effects of dopamine. The hippocampus also receives a rich cholinergic innervation from neurons of the basal forebrain, whose effects are mediated primarily by muscarinic receptors. Slowing of fast inactivation of Na^+ currents by muscarinic receptor action via the PKC pathway would subtly increase the duration of the action potential and possibly alter the pattern of action potential firing. Reduction of peak Na^+ current by this pathway would more strongly influence the functional properties of target neurons by shifting the threshold for action potential generation toward more depolarized potentials and reducing the frequency at which the cell is capable of generating action potentials. Consistent with these expectations, cholinergic input to the hippocampus acting through muscarinic acetylcholine receptors and PKC inhibits intrinsic bursting activity of CA1 neurons, converting their firing pattern from phasic bursting separated by quiescent periods to tonic firing of single spikes. These effects are correlated with a reduction of persistent Na^+ current in CA1 neurons, which is likely to be accompanied by a similar reduction in peak Na^+ current. Since generation of bursts is a major mechanism of information transmission, these effects are likely to strongly affect input–output relationships in hippocampal neurons.

Similar modulatory effects of dopamine and acetylcholine are observed in cortical pyramidal neurons. Cholinergic input to the cortex from the nucleus basalis causes a shift in spike generation from phasic bursts to tonic spiking. Dopaminergic input to the prefrontal cortex reduces Na^+ currents and increases the threshold for action potential generation. Thus, neuromodulation of Na^+ channels may contribute to cellular plasticity in both hippocampus and cerebral cortex.

Hyperalgesia is associated with abnormal bursting activity in primary sensory neurons involved in nociception. Heightened excitability in these neurons occurs within moments of an inflammatory stimulus and involves a negative shift in response threshold and an increase in spontaneous activity. Hyperexcitability is correlated with PKA/PKC-dependent upregulation of the TTX-resistant Na^+ current. Application of PGE_2 increases the excitability of rat dorsal root ganglion neurons by reducing firing threshold and altering the response to stimulation so that a single evoked action potential is converted to a train of action potentials. Expression of the TTX-resistant Na^+ channels is restricted to a subpopulation of sensory neurons that are likely to be involved in nociception, suggesting a specialized role for TTX-resistant Na^+ channels in mediating pain responses. Deletion of the gene encoding $Na_v1.8$ causes specific (but mild) deficits in nociception. The biophysical properties of TTX-resistant Na^+ channels make them ideal candidates for mediating repetitive firing behavior in response to prolonged membrane depolarization. Moreover, inflammatory mediators, including PGE_2, serotonin, and adenosine, decrease the activation threshold, increase the rates of activation and inactivation, and increase the magnitude of the TTX-resistant Na^+ current, consistent with the effects observed for $Na_v1.8$ expressed in transfected cells. This modulation is inhibited by

activation of μ-opioid receptors that block inflammatory hyperalgesia. Together, these results provide strong support for the idea that upregulation of Na^+ channel function is an essential component of the hyperalgesic response, and $Na_v1.8$ and $Na_v1.9$ are now considered to be prime therapeutic targets for treatment of intractable pain.

In the retina, the bipolar neurons control the dynamic response to light intensity. In dim conditions, Na^+ currents amplify the inputs to the bipolar cells and increase their activity. In bright light, dopamine released from amacrine cells inactivates Na^+ channels and reduces bipolar cell responses. These results show that neuromodulation of Na^+ channels by dopamine contributes significantly to light adaptation.

Other Regulatory Pathways

Neuromodulation of Na^+ channels by other cellular kinase signaling pathways may also have an important effect on neuronal development and function. Phosphorylation and dephosphorylation of Na^+ channels on tyrosine residues by specifically bound Fyn kinase modulates Na^+ channel inactivation, and receptor tyrosine phosphatase-β is physically associated with Na^+ channels and may regulate their function in response to cell–cell interactions. Neuromodulation of voltage-gated Na^+ channels may be important in neuroprotection during anoxia, and the NO pathway may regulate Na^+ channels under physiological and pathological conditions. Direct interactions of Na^+ channels with G-proteins may regulate voltage-dependent gating and persistent Na^+ currents. It is likely that we are only beginning to understand the broad influence of Na^+ channel regulation in mediating functional responses in the central nervous system. A greater understanding of the regulatory systems that target voltage-gated Na^+ channels and mediate different forms of cellular plasticity may provide insight into the regulation of electrical excitability and the mechanisms of many neurological disorders and may help to identify new therapeutic interventions.

Neuromorphic Engineering

Neuromorphic engineering is concerned with the design and fabrication of artificial neural systems whose architecture and design principles are based on those of biological nervous systems. Neuromorphic systems of neurons and synapses can be implemented in the electronic medium CMOS (complementary metal oxide semiconductor) using hybrid analog/digital VLSI (very large-scale integrated) technology.

The notion of neuromorphic engineering has appeared in various forms during the last few centuries: From the French and Swiss mechanical automata of the eighteenth to nineteenth centuries (e.g., Vaucanson's duck) through the biological robots of the 1950s (e.g., Grey Walter's turtle) to the early neural electrical circuits of the 1960s and 1970s (e.g., Fukushima in Japan, Mueller at the University of Pennsylvania, and Lettvin at MIT). The concept took root again at Caltech during the mid-1980s, this time in the research of Carver Mead, who had already made major conceptual contributions to the design and construction of digital VLSI systems. He recognized that the use of transistors for computation had changed very little from the time when John Von Neumann first proposed the architecture for the programmable serial computer. The bit-perfect, strictly synchronous, and largely serial processing strategy required by present computers is untenable in the long run because it does not scale. Moreover, this design implies an exponentially greater power consumption for larger systems and exponentially higher costs of constructing, testing, and maintaining elements that must be fault-free in operation.

The design of biological neural computation is very different from that of modern computers. Neuronal networks process information using energy-efficient, asynchronous, event-based methods. Biology uses self-construction, self-repair, and self-programming, and it has learned how to flexibly compose complex behaviors from simpler elements. Of course, these biological abilities are not yet understood. But they offer an attractive alternative to conventional technology and have enormous consequences for future artificial information processing and behavior systems.

The challenge for neuromorphic engineering is to explore the methods of biological information processing in a practical electrical engineering context. Can existing CMOS VLSI technology be deployed in a novel way that reflects more closely the neuronal approach to computation? And can we thereby reap some of the computational facility, speed, and efficiency that biological nervous systems bring to the solution of real-world problems? Conversely, can we, by engineering artifacts, gain new insights into how biology organizes computation?

Digital and Analog in Neuromorphic VLSI Systems

The majority of integrated circuits represent numbers as binary digits. Binary digits are used because it is possible to standardize the behavior of transistors so that their state can be determined reliably to a single bit of accuracy. The reliable bits can then be combined to encode variables to an arbitrarily high precision. It is the combination of this precision and the synchronous, serial model of processing that has been the foundation of the long boom in digital electronics. One unnecessary consequence of this exuberance is that modern computers use deterministic high precision to deal even with real-world tasks whose variables can often be encoded with only a few bits.

For many such problems, particularly those in which the input data are ill-conditioned and the computation can be specified in a relative matter, biological solutions are many orders of magnitude more effective than those we have been able to implement using digital methods. This advantage is due principally to biology's use of elementary physical phenomena as computational primitives and to the representation of information by the relative values of analog signals rather than by the absolute values of digital signals. Typically, it is this style of processing that neuromorphic engineers explore. Their systems are large collections of communicating computational primitives implemented either in analog or, more commonly, in hybrid analog–digital circuits.

Analog computing has a number of interesting features. First, analog processors are inherently more dense than digital ones because the individual electrical nodes of analog circuits can represent multiple bits of information. Second, unlike conventional digital circuits, whose coordination is governed by a global clock, analog circuits are naturally synchronized in physical time (as opposed to being synchronized against clock time). This property is particularly useful for systems that model and interact with real-world processes because, if the time

constants of the analog circuits are appropriately set, their processing can be scaled to match those of the real-world processes with which they interact.

Unfortunately, an analog process is much more difficult to implement than its digital counterpart. Usually an analog processor must be purpose-built and does not have the general character of digital systems. The analog circuits are difficult to implement because the physics of the material used to construct the circuits plays an important role in the solution of the problem. It is also difficult to control the physical properties of micron-size devices such that their analog characteristics are well matched. This matching of analog device characteristics is a major difficulty facing an analog designer. And digital machines have an advantage over analog ones when high precision is required. The analog approach usually requires adaptive techniques to mitigate the effects of component differences. However, this kind of adaptation leads naturally to systems that learn about their environment.

Digital systems depend on a small set of primitives that can support universal logical computation. For example, any logic function can be implemented using only NAND gates. In principle, a similar mathematical universality is possible in analog circuits by using primitive circuits for addition and multiplication. However, the neuromorphic engineer is usually more concerned with identifying the primitives needed to emulate neuronal processing than with mathematics *per se*.

For many crucial neuronlike operations, dedicated analog processors can be constructed much more compactly than their digital counterparts. Some neuromorphic primitives are obvious, such as the simple addition of currents by joining their conductors. Others provide useful generic functions, such as logistic and tanh circuits. Yet others are simple but sophisticated processors (e.g., Mahowald and Mead's elementary contrast reporting pixel and Delbrück's correlation circuit) (Figure 1).

These circuits are usually based on CMOS field effect transistors (FETs), whose conductivity can be altered by an applied electric field. A FET is a device in which the flow of current between its source and drain terminals is controlled by a voltage applied to its gate terminal. The relationship between the gate voltage and the current that flows across the transistor's channel is rather subtle. There are two primary regimes of behavior. In the subthreshold regime, in which small voltages are applied between the gate and the source, the transistor current grows exponentially with the gate voltage. In above-threshold regime, in which larger voltages are applied, the current grows more slowly. Conventionally, transistors

Figure 1 A neuromorphic VLSI chip. The background shows a 1×1 mm section of the chip layout, comprising an array of silicon synapses, a row of silicon neurons, and peripheral interfacing circuits. The foreground shows a picture of the 3×3 mm chip bonded to its package. VLSI, very large-scale integrated.

are operated in the above-threshold regime, and in the extreme case of digital circuits only very large gate voltages are used so that the transistors are either fully off or fully conducting.

By contrast, neuromorphic circuits typically exploit the otherwise unpopular subthreshold regime because this regime offers some striking advantages for nondigital circuits. The exponential increase in transistor current with gate voltage means that the gain (loosely defined as the change in current for a given change in voltage) of the subthreshold transistor is very high, and gain is the lever of information processing. The exponential property can be used to compose interesting analog circuits with natural exponential and logarithmic properties that are useful for emulating neuronal properties. A further feature of subthreshold circuits is that the absolute currents flowing through the transistors are very small, so these circuits operate at very low power. The downside is that the signals are very small, so the circuits are susceptible to noise and fabrication variations.

All these interesting properties offer the possibility of constructing very low-power brainlike electronic

circuits that operate in real time. An important strategic consideration in this quest is that the basic CMOS VLSI technology does not have to be developed by the neuromorphic engineering community. The development of VLSI technology is fueled by the digital information technology (IT) market, so those developments need only be applied to the needs of subthreshold analog neuromorphic engineering. The very same technology used to construct digital computers can also be used (in subthreshold) to construct computational primitives for systems of neuronlike processors. Unlike digital systems, which have a relatively small number of general-purpose processors that process a command stream sequentially, the performance of neuromorphic systems depends on the parallel configuration of large numbers of these special-purpose primitives.

Emulation versus Simulation

What advantages do these neuromorphic circuits have? One advantage is that they offer a medium in which neuronal networks can be emulated directly in hardware rather than simply simulated on a general-purpose computer. However, it should be noted that the uses of emulation are not the same as those of simulation. Digital simulation is generally used to explore the quantitative behavior of neuronal systems. Because they are composed of large numbers of nonlinear elements and have a wide range of time constants, their mathematical behavior can rarely be solved analytically. But the speed of simulation is limited by the shortest time constant of the problem, so simulation performance slows dramatically as the number and degree of coupling of elements increase.

By contrast, neuromorphic emulations operate in real time, and the speed of the network is independent of the number of neurons or their coupling. However, analog circuits provide only a good qualitative approximation of the exact performance of simulated neurons. Moreover, the design of special-purpose hardware is a significant investment, particularly if it is analog hardware because analog VLSI (aVLSI) design remains very much an art form. Designing robust novel circuits depends on engineers with considerable experience, preferably working in small groups with sufficient collective knowledge to monitor and criticize one another's design assumptions and circuit layouts. So, in their present form, neuromorphic circuits are not suitable for quantitative simulation.

On the other hand, where the electronic neural circuits do provide a tangible advantage is in the investigation of questions concerning the strict real-time interaction of the system with its environment, possibly taking sensory input from neuromorphic sensors such as silicon retinas or silicon cochleas. Neuromorphic retina and cochlea sensors represent examples of extremely successful systems built with these design principles. Neuromorphic retinas are vision sensors that can adapt in real time to local changes in illumination over a wide range of intensities and that reproduce many of the functionalities of the retina's outer plexiform layer. Thanks to their adaptation and real-time response properties, they are currently being applied to machine vision tasks that are difficult to solve using conventional approaches. These include, for example, traffic monitoring in open uncontrolled environments such as freeways or fast robotics, in which the low latency and sparsity of address–event representation (AER) sensor data are very advantageous. Similarly, silicon cochleas convert auditory signals into sequences of spikes generated by populations of silicon neurons arranged tonotopically along the frequency axis, similar to the inner-ear hair cells located along the basilar membrane of real cochleas. These devices have promising application domains, both as alternative low-power solutions for cochlear implants and as computational devices for engineering applications.

Neurons in Silicon

One of the central goals of neuromorphic engineering is to capture the computational principles of neurons and their networks in hardware. A cornerstone of this quest has been the development over the last decade of hybrid analog–digital VLSI neurons, together an infrastructure for composing networks of these neurons. It is now possible to assemble quite complex systems of such neurons.

Integrate-and-Fire Models

Neurons communicate by pulses (or spikes) that propagate along electrically lossy point-to-point wires that are the axons. Real neurons have a complex morphology and even more complex biophysics, whose full emulation is beyond the reach of present electronic technology. Nevertheless, the integrate-and-fire neuron (I&F), which is a bold simplification of real neurons, has proved to have significant explanatory power in understanding the behavior of neuronal networks both in theory and simulation. So far, it is this simplified model that has received the most attention in neuromorphic circles.

I&F neurons integrate presynaptic input currents and generate a voltage pulse analogous to an action potential when the integrated voltage reaches a threshold. Many variants of these circuits were built during the 1950s and 1960s using discrete electronic components. The first simple VLSI version was probably the

Axon Hillock circuit, built by Mead in the late 1980s. In this circuit, a capacitor that represents the somatic membrane capacitance integrates current input to the neuron. When the capacitor voltage crosses a threshold, it is reset by a positive feedback loop. More recent models include additional neural characteristics, such as spike-frequency adaptation properties and refractory period mechanisms. These features can be combined in a compact low-power circuit such as the one shown in Figure 2.

Conductance-Based Models

These VLSI I&F neurons provide convenient approximations of the behavior of neuronal somata without committing to the overhead of emulating the plethora of voltage-dependent conductances and currents present in real neurons. But, if necessary, these conductances can be emulated using subthreshold CMOS circuits. For example, the silicon neurons of Mahowald and Douglas are composed of connected compartments, each of which is populated by modular subcircuits that emulate particular ionic conductances. The dynamics of these types of circuits is qualitatively similar to the Hodgkin–Huxley mechanism without implementing their specific equations. An example of this type of silicon neuron circuit is shown in Figure 3.

In this circuit, the membrane capacitance C_{mem} is connected to a transconductance amplifier that implements a conductance term, whose magnitude is modulated by the bias voltage G_{leak}. This passive leak conductance couples the membrane potential to the potential of the ions to which the membrane is permeable (E_{leak}). Similar strategies are used to implement the active sodium and potassium conductance circuits. In these cases, transconductance amplifiers configured as simple first-order low-pass filters are used to emulate the kinetics of the conductances. A current mirror is used to subtract the sodium activation and inactivation variables (I_{Naon} and I_{Naoff}) rather than multiply them, as in the Hodgkin–Huxley formalism. Additional current mirrors half-wave rectify the sodium and potassium conductance signals, so that they are never negative.

Several other conductance modules have been implemented using these principles. For example,

Figure 2 Diagram of an integrate-and-fire neuron. The input current I_{in} is integrated on to the neuron's membrane capacitor C_{mem} until the spiking threshold is reached. At that point the output signal V_{spk} goes from zero to the power supply rail, signaling the occurrence of a spike. Then the membrane capacitor is reset to zero, and the input current starts to be integrated again. The leak module implements a current leak on the membrane. The spiking threshold module controls the voltage at which the neuron spikes. The adaptation module subtracts a firing rate dependent on current from the input node. The amplitude of this current increases with each output spike and decreases exponentially with time. The refractory period module sets a maximum firing rate for the neuron. The positive feedback module is activated when the neuron begins to spike and is used to reduce the transition period in which the inverters switch polarity, dramatically reducing power consumption. The circuit's biases (V_{lk}, V_{adap}, V_{alk}, V_{sf}, and V_{rf}) are all subthreshold voltages that determine the neuron's properties.

Figure 3 A conductance-based silicon neuron. The passive module implements a conductance term that models the passive leak behavior of a neuron; in the absence of stimulation, the membrane potential V_{mem} leaks to E_{leak} following first-order low-pass filter dynamics. The sodium module implements the sodium activation and inactivation circuits that reproduce the sodium conductance dynamics observed in real neurons. The potassium module implements the circuits that reproduce the potassium conductance dynamics. The bias voltages G_{leak}, $V_{\tau Na}$, and $V_{\tau K}$ determine the neuron's dynamic properties, whereas G_{Naon}, G_{Naoff}, G_K, and V_{thr} are used to set the silicon neuron's action potential characteristics.

there are modules for the persistent sodium current, various Ca^{2+}currents, Ca^{2+}-dependent potassium current, potassium A current, nonspecific leak current, and an exogenous (electrode) current source. The prototypical circuits can be modified in various ways to emulate the particular properties of a desired ion conductance. For example, some conductances are sensitive to Ca^{2+} concentration rather than membrane voltage and require a separate voltage variable representing free Ca^{2+} concentration.

Synaptic conductance circuits have also been developed using similar principles. But synaptic conductances are sensitive to ligand concentrations rather than membrane voltage, so these circuits require a voltage variable that represents neurotransmitter concentration. This set of ionic conductances, with their different dependencies and time constants, gives rise to state-dependent dynamics when embedded in the resistive capacitive network that represents the passive electrical structure of a neuron. These circuits can be composed in this way to model in detail the electrophysiological behavior of several types of neurons, for example, pyramidal cells.

Axons, Action Potentials, and the Address–Event Representation

Biological neurons communicate with one another using dedicated point-to-point axons. The all-or-nothing action potential can be translated into a discrete level signal, that is robust against noise and interchip variability, and can be conveniently transmitted between chips and easily interfaced to standard logic and computer systems. In the AER method developed by Mahowald and others, the action potentials generated by a particular neuron are transformed into an address that identifies the source neuron and then broadcast on a common data bus. Many silicon neurons can share the same bus because switching times in CMOS and on the bus are much faster than the switching times of neurons. Events generated by silicon neurons can be broadcast and removed from a data bus at frequencies greater than a megahertz. Therefore, more than 1000 address events could be transmitted in the time it takes one neuron to complete a single action potential. The addresses are detected by the target synapses, which then initiate their local synaptic action (see Figure 4). In this way, synapses that should be connected to the source neuron initiate a synaptic input whenever the source neuron spikes. These multiplexing strategies are most effective if, like their biological counterparts, the neurons of a network are only sparsely active.

Event-based digital encoding methods are convenient for configuring large networks because the network connectivity can be implemented by a programmable digital address mapper. The mapper receives an address event from a source neuron and translates it into one or more target addresses that are transmitted on the presynaptic bus. Because the mapping table is programmable, arbitrary network topologies can be set and modified dynamically. This method greatly facilitates the configuration and testing of large multichip systems.

Figure 4 Asynchronous communication scheme between two chips using the address–event representation (AER). When a neuron on the source chip generates an action potential, its address is placed on a common digital bus. The receiving chip decodes the address events and routes them to the appropriate synapses.

Synapses in Silicon

Silicon synapses come in many forms, depending on the underlying model and the circuit implementation. The models range from simple current source models to more complicated conductance-based models including approximations of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and *N*-methyl-D-aspartate (NMDA) excitatory synapses, and potassium-mediated and chloride-mediated (shunting) inhibitory synapses. An example of a synaptic circuit that can reproduce the exponential dynamics observed in real synapses is shown in Figure 5.

Plasticity and Learning

One of the key properties of biological synapses is their short- and long-term plasticity. Short-term plasticity produces a dynamic modulation of the synaptic strength by the timing of the input spikes alone, whereas long-term plasticity produces sustained changes in synaptic strength that are induced by the correlations in the spiking activity of the pre- and postsynaptic processes.

Circuits have been developed that emulate the short-timescale synaptic depression; also, various learning circuits that implement long-term plasticity of synapses use spike-timing information and/or rate information. Spike-timing-dependent plasticity (STDP) mechanisms are particularly well suited to the VLSI neuromorphic networks described here because these networks process AER signals. In STDP, the precise timing of spikes generated by the pre- and postsynaptic neurons have an important role in shaping the synaptic efficacy. If a presynaptic spike arrives at the synaptic terminal before a postsynaptic spike is emitted, during a window of causality, the synaptic efficacy is increased. Conversely, if the postsynaptic spike is emitted soon, before the presynaptic one arrives, the synaptic efficacy is decreased. Several modeling studies have developed learning algorithms based on STDP and have demonstrated how systems that use these types of algorithms can carry out complex information processing tasks. The excitatory synaptic circuit of Indiveri and colleagues implements both long- and short-term plasticity.

Memory and Synaptic Weight Storage

There are a number of practical problems that slow down the development of large-scale, distributed, massively parallel networks of VLSI I&F neurons. Three of the most important ones are (1) how to access the individual synapses of the network to provide input signals, and how to read from each neuron to generate output signals; (2) how to set and/or store the weights of individual synapses in the network; and (3) how to (re)configure the network topology on the same chip. Of course, these problems arise directly from the fundamental difference in architecture between conventional computers and neural networks. Conventional computers have a single processor, or small number of processors, connected to a random access memory. This global access

Figure 5 A compact synaptic circuit that exhibits the exponential dynamics observed in real synapses. The circuit's analog output current I_{syn} encodes the frequency of the input spikes, represented as digital voltage pulses arriving at the V_{spk} node. The circuit's time constant is set by adjusting the value of the I_τ current. The V_g bias in the gain module can be used to set the circuit's gain; lower values increase the gain, whereas higher ones decrease it. Similarly, the synaptic efficacy is controlled by the V_w bias voltage in the weight module. In this case, higher values of V_w lead to higher output currents. Additional circuits can be connected to the V_w node to implement short-and/or long-term plasticity mechanisms and to locally store or refresh the value of the weight.

means that the state of the machine can be conveniently loaded and examined. By contrast, in neuronal networks the memory and processing is massively distributed and is co-localized at the synapses. In this case, direct loading and inspection are not possible, except at the huge cost of providing duplicate access lines. Long-term plasticity circuits alleviate these problems slightly (for both biology and neuromorphic VLSI) by allowing the weights of synapses to be set automatically, without requiring dedicated access to individual synapses. But the difficulty of experimental observation and control remains for these circuits.

Basic considerations about the relation between precision and required silicon area suggest that biologically realistic low-resolution weights could also be stored as analog values as voltages across capacitors. But conventional CMOS capacitors are subject to leakage, so their voltages decay over seconds if not refreshed. Alternatively, the analog values can be stored using nonvolatile technology similar to that used in electrically erasable programmable memory (EEPROM). In this case, the analog value is stored as charge on a floating gate, that is the gate of an FET sandwiched between two layers of (perfect) oxide insulator. Charge is added or removed from the floating gate by Fowler–Nordheim tunneling and impactionized hot-electron injection. The uncontrolled decay of charge from floating gates is negligible, so learned synaptic weights can be retained for decades, even when the power to the circuits is off. This exciting technology is still under development, but simple structures such as single transistor synapses and examples of networks that implement learning algorithms based on these circuits have been demonstrated. The problem of synaptic weight storage would be simplified considerably if only one binary bit, rather than an analog value, need be stored. In fact, it has been demonstrated that networks of sufficiently large numbers of binary synapses are adequate for any memory task. Circuits for such binary synapses have been proposed that bypass the need to have specialized structures for nonvolatile analog memory within each synapse.

Multichip Neural Networks

Several examples of successful multichip networks of spiking neurons have been demonstrated during recent years. Using present CMOS technology, it is possible to implement on the order of hundreds of neurons and thousands synapses per square millimeter of silicon. In principle, networks of this type can be scaled up to any arbitrary size, but in practice the network size is limited by the maximum silicon area and AER bandwidth available. Given the current speed and specifications of the AER-interfacing circuits and the availability of present silicon VLSI technology, the network size could be increased by at least two orders of magnitude. It is likely that large neuronal networks, such as those of the neocortex, are dominated by local connectivity, with only a relatively small fraction of long-range connections. In this case, it may be possible to make similarly large-scale VLSI networks in which multiple regional AER buses with the same address spaces carry local-event traffic and are interconnected by sparser long-range traffic between local domains. However, before testing those connectivity limits, there is more immediate interesting work to be done with these multichip networks. For example, existing methods can be used for investigating complex spike-based learning algorithms in real time. And these studies are all the more

interesting when we consider problems of adaptation and learning in neuronal networks interfaced to neuromorphic AER sensors, such as silicon retinas and silicon cochleas.

Impact of Neurobiology on Computer Engineering

Conventional engineering computing systems are beginning to face challenges that have many points in common with those faced by neuromorphic and biological neural systems. As VLSI technology scales to the submicron feature size, power consumption per square micron starts to become a serious limiting factor and single transistors start to behave like unreliable stochastic devices. Under these conditions, insights obtained from building low-power neuromorphic circuits and biologically inspired methods for computing reliably with unreliable components can bring crucial knowledge to advanced computing technologies. Similarly, the current trend toward multicore digital processors in the IT industry will continue and will require the understanding of massively parallel computation, which is also a central question of neuroscience. The principles of unclocked, real-time asynchronous event-driven computation are still far from clear, but it seems likely that this form of communication and processing lies at the heart of biology's ability to achieve effective collective behavior from massively distributed, weakly connected, and relatively slow neuronal processors. We expect that the exploration of neuromorphic systems will continue to contribute strongly to solving this intriguing puzzle.

Neural Control of Muscles

Movement is a feature of all animals, and a central function of all nervous systems is to control movement in a way that promotes survival. In most animals, movement results from the neural activation of specialized contractile cells, the muscle fibers. This activation occurs at the neuromuscular junction (NMJ), the interface between nerve and muscle. While many features of muscle innervation and neuromuscular transmission are similar in all vertebrates, there are also many important differences. This article describes this diversity and how patterns of neuromuscular connectivity have changed during vertebrate evolution.

There are several distinct types of vertebrate muscles. In all of them, contraction arises from the interaction of the motor protein myosin with the cytoskeletal protein actin. However, myosin and actin are organized in different ways in different types of muscles. In striated muscles, they are present in extended arrays of overlapping filaments that give rise to periodic cross-banding, visible in the large cylindrical cells known as muscle fibers. Striated muscles that are attached to skeletal elements, and are used to move body parts (e.g., limbs, digits, eyes) relative to the external environment, are known as skeletal muscles. They are innervated by motor neurons at highly specialized NMJs.

The muscles of the internal organs are controlled by the autonomic nervous system. The cardiac muscle that causes the forceful pumping action of the heart is striated but has a very different cellular organization from skeletal muscle. In the smooth muscles of most internal organs, the actin and myosin arrays are less highly organized and no striations are present. Many cardiac and smooth muscles are intrinsically active, producing myogenic cycles of contraction and relaxation. The effect of the autonomic innervation is to alter the frequency and strength of these cycles. This involves both excitatory and inhibitory effects, mediated by different transmitters. These transmitters are released from beadlike swellings, or varicosities, along the autonomic motor axons. Although the molecular basis of release and transmitter action is similar to that in skeletal muscle, the elaborate NMJs that mediate rapid neuromuscular transmission in skeletal muscles are not present.

The rest of this article is limited to a consideration the innervation of skeletal muscles in vertebrates.

Diversity of Vertebrate Skeletal Muscles

The properties of individual skeletal muscles, and of the fibers within them, vary greatly both between and within vertebrate species. A particularly important distinction exists between muscle fibers that are electrically excitable, that is, that generate propagating action potentials when adequately depolarized, and those that are not. Muscle contraction is regulated by the concentration of free calcium in the cytoplasm of the muscle fiber and this, in turn, is controlled by the electric potential across the muscle fiber membrane. In lower vertebrates, as in most invertebrates, inexcitable muscle fibers are relatively common. They are innervated at multiple sites along the muscle fibers where nerve impulses give rise to local depolarizations (see later). The summed effect of these local depolarizations causes what may be very finely graded contractions of the muscle fiber. In general, the speed of contraction of these fibers is relatively slow (see later). This class of muscle fiber has been variously referred to as slow, tonic, and red, depending on the context. An example is found in the frog, where the properties of inexcitable fibers in vertebrates were first studied in detail, and where they were referred to as slow. Unfortunately, slow is also used to distinguish different subclasses of excitable fibers (see later). In this article, electrically inexcitable, multiply innervated muscle fibers are referred to as 'nonEx-MIF.'

Most muscle fibers, even in lower vertebrates, are electrically excitable. Each action potential in the muscle fiber gives rise to a brief contraction of relatively constant amplitude known as a twitch; fibers excited in this way are called twitch fibers. Within this broad class, there is considerable diversity of functional properties. This has led to definition of fast and slow subtypes of twitch muscle fibers on the basis of contraction speed. In addition, the situation is further complicated by classification of muscle fibers into red and white, based on the appearance of the live muscles. Red fibers tend to contract slowly and to be able to maintain their contraction for long periods of time. Associated with this ability are a predominantly oxidative energy metabolism, a rich vascular supply, and a high concentration of the oxygen-carrying heme protein myoglobin, which gives the fibers their red color. White fibers tend to contract more rapidly but also to fatigue more rapidly. They tend to utilize anaerobic metabolism, to have a less dense vascular supply, and

to have a much lower concentration of myoglobin, making them uncolored, or 'white.'

In addition to these two broad classes of muscle fibers, nonEx-MIF and twitch, there are numerous intermediate forms. In several animal groups, fibers exist that are multiply innervated but can also generate action potentials. While white fibers are generally twitch in character, red is used in the literature to describe both nonEx-MIF and slow twitch muscles. This makes for a confusing nomenclature, but it also highlights the important underlying natural diversity of muscle properties. Not surprisingly, this is reflected in a similar diversity in the patterns of muscle innervation.

General Features of the Motor Innervation of Skeletal Muscles

Skeletal muscles are innervated by specialized motor neurons. The cell bodies of most vertebrate motor neurons are located in the ventral horn of the spinal cord and in corresponding regions of the brain stem. Each spinal motor neuron has a single axon that leaves the central nervous system via the ventral spinal roots. It then extends unbranched in one of the peripheral nerves until it reaches its one target muscle. There, it branches extensively to make contact with many muscle fibers.

In the twitch muscles of higher vertebrates, it is generally the case that every action potential in a motor neuron causes contraction of every muscle fiber that neuron innervates. As a result, each motor neuron, together with the set of muscle fibers it innervates, operates as a functional 'motor unit.' The muscle fibers within a motor unit tend to have very similar functional properties, so that the motor unit as a whole is, for example, fast or slow. In lower vertebrates, as in most invertebrates, muscle fibers are often innervated by more than one motor neuron. They may thus be viewed as parts of more than one motor unit. It is likely that these muscle fibers are used in different ways, depending on which of their neuronal inputs is active.

The force of contraction of a muscle can be controlled by the nervous system in several ways. One is by regulating the frequency of activation of a given motor unit. Skeletal muscle fibers respond to a single nerve action potential with an all-or-none twitch that is brief, but nonetheless much longer than an action potential. If a second nerve action potential arrives before the first twitch has fully decayed, the second twitch will sum with it and the peak force achieved will be greater than that in a single, isolated twitch. Within a range that differs for different muscles, the peak force developed by a muscle increases with increasing frequency of neural activation. Many fast motor neurons fire in stereotyped high-frequency bursts, during which the force developed by the muscle increases rapidly to a maximum. In some situations the duration of these bursts, and with it the peak force, are varied as an additional means of regulating force output.

A second, very different, type of control can be achieved by varying the number of active motor units. In mammalian muscles, the force generated by activation of a small set of motor units is nearly linearly related to the sum of the forces of the motor units when they are stimulated independently. The fineness with which contraction can be graded by this form of control is determined by the number of motor units in a muscle.

Phylogenetic Variation in Patterns of Skeletal Muscle Innervation

During the course of vertebrate evolution, there have been major changes in the organization of muscles and the patterns of their innervation. The appearance of limbs and the increasingly sophisticated control of digits are reflected in the increasingly specific control over small groups of muscle fibers by the central nervous system. This is most developed in humans where pyramidal cells of the motor cortex make direct synaptic input to spinal motor neurons. In what follows, some of the main features of muscles and their innervation in the major groups of vertebrates are described. For each group, the species for which most information is available is indicated.

Agnatha (Hagfish, Lamprey)

In primitive vertebrates of the class Agnatha, the arrangement of muscles and their innervation differ from that in other vertebrates. Within the segmental myotomes, the muscle fibers are arranged into 'muscle units' in which large-diameter 'white' fibers are placed centrally. They are surrounded by a superficial layer of much smaller 'red' fibers.

Within the muscle units, the large central fibers are typical twitch fibers. Those nearest the abdominal cavity are innervated at their tendinous ends, sometimes by more than one axon. Stimulation of the nerve evokes an all-or-none action potential that propagates along the full length of the muscle fiber and evokes contraction. In lampreys, though probably not in hagfish, the remaining central fibers (those nearest the skin) are apparently not directly innervated but are electrically connected to innervated fibers by gap junctions. This ensures rapidly synchronized contraction

of the central fibers in each unit and an economy of innervation. However, it appears to be a relatively inflexible arrangement designed for speed, rather than subtlety, of action.

The most superficial fibers are not electrically excitable. Both anatomical and electrophysiological observations indicate that they are innervated at multiple sites along their length, often by the axons of more than one motor neuron. Thus they are similar to the nonEx-MIF fibers of other vertebrates.

Cartilaginous Fish (Dogfish)

In the myotomes of both cartilaginous and bony fish, two distinct types of muscle fibers, often referred to as white (or fast) and red (or slow), are present. In both types of fish, the white fibers form the central bulk of the muscles, while the red fibers form a superficial layer (Figure 1, dogfish). As in Agnatha, the white fibers in dogfish appear to be innervated mainly at their ends, while the red fibers are innervated at multiple sites along their length. However, so-called aberrant fibers are also present in which innervation occurs at a single centrally placed site, as in many higher vertebrates.

Bony Fish (Tench, Zebra Fish)

In many teleosts (bony fish), as in sharks, fast and slow muscle systems exist, with the slow fibers present in a superficial layer. The slow fibers are innervated at multiple sites by branches of several fine motor axons. There is considerable variation in the patterns of innervation of the fast white fibers in different species. In the catfish and eel, the pattern is similar to that in sharks, with nerve–muscle contacts made at the ends of the fast fibers. In most other teleosts that have been examined, the pattern of innervation of the white fibers is similar to that of the red fibers, with several sites of nerve–muscle contact, originating from more than one motor neuron, along the fibers (Figure 1, tench). Nonetheless, the white muscle fibers generate action potentials and twitch contractions, so are not typical nonEx-MIF fibers.

In the zebra fish, two distinct populations of motor neurons innervating the fast white muscles have been identified in the spinal cord. Primary motor neurons have large cell bodies and axons and are the first to appear during development. There are three primary motor neurons innervating each segmental myotome on each side of the fish. The primary motor neurons innervate a nonoverlapping set of muscle fibers within the myotome. Their axonal arbors do not cross the boundaries between segments. These motor neurons can thus be recognized unambiguously from one individual to the next.

In addition to the primary motor neurons, there is an additional class of secondary motor neurons. These are smaller than the primaries and have peripheral fields of innervation that are smaller and less focused than those of the primary motor neurons, often innervating muscle fibers in more than one segment. Individual white muscle fibers receive input from one primary and several secondary motor neurons. These synaptic inputs differ in the strength of their effect on the muscle fibers. Stimulation of the primary neurons evokes a large, short-latency endplate potential, suggesting that they may be used to in escape behavior. In contrast, secondary neurons evoke smaller, longer latency endplate potentials. Because white muscles of fish are both multiply innervated and generate action potentials, they form a group with properties intermediate between nonEx-MIF and twitch fibers as described previously.

Amphibia (Salamanders, Frogs)

The evolution of limbs made important new demands on the organization of skeletal muscles and their innervation. In what was to prove to be the beginning of a sustained evolutionary trend, the slow fiber system that plays an important part in normal fish behavior appears to be reduced in importance in amphibia, and greater reliance is placed on focused innervation of individual fast muscle fibers.

Urodeles In salamanders and newts, both twitch and nonEx-MIF muscle fibers are present. The twitch muscle fibers are generally innervated by several motor axons (typically one to three), as in fish. The contractile properties of individual motor units vary greatly. Interestingly, individual muscle fibers may belong to motor units with quite different contractile properties.

Anura In frogs and toads, most muscle fibers are twitch fibers, and are innervated by a single motor neuron (Figure 1, frog – fast). These twitch fibers vary in their functional and molecular properties, and two or three different types have been defined. NonEx-MIF fibers are also present in many anuran muscles (Figure 1, frog – slow). However, in contrast to fish, they are generally not present as contiguous groups. In addition, some muscle fibers of an intermediate type have been found in frogs (submaxillary muscles) that are electrically excitable, but are innervated by several motor axons.

Reptiles (Garter Snake, Lizard, Turtle)

Reptiles, like fish and amphibia, have both nonEx-MIF and twitch muscle fibers. In most reptiles, however, the

Figure 1 Some common patterns of innervation of vertebrate muscles. In dogfish, multiply innervated slow muscle fibers form a superficial layer surrounding the central fast muscle fibers. The latter are mainly innervated by basketlike endings at the ends of the fibers. Some intermediate forms, with centrally located plaquelike endings, are also present. In the tench, as in many bony fish, both fast and slow muscle fibers are multiply innervated. Reproduced from Bone Q (1964) Patterns of muscular innervation in the lower chordates. *International Review of Neurobiology* 33: 99–147, with permission from Elsevier. In frogs, fast muscle fibers are generally innervated at a single site by nerve endings whose several branches extend along the muscle fiber. In addition, electrically inexcitable, multiply innervated muscle (nonEx-MIF) fibers are present which are innervated at multiple sites by more diffuse endings. The intrafusal muscle fibers present in the sensory muscle spindles are innervated by branches of the motor neurons that innervate both twitch and nonEx-MIF extrafusal fibers. From Barker D (1968) L'innervation motrice du muscle strié de vertebrés. *Actualités Neurophysiologiques* 8: 23–71. In mammals, most twitch muscle fibers are innervated at a single site, but in some, multiply innervated muscle fibers are present in the extraocular muscles that control the position of the eye (sheep extraocular). Reproduced from Harker DW (1972) The structure and innervation of sheep superior rectus and levator palpebrae extraocular muscle. *Investigative Opthamology and Visual Science* 11: 956–969, with permission. The contractile intrafusal fibers of the mammalian muscle spindle (cat) receive multiple motor innervation derived from both α- and γ-motor neurons. The latter terminate in both compact plaque endings and more diffuse trail endings. Reproduced from Barker D (1970) Fusimotor innervation in the cat. *Philosophical Transactions of the Royal Society B* 8: 336, with permission from Philosophical Transactions of the Royal Society B.

twitch fibers are generally innervated by a single motor neuron. Different functional types (fast and slow) of twitch fibers have been identified. In the sheetlike transversus abdominis muscle of the garter snake, fast and slow twitch fibers alternate with nonEx-MIF fibers in a highly regular pattern. Available evidence suggests that this pattern is not determined by the nerve and is therefore assumed to be determined by inherent differences in the muscle fibers. In turtles, nonEx-MIF fibers are present and of particular importance in the neck muscles that support the head.

Birds (Chicken)

Chickens also have both multiply innervated nonEx-MIF and singly innervated muscle fibers. In contrast to nonEx-MIF fibers in frogs, those in chickens are capable of generating regenerative action potentials, at least in laboratory conditions. Whether this occurs during normal use is unclear. One often studied chicken muscle, the anterior latissimus dorsi, is composed predominantly of slow, multiply innervated nonEx-MIF muscle fibers.

Mammals (Human, Rat, Mouse, Cat)

In mammals, virtually all muscle fibers are twitch fibers (but see later). Each fiber receives innervation at a single site from a single motor neuron. The number of muscle fibers in a mammalian motor unit varies from less than 10 to 1000 or more. The number of motor units in an individual muscle ranges from about 25 to several hundred, and sets limits on how finely contractions can be graded.

There is considerable variability in the properties of mammalian twitch fibers. In particular, they vary in their speed of contraction and in their ability to maintain contraction without fatiguing. Mammalian twitch fibers are generally recognized as being slow twitch (or type I) or fast twitch (or type II). However, the fast-twitch fibers are further subdivided into subtypes (IIA, IIB, IIX) based on their contractile properties and the main subtype of myosin expressed in them. The muscle fibers in a single motor unit are normally all of the same subtype.

Like muscle fibers, mammalian motor neurons vary in their properties. For example, within the set of motor neurons innervating an individual muscle, some motor neurons have larger cell bodies than others. Axon diameter, and hence the speed of action potential conduction, are closely correlated with cell body size. In this sense, large motor neurons are also fast. Fast motor axons branch more extensively within the muscle and innervate more muscle fibers than do smaller, slower, ones. As a result, fast motor units tend to generate more force than do slow ones. Finally, the muscle fibers innervated by fast motor neurons are themselves functionally fast. Thus the functional properties of the nerve and muscle fibers are closely matched in each motor unit.

In contrast to lower vertebrates, there are very few nonEx-MIF muscle fibers in mammals. The extraocular muscles are a notable exception (**Figure 1**, sheep extraocular). Some of these have a substantial population of nonEx-MIF fibers that are capable of generating finely graded contractions in response to varying frequencies of neural input. It has been suggested that the pattern of innervation of these fibers may be a relic of a primitive anterior 'vegetative' region of the vertebrate body.

NonEx-MIF fibers of a second group are contained within the sensory muscle spindles. These so-called intrafusal fibers (within the spindle, as distinct from the majority of extrafusal fibers) are primarily innervated by a distinct class of γ-motor neurons (**Figure 1**, cat-spindle). Some of these neurons terminate in plaque endings, similar to those of the α-motor neurons on extrafusal twitch fibers, and others end in more diffuse trail endings, reminiscent of endings on the nonEx-MIF fibers of lower vertebrates. Indeed, in frogs, the motor axons ending in trail endings sometimes also innervate extrafusal nonEx-MIF fibers (**Figure 1**, frog – spindle). Some intrafusal fibers are of an intermediate type in that they are capable of generating action potentials.

Variations in NMJ Properties

Vertebrate NMJs are as diverse as the motor neurons and muscle fibers of which they are composed. At most vertebrate NMJs, the sites of quantal release are small domains 2–5 μm in diameter, known as boutons. Separate boutons are generally connected by fine unmyelinated axon branches, as in fish, snakes, and humans. However, in some species, they may be variably fused into more linear arrays, as in the frog and turtle (**Figure 2**). In the great majority of mammalian muscles, each muscle fiber is innervated at a single point by the dense plaquelike ('en plaque') terminal of a single motor neuron. By contrast in lower vertebrates, and in fish in particular, multiterminal polyaxonal innervation is more common, and individual terminals often consist of a dispersed set of boutons, often described as like a bunch of grapes ('en grappe').

Associated with the differing patterns of innervation in different muscle types and in different animal groups is a range of the efficacy of neuromuscular transmission. In mammals, at one extreme, each motor nerve impulse leads to a depolarization of the muscle fiber that is several times greater than required

Figure 2 Variations in neuromuscular junction structure in different vertebrates. The top row of drawings shows the typical appearance of individual NMJs in twitch muscle fibers of the species indicated. Many of these consist of distinct boutons which are the sites of transmitter release. In some species these are variably merged so that the nerve terminal becomes a continuous band. In fish, each NMJ has two types of endings, one more continuous than the other. Frogs are one of few species in which the NMJ is greatly elongated in the long axis of the muscle fiber. In snakes and humans, the individual boutons are distinct but much more numerous in the snake.

to trigger an action potential. Two main factors contribute to this high safety factor. On the one hand, the nerve routinely releases more transmitter than is needed to reach threshold. On the other, the threshold for action potential generation in the muscle is lowered in the region of the NMJ. Each of these factors is associated with distinctive structural features of the NMJ.

Many studies have shown that the amount of transmitter released from a motor nerve terminal is roughly proportional to its area of contact with the muscle. The transmitter at the NMJ, acetylcholine (ACh), is released in multimolecular packets known as 'quanta.' Each quantum corresponds to the ACh contained in a single presynaptic vesicle. The number of quanta released by a single nerve impulse is known as the 'quantal content' of release. During low-frequency stimulation (1 Hz) *in vitro*, many NMJs release 0.15–0.25 quanta μm^{-2}. In contrast, there are substantial variations in quantal content at NMJs in different species (e.g., frog, 200; human, 20). In many cases, the differences in quantal content are associated with equivalent differences in NMJ size (Figure 3(a)).

The effect of the ACh released from the nerve on the membrane potential of the muscle fiber is also influenced by structural factors. For example, the smaller the fiber, the higher its electrical 'input' resistance and the greater the depolarization caused by the current flowing through the ion channels opened by a quantum of ACh. In order for the depolarization caused by ACh to trigger an action potential, it must open an adequate number of the voltage-gated sodium channels that underlie the action potential. These channels are concentrated in the postsynaptic membrane, so a smaller fraction of them needs to open to trigger an action potential than if their density was lower. In many species, particularly of higher vertebrates, the postsynaptic membrane is highly folded (Figure 3(b)). This enhances the effect of the increased concentration of sodium channels in the postsynaptic membrane and has led to the suggestion that an important function of the folds is to act as amplifiers of the effect of the ACh released from the nerve.

The NMJs in different animal groups use different balances between pre- and postsynaptic effects to achieve the necessary reliability of neuromuscular transmission (Figure 3(c)). In humans the terminals are small and release relatively few quanta. However, human NMJs have very extensive postsynaptic folds which amplify the effect of the modest amount of ACh released. It is likely that this plays an important part in ensuring an adequate safety factor of transmission. In frogs, the terminals are large and release many quanta but the folding is less extensive than in humans. Rats and mice have intermediate degrees of folding. In fish and chickens, postsynaptic folds are generally lacking and it is possible that the safety factor is relatively low in these species. Finally, in electrically inexcitable fibers, postsynaptic folds are absent. Thus there is a clear correlation between the extent of postsynaptic folding and the tendency to generate an action potential in the muscle cell.

Patterns of Motor Unit Use in Vertebrate Muscles

The diversity of functional properties of vertebrate muscle fibers only makes physiological sense because fibers with different properties can be specifically activated by motor neurons which themselves have distinctive properties and patterns of activity. However, the selective innervation of individual muscle fibers with specific properties is a much more prominent feature of higher vertebrates such as mammals than of lower vertebrates such as fish.

In fish, the fast white muscle fibers are innervated by both primary and secondary motor neurons (see earlier). The secondary motor neurons activate the relatively low-force, and possibly more finely regulated, contractions needed to power smooth movement. The primary motor neurons trigger the rapid movements that give rise to escape behavior. Since each primary motor neuron innervates a large block of muscle fibers in each segment (see earlier), it is clear that all these fibers are likely to fire simultaneously during rapid escape movements. As most white fibers are innervated by both primary and secondary motor neurons, it is likely that they are used in the generation of both slow and fast movements.

Figure 3 Neuromuscular junctions vary in size and extent of postsynaptic folding. (a) Light microscope views of NMJs in frog, rat, and human, showing region of NMJ in white, muscle fiber in black. (b) Electron microscope views of NMJs in the same species, showing much more extensive folding in humans. (c) Inverse relationship between extent of folding ('folding index') and amount of transmitter released ('quantal content').

In mammals, individual muscle fibers are innervated by a single motor neuron, and are only active when that neuron fires. Studies of rat leg muscles show that motor neurons innervating type I muscle fibers (slow twitch) fire at about 10–20 Hz, in prolonged trains, which are associated with sustained postural contractions of anti-gravity muscles. In contrast, motor neurons innervating type II fibers (fast twitch) fire in brief stereotyped bursts of 5–10 action potentials at a frequency of about 50–100 Hz. In the type I fibers, as found in the rat soleus muscle, the natural frequency of firing is the lowest that maintains maximal force output. By contrast type II motor units, which are often used when a rapid acceleration of a body part is required, fire in short bursts of closely spaced impulses that are optimal for the rapid development of force.

The distinctive patterns of activity in different mammalian motor neurons are largely determined by the intrinsic properties of their membranes rather than by the temporal patterns of inputs to them. Following an action potential in a motor neuron, there is generally a period of increased negativity during which generation of another action potential is suppressed. The duration of this afterhyperpolarization (AHP) is greater in motor neurons innervating type I muscle fibers than in those innervating type II muscle fibers. There is a close correlation between the time course of the AHP and of the twitch of the muscle fibers in the motor unit. This illustrates further the effect of matching of the properties of motor neurons to those of the muscle fibers they innervate.

A second aspect of motor unit use is revealed during graded voluntary contractions in mammals when there is an orderly increase in the number of active motor units. For relatively weak contractions, such as are used to maintain posture, the motor units activated are small and slow. As the force output increases, as during a rapid movement of a limb, increasingly large and fast motor units are recruited. An important effect of this orderly recruitment is that the greater the preexisting force being generated, the greater is the extra force added by each newly recruited motor unit. Thus the fractional increase in force per recruited unit stays roughly constant. This tendency for an orderly recruitment of motor units of increasing size and speed was first emphasized by Henneman and his colleagues and is known as the 'size principle.'

A simple biophysical feature of motor neurons appears to underlie the size principle. Thus, consistent with Ohm's law, small motor neurons have a relatively high 'input resistance.' As a result, a synaptic current of a given intensity causes a larger depolarization and is more likely to trigger an action potential than it would in a larger, lower resistance, neuron. As the synaptic input, or 'drive,' to a pool of motor neurons innervating a muscle increases, the first neurons to be recruited are therefore likely to be those with the highest input resistance and, hence, the smallest size and slowest conducting axons. This relationship assumes that the intrinsic membrane properties of motor neurons of different sizes are similar. Important exceptions to the size principle are known to exist. Thus, during constant activation of the motor neuron pool, some units may abruptly cease firing while others of similar strength begin to fire. This allows individual units to have periods of rest without loss of overall force.

There is relatively little information about the natural activity patterns of motor units in freely moving lower vertebrates. It is therefore difficult to interpret the functional consequences of the varied arrangements of muscle fiber types and arrangements seen in those animals. It seems very likely that motor units composed of nonEx-MIF muscle fibers, whether they are distributed throughout a mixed muscle or concentrated into a single muscle, are used to generate slow, maintained contractions that can be very finely graded in strength. A good example may be the extraocular muscles that must position the eye with great accuracy. The 'stepwise' increase in tension associated with the recruitment of additional motor units may simply be too coarse for this purpose.

Conclusions

It is clear that vertebrate muscles and their innervation are specialized to carry out distinctive sets of tasks. As the vertebrate body plan has evolved, muscles and their innervation have become adapted to new functional requirements. Several general trends can be identified in this process. One of these is the increasing specificity of control of individual muscle fibers by the nervous system. In Agnatha, many muscle fibers are not even directly innervated, and depend on electrical coupling to innervated fibers for their control. In this situation the nerves exert their control on blocks of muscle fibers. This results in speed of response but limited flexibility of how muscles are used. In fish and some amphibia, while all muscle fibers are innervated, many are innervated by more than one motor neuron. This means that individual muscle fibers are part of several motor units, and are presumably used in somewhat different ways depending on the circumstances. Elucidating the way in which the several inputs to each muscle fiber interact to control overall behavior in these animals remains an important task for the future. By contrast, in higher vertebrates, including mammals, virtually all muscle fibers are innervated at a single point by a single motor neuron whose properties are closely matched to those of the muscle fibers it innervates. This gives the nervous system unambiguous access to highly specialized sets of muscle fibers, allowing appropriate ones to be activated for particular tasks. As with many phylogenetic trends, the loss of polyneuronal innervation of muscles is repeated in the ontogeny of higher vertebrates.

A second closely related trend is the loss of importance of the system of multiply innervated muscle fibers. These are present in most muscles of most vertebrates up to birds, but are largely absent in mammals. Thus the pattern of innervation that is predominant in higher vertebrates may be seen to derive from the fast system associated with escape behavior in lower vertebrates. It may be that the fine of control of force associated with the graded activation of nonEx-MIF motor units in lower vertebrates is achieved in other ways in mammals, possibly involving more subtle regulation of antagonistic muscles under the control of the sensory muscle spindles.

A third trend is the gradual increase in the efficacy of neuromuscular transmission. In Agnatha and fish, most individual motor nerve terminals are small and release relatively few quanta of ACh. Thus activation of the muscle requires either repetitive firing of the nerve or activation of more than one axon or both. In most vertebrates higher than fish, every nerve impulse causes a sufficient depolarization of the muscle fiber membrane to trigger an action potential. The high safety factor of neuromuscular transmission in these species is either associated with large neuromuscular junctions, a highly folded postsynaptic membrane rich in voltage-gated sodium channels, or both.

Neuromuscular Junction (NMJ): A Target for Natural and Environmental Toxins in Humans

J Harris, Newcastle University, Newcastle upon Tyne, UK

© 2009 Elsevier Ltd. All rights reserved.

Natural Toxins and the Neuromuscular Junction

The neuromuscular junction (NMJ) is the ultimate relay between the motor cortex, which controls the excitation of skeletal muscle, and the mechanical response of the muscle, which results in physical movement. Anything that perturbs the functioning of the neuromuscular system clearly threatens the survival of the organism. It should be no surprise, therefore, that numerous animals – plants, fungi, bacteria, and protists (Figure 1) – have evolved highly specific toxins that target specific components of the NMJ. The toxins may be used defensively to ward off potential predators or offensively to restrain prey. In some cases, it is not clear why the toxins are of any benefit to the organism; for example, some soft-bodied anthozoans produce the highly toxic polyether palytoxin (*qv*), one of the most dangerous of all toxins to mammals, and it is assumed that the poison is used by the anthozoans to protect their growing space from competitors. All components of the NMJ may be targets of natural toxins. These include voltage-gated ion channels of all kinds located on the axon, the nerve terminal, and the postjunctional membrane of the muscle fiber; membrane-bound ATPases; synaptic vesicle-docking proteins (e.g., synaptobrevin, SNAP-25, and syntaxin); junctional acetylcholine esterase; and the postjunctional acetylcholine receptor.

Natural toxins are structurally highly diverse. Some are simple amino acids, some are small polypeptides of between 15 and 150 amino acids, and some are very large and complex polypeptides such as the clostridial toxins. Other common toxins such as palytoxin are large polyethers and toxical kaloids are produced by numerous plants and algae. The diversity of structures is illustrated in Figure 2.

It is difficult to identify a single coherent system for the classification of natural toxins. Classification according to chemical structure has an obvious logic, but there is little relationship between chemical structure and pharmacological activity. For example, among the toxins that block the acetylcholine (ACh) receptors at the vertebrate NMJ are alkaloids (e.g., tubocurarine); polypeptides (e.g., α-bungarotoxin); and toxins that block the ion pore of the voltage-gated sodium channel, including cyclical guanidiums (e.g., tetrodoxin and saxitoxin) and small polypeptides (e.g., the μ-conotoxins). Classification according to the source (i.e., phylum or class) is suitable in some circumstances, but a discussion, for example, of the venom toxins of the squamata would require considerable subclassification according to the function of the toxins. Because this article concerns the NMJ, natural toxins have been considered in terms of their molecular or subcellular target.

Whichever method of classification is used, two important complicating factors need to be borne in mind. The first is that some toxins may modify function by a direct action on a recognized molecular target and others act by comprising the structural integrity of the target. For example, many of the presynaptically active phospholipases of snake venoms cause enhanced exocytosis, the depletion of synaptic vesicles, and the eventual degeneration of the nerve terminal, but these changes are initiated by the hydrolysis of the nerve terminal phospholipids and nerve-terminal depolarization. The α-latrotoxins bind to specific nerve-terminal proteins neurexin and synaptophilin to cause enhanced exocytosis and the eventual depletion of the synaptic vesicles without tissue degeneration. The second factor is that many animals, plants, and microorganisms elaborate or accumulate multiple isoforms or derivatives of major toxins and often use a battery of toxins of different types as part of their armory. For example, snakes of the genus *Dendroaspis* (the mambas) elaborate *inter alia* in their venom glands two types of toxins that block the nicotinic ACh receptor: toxins that inhibit acetylcholinesterase activity and bind to muscarinic ACh receptors, and toxins that block voltage-gated potassium channels. Similarly, the fish-eating cone snails (e.g., *Conus magus* and *Conus geographus*) produce toxins that block ACh receptors and voltage-gated Na^+ and Ca^{2+} channels. Filter-feeding shellfish and detritus-grazing Xanthid crabs accumulate a range of neurotoxic toxins, including tetrodotoxin, saxitoxin, and palytoxin, all of which are produced by marine microorganisms.

Voltage-Gated Ion Channels

Voltage-gated sodium, calcium, and potassium channels are the molecular targets for a wide range of very potent natural toxins. The toxins interact with voltage-gated ion channels in three ways: occluding the ion pore, thus disrupting function by physically preventing the

Figure 1 Organisms that produce major toxins that are active on the nervous system: (a) *Gonyaulax,* a dinoflagellate that produces saxitotoxin and a range of related toxins that block voltage-gated Na^+ channels; (b) *Palythoa caesia*, a zoanthid that is a source of palytoxin, a complex toxin that converts Na^+/K^+ adenosine triphosphate (ATP)ase to nonselective cation channels in numerous cells; (c) a tarantula and a (much smaller) black widow spider, which produce toxins resulting in the accelerated release of neuromuscular transmitter; (d) an Australian tiger snake, whose venom contains toxins that block acetylcholine receptors, damage skeletal muscle, and destroy nerve terminals.

movement of ions across the cell membrane; or modifying the gating process by binding to extracellular sites and affecting the voltage sensitivity of the channel; or modifying the kinetics of the opening and/or closing the ion channels. Lipid soluble toxins may enter the channels and bind to stabilize the channel in one particular state (open, closed, or inactivated). The extensive molecular diversity within the superfamily of voltage-gated ion channels, their respective distribution between different excitable tissues (e.g., muscle and nerve), and the highly selective predatory behavior of venomous animals suggest that most toxins targeting voltage-gated ion channels are selective for both ion channel subtype and animal species. Although detailed information on these issues is not routinely collected, there are good examples of such selectivity. For example, the voltage-gated sodium ion channels can be differentiated on the basis of their speed of inactivation and their sensitivity to tetrodotoxin and saxitoxin. The sodium channel subtypes $Na_v1.1$, 1.2, 1.3, 1.4, 1.6, and 1.7 are widely distributed in tissues of the central nervous system (CNS), peripheral nervous system (PNS), and skeletal muscle; and regardless of location, all are blocked by saxitoxin and tetrodotoxin at concentrations between 5 and 15 nM. Subtypes 1.5, 1.8, and 1.9 are also widely distributed, but are blocked at concentrations between 2 and 60 μM. This distinction led to the observation that in skeletal muscle the immature form of the voltage-gated ion channel is the tetrodotoxin-resistant $Na_v1.5$ and that its expression is suppressed by imposed or neurally regulated activity, at which time the adult $Na_v1.1$ subtype is upregulated and sensitivity to tetrodotoxin appears. The $Na_v1.5$ subtype reappears after denervation and during the early stages of regeneration of skeletal muscle and is suppressed during reinnervation (see Figure 3). Species sensitivity is particularly marked in the toxins of spider and scorpion venoms, and more than 30 different toxins selectively targeting insect voltage-gated sodium ion channels have been identified in scorpion venoms alone.

Figure 2 Diverse structures of natural toxins: (a) long and short α-neurotoxins from snake venoms, which block acetylcholine receptors at the neuromuscular junction and are small, highly folded polypeptides; (b) anatoxin, which is a natural anticholinesterase produced by blue-green algae; (c) saxitoxin, which is produced by marine dinoflagellates and blocks voltage-gated Na^+ channels. In (a), β-pleated sheet formations are indicated by plates and disulfide bridges are indicated by dotted lines.

Sodium Channels

The voltage-gated sodium channels comprise a single protein complex containing the α subunit, which contains both the pore-forming and voltage-sensing elements, and one or two subsidiary β subunits. The α subunit has four transmembrane regions, each of six hydrophobic segments. A hydrophobic loop between the fifth and sixth segment forms the neck of the ion channel (Figure 4). Activation of the sodium channel results in the reorientation of the fourth segments in each of the four transmembrane regions and the opening of the channel to allow the passage of sodium ions down their electrochemical gradient into the cell. Toxins binding with high degrees of specificity to voltage-gated sodium channels have been isolated from the venoms of snakes, scorpions, cone snails, and sea anemones; from the skin secretions of tropical frogs; from marine bacteria and dinoflagellates; from blue-green algae; and from plants. Six distinct binding sites have been identified in the voltage-gated sodium channel.

Toxins active at site 1 occlude the sodium channel to produce a complete block of neurotransmission and a potentially fatal neuromuscular paralysis (Figure 4). The toxins most commonly involved are tetrodotoxin, a heterocyclic guanidinium produced by symbiotic marine bacteria and isolated originally from puffer and sun fish; saxitoxin, a structurally related toxin produced by marine dinoflagellates of the genus *Gonyaulax* and usually isolated from filter-feeding shellfish; and the μ-conotoxins, small polypeptides of approximately 22-amino-acid residues produced by a number of marine snails of the genus *Conus*. Site 2 on segment 6 is the binding site for a number of

Figure 3 Tetrodotoxin (TTX) and voltage-gated Na^+ channels: (a) in controls and after denervation; (b) during reinerveraton. In (a), TTX (10^{-6} M) blocks voltage-gated Na^+ channels in mature mammalian skeletal muscle and this prevents action potential generation (top traces). After denervation, during development, or during regeneration, the gene for the TTX-resistant $Na_V1.5$ channel is upregulated and the toxin no longer blocks action potential generation (bottom traces). In (b), the generation of TTX-resistant action potentials in muscle fibers declines as reinnervation returns in denervated muscles.

Figure 4 Voltage-gated Na^+ channel: (a) organization; (b) major binding sites for natural toxins. Modified from Catterall WA, Cestèle S, Yarov-Yarovoy V, Yu F, Konoki K, and Scheuer T (2007) Voltage-gated ion channels and gating modifier toxins. *Toxicon* 49(2): 124–141.

lipophilic alkaloids such as batrachotoxin, isolated from the skin secretions of Dendrobatid frogs of the genus *Phyllobates*, and veratridine, isolated from plants of the genus *Schoenocaulen*. Some of the toxic alkaloids are preferentially active on the nervous system of insects and therefore have potential use as biological insecticides. Toxins acting on site 2 cause the activation of the sodium channel and reduce

sodium channel inactivation, leading to a prologation of the action potential and repetitive firing at the NMJ.

Site 3 is an extracellular site occupied by a number of small polypeptides isolated from the venoms of sea anemones, the α-toxins of scorpions and the μ-agatoxins isolated from the venom of spiders of the genus *Agelenopsis*. Although the α-toxins of scorpion venoms and the sea anemone toxins all delay sodium channel inactivation, and thereby prolong action potential duration, they are structurally distinct. The scorpion toxins are small poypeptides of 60–70 residues; the sea anemone toxins are only 45–50 residues. The prolongation of the action potential in the peripheral motor system results in hyperexcitability and repetitive firing at the NMJ (Figure 5).

Site 4 is occupied by β-toxins of scorpion venoms and some spider toxins, which act to enhance activation by reducing the voltage dependence of activation. Site 5 is occupied by brevetoxin, a toxin produced by marine dinoflagellates of genus *Ptychodiscus* to cause persistent activation of the sodium channel. Site 6 is the binding site for a specific group of δ-conotoxins. These toxins cause a slow inactivation of voltage-gated sodium channels in marine molluscs.

Figure 5 Effects of ATX-II, a toxin from the sea anemone *Anemonia sulcata*: (a) on Na^+ channel and action potentials; (b) on neuromuscular junction. (1) control; (2) first action potential after ATX-II; (3) tenth action potential; (4) fiftieth action potential. In (a), the Na^+ channel is inactivated (2), and this results in the prolongation of the action potential in the skeletal muscle and axons, the duration of the action potential increasing with time and activity. In (b), the prolongation of the action potential in motor axons leads to repetitive firing at the neuromuscular junction.

Calcium Channels

The voltage-gated calcium channels are major signaling transducers, converting the depolarization of a cell membrane into the influx of Ca^{2+}. The structural organization of the voltage-gated Ca^{2+} channel is virtually identical to that of the voltage-gated sodium channel, comprising an α subunit, which contains those structures that form the ion channel and the signaling domains, and one or more auxiliary subunits. As in the sodium channel, the α subunit of the calcium channel is composed of four domains, each containing six hydrophobic sequences, the pore being formed when the four domains form a pseudo-symmetrical array across the cell membrane. The known voltage-gated calcium channels fall into one of three major types, defined by their role. Ca_V1 voltage-gated calcium channels, also known as type L, are involved in the activation of intracellular signaling processes, including gene regulation, endocrine secretion, and the contraction of smooth, cardiac, and skeletal muscle. Ca_V2, also known as types N, P/Q, and R channels, regulate fast synaptic transmission in the nervous system; Ca_V3, also known as T-type channels, are primarily involved with the regulation of repetitive firing in the nervous system. There is a great deal of diversity of function within the individual types of voltage-gated calcium ion channels because there are at least ten recognizable isoforms of the α subunit, further complicated by extensive alternative splicing. A similar diversity among the auxiliary units gives rise to a high degree of combinatorial heterogeneity.

Natural toxins targeting voltage-gated calcium channels are produced by large numbers of predatory animals. The toxins involved include the ω-conotoxins, toxins from the venoms of spiders of the genera *Agenelopsis, Grammostola, Hololena,* and *Plectreurys* and of snakes of the genera *Dendroaspis*. The ω-toxins of Conus (i.e., the ω-conotoxins) and *Agelenopsis* (i.e., the ω-agatoxins) are by far the most widely used toxins in calcium channel pharmacology. Despite the very high specificity of the ω-conotoxins and-agatoxins for voltage-gated calcium channels, they are structurally unrelated. The ω-conotoxins are small polypeptides of 24–30 residues cross-linked by three disulfide bonds; the ω-agatoxins are small

polypeptides of 45–75 residues cross-linked by four disulfide bonds. With care, the pharmacological differentiation between the various types of calcium channel may be made on the basis of sensitivity to a small number of agents. L-type channels are very sensitive to the dihydropyridines and are resistant to the majority of ω-conotoxins and-agatoxins. P/Q channels are particularly sensitive to ω-conotoxin MV11C and ω-agatoxin 1VA, and N channels are particularly sensitive to ω-conotoxin GV1A. This approach to the classification of calcium channels is, however, fraught with difficulty, especially when a novel calcium channel is being classified, because the majority of ω-toxins are selective for voltage-gated calcium channels but are not particularly specific for an individual channel type.

Other toxins directly affecting voltage-gated calcium channels include ω-grammotoxin SIA, isolated from the venom of the Chilean tarantula *Grammostola spatulata,* which blocks N-, P-, and Q-type channels but not L-type; hololena toxin from the venom of the spider *Hololena curta;* and PLTX11 from the venom of the spider *Plectreurus tristes,* which block voltage-gated calcium channels in insects. Calciseptine, isolated from the venom of the mamba *Dendroaspis polylepis*, inhibits L-type Ca^{2+} channels in the aorta, ventricular muscle, and dorsal root ganglia; calcicludine, from the venom of *Dendroaspis augusticeps,* blocks L-, N-, and P-type channels in the CNS. The typical response to the blockade of voltage-gated calcium channels at the NMJ is the failure of evoked transmission and the packing of the nerve terminal with synaptic vesicles.

Potassium Channels

Voltage-gated potassium channels regulate the movement of potassium ions across cell membranes. Activation leads to an increase in conductance and the termination of action potentials, hyperpolarization, and a reduction in excitability. Conversely, a block of the channels leads to depolarization, prolongation of action potentials, repetitive firing, and increases in transmitter release and endocrine activity. The channels are homo- or heterotetramers, comprising four subunits, each composed of six transmembrane segments (Figure 6). Thus, each subunit is analogous to a single domain in the α subunit of a voltage-gated sodium or calcium channel.

The toxins known to block potassium channels fall into five major groups. The apamin group comprises two homologous small polypeptides isolated from the venom of the honey bee, *Apis mellifera*. The toxins are 18 and 22 residues in length, respectively, and each is cross-linked by two disulfide bridges. Apamin binding sites have been identified in both the CNS and a number of peripheral sites, both neuronal and non-neuronal, but it is particularly toxic when administered by directly into the CNS, where it is a potent inhibitor of small conductance Ca^{2+}-activated potassium

Figure 6 Organization of the tetrameric voltage-gated K^+ channel: (a) X-ray structure, extracellular domain to top; (b) side view of two lateral subunits; (c) view through pore from extracellular side. Red spheres are K^+ ions. From Swartz KJ (2007) Tarantula toxins interacting with voltage sensors in potassium channels. *Toxicon* 49(2): 213–230.

channels. MCDP blocks delayed noninactivating outward rectifier potassium channels in the CNS to cause arousal and epileptiform discharges.

The second group of toxins targeting potassium channels are members of the charybtoxin group. All toxins in this group are isolated from the venoms of scorpions. They are small homologous polypeptides, comprising 35–40 residues cross-linked by three disulfide bridges. The toxins vary greatly in their selectivity for the different types of potassium ion channel. Charybtoxin (isolated from the venom of *Leirus quinqestriatus*) is not particularly selective, blocking both $K_v1.3$ maxi-potassium channels and small conductance Ca^{2+}-activated potassium channels. Iberiotoxin (isolated from the venom of *Buthus tamulus*) appears to be highly specific for maxi-potassium channels. The ubiquitous distribution of potassium ion channels means that most of the charybtoxin group of toxins have high-affinity binding sites similarly widely spread throughout the body of both vertebrates and invertebrates. Neural targets are most widely distributed within the CNS, and as a result the toxins tend to be most toxic when administered directly into the CNS. Peripherally, the toxins tend to cause an instability of both the heart rate and blood pressure and to cause an increase in both somatic and autonomic activity – signs and symptoms generally ascribed to enhanced transmitter release from all accessible nerve terminals. Myogenic activity of smooth muscle is common. There is some evidence that at motor nerve terminals maxi-potassium channels co-localize with voltage-gated calcium channels and thus play a role in the regulation of both spontaneous and evoked transmitter release. The scorpion toxins are generally considered to block the potassium ion pore, but there is little detailed understanding of their molecular targets.

The third group of toxins targeting potassium ion channels are the dendrotoxins isolated from the venoms of three species of African mamba (*Dendroaspis augusticeps, D. viridis, and D. polylepis*). The toxins are small basic polypeptides of 57–60 residues cross-linked by three disulfide bridges. The dendrotoxins were first studied as a result of their ability to cause a facilitation of transmitter release and repetitive firing at the vertebrate NMJ. The toxins block voltage-gated potassium channels of types $K_v1.2$, $K_v1.1$, and $K_v1.6$. Because these channel types are widespread throughout the nervous system, it is not surprising that, like other toxin types blocking potassium channels, the dendrotoxins are more toxic following injection into the CNS than following intraperitoneal or intravenous injection. Several natural variants of the dendrotoxins have been identified and it is presumed that individual potassium channels exhibit different susceptibilities to the respective variants.

The fourth group of toxins comprise a distinct group of small (35–37 residues) basic polypeptides isolated from the venom of sea anemones and a group of dendrotoxin-like toxins of 58–59 residues. The precise details of binding of these toxin groups have not been fully characterized.

Presynaptically Active Neurotoxins

Snake venoms are rich sources of Ca^{2+}-dependent phospholipases A_2 (PLA_2). Although the primary role of these enzymes is probably digestive, many of the enzymes are potent, presynaptically active neurotoxins. Snakes of the family Elapidae and their close relatives the sea snakes produce enzymes homologous with pancreatic phospholipases; the viperid and crotalid snakes produce enzymes that are homologous with intracellular PLA_2. These two groups of enzyme are classified as Class 1 and Class 2 enzymes, respectively. A number of viperid snakes also produce a toxic PLA_2homolog in which the Ca^{2+}-binding Asp-49 has been substituted for a Lys residue, resulting in a reduction of hydrolytic activity. The snake venom PLA_2 toxins are polypeptides of between 115 and 125 residues. Other species producing toxic phopholipases include bees and the lizards *Heloderma suspectum* and *H. horridum,* but the enzymes are glycoproteins with little similarity with those of snake venoms, and conopidene, a dimer of two small polypeptides of 72 and 42 residues, respectively, linked by a single disulfide bond (recently isolated from the venom of *Conus magus*) appears to be a ligand for L-type calcium channels. Class 1 and Class 2 toxins may be single-chain polypeptides (e.g., notexin from the venom of the Australian tiger snakes, *Notechis* sp.), heterodimers with no covalent linkage between the two chains (e.g., crotoxin from the venom of the South American rattlesnake, *Crotalus durissus terrificus*), heterodimers of covalently bound subunits (e.g., β-bungarotoxin from the venom of kraits, *Bungarus* sp., of Southeast Asia), or multimers of up to five subunits (e.g., textilotoxin from the venom of *Pseudonaja textiles*, the Eastern brown snake).

Although the neurotoxic PLA_2 are very selective for motor nerve terminals of vertebrates, they do not have a specific identifiable receptor. Rather, they appear to bind one or more integral membrane lipids or glycoproteins. The hydrolysis of membrane phospholipids is their primary mode of action. This results in a complex sequence of events including a short-lived reduction in spontaneous and evoked reduction in transmitter release, followed by a transient recovery

before a progressive and irreversible complete failure of neuromuscular transmission. At the point of failure, neither axonal conduction nor postsynaptic function is impaired.

There is no general agreement on the biological basis of the resulting neuromuscular paralysis. However, there is agreement that the hydrolytic activity of the toxins is important and that the products, free fatty acids and lysophophatides, play a role in the expression of toxicity. One view is that the hydrolytic activity of the toxins causes a depolarization of the nerve terminal, a loss of ion homeostasis, a loss of mitochondrial metabolic capacity, the depletion of synaptic vesicles, and the degeneration of the nerve terminal (Figure 7). Another is that the depolarization is associated with the internalization of the toxins, the partial hydrolysis of internal membranes, and a failure of synaptic vesicle recycling without degeneration of the nerve terminal.

There is physiological and morphological evidence for both points of view. It was suggested that the two points of view can be resolved if it is imagined that under circumstances in which the neurotoxic potential of the toxin was high (e.g., as a result of the inherent activity of the enzyme, its concentration, the choice of tissue, and the technical aspects of the experiment), neurodegeneration is most likely outcome, and under circumstances in which the neurotoxic potential was lower, the outcome is less severe. The highly selective susceptibility of the motor nerve

Figure 7 Effect of neurotoxic phospholipases on mammalian neuromuscular junctions: (a) control; (b) exposure to phospholipases, causing an initial depletion of synaptic vesicles; (c) the subsequent degeneration of the terminal. In (a), the nerve terminals sit in a deeply folded depression on the muscle fiber. The terminals are filled with mitochondria (M) and synaptic vesicles (V).

terminal is unexplained. Many of the neurotoxic PLA_2 are also myotoxic and thus nerve terminal and muscle pathology may coexist (see the section titled 'Myotoxic activity').

The black widow spiders, *Lactrodectus* sp., produce presynaptically active toxins typified by α-latrotoxin. This is a single-chain, mildly acidic polypeptide of 1401 residues. α-Latrotoxin causes a massive increase in the spontaneous release of transmitter from all tested peripheral and central synapses, causing a well-characterized syndrome that includes acute pain, fasciculation and fibrillation, fluctuating blood pressure and heart rate, and anxiety. The mechanism of action of the toxin is not well understood. The enhanced release of transmitter is partially Ca^{2+}-dependent, mediated by membrane-bound neurexin 1a, but can occur in the absence of external calcium when the activity is mediated by synaptophilin. Depolarization and a rise in internal calcium are also involved. The depletion of synaptic vesicles is the end result of severe latrodectism. The insect-specific neurotoxin α-latroinsectotoxin is homologous with the mammalian-specific α-latrotoxin, but its membrane-bound receptors have not been identified.

The clostridial toxins tetanospasmin and botulinum toxins are extremely important, presynaptically active neurotoxins targeting major soluble *N*-ethylmaleimide-sensitive factor attached protein receptor (SNARE) proteins syntaxin, synaptosomal-associated protein of 25 kDa (SNAP-25), and synaptotagmin.

Postsynaptically Active Toxins

The ACh receptors involved in neuromuscular transmission at the mammalian NMJ are located at the top of the synaptic folds of the muscle-fiber plasma membrane. The receptor is a heteropentameter with a stoichiometry of α2, β1, δ1, and ε1. The ε subunit is developmentally regulated, replacing the immature γ subunit during NMJ formation. The five subunits are arranged to form a central pore in the circular sequence α, β, α, ε, and δ. There are two binding sites for ACh, one at the δ–α interface and one at the α–ε interface. The binding of ACh results in a conformational change in the receptor and the opening of the ion channel. The channel is not particularly selective, and there is an increase in conductance for sodium, potassium, and calcium ions.

Postsynaptically active neurotoxins (conventionally referred to as α-neurotoxins) are elaborated in the venom glands of elapid snakes, their close relatives the sea snakes, and the fish-eating cone snails. The toxins are used by both groups of animals to immobilize their prey prior to ingestion. It is another interesting example of convergent evolution in the sense that completely different groups of animals have evolved structurally distinct polypeptides to target very specifically the postjunctional ACh receptor.

The α-neurotoxins of the elapid and sea snakes are single-chain polypetides of either 60–62 residues (the short neurotoxins) or 66–74 residues (the long neurotoxins), cross-linked by four or five disulfide bridges The most widely used α-neurotoxin is α-bungarotoxin, isolated from the venom of the krait *Bungarus multicinctus*. The toxin is a single chain of 74 residues folded into three major loops cross-linked by five disulfide bridges. Its very high affinity for ACh receptors (K_d 10^{-12}–10^{-10} M) allows it to be used very extensively in neurobiology. The precise details of binding between the ACh receptor and the α-toxins are not known, but it is clear that the toxins engage in multipoint interactions. The α-neurotoxins of cone snails are typically 13–15 residues in length with two disulfide bridges.

All the α-neurotoxins toxins bind selectively to the postjunctional ACh receptors at the vertebrate NMJ. It is often stated that the snake toxins bind preferentially to the δ–α binding site and the conotoxins bind to the α–ε site, but this is misleading because the precise affinity for the two binding sites largely depends on the primary sequences of the respective α, δ, and ε subunits. For example, sequence changes around the binding site on the α subunit are the reason for the remarkable resistance of the mongoose to the venom of the cobra and probably underlie many other apparently anomalous data on interspecies variation in sensitivity to α-neurotoxins. Toxins that target directly other sites on the ACh receptor are rather uncommon, but they are well established. A toxin isolated from the viper *Tropidolaemus wagleri* binds selectively to the ε subunit and can cause a potentially fatal failure of neuromuscular transmission; a toxin from the cone snail *Conus obscurus* specifically inhibits the immature ACh receptor. Natural toxins that target ACh receptor populations in the CNS and muscarinic ACh receptors are not considered here.

Myotoxic Activity

Most of the neurotoxic phospholipases A_2 are also myotoxic. Details of the myotoxic process have been studied only for notexin, a neurotoxic phospholipase isolated from the venom of the Australian tiger snake, *Notechis scutatus*. The toxins bind to and hydrolyze the sarcolemma. The hydrolysis of the membrane leads to the breakdown of the internal structure of the muscle fiber (Figure 8). The postsynaptic membrane (including its integral ACh receptors) appears to be relatively resistant to the process of degeneration, even when both muscle fiber and nerve terminal have been destroyed. The basal lamina of the muscle fiber,

Figure 8 Muscle damage caused by myotoxic phospholipases from snake venoms: (a) control muscle; (b) 24-h after exposure to the toxin notexin; (c) scanning electron micrographs of single muscle fibers, showing hypercontraction and membrane lesions in the damaged fibers. In (b), note the enlarged pale muscle fibers and the survival of the intrafusal fibers of the muscle spindle.

the satellite cells, and the microcirculation are preserved in muscle fibers damaged by these toxins, and as a result regeneration begins within 3 days. The myotoxic activity does not extend to smooth muscle, but cardiac muscle may be susceptible.

The Anatoxins

The anatoxins are toxic constituents of blue-green algae produced by *Anabaena flos-aquae* and a number of other freshwater species of cyanobacteria. The toxins are water-soluble alkaloids that have been responsible for a number of incidents of human poisoning, some of which have been fatal. Anatoxin a and homoanatoxin are powerful agonists of the ACh receptor, causing prolonged excitation at the NMJ. Anatoxin a (s) is a natural organophosphate that causes a prolonged inhibition of acetylcholinesterase. The anatoxins may be expressed in the absence or presence of the microcystins. Anatoxin-producing cyanobacteria have been identified in freshwater lakes and reservoirs in the United Kingdom, Japan, and North America.

Miscellaneous

A number of toxins commonly identified as neurotoxins cause neurotoxic signs as an indirect consequence of a more general pharmacological effect. For example, the pore-forming toxins such as equinotoxins, produced by a large number of sea anemones of the genus *Actinaria* and pardaxin from the skin secretion of the fish *Pardachirus marmoratus* are primarily cytotoxins, causing *inter alia* an increase in exocytosis from a number of synapses and palytoxin that was first isolated from soft anthozoans *Palythoa*. The toxin converts Na^+/K^+ ATPase from a selective Na^+/K^+ exchanger into a nonselective open cation pore. It, too, causes an enhanced exocytosis.

Summary

This article has clearly been limited, but natural neurotoxins that have evolved in a very large number of species are discussed. Most have arisen in the predatory animals that use venoms as tools to subdue prey and to defend themselves against predators.

The polypeptide toxins are very common, and many animals use a battery of such toxins as part of their armory; for example, the fish-eating cone snails include toxins that bind to the ACh receptor and block voltage-gated Na^+ and Ca^{2+} channels, along with numerous other constituents. Often the natural toxins are very selective in terms of their molecular targets, and this allows the toxins to be used as biological tools in the study of synaptic activity and receptor and ion channel pharmacology. There is also growing interest, as well, in the use of these highly selective ligands as potential new therapeutic agents.

Neuromuscular Junction (NMJ): Acetylcholinesterases

R L Rotundo, University of Miami Miller School of Medicine, Miami, FL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Acetylcholinesterase (AChE) was first described by Sir Henry Dale in 1914 as an "esteratic activity" present in mammalian tissues that could hydrolyze certain esters of choline. He later went on to share the Nobel Prize in Physiology and Medicine in 1936 with Otto Loewi for their discovery of acetylcholine, the first neurotransmitter, and for their work demonstrating chemical neurotransmission at synapses. Thus began the study of AChE, the first identified synaptic component, almost 100 years ago. Today, this enzyme is still being studied as a marker for cholinergic synapses in the central nervous system (CNS) and peripheral nervous system, some of which degenerate in certain diseases such as Alzheimer's and some forms of myasthenias; as a target for therapeutic drugs in humans and animals; as part of the mechanism of action for several important pesticides used worldwide; and unfortunately as the major target for many highly toxic nerve gases. Although this enzyme has been well studied for many years, only within the past 25 has the biochemistry, cell, and molecular biology of AChE been worked out in detail. Modern methods of visualizing AChE at synapses, such as the use of fluorescently tagged toxin molecules that bind specifically to the enzyme, are used to observe the presence of the molecules at the neuromuscular synapse, where they co-localize with those of the nicotinic acetylcholine receptor (Figure 1). This article focuses specifically on the biogenesis and localization of AChE at the neuromuscular synapse.

The major if not unique function of AChE, in fact the only indisputable function, is to terminate neurotransmission at cholinergic synapses in the CNS and peripheral nervous system. This function is accomplished through the hydrolysis of acetylcholine into choline and acetic acid. Once hydrolyzed, the products are free to diffuse away from the synapse or are taken up by the presynaptic terminals. AChE is essential for normal function of the nervous system, and the irreversible inhibition of its activity by specific organophosphate compounds such as nerve gases and certain pesticides are often fatal. A transgenic mouse has been developed that is AChE null and survives weakly in captivity, most likely because the phenotype has been rescued by another enzyme called butyrylcholinesterase. Inhibition of butyrylcholinesterase, which normally has no effect on the organism, results in rapid death of the AChE-null mice. Otherwise, the mice appear morphologically and physiologically normal.

AChE was also the first synaptic component to be studied at the structural level; it was ultimately crystallized in the laboratory of Joel Sussman and Israel Silman. Hence, we probably know more about the details of this molecule than any other at the synapse. This has greatly facilitated our understanding of the mechanisms of catalysis as well as the mechanisms of localization. However, one surprise was that the catalytic site of the enzyme was not near the surface, as was widely believed because of its very high turnover number, but rather deeply embedded within the center molecule and accessible only by diffusion through a long narrow space called the gorge. It is still not clear how the enzymatic reaction products leave the active site of the enzyme while new substrate molecules enter. One working hypothesis is that there is in fact a back door through which choline and acetate can diffuse out while the new substrate molecules enter through the front door near the peripheral anionic site.

AChE Detection and Assay

With one of the highest turnover numbers of any enzyme known, AChE is one of the easiest and most sensitive to measure. Many different assays based on catalytic activity (based on the hydrolysis of acetylcholine to choline and acetic acid) have been developed over the years, with almost as many detection methods. The products of acetylcholine hydrolysis are easily measured; acetic acid reacts with bicarbonate to produce CO_2, whose rate of production can be quantified, and the acid can also be measured by acid–base titration, potentiometrically, and colorimetrically. Choline production can also be assayed, and radioisotopically tagged versions of the substrate can be measured quantitatively. Chemically modified substrates, such as acetylthiocholine, can be used as well because they can be measured colorimetrically. Finally, radioactive and fluorescently tagged AChE ligands, such as many organophosphate compounds and toxins, have been used to visualize the enzyme *in situ* at the light- and electron-microscopic levels. Thus, AChE can be detected, visualized, and quantified at the biochemical, cellular, tissue, and organismic levels with ease, making it one of the best-studied enzymes and an important tool for biologists in many disciplines.

Structure of AChE

In all vertebrate species, AChE is encoded by a single gene that gives rise to multiple forms of the enzyme in a cell type-specific manner (Figure 2). Depending on the species, this gene can give rise to either one or two alternatively spliced variants and, in a least one species, to a third form referred to as the readthrough form. Although more than 90% of the amino acid sequence is shared by all AChE forms in each species, the two major alternative splicing variants encode different C-termini. The first is capable of assembling with one of two noncatalytic subunits that specify cellular location, the variant expressed in the skeletal muscles and neurons of higher vertebrates, and is called the t form of the AChE catalytic subunit ($AChE_t$) after its original association with a collagen-like tail. The other, called the h form for hydrophobic ($AChE_h$), signals the addition of a glycophosphoinositol (GPI) lipid membrane anchor. This latter form is expressed only in cells of the hematopoietic lineages, red and white blood cells.

The overall structure of AChE is virtually identical in all species examined. The catalytic monomer consists of a single polypeptide chain of approximately 600 amino acids in most species and contains three to four asparagine-linked oligosaccharide side chains that are processed differently depending on the cell type in which they are expressed. However, all contain the core high mannose residues as well as *N*-acetylglucosamine and *N*-acetylglactosamine residues. Variable residues include the presence of and extent of a terminal sialic acid addition as well as the presence of as yet incompletely characterized sugar residues. Thus, AChE is approximately 15% carbohydrate by weight. No other posttranslational modifications have been described other than the addition of the GPI anchors, except for possible palmitoylation in one instance and the addition of HNK epitopes in another.

Figure 1 Comparison of the distribution of acetylcholine receptors (AChRs) and acetylcholinesterase (AChE): (a) distribution of the nicotinic AChRs (labeled with oregon green conjugated α-bungarotoxin); (b) distribution of AChE at the mouse neuromuscular junction (labeled with Rhodamine-fasciculin 2). Notice the near perfect alignment of the two molecules at the synapse involved in initiating and terminating neurotransmission.

AChE Oligomeric Forms

The different AChE forms arising from these gene products are illustrated in Figure 2. The molecular mass of this protein is approximately 75 kDa in most species; however, in birds it is closer to 100–110 kDa for each catalytic subunit. The soluble globular $AChE_t$ subunits can associate to form homomeric disulfide-bonded dimers and tetramers. These tetramers, in turn, can associate with a 154-amino-acid

Figure 2 Structure of the acetylcholinesterase (AChE) oligomeric forms: (a) globular forms; (b) membrane-bound forms; (c) extracellular matrix (ECM)-associated form. The AChE forms expressed in nerves and muscle can assemble into several different oligomeric forms depending on which alternative splicing variants or which noncatalytic subunits are expressed by the cells. These forms include soluble globular forms in (a), referred to as the G forms, and the membrane-bound dimers and tetramers (b), the former being a glycolipid-anchored molecule encoded by an alternative spliced mRNA expressed in many species and the tetramer that is attached to a 154-amino-acid transmembrane polypeptide chain. The complex hetero-oligomer associated with the ECM forming the synaptic basal lamina at the neuromuscular junction (c) is the collagen-tailed form ColQ-AChE, which consists of three tetramers covalently attached to a three-stranded collagen-like tail.

transmembrane peptide called the p peptide or proline-rich membrane anchor (PRiMA) that anchors it in the membranes of neurons and maybe some types of muscle. Alternatively, the tetramers can associate with the approximately 150 kDa three-stranded collagen-like tail (each of three strands approximately 500 amino acids long), called ColQ, which attaches it to the synaptic basal lamina of skeletal muscle. This appears to be the unique form associated with the neuromuscular junction.

The basic functional unit of AChE is the catalytically active monomer, an exportable glycoprotein that acquires its activity shortly after synthesis and rapidly assembles with another monomer to form the dimeric enzyme. This applies to both the $AChE_t$ and $AChE_h$ types of subunits. The $AChE_r$, what little there is, always appears to be a monomer. These AChE dimers can form covalent interchain disulfide bonds via a C-terminal cystein. For the $AChE_t$ molecules, the dimers can, in turn, associate with other dimers to form the tetrameric AChE molecules. Both the dimers and tetramers can be secreted unmodified or further assembled with one of the noncatalytic subunits described next. For the $AChE_h$ the monomers can form disulfide-bonded dimers, both of which are glycolipid-anchored, but cannot further associate with other subunits. These, as already mentioned, are destined for the cell surface of erythrocytes and certain types of lymphocytes, where their function is yet to be determined.

Noncatalytic AChE Subunits

Two types of noncatalytic AChE subunits have been described. The first, discovered in the late 1960s in Jean Massoulié's lab in Paris, is ColQ. This three-stranded molecule, a trimer consisting of three identical 50 kDa polypeptide chains, can attach through a specific region near the N-terminus to the C-terminus of the AChE catalytic subunit (see Figure 2(c)). This subunit is encoded by a separate gene, in fact on a separate chromosome, and exists in a least two alternative splicing variants expressed in skeletal muscle. These two variants differ in their N-terminus primarily in the region encoding the leader peptide. The function of this variation is not known.

The primary and secondary structure of ColQ is well established. This almost 50 kDa subunit consists of approximately 460 amino acids with no known posttranslational modifications, divided into roughly three regions. The first of these is an N-terminus consisting of the first 95 amino acids including the cleavable leader peptide and containing the proline-rich attachment domain or PRAD, the 17-amino-acid proline-rich sequence that interacts with the α-helix-rich C-terminal domain of AChE to form the tetramers. The second region comprises a glycine- and proline-rich stretch approximately 200 amino acids long containing hydroxyproline and that is virtually indistinguishable from a regular collagen molecule. This domain forms a triple helical structure after synthesis and assembly and contains two binding sites for interactions with heparin. The third main region is the C-terminal 160 amino acids and consists of a stretch of hydrophilic amino acids followed by a cystein-rich region with ten cystein residues that most likely forms a tight globular structure. This region is essential for attachment to the extracellular matrix of the synaptic basal lamina, and some single amino acid mutations in this region are capable of preventing the attachment of AChE to the neuromuscular junction.

The second type of noncatalytic subunit is the 154-amino-acid transmembrane polypeptide PRiMA. This relatively small molecule has a roughly 24-amino-acid leader sequence, a 67-amino-acid extracellular domain followed by a 22-residue transmembrane segment, and a 41-amino-acid intracellular domain. This polypeptide is also encoded by a separate gene and exists in at least two distinct splicing variants. Again, the functional significance of these variants has not yet been determined. Like ColQ, this subunit also has a PRAD domain at the N-terminus that interacts with the AChE catalytic subunits to form tetramers. These tetramers are the major form expressed in the nervous system of higher vertebrates, where they localize the enzyme to specialized regions of the neuronal cell surface.

Biogenesis, Processing, and Assembly of AChE

All AChE forms are glycoproteins destined for secretion or localization on the cell surface and, hence, are synthesized on the rough endoplasmic reticulum and co-translationally glycosylated. It appears that only asparagine-linked oligosaccharides are associated with the AChE catalytic subunit, whereas no posttranslational modifications has been found on either of the noncatalytic subunits which are also synthesized on the rough endoplasmic reticulum. The catalytic subunit appears to be synthesized as an initially catalytically inactive molecule which then undergoes the necessary folding and processing to produce the catalytically active enzyme. The active molecules can then associate to form active dimers and tetramers that, in turn, transit the Golgi apparatus and undergo additional carbohydrate processing to yield the fully mature forms. These mature and immature molecules can be distinguished by their resistance to specific endoglycosidases as well as structural stability. The inactive

AChE forms, consisting mostly of monomers and some dimers, are rapidly degraded by the endoplasmic reticulum-associated protein degradation system.

The intracellular assembly sites of the different AChE oligomeric forms are still incompletely understood. The dimeric and tetrameric forms are clearly assembled in the endoplasmic reticulum, as is the cleavage of the $AChE_h$ C-terminal amino acids and the addition of the glycolipid anchor. The addition of the transmembrane polypeptide anchor most likely occurs in the endoplasmic reticulum as well, although this has not yet been proven. Only one study has addressed the site of assembly of the ColQ AChE form, and it appears that assembly occurs in the Golgi apparatus approximately 90 min following synthesis of the globular forms. This is based on pulse–chase studies of catalytically active enzyme as well as the timing of the addition of the terminal carbohydrate residues which are known to occur in the Golgi apparatus. However, it appears that we cannot easily distinguish between an AChE tetramer and a tetramer associated with a single strand of the ColQ subunit. Thus, additional studies will need to be done to fully understand the assembly of the synaptic ColQ AChE form.

Skeletal muscle fibers are long multinucleated cells that can contain well over 1000 individual nuclei. Yet the motor nerve terminal contacts the muscle fiber on only a very small portion of the total surface membrane, usually less than 1% (Figure 3). Beneath this small region of contact a number of muscle cell nuclei accumulate, referred to as the subsynaptic or junctional nuclei, and their role appears to be to express many if not all of the genes encoding the proteins involved in forming the muscle's portion of the synapse. Thus, the genes encoding AChE, the acetylcholine receptor subunits, and at least several other synapse specific proteins have been shown to be selectively expressed by the subsynaptic nuclei. Moreover, once synthesized, these molecules appear to be co-packaged and co-transported to the plasma membrane, where they are jointly inserted into the synaptic domain. This highly localized expression of AChE ensures that the synapse has sufficient numbers of enzyme molecules to terminate neurotransmission.

Figure 3 Organization of the nerve terminal in relation to the muscle fiber. The acetylcholinesterase (AChE) forms expressed in nerves and muscle can be regulated at several different levels depending on where they are in the muscle fiber. Although the extrajunctional nuclei are distributed evenly throughout the length of the muscle fiber, a small number (usually 5–10) of specialized nuclei accumulated beneath the site of nerve muscle contact. The junctional nuclei express the genes encoding synaptic components. EJD, extrajunctional domain; JD, junctional domain.Adapted from Rotundo RL, Rossi SG, Kimbell LM, Ruiz C, and Marrero E (2005) Targeting acetylcholinesterase to the NMJ. *Chemico-Biological Interactions* 157–158(1): 15–21, with permission from Elsevier.

Mechanism of AChE Localization at the Neuromuscular Junction

We have only recently begun to understand the molecular mechanisms involved in localizing AChE at the neuromuscular synapse. Depending on the species, a density of between approximately 500 and 2500 AChE catalytic subunits μm^{-2} are required to maintain normal transmission at the neuromuscular synapse. This includes an approximately fivefold safety factor because cholinergic transmission is not significantly impaired until approximately 80% of the AChE molecules at the synapse are inactivated. More than 25 years ago, ColQ AChE was shown to be highly concentrated at the neuromuscular junction, and its appearance was demonstrated to be under neural control. In addition, a strong basement membrane surrounds each muscle fiber, enveloping it like a cocoon, with a specialized region being interposed between the nerve terminal and the postsynaptic acetylcholine receptor-rich membrane. This specialized region is referred to as the synaptic basal lamina, and it contains many molecules unique to sites of nerve–muscle contact. The synaptic AChE was shown to be tightly associated with the synaptic basal lamina, where it could persist for weeks or months after denervation and could interact directly with several components of the synaptic basal lamina. The synaptic ColQ AChE form was shown to bind directly to several different extracellular matrix molecules *in vitro*, including fibronectin, chondroitin sulfate, and heparan sulfate proteoglycans, but it was not until direct binding of ColQ AChE to the synaptic basal lamina was demonstrated that the idea that a specific acceptor molecule was present at the synapse was entertained.

The molecule that ColQ AChE appeared to be binding to was subsequently identified as perlecan, a multifunctional heparan sulfate proteoglycans present in many tissues and highly concentrated at the neuromuscular junction. Direct binding of ColQ AChE was shown *in vitro* and *in vivo*, and both perlecan- and dystroglycan-null mice (dystroglycan is a transmembrane molecule involved in tethering perlecan to the

muscle cell surface) were shown to be devoid of synaptic AChE. Thus, a reasonable case can be made for perlecan being the major binding site for AChE at sites of nerve–muscle contact.

Putting together many of the studies described here, it now appears that local expression of the AChE gene, local translation of the mRNA, and local assembly and transport of the molecules to the cell surface underlie the specific accumulation of the enzyme at the neuromuscular synapse. This all occurs in what is referred to as the junctional domain (Figure 3). The role of perlecan, then, appears to be to retain the ColQ AChE on the synaptic basal lamina, thus preventing its diffusion into the circulation. However, what ultimately determines the numbers of AChE molecules present on the synaptic basal lamina at any one time remains to be determined. Also, how AChE is turned over at the synapse and the mechanisms that determine the density and distribution of AChE at the sites of nerve muscle contact remain to be understood.

Appearance of AChE during Development of Skeletal Muscle

The motor neurons form their initial contacts with the muscle fibers very early during embryonic development, shortly after they differentiate and grow out of the spinal chord into the muscle cells mass. In fact, the spinal chord motor neurons are the first neurons to differentiate in vertebrates, and the neuromuscular connections are the first functional synapses to form in the nervous system. Thus, all the molecules necessary for initiating and terminating neurotransmission must appear very early during development. And that is exactly what has been observed by many investigators. The nicotinic acetylcholine receptors begin to accumulate at sites of nerve–muscle contact within minutes after the first contact has formed, and the esterase molecules follow shortly behind.

However, how quickly the AChE molecules appear is not yet precisely known because of the large differences in the numbers of receptor versus esterase molecules that populate the neuromuscular synapse. The number of AChE molecules at the synapse is approximately 5–20% of the number of receptors, and thus it is more difficult to detect synaptic AChE during the earliest stages of development. Moreover, early studies on the developmental appearance of AChE relied entirely on the colorimetric histochemical localization techniques which require the reaction products to bind to molecules localized at the synapse themselves. It is quite likely that the immature synapse does not bind many of these reaction products, thus preventing the existing AChE molecules from being detected.

The current view on the appearance of AChE at the developing neuromuscular junction is that it appears some time after the initial appearance of the nicotinic acetylcholine receptors. How much time depends on the method of detection, but it can be between 8 and 48 h. This model holds that the nerve signals the muscle cell to start aggregating synaptic components at sites of nerve–muscle contact, producing surface clusters of these molecules, with components like the receptor moving in first. Subsequently, other components accumulate to stabilize the synapse, including the appearance of extracellular matrix molecules that, in turn, anchor the ColQ AChE to the synaptic basal lamina.

Regulation of AChE Expression in Muscle

It is essential that the correct number of AChE molecules be maintained at the neuromuscular synapse for synaptic transmission to occur. Too few enzyme molecules interposed between the nerve terminal and the postsynaptic membrane allow too many acetylcholine molecules to pass through and overstimulate the muscle, causing abnormal and prolonged contraction. Conversely, too many AChE molecules hydrolyze the acetylcholine before it can reach the postsynaptic membrane, thereby effectively preventing neurotransmission. In both cases, the result is muscle failure and death because the diaphragm muscle depends on rhythmic acetylcholine release to contract so that breathing to occur.

Regulation of AChE expression occurs at many levels. The regulation of AChE is very complex, occurring at the transcriptional, posttranscription, translational, and posttranslational levels. Even the assembly process itself is highly controlled. First, during muscle development the proliferating mononucleated myoblasts do not express AChE transcripts. It's not until after the proliferating cells have withdrawn from the cell cycle and undergone terminal division that the AChE genes are expressed. However, the newly expressed mRNAs must also be localized and regulated, and here several important RNA-binding proteins associate with the transcript to regulate its translation. Once translated, the newly synthesized polypeptides must undergo conformational maturation to acquire catalytic activity and associate with other catalytic as well as the noncatalytic subunits. Improperly folded and inactive enzyme molecules are rapidly degraded intracellularly, whereas the correctly assembled molecules transit the cell and are allowed to reach the cell surface.

In skeletal muscle, AChE is regulated by the activity state of the fiber, that is, the extent to which it is contracting and the membrane depolarized, as well as specific signals from the nerve. All these signals and events are integrated by the muscle fiber to ultimately control the rate of AChE production, determine which oligomeric forms are expresses, and determine how many reach the synapse to be integrated into the molecular signaling machinery necessary to elicit muscle contraction.

Consequences of AChE Inactivation in Muscle, Pesticides, Nerve Gases, Congenital Myasthenia, and Alzheimer's Disease

As discussed earlier, the function of AChE is to terminate neuromuscular transmission by rapidly hydrolyzing the acetylcholine released by at the motor nerve terminal. This hydrolysis of acetylcholine occurs extremely rapidly, with a half-life of approximately 1 ms, and is absolutely necessary for normal synaptic transmission. Imagine a hummingbird beating its wings at over 100 times s^{-1}; each cycle of muscle contraction and relaxation of the pectoral muscles must occur within less than 10 ms if the flight pattern is to be maintained. If the half-life of acetylcholine in the synaptic space is 1 ms, then it requires approximately 4 ms to reduce the local neurotransmitter concentration to less than 90% of its initial amount, allowing for a small safety margin. Although this may be an extreme example, there are many rapidly moving muscles in humans and other mammals, such as the extraoccular muscles of the eyes that need to move to rapidly in order to track moving objects or even limb-muscle contracting in response to a noxious stimulus.

The behavior of the acetylcholine molecules released by the motor nerve at the synapse and the effects of inhibiting AChE are depicted in Figure 4. These beautiful images are supercomputer simulations modeling the time course of the distribution of acetylcholine molecules once released from a point source at the presynaptic terminal. Figure 4(a) shows the time course of acetylcholine hydrolysis under normal conditions and following inactivation by an irreversible inhibitor, such as a nerve gas or organophosphate pesticide. The several-fold longer time course of acetylcholine receptor activation following AChE inhibition allows for continued membrane depolarization and a protracted time of muscle contraction. In fact, depending on the rate of nerve stimulation, this can be so severe that the muscles do not have time to relax, resulting in muscle paralysis. When this affects the muscles of the diaphragm, death can result within minutes.

Another consequence of the overactivation of the acetylcholine receptors at the neuromuscular synapse is the excessive influx of Ca^{2+} ions that can occur through both the nicotinic receptor itself and the voltage-dependent Ca^{2+} channels in the muscle membrane responsible for initiating muscle contraction. This excessive Ca^{2+} can activate specific proteases such as calpain that, in turn, can partially digest the muscle-specific proteins making up the contractile apparatus. Thus, excessive stimulation of muscle can result in severe muscle degeneration and a destruction of the synaptic region of the muscle from the inside.

Again, in most animals, the complete inactivation of AChE is invariably fatal. For this reason, many of the most successful and lethal pesticides and nerve gases are anticholinesterase compounds. Pesticides, such as malathion and parathion, are organophosphates structurally similar to nerve gases that have a greater specificity for insect AChE than for vertebrate AChE. However, their specificity is dose-dependent, and at high enough doses they can also irreversibly inhibit the vertebrate enzyme. In underdeveloped countries, for example, where the pesticides are not as carefully controlled and training in their use is minimal, tens of thousands of people die annually from exposure to pesticides. Some estimates range as high as in the low hundreds of thousands. Likewise, nerve gases pose a continuous problem in many parts of the world. Although many of the developed countries are destroying their stocks, many more countries are keeping large stockpiles as a deterrent to land invasions. Sadly, nerve agents are also serious potential threats from nefarious groups, as occurred in the 1995 Tokyo subway disaster in which thousands of people were seriously poisoned and almost a dozen killed when the nerve agent sarin was released by a fringe cult. Unfortunately, these compounds are all too easily made by someone who barely has taken a first-year college chemistry course.

Because of its essential role in neuromuscular transmission, disorders involving the loss of AChE are extremely rare. A congenital form of myasthenia with synaptic AChE deficiency was discovered by the neurologist Andrew Engel in which the patients exhibit normal expression of the AChE catalytic subunit but are either lacking or express mutated forms of the collagenic tail. The disorder is so devastating that only a few dozen cases have been described worldwide, and those that have survived it most likely have done so because of other compensatory changes, such as possibly the expression of high levels of butyrylcholinesterase. It is likely that the majority of individuals with this rare and devastating disorder are either still born or die shortly after birth due to respiratory failure.

Figure 4 Effects of inhibiting acetylcholinesterase (AChE) on the amplitude and time course of the synaptic currents: (a) measured experimental postsynaptic responses (M_{EPC}s), the number of open acetylcholine receptor (AChR) channels; (b) realistic low-magnification view of the model neuromuscular junction (NMJ) used in the simulation, with folded postsynaptic muscle membrane and synaptic vesicles aligned for release from the nerve; (c) higher-magnification visualization of the neurotransmission at the vertebrate NMJ (the rectangle outlined in (b)) using the Monte Carlo simulation in the MCell/DReAMM environment for spatially realistic micro-physiological simulations. The M_{EPC}s in (a) and results of the simulation (b–c) completely overlap, showing that AChE inhibition causes an increase in amplitude and a prolongation of the decay time course. In (c), each image shows an oblique view of the folded muscle membrane, and three synaptic vesicles are indicated by gray spheres (50 nm in diameter). The nerve terminal membrane is transparent for clarity, as are AChE active sites within the cleft space. Unbound muscle AChRs are visible as blue stippling on the membrane surface. AChRs with a single bound ACh are red. Double-bound AChRs in the closed ion-channel conformation are green, and those in the open conformation are yellow. A comparison of the right and left images illustrates the spatiotemporal effects of AChE inhibition: the additional and prolonged spread of diffusing ACh molecules released from the vesicles and the overlap of the resulting AChR activation during the current rising phase (top; at 50% of peak amplitude), peak amplitude (middle), and falling phase (bottom; at 50% of peak amplitude). All these increase the rise time, peak amplitude, and, most dramatically, the falling phase. Simulations and visualizations by Jacob Czech and Joel Stiles, Center for Quantitative Biological Simulation, Pittsburgh Supercomputing Center, Carnegie Mellon University. Courtesy of Joel R Stiles and Lili Anglister; adapted following Anglister L, Stiles JR, and Salpeter MM (1994) Acetylcholinesterase density and turnover number at frog neuromuscular junctions, with modeling of their role in synaptic function. *Neuron* 12: 783–794.

On a more positive note, most of the important current treatments for Alzheimer's disease are selective AChE inhibitors. Their actions are important in the CNS, however, in which degeneration of the major cholinergic inputs to centers involved in memory and learning occur. Here, the inhibition of AChE is beneficial insofar as it prolongs the actions of acetylcholine at certain CNS synapses and enhances the persistence of short-term memory. In the peripheral nervous system, AChE inhibitors such as neostigmine and pyridostigmine that do not cross the blood–brain barrier, and that hence have no CNS effects, are used for the treatment of myasthenia gravis, an autoimmune disorder affecting the numbers of acetylcholine receptors at the neuromuscular synapse.

Epilogue

AChE has been studied for almost 100 years, during which time it has served as a model molecule for understanding enzyme catalysis; cellular differentiation; nerve–target interactions; regulation of gene expression; and many other aspects of biochemistry, pharmacology, cell biology, physiology, and molecular biology. While we do know quite a bit about AChE at the neuromuscular synapse, much more remains to be learned regarding the regulation of this molecule in both the CNS and peripheral nervous system. Thus, there is still much more to be gleaned from investigations at the cellular, molecular, and organismic levels, and many more applications of this work for the solution of biomedical problems.

Neuromuscular Junction (NMJ): Activity-Dependent Muscle Fiber Modulation

T Lømo, University of Oslo, Oslo, Norway

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Motor neurons act as the 'final common path' for the entire central motor system. Only motor neurons can directly drive the skeletal muscles to produce movements, perform work, or stabilize joints. In higher vertebrates, the focus of this article, the peripheral motor system is organized into units, each motor unit consisting of a motor neuron and all of the muscle fibers that it exclusively innervates. Motor units display striking differences in the firing patterns of their motor neurons, the properties of their neuromuscular junctions (NMJs), and the contractile speed and resistance to fatigue of their muscle fibers, properties that are well matched to the different types of work that different types of motor units do.

The functional tasks of individual motor units vary throughout life – for example, with changes in body size, occupational workloads, amount and type of physical exercise, or as a consequence of aging, disease, or injury. To function efficiently under such changing conditions, the motor units must have the property of plasticity and must be capable of adaptation. Plasticity comes in two forms: one form is observed in the brain, when brief synaptic inputs lead to long-lasting changes in synaptic efficacy through processes that are important for learning and memory; the other form is observed when structures such as synapses or muscle cells respond to new conditions by adaptive changes, which last only as long as the conditions inducing the changes last. While plasticity is a striking property of NMJs and skeletal muscle cells, it is only of the adaptive kind. In this article, the properties of different types of motor units and the adaptations of their NMJs and muscle fibers to different patterns of activity are described mainly for mammals (e.g., the rat), together with some discussion of underlying mechanisms.

Motor Neurons Form Motor Units to Drive the Muscles

Motor neurons drive their muscle fibers by generating action potentials that are conducted as nerve impulses along their axons in the peripheral nerves to their terminals in the muscles, where the impulses are transmitted across NMJs to the muscle fibers. In mature mammals, only one NMJ is formed by one motor neuron on each muscle fiber. But each motor neuron has many terminal branches in the muscle and forms NMJs with tens or hundreds of muscle fibers, creating a motor unit. All of the muscle fibers in one motor unit have essentially the same properties. In rat limb muscles, the fibers express either type 1, 2A, 2X, or 2B myosin heavy chains (MyHCs), giving rise to correspondingly named fiber types which have properties that range from slow to fast, with respect to contractile speed, and from sensitive to resistant, with respect to fatigue. Reflecting such differences, motor units, including the motor neurons, are often called fast fatigable (FF), fast intermediate (FI), fast fatigue resistant (FR), or slow fatigue resistant (S). However, the concept of divisions into types of motor units often obscures the fact that many properties within one type can be quite graded and not well separated from those of another.

The Firing Patterns of Motor Neurons

The function of the NMJ of higher vertebrates is to transform every nerve impulse arriving at its presynaptic nerve terminals into a postsynaptic muscle impulse, which then travels to each end of the muscle fiber, eliciting intracellular calcium release and fiber contraction along the way. Consequently, it is possible to obtain an exact replica of the firing pattern of any motor neuron by implanting fine electrodes into a muscle and recording the action potentials from the muscle fibers that it innervates. Such single motor unit recordings have been made continuously over 24 h from soleus (SOL) and extensor digitorum longus (EDL) muscles of adult rats that move unrestrained in their cages.

Three distinct firing patterns are observed. In the SOL, which contains >95% slowly contracting, fatigue-resistant type 1 fibers, the amount of single motor unit impulse activity over 24 h is high, the trains of impulses are often very long, and the frequency of firing is relatively low (~20 Hz; Figure 1). In contrast, the EDL contains >95% rapidly contracting type II fibers, many of which are very sensitive to fatigue, although others are relatively resistant. In the EDL, two different firing patterns are revealed, each of which differs markedly from that in the SOL. One pattern, EDL-1, is characterized by relatively few impulses over 24 h and isolated episodes of either single impulses or brief, high-frequency bursts of impulses (Figures 1 and 2(a)). Typically, the first interpulse interval is particularly short (~5 ms; Figure 2(b)) so that each burst begins with an 'initial doublet'

Firing patterns	Median firing frequency (Hz)	Longest train duration (s)	Impulses per 24 h (#)	Time on per 24 h
	69–91	0.8–3.9	2600–11 200	0.5–3 min
	48–83	59–141	89 500–243 100	23–72 min
	18–21	290–548	309 500–495 800	5.3–8.4 h

Figure 1 Firing patterns of motor neurons innervating extensor digitorum longus (EDL) and soleus (SOL) muscles of adult rats. The numbers are based on continuous recordings over 24 h from single motor units during spontaneous motor behavior of unrestrained adult rats in large cages. They represent a range of median values from five EDL-1, five EDL-2, and six SOL motor units. Drawn patterns to the left are based on segments of recorded activity at the onset of a burst of EDL-1 and a train of EDL-2 or SOL unit activity, as indicated. Inset shows another burst of an EDL-1 unit, as recorded. Note initial doublet and short duration of the EDL-1 bursts. The trains of EDL-2 and SOL units continued beyond the segments shown here. Adapted from Hennig R and Lømo T (1985) Firing patterns of motor units in normal rats. *Nature* 314: 164–166.

Figure 2 Firing patterns of extensor digitorum longus (EDL) and soleus (Sol) motor neurons and functional consequences. The underlying data are the same as for **Figure 1**. (a) The most common firing event for EDL-1 units over 24 h is one impulse, the next common event is two impulses, then three, and so on. (b) The first interspike interval is the shortest in bursts of impulses in EDL-1 units. (c) For EDL-1 units, interspike intervals stay the same, whereas for EDL-2 units (not shown) and Sol units, they become shorter, with increased number of impulses per train of impulses. (d) Muscle force output of EDL increases as the number of stimuli delivered to EDL axons increases from one to six. This increase in force output is further speeded up and augmented by making the first pulse interval short (~5 ms, initial doublet). (a–d) From Hennig R and Lømo T (1985) Firing patterns of motor units in normal rats. *Nature* 314: 164–166; and Hennig R and Lømo T (1987) Gradation of force output in normal fast and slow muscles of the rat. *Acta Physiologica Scandinavica* 130: 133–142, with permission from Blackwell Publishing.

(see later). Most likely, this pattern reflects the activity of motor neurons innervating fast glycolytic type 2B fibers to form fast-fatigable motor units. The other pattern, EDL-2, also consists of relatively high-frequency impulses, but the amount of activity over 24 h is greater, the trains last longer, and the median frequency is lower (Figure 1). Most likely, this pattern reflects the activity of motor neurons innervating type 2A fibers to form fast fatigue-resistant motor units. However, the two categories, EDL-1 and EDL-2, might also include intermediate units containing type 2X fibers.

Summation of all the times that an individual unit is active over 24 h reveals that SOL units are on duty up to 8 h day^{-1}, whereas the corresponding duty time for EDL-1 units is only about 1 min (Figure 1). The most common episode of EDL-1 activity is a single isolated impulse; two impulses are less common, three impulses still less common, and so on (Figure 2(a)). Together, isolated episodes of one to five impulses of EDL-1 activity make up ~60% of all episodes of EDL-1 activity over 24 h (Figure 2(a)). Moreover, only EDL-1 units display initial doublets. EDL-2 and SOL units frequently generate single impulses or brief impulse trains as well as long episodes of tonic activity. Thus, in contrast to EDL-1 units, EDL-2 and SOL units fire both phasically and tonically, but given their long durations, the periods of tonic activity are responsible for more than 90% of the total amount of activity over 24 h. During tonic activity at around 20 Hz, SOL units generate more than 80% of maximal tetanic tension owing to their long contraction times and effective twitch summation at this frequency. Differences in firing pattern, such as those just described, pose different demands on motor units to which both their NMJs and muscle fibers must adapt.

Plateau Potentials Generate Tonic Firing

Tonic firing in motor neurons does not require continuous excitatory synaptic drive. A brief excitatory synaptic input can start it and, at different times afterwards, a brief inhibitory synaptic input can stop it. The excitatory input activates a self-sustained persistent inward current carried mainly by calcium ions. This generates a plateau potential, which, in turn, elicits the tonic firing. In rat SOL motor neurons, such firing occurs at a remarkably stable rate of about 20 Hz. The generation of self-sustained plateau potentials in motor neurons depends on and is controlled by monoaminergic inputs descending from the brain stem, particularly serotonergic fibers acting on serotonin (5-hydroxytryptamine; $5HT_{2A}$) receptors ($5HT_{2A}Rs$) on cell bodies and dendrites of the motor neurons. Rat SOL lumbar motor neurons begin to display detectable $5HT_{2A}Rs$ and to fire tonically in the second week after birth. Thereafter, both the intensity of $5HT_{2A}R$ labeling and the amount of tonic firing increase gradually as the rat's legs support an increasing body weight. During this period, a substantial number of the SOL muscle fibers are transformed from a phenotype of fast type 2 fibers soon after birth to that of slow type 1 fibers in the adult, reflecting adaptation to the postnatal increase in weight bearing and accompanying postural tonic activity (see later).

There are apparent advantages in controlling tonic firing in this way. With a mechanism for turning on or off self-sustained tonic firing, more costly sustained synaptic drives can be dispensed with. The mechanism favors steady and predictable firing suited for supporting the relatively constant load of the body weight. As demonstrated experimentally, it also allows for cycling of activity between motor units from one tonic period to another, in contrast to the fixed order of recruitment and derecruitment of motor units occurring during voluntary contractions against increasing or decreasing loads, also known as the 'size principle.' In addition, we have unpublished evidence that the tonic activity described here can be used independently of motor control to produce heat to fine-tune body temperature around its set point when ambient temperature varies.

Motor Neuron Firing Regulates Muscle Force Output

Regulation of muscle force output by motor neurons is commonly presented as relying simply on motor unit recruitment and firing rate modulation. However, given the actual firing patterns during natural spontaneous motor behavior as described for the rat, this classic view needs to be expanded. Two results stand out: the predominance of single episodes of one or a few impulses and, for EDL-1 units, the constancy of interpulse intervals regardless of the number of impulses in the trains (Figure 2(c)). Consequently, the force output of EDL-1 units is regulated not by modulating the firing rate but by varying the number of impulses in the burst and hence the amount of twitch summation obtained (Figure 2(d)). Thus, it is the duration and not the intensity of the excitatory synaptic drive on the motor neuron that appears to be regulated. Similar regulation by impulse number has been described for ballistic movements in humans. A further consequence of the firing pattern of EDL-1 units is that the presence of initial doublets speeds up the contraction by exploiting a catchlike property in the muscle fibers whereby force output develops at maximum speed and then remains at a higher level than in the absence of such doublets (Figure 2(d)).

Comparable regulation by impulse number also occurs for EDL-2 and SOL units during brief episodes of activity, but for these units the pulse interval decreases with increasing number of impulses per train (Figure 2(c)). Presumably, this gradual decrease reflects an increasing excitatory synaptic drive on the motor neurons. Accordingly, force regulation for such units occurs by a combination of variable impulse number (for short episodes of activity) and variable excitatory synaptic drive on the motor neurons. In addition, of course, there is regulation by motor unit recruitment for all unit types.

Differences in motor neuron firing pattern thus play an important role in the execution of diverse motor tasks. This conclusion is reinforced by experiments showing that muscle fibers and NMJs continually adapt their properties to the pattern of activity.

The Neuromuscular Junction

To transform every nerve impulse into a muscle impulse, transmission across vertebrate NMJs must be highly efficient and reliable. Many specializations at the NMJ contribute to this efficiency. For example, each nerve impulse releases tens of quanta of the transmitter acetylcholine (ACh); these act on a high number and density of ACh receptors (AChRs) in the postsynaptic membrane of the muscle fiber. The postsynaptic membrane is generally highly infolded, which increases the efficiency of transmission. In the depths of these folds, voltage-sensitive sodium channels are present at high density, which further facilitates the generation of muscle impulses. There is no afterhyperpolarization (AHP) following each muscle impulse and no persistence of released ACh because of highly active ACh esterase (AChE) in the synaptic cleft. As a result, the membrane potential returns quickly to its resting level after an impulse and is ready to effectively transmit the next impulse even at the high frequencies that characterize FF motor units.

Motor neurons induce formation of the NMJs during development by releasing neural agrin and acetylcholine from their nerve terminals in the muscles. Neural agrin causes the aggregation of AChRs and other synapse-specific proteins underneath the terminals and ensures the development and maintenance of the NMJ by rendering the synthesis and organization of synapse-specific proteins resistant to the inhibitory effects of nerve-evoked muscle impulse activity. Such evoked activity then regulates the size and other properties of the developing NMJ, while blocking the expression of AChRs along the rest of the muscle fiber and preventing synapse formation there.

In the adult, numerous features affect the efficacy of transmission at NMJs, among them the number and lifetime of AChRs in the postsynaptic membrane. After inactivation of NMJs by denervation or chronic applications of tetrodotoxin (TTX) or botulinum toxin, the postjunctional membrane gradually loses more and more AChRs, while those that remain, or are subsequently inserted, turn over much more rapidly than before. Direct stimulation of the denervated muscle prevents these effects, but only if the stimulation starts within the first day after denervation. In that case, the number and stability of postjunctional AChRs stay normal for at least 2 months. If the stimulation starts progressively later, up to 2 weeks after denervation, its effectiveness gradually declines so that muscles stimulated from the end of that time go on to lose as many receptors as unstimulated muscles do. These results suggest that muscle impulse activity is necessary to preserve a nerve-derived 'trace' at the denervated NMJ that influences the number and lifetime of AChRs in the postsynaptic membrane. This trace may be neural agrin itself or any of its downstream postsynaptic effects, since neural agrin both clusters AChRs and regulates their lifetime in the membrane.

NMJs Differ in Structure and Function

NMJs on fast and slow muscle fibers, such as those on the fast EDL and slow SOL of the rat, differ both in structure and function. Presynaptically, fast nerve endings and slow nerve endings arborize differently, and fast nerve endings contain more terminal swellings (varicosities). The fast endings release more acetylcholine at the onset of impulse trains, but since they have smaller vesicle pools, they fatigue more easily as release runs down faster during continued stimulation. Postsynaptically, relative to slow NMJs, fast NMJs have denser, deeper, and more branched infoldings. They also respond to given doses of ACh with larger postsynaptic currents. In their synaptic clefts, fast NMJs contain predominantly the large A12 form of AChE, whereas slow NMJs contain more of the smaller A8 and A4 forms. The AChE molecules are anchored to the synaptic basal lamina by one of two types of collagen-tailed proteins encoded by different transcripts from the same *ColQ* gene in fast and slow muscle fibers. Two distinct promoters for the *ColQ* gene have been identified; these are differentially expressed in fast and slow muscle fibers. The promoter present in slow fibers is activated by the transcription factor called nuclear factor of activated T cells (NFAT) at a 'slow upstream regulatory element' (SURE), whereas the promoter expressed in fast fibers contains a 'fast intronic

regulatory element' (FIRE). Assuming that different compositions of AChE isoforms reflect differences in function, such findings suggest that the fast and slow impulse patterns transmitted by fast and slow NMJs pose different demands on AChE function.

Plasticity of NMJs

The appearance of individual NMJs in adult mice or rats is remarkably stable when observed repeatedly over weeks or months *in vivo*. But this is probably as it should be in animals that live under relatively constant animal housing conditions. Whenever such conditions change – for example, with the seasons in lower vertebrates or with hormonal interventions, exercise, muscle unloading (as in space flights or hind limb suspension), or any other manipulation that alters the impulse activity in motor units or the size of the muscle fibers – signs of synaptic remodeling appear. For example, procedures that cause muscle fibers to increase or decrease in size also cause the NMJs on them to increase or decrease in extent, like an imprint on a balloon that inflates or deflates. But changes in nerve terminal dimensions and branching patterns may also occur independently of muscle fiber size. Moreover, such remodeling is reversible, as expected from purely adaptive processes.

Striking functional changes have been observed at NMJs in adult rat EDL and SOL muscles subjected to altered patterns of synaptic inputs. In these experiments, complete control of the amount and pattern of impulses arriving at the NMJs was obtained by applying TTX locally to the sciatic nerve for 3–4 weeks and stimulating the axons to EDL or SOL with slow (20 Hz for 20 s every 30 s) or fast (150 Hz for 1 s every 60 s) stimulus patterns through electrodes implanted below the TTX block. In this way, only the applied slow pattern of impulses arrived at the fast NMJs in the EDL, and only the applied fast pattern of impulses arrived at the slow NMJs in the SOL. At the end of such treatments, run down of end plate potential amplitude was much less than normal in EDL and much greater than normal in SOL, reflecting >70% transformation of sensitivity to fatigue in either direction (**Figures 3(a) and 3(b)**). In addition, the ratio of quantal content to total vesicle pool size became much lower in EDL than in SOL, whereas normally it is much higher in EDL than in SOL (**Figures 3(c) and 3(d)**). Vesicle recycle time was not affected by the chronic stimulation, nor was any effect expected since NMJs in normal EDL and SOL are similar in this respect.

Similar transformations between fast and slow phenotypes occur with respect to AChE. Thus, fast and slow patterns of stimulation affect AChE expression differentially in rat SOL and EDL muscles, as the distribution of AChE isoforms becomes more like that of fast NMJs under the influence of fast pattern stimulation and more like that of slow NMJs under the influence of slow pattern stimulation. Moreover, since these stimulations were applied to denervated muscles, the different forms of AChE almost certainly derived from the postsynaptic muscle fibers and, presumably, as a consequence of muscle impulse pattern-dependent activation of SURE or FIRE promoter elements of the *ColQ* gene (as discussed previously). Consistent with this interpretation, similar SURE and FIRE elements have been described for several genes encoding contractile proteins; these are differentially regulated by slow or fast activity patterns. Therefore, adaptation to different motor unit firing patterns appears to occur by differential postsynaptic gene expressions affecting both synaptic and contractile properties.

Mechanisms of Plasticity

The firing patterns of motor neurons play a dominant role in the regulation of plastic changes at NMJs. Such changes may be initiated in the cell body of the motor neuron, at the NMJ itself, or in the muscle fiber. An example of initiation in the cell body comes from crayfish, where chronic slow pattern stimulation of the fast axon central to a local TTX block makes the NMJs distal to the block slow through mechanisms that are blocked by local application of calcium channel blockers to the cell body. An example of initiation in the muscle comes from cats, in which chronic fast pattern stimulation of the sciatic nerve distal to a TTX block shortens the afterhyperpolarization after each action potential in SOL motor neurons, an effect that is not observed after chronic slow pattern stimulation. A reasonable interpretation of this result is that the fast stimulation transformed the SOL muscle into a fast muscle (as described later), and that this switch in phenotype gave rise to factors that fed back across the NMJs and retrogradely shortened the afterhyperpolarization in the SOL motor neurons, with the result that the SOL motor neurons would now fire at higher than normal frequencies. In this way, the firing characteristics of the SOL motor neurons would become better matched to their newly acquired rapidly contracting muscle fibers for rate modulation of muscle force output, while their NMJs would adapt to the faster impulse patterns. At the level of the NMJ, there is evidence that growth factors and other signaling molecules released locally from nerve terminals and

Figure 3 Impulse pattern-dependent fast-to-slow and slow-to-fast transformations of transmitter release characteristics. (a) Decrease in quantal content during 10 min of 20 Hz acute nerve stimulation is fast at normal extensor digitorum longus (EDL) neuromuscular junctions but becomes slower after 3–4 weeks of chronic slow pattern stimulation of EDL axons (20 Hz for 20 s every 30 s). (b) Conversely, the decrease in quantal content is slow at normal SOL neuromuscular junctions but becomes faster after chronic fast pattern stimulation of SOL axons (150 Hz for 1 s every 60 s). (c, d) Quantal content is relatively large and total vesicle pool size is relatively small at normal EDL neuromuscular junctions, whereas the opposite is true at normal SOL neuromuscular junctions. Therefore, the ratio quantal content:vesicle pool size is relatively large at normal EDL neuromuscular junctions (c) and relatively small at normal SOL neuromuscular junctions (d). Following chronic slow pattern stimulation, EDL neuromuscular junctions become like normal slow SOL neuromuscular junctions in this respect (c), and following chronic fast pattern stimulation SOL neuromuscular junctions become more like normal EDL NMJs (d). Adapted from Reid B, Martinov VN, Njå A, et al. (2003) Activity-dependent plasticity of transmitter release from nerve terminals in rat fast and muscles. *Journal of Neuroscience* 23: 9340–9348.

muscle fibers, as well as terminal Schwann cells, can affect the properties of NMJs.

The Muscle Fibers

The work muscle fibers do varies. Fibers belonging to FF motor units bring about brief, rapid, and forceful contractions that are relatively rare, partly because their motor neurons have high thresholds of activation. In contrast, fibers belonging to S motor units are usually tonically active over long periods of time, as they are frequently used to stabilize joints or counteract gravity. Consequently, muscle fibers must be specialized – for example, for high speed and force output or high resistance to fatigue. But such specializations come at a price, as the fastest units are also the least fatigue resistant, and the most fatigue-resistant units are also the slowest. Many properties of motor units may therefore be placed on a scale from the slowest and most fatigue-resistant units to the fastest and most fatigue-sensitive units.

Specializations for different tasks are revealed at many levels and in interesting ways. For example, in tonically active, fatigue-resistant postural muscles such as the SOL, numerous capillaries supply the oxygen that the numerous mitochondria and well-developed oxidative enzyme systems in such muscles need to produce the necessary ATP for sustained work. At another level, selective expression of slow types of myosins and a slow transporter of calcium ions into sarcoplasmic reticulum conserves energy by prolonging the contractions, slowing the breakdown of ATP, and decreasing the utilization of ATP per unit work. In contrast, in fast fatigue-sensitive muscles,

such as the rat EDL, the blood perfusion rate is much lower and energy mobilization is much faster, owing to rapid breakdown of ATP by glycolysis. Selective expression of fast types of myosin speeds up ATP utilization and sarcomere shortening, while selective expression of a fast transporter for bringing calcium back into the sarcoplasmic reticulum further speeds up the twitch so that it can match the high firing rates of their motor neurons.

Plasticity of Muscle Fibers

Muscle fibers are plastic. They adapt their properties to altered use as dictated by the firing patterns of their motor neurons. Whether motor nerve terminals also release so-called trophic factors to regulate contractile and other nonjunctional properties of muscle has been the subject of numerous studies and much debate. So far, however, no one has been able to identify such factors. Moreover, results that appear to support such a mechanism have other and more plausible interpretations. Therefore, in the continued absence of direct and incontrovertible evidence for trophic control of this kind, this particular hypothesis can be laid to rest. While muscle load and hormones, such as thyroxin, may clearly modulate the expression of contractile proteins, it is the firing patterns of the motor neurons that play the overriding role in the day-to-day regulation of the properties of muscle fibers and NMJs.

Adaptation to Fast and Slow Impulse Patterns

Different exercise regimes may induce marked changes in muscle strength, endurance, and, to a lesser degree, in fiber types. Mechanisms underlying such changes are revealed in muscles that have been stimulated over days and weeks with stimulus patterns that mimic to some extent the natural firing patterns of fast and slow motor neurons (described earlier). Muscles have been stimulated directly after denervation, in which case the imposed pattern is exactly known, or indirectly through the nerve, in which case an unknown pattern of endogenous activity from the motor neuron is added to the imposed pattern. The general outcome of such studies is that increasing amounts of activity cause fast fibers to become more fatigue resistant as more capillaries appear around them and they acquire more mitochondria and well-developed oxidative enzyme systems. They also become slower contracting as the expression of slow proteins is turned on and that of fast proteins suppressed. When the stimulation is interrupted, the muscle fibers return to their previous state, as expected from purely adaptive processes. Conversely, slow fibers become faster and less fatigue resistant during stimulation with a fast stimulus pattern.

Matching Impulse Patterns and Contraction Speed

In denervated rat slow SOL muscles, 3 weeks of direct fast pattern stimulation is sufficient to make the twitch almost as fast as that of the normal EDL, while slow pattern stimulation maintains the normal slow twitch (Figure 4(a)). Such impulse pattern-dependent changes in twitch speed have interesting functional implications. As the impulse frequency increases, the SOL twitch becomes faster (shorter in duration) (Figure 4(c)). Higher impulse frequencies are therefore needed for twitch summation. As a result, the steep part of the tension frequency curve moves toward the imposed frequency (Figure 4(b)) and the SOL twitch becomes better matched to the imposed frequency for frequency gradation of force output. But in SOL, the amount of impulse activity also affects twitch speed, as increased amounts slow down, and decreased amounts speed up, the twitch (Figure 4(c)). In EDL and other fast muscles, an altered amount rather than altered frequency of impulses affects twitch speed. The fastest fibers normally receive low amounts of activity at high frequency and are as fast as they can become. Any change in twitch speed will therefore be in the slow direction. Nevertheless, it remains an open question whether changes in impulse frequency contribute to the fine-tuning of contractile properties among the different types of fast units.

Adaptation within Adaptive Ranges

It has not been possible by cross-reinnervation or by electrical stimulation of adult rat EDL and SOL muscles by fast or slow stimulus patterns, either indirectly through the nerve or directly after denervation, to completely transform the properties of either muscle into those of the other. Figure 4(d) illustrates schematically results obtained after ~2 months of such stimulations. Under fast pattern stimulation, SOL muscles become only about half as fast as the normal EDL with respect to intrinsic shortening velocity (V_{max}), which is consistent with the finding that such transformed SOL muscles express fast types 2A and 2X MyHCs but not type 2B. Similarly, under slow pattern stimulation, the EDL twitch becomes as slow as that of slow type 1 muscle fibers in EDL but only about half as slow as that of slow type 1 fibers in normal SOL muscles. Such changes occur within the adaptive range of a particular property in a particular muscle, as illustrated by the arrows in Figure 4(d). Within such a range the changes are graded and, as shown in Figure 4(c) for the rat SOL, depend on both the rate and amount of imposed impulse activity. However, other features of motor

Figure 4 Adaptive range of muscle fiber properties. (a) The twitch of denervated soleus (SOL) muscles becomes almost as fast as that of extensor digitorum longus (EDL) muscles during direct fast pattern stimulation (60 pulses at 100 Hz every 60 s; ○), but remains slow during slow pattern stimulation (150 pulses at 15 Hz every 15 s; ●). (b) The SOL was denervated and stimulated directly with the fast pattern for 7, 14, or 130 days (○). The steep part of the tension–frequency curve of the normal SOL (●) moved progressively toward that of the normal EDL (■). (c) Denervated SOL muscles were stimulated directly for 28–106 days (mean 55 days), with 60 pulses at the frequencies indicated along the abscissa every 60 s (same number of pulses, mean frequency 1 Hz). For each increase in frequency, the twitch speed (ordinate) increased (○). At some frequencies (10, 15, 20, or 100 Hz), the amount of activity was increased (▲) or decreased (▼) by increasing or decreasing the number of pulse trains, which resulted in slower or faster twitches. (d) Scheme to illustrate that EDL and SOL respond differently to fast and slow impulse patterns, as these patterns fail to completely transform several properties of one muscle into those of another. Although overlapping, the adaptive ranges of diverse contractile properties are different in adult rat EDL and SOL muscles owing to intrinsic differences between them. The present scheme is based on results obtained after ~2 months of chronic stimulations. Longer periods of stimulation may expand the ranges shown here. (a, b) Adapted from Gorza L, Gundersen K, Lømo T, et al. (1988) Slow-to fast-transformation of denervated soleus muscles by chronic high-frequency stimulation in the rat. *Journal of Physiology* 402: 627–649. (c) From Westgaard RH and Lømo T (1988) Control of contractile properties within adaptive ranges by patterns of impulse activity in the rat. *Journal of Neuroscience* 8: 4415–4426.

neurons' firing patterns, such as initial doublets, also affect the position along its adaptive range that a given property may attain. Interestingly, the differences in firing pattern achievable in experimental settings, and the resulting adaptations of the muscles, are much more extreme than can be achieved voluntarily in an intact animal or human.

That muscles such as rat EDL and SOL muscles respond so differently to a given impulse pattern and display such different adaptive ranges indicates the existence of intrinsic differences between these muscles. Recently, intrinsic differences between the satellite cells in EDL and SOL that give rise to regenerated fibers after injury have also been reported. Nevertheless, the capacity for adaptation in diverse muscle fibers is substantial, so that their properties may be adjusted in a graded manner to the prevailing firing patterns of their motor neurons and the types of work that are imposed on them.

Cellular Mechanisms of Adaptation

By what mechanisms do fast and slow impulse patterns turn on or off fast and slow gene programs in muscle fibers? Probably, they involve calcium

signaling, because fast and slow impulse patterns raise free intracellular calcium concentration differently with respect to rate, magnitude, and duration and because such factors differentially affect gene expression in other cells. While it is still unclear how time- and space-dependent changes in free calcium levels work in muscle cells, their downstream effects are being clarified. For example, only the slow impulse pattern activates the pathway calcium/calmodulin → calcineurin → NFAT, which causes depophosphorylated NFAT to enter the muscle nuclei and activate genes for many different slow contractile proteins, and presumably, the forms of junctional AChE that dominate at slow NMJs (see earlier). This entry into the muscle nuclei occurs within minutes of starting slow pattern stimulation, as recently shown *in vivo* in muscle fibers transiently expressing an isoform of NFAT (NFAT c1) that had been coupled to green fluorescent protein (GFP) to make NFAT and its movements in the cell visible. Conversely, upon cessation of stimulation, NFAT moves equally rapidly out of the nuclei. For NFAT transcriptional activity to be effective, however, not only nuclear translocation but also other conditions must be met.

A different signaling pathway includes the sequence phosphoinositide 3-kinase (PI3K) → protein kinase B (also known as AKT) → mammalian target of rapamycin (mTOR). Activation of this pathway, which can occur by innervation, muscle stimulation, or insulin-like growth factor 1 (IGF-1), regulates muscle size but not fiber type. Recent studies have thus revealed several intracellular signaling pathways that independently or in combination regulate the phenotype of muscle fibers.

Studies have shown that muscle fibers adapt to virtually any change in the pattern of impulse activity imposed on them, whether it is the number or frequency of pulses, the duration or spacing of pulse trains, or the presence or absence of initial doublets. Therefore, it appears that muscle fibers continually fine-tune their contractile properties to the impulse patterns imposed on them at any time, and that this tuning is mediated by intracellular signaling pathways that are sensitive to subtle changes in these patterns.

Conclusions

Motor neurons to leg muscles in adult rats generate markedly different impulse patterns. Such firing patterns reflect the different types of work that motor neurons evoke from the muscle fibers in their motor units. The properties of NMJs and muscle fibers in motor units are well matched to the firing patterns of their motor neurons for effective neuromuscular transmission and muscle work. Thus, NMJs and muscle fibers belonging to fast motor units are specialized for effective transmission of brief, high-frequency bursts of impulses and rapid, forceful contractions at the cost of fatigue resistance, while NMJs and muscle fibers belonging to slow motor units are specialized for effective transmission of prolonged trains of impulses and slow, fatigue-resistant contractions.

NMJs and muscle fibers display substantial plasticity when new impulse patterns are imposed on them. This plasticity is of the adaptive kind. It lets NMJs and muscle fibers fine-tune their properties to effectively transmit impulses and do muscle work under changing circumstances. The adaptations occur within adaptive ranges that may overlap but are intrinsically different in different types of motor units. Intracellular signaling pathways that transform the different impulse patterns into particular gene expression patterns and phenotypes are presently being identified and clarified.

Much greater changes in muscle speed can be obtained by electrical stimulation of muscles using fast or slow pulse patterns than by physical training, presumably because the firing pattern of individual motor neurons in the intact organism cannot be switched to similar degrees. Thus, there seems to be a large potential for adaptation in muscle that can be tapped as more extreme forms of training and motivation expand the range of firing patterns that individual motor neurons are capable of. Perhaps this is one reason why athletes continue to set new world records.

Neuromuscular Junction (NMJ): Aging

G C Sieck and C B Mantilla, Mayo Clinic College of Medicine, Rochester, MN, USA

© 2009 Elsevier Ltd. All rights reserved.

The neuromuscular junction (NMJ) is the final effector for neural control of muscle contraction. Mammalian NMJs serve as the sole communicative link between a motor neuron and the muscle fibers it innervates, which together constitute a motor unit (Figure 1). Mechanical properties of motor units are critically important in determining the functional performance of a skeletal muscle across a range of physiological behaviors. In fact, motor units exhibit considerable diversity in terms of their morphological, mechanical, and fatigue properties, and recruitment of specific types of motor units is a major mechanism in neural control of muscle force generation. Despite the diversity among motor unit types, there is remarkable homogeneity in the mechanical and biochemical properties of muscle fibers comprising an individual motor unit. Thus, the properties of muscle fibers and motor neurons appear to be precisely matched to facilitate neuromotor control.

Synaptic plasticity is a hallmark of the nervous system's adaptive response to both intrinsic and extrinsic stimuli and forms the basis for changes in the efficacy of synaptic transmission. With aging, there are a number of changes that could affect plasticity of the NMJ: (1) neuromuscular activity is generally reduced with concomitant unloading of limb muscle fibers; (2) the number of motor neurons is reduced, resulting in denervation of some muscle fibers, which are subsequently reinnervated by the sprouting of axons from remaining motor neurons; and (3) muscle fiber size is reduced in a fiber-type-dependent manner. In the late 1940s, Donald Hebb introduced the concept of activity-dependent synaptic plasticity, which addresses the structural and functional changes that occur at synapses in response to altered use (either an increase or a decrease in activity). According to the Hebbian theory, synaptic efficacy is enhanced when the extent of correlation between pre- and postsynaptic activity increases. With an age-related decrease in neuromuscular activity, synaptic plasticity may occur, but only if there are alterations in the fidelity of neuromuscular transmission (i.e., the extent of correlation between pre- and postsynaptic activity). Clearly, conditions other than changes in activity can also drive synaptic plasticity. For example, with aging there is a loss of motor neurons, which leads to denervation. Following denervation, axonal regeneration and reinnervation of muscle fibers can occur, but this is affected by activity and trophic influences. With aging, there is also a decrease in muscle fiber size (i.e., age-related sarcopenia). A number of studies have reported changes in NMJ morphology and neuromuscular transmission in conditions in which muscle fiber size either increases or decreases, which may relate to common trophic influences. Each of these conditions, in which long-term plasticity of the NMJ occurs, varies with motor unit and/or muscle fiber type.

Although motor unit heterogeneity in mammalian skeletal muscles reflects a continuum of mechanical and biochemical properties of muscle fibers, motor units are generally categorized into different types based on mechanical and fatigue properties of motor unit fibers. Accordingly, motor units are classified into four types: (1) slow-twitch, fatigue-resistant (type S); (2) fast-twitch, fatigue-resistant (type FR); (3) fast-twitch, fatigue-intermediate (type FInt); and (4) fast-twitch, fatigable (type FF) (Figure 2). Muscle fiber type classification follows a corresponding scheme, whether based on histochemistry or myosin heavy chain (MHC) isoform expression. Thus, muscle fibers are classified into four types: type I (MHC_{Slow}), type IIa (MHC_{2A}), type IIx (MHC_{2X}), and type IIb (MHC_{2B}). The innervation ratio (i.e., the number of muscle fibers innervated by a motor neuron) varies across muscles, ranging from 10 or less in small intrinsic hand and eye muscles to several hundred in larger limb and postural muscles. Within a muscle, the innervation ratio is greater at type FInt and FF motor units compared to type S and FR units. In muscles of mixed fiber type composition, differences in fiber size also exist across motor unit types, with type IIx and/or IIb fibers having greater cross-sectional area than type I or IIa fibers. Across muscles the cross-sectional areas of a given fiber type may vary. For example, type I fibers in the rat soleus muscle are much larger than type I fibers in muscles with mixed fiber type composition such as the diaphragm. Although controversial, some studies suggest that the specific force (i.e., force per unit cross-sectional area) of type IIx and/or IIb fibers is greater than that of type I and IIa fibers. Together, the greater innervation ratio, larger fiber size, and greater specific force contribute to the greater forces generated by type FInt and FF motor units compared to type S and FR units. The recruitment of motor units is generally matched to these mechanical and fatigue properties, such that type S and FR motor units are recruited first, followed by type FInt and FF units. In fact, forces generated during most sustained motor behaviors

require the recruitment of only type S and FR motor units, and only during high-force, short-duration motor behaviors would it be necessary to recruit more fatigable FInt and FF units.

Aging Effects on Motor Units

The basis for classification of motor unit types does not change with aging. However, age-related changes can affect the proportion of motor unit types, their innervation ratio, and their mechanical properties. For example, with aging there is a decrease in the number of motor neurons innervating skeletal muscles, and this loss of motor neurons appears to be selective for FInt and FF motor unit types. Thus, the proportion of these motor unit types decreases with age. It is possible that the selective loss of more fatigable motor units reflects age-related changes in neuromuscular activity, but this has not been clearly established. With the loss of motor neurons, some type IIx and/or IIb fibers are denervated. As a result, remaining motor axons sprout and reinnervate these muscle fibers, leading to an increase in innervation ratio of the remaining motor units. In addition, the size of type IIx and/or IIb fibers decreases with age, possibly the result of motor neuron loss and denervation, decreased neuromuscular activity, unloading, or other underlying mechanisms. Finally, specific force also decreases with age, being more pronounced at type IIx and/or IIb fibers. Together, these age-related changes tend to decrease the diversity among motor unit types, with a lower proportion of FInt and FF motor unit types that generate greater forces. The age-related decrease in the force generated by FInt and FF motor units (due to decreased fiber cross-sectional area and specific force) may be partially offset by a concomitant increase in the force generated by type S and FR motor units (due to an increased innervation ratio). Certainly, these changes

Figure 1 Schematic representation of the elements of a motor unit. The neuromuscular junction (NMJ) serves as the sole communicative link between the motor neuron and the muscle fibers it innervates.

Figure 2 Motor units are classified based on their mechanical and fatigue properties. Four types are commonly described: (1) slow-twitch, fatigue-resistant (type S); (2) fast-twitch, fatigue-resistant (type FR); (3) fast-twitch, fatigue-intermediate (type FInt); and (4) fast-twitch, fatigable (type FF). These generally correspond to the expression of specific myosin heavy chain (MHC) isoforms in the muscle fibers: type I, MHC_{Slow}; type IIa, MHC_{2A}; type IIx, MHC_{2X}; and type IIb, MHC_{2B}. Activation history of motor units also differs, with type S and FR motor units (innervating type I and IIa muscle fibers, respectively) being more frequently recruited than type FInt and FF motor units (innervating type IIx and/or IIb muscle fibers).

Figure 3 The structure of neuromuscular junctions (NMJs) varies across muscle fiber types. Rat diaphragm muscle fibers were labeled with antibodies specific to the MHC_{2B} isoform (blue). Note that other muscle fibers remain unlabeled and appear black. The motor nerve endings were labeled with antibodies specific to neurofilamin (red), whereas the motor end-plates were stained with rhodamine-conjugated α-bungarotoxin (green). Note the differences in size and complexity (number and length of branches) across fiber types, with NMJs present at type I or IIa fibers being smaller and less complex than those at type IIx and/or IIb fibers (magnification, ×400).

in mechanical properties might affect recruitment of motor units, particularly during high-force, short-duration motor behaviors. With aging, there appears to be a preservation of mechanical properties of motor units required for low-force, sustained motor behaviors. In some cases, the advantage of such preservation is quite obvious – for example, recruitment of type S and FR motor units in the diaphragm muscle to sustain ventilation or a similar recruitment of motor units in antigravity muscles to sustain posture.

Structure of Neuromuscular Junctions

The structural properties of NMJs also vary considerably across different motor unit types (Figure 3). In rat muscles of mixed fiber type composition, NMJs at type I and IIa fibers are smaller, more compact, and show less complexity in branching patterns than NMJs at type IIx and/or IIb fibers. However, in the soleus muscle, NMJs are larger compared to NMJs at type IIx and/or IIb fibers in the extensor digitorum longus muscle, which is also a muscle with fairly homogeneous fiber type composition. It is possible that fiber size is an important determinant of NMJ size regardless of fiber type. Other factors, such as age, species, and activation history, may play important roles in determining NMJ size. Differences also exist across motor unit types in the ultrastructure of pre- and postsynaptic elements of NMJs. The presynaptic terminal surface area is greater at type IIx and/or IIb fibers compared to type I and IIa fibers. The density of active zones at presynaptic terminals does not appear to differ across fiber types; however, because of the difference in total surface area, the total number of active zones is greater at type IIx and/or IIb fibers compared to type I and IIa fibers. The number of docked vesicles at each active zone

Figure 4 Electron micrograph showing the ultrastructure of neuromuscular junctions.

(i.e., the readily releasable pool, defined morphologically as those vesicles that are fused to the terminal membrane and thus immediately available for release) is comparable across fiber types (Figure 4). However, given the greater number of active zones at type IIx and/or IIb fibers, the total number of synaptic vesicles in the readily releasable pool is greater at these fibers compared to type I and IIa fibers. Synaptic vesicles at presynaptic terminals are also separated into a pool of vesicles that are immediately adjacent to active zones (within 200 nm) and those that are more distant (reserve pool). The densities of synaptic vesicles in both the immediately adjacent pool and the reserve pool are greater at presynaptic terminals of type I and IIa fibers compared to type IIx and/or IIb fibers. Mitochondrial volume density is also greater at presynaptic terminals innervating type I and IIa fibers compared to those innervating type IIx and/or

IIb fibers, possibly reflecting the metabolic requirements of increased activation of these presynaptic terminals.

At motor end-plates of type I and IIa fibers, postsynaptic folding is less complex compared to those at IIx and/or IIb fibers. In addition, at type I and IIa fiber motor end-plates, cellular organelles including mitochondria, rough endoplasmic reticulum, free polysomes, and nuclei are frequently interposed between postsynaptic specializations and myofibrils. Indeed, muscle fiber types can be classified based on these morphological differences at the NMJ. There is no evidence for fiber type differences in the density of cholinergic receptors at the postsynaptic membrane. However, the density of sodium channels near the motor end-plate is much higher at type IIx and/or IIb fibers than at type I fibers.

Aging Effects on NMJ Structure

Aging is associated with an increased number of nerve terminal branches at type IIx and/or IIb diaphragm muscle fibers and a greater fragmentation of nerve terminals. This has also been reported as an age-related increase in complexity of nerve terminal arborization at type IIx and/or IIb fibers. The increased number of terminal branches may reflect sprouting as motor neurons degenerate with aging. The increased branching and fragmentation (complexity) of presynaptic terminals with aging does not lead to an increase in the actual surface area of presynaptic terminals. Indeed, presynaptic terminal area has been reported to decrease with aging. Thus, although it has not been directly assessed, it may be that the total number of active zones at presynaptic terminals decreases with aging and, as a result, the number of synaptic vesicles in the readily releasable pool may decrease. Such changes may reflect alterations in the cyclical remodeling of NMJs reflecting outgrowth and retraction of pre- and postsynaptic elements. It is possible that trophic influences that affect this normal remodeling are altered with aging. Note that an increase in the size of NMJs does not necessarily correlate with improved synaptic efficacy. A possible reflection of instability of NMJ remodeling may be the increased expression of neural cell adhesion molecule that occurs with aging. There is an age-related gradual decrease in the number of cholinergic receptors at the motor end-plate and extrajunctional receptors appear. With aging, there is no change in the numbers of sodium channels at skeletal muscle fibers. However, it is not known whether the relative proportion of junctional, perijunctional, or extrajunctional channels changes with age.

Neuromuscular Transmission

Neuromuscular transmission also varies across motor unit types as a result of differences in safety factor, especially during repeated activation. Safety factor is determined by the ratio of end-plate potential (EPP) amplitude to the threshold for muscle fiber action potential generation. The amplitude of EPPs is greater at type IIx and/or IIb fibers, whereas the threshold for action potential generation is lower at type I and IIa fibers. Overall, the safety factor for neuromuscular transmission during a single evoked response is higher at type IIx and/or IIb fibers compared to type I or IIa fibers. However, during repetitive stimulation the EPP amplitude progressively declines across all fiber types, but the decline is greater at type IIx and/or IIb fibers. Accordingly, type IIx and/or IIb fibers are more susceptible to neuromuscular transmission failure.

Across muscles, whether of mixed or homogeneous fiber type composition, the total number of vesicles in the readily releasable pool is greater at type IIx and/or IIb fibers compared to type I and IIa fibers. The total number of synaptic vesicles released during a single nerve impulse (i.e., quantal content) is higher at type IIx and/or IIb fibers than at type I and IIa fibers. However, there appears to be no fiber type difference in the probability of synaptic vesicle release during a single nerve impulse. With repetitive nerve stimulation, quantal content decreases across all fiber types. Initially, there is a rapid decline (within the first 500 ms) in quantal content that is dependent on the rate of stimulation. This rapid decline in quantal content reflects both a depletion of the readily releasable pool of synaptic vesicles and a decrease in the probability of release. Quantal content continues to decline during repetitive stimulation but at a much slower rate, reflecting a balance between depletion and repletion of the readily releasable pool of synaptic vesicles. Two mechanisms underlie replenishment of synaptic vesicles in the readily releasable pool: (1) recruitment from the immediately adjacent (or available) pool of vesicles and (2) recycling of released vesicles. As mentioned previously, the density of vesicles in the immediately available pool is greater at type I and IIa fibers compared to type IIx and/or IIb fibers. This is consistent with a higher rate of recruitment of vesicles into the readily releasable pool at type I and IIa fibers. It also appears that the extent of synaptic vesicle recycling (e.g., as measured by the uptake of styryl dyes such as FM4–64 or FM1–43) is greater at type I and IIa fibers compared to type IIx and/or IIb fibers. A greater extent of replenishment of the readily releasable pool at type I and IIa fibers during repetitive stimulation may underlie their reduced susceptibility to neuromuscular transmission

failure. Clearly this is important since these motor units are more frequently recruited and are responsible for sustained motor behaviors (e.g., breathing and posture).

Aging Effects on Neuromuscular Transmission

With aging, it has been reported that the safety factor for neuromuscular transmission decreases progressively. Unfortunately, there is little, if any, information regarding the effect of aging on safety factor across different fiber types. As mentioned previously, the safety factor for neuromuscular transmission depends on both EPP amplitude and the threshold for generating an action potential in muscle fibers. Quantal content and EPP amplitude decrease with aging, especially at type IIx and/or IIb fibers. However, the cross-sectional area of type IIx and/or IIb fibers also decreases with aging, which would be associated with an increase in input resistance and, thus, a lower threshold for action potential generation. Therefore, although it has not been directly examined, the safety factor for neuromuscular transmission at type IIx and/or IIb fibers may not be affected by aging. In contrast, the cross-sectional area of type I and IIa fibers changes very little with aging. Accordingly, the threshold for action potential generation would remain unaffected, and an age-related decrease in EPP amplitude would be associated with a decrease in safety factor at these fibers. Such an effect would be especially pronounced during the rapid decline in quantal content that occurs with repetitive stimulation.

Conclusions

There is surprisingly little direct information about the effects of aging on the long-term plasticity of NMJs. Yet aging is clearly associated with changes that could affect plasticity of the NMJ. Physical activity is reduced with aging, and the resulting unloading of limb muscles clearly has an effect on NMJ structure and function that is more pronounced than in younger animals. There is a loss of motor neurons with aging, resulting in the functional denervation of muscle fibers, which are subsequently reinnervated by the sprouting of axons from remaining motor neurons. This process leads to loss of motor unit diversity, with greater loss of those motor units that are able to generate greater forces. Concomitantly, there is a reduction in muscle fiber size at these same motor units. Thus, with aging, there appears to be preservation of motor units required for low-force, sustained motor behaviors, which may be advantageous, for example, in the maintenance of adequate ventilation or posture.

Neuromuscular Junction (NMJ): Inherited and Acquired Disorders

A Vincent, University of Oxford, Oxford, UK

© 2009 Elsevier Ltd. All rights reserved.

Background

The neuromuscular junction is a prototype synapse between the terminal arborizations of the motor nerve and the postsynaptic specialization of the muscle surface. The chemical nature of neuromuscular transmission and the main anatomical features have been known for decades and are described in detail elsewhere. Over the last 30 years the main functional molecules involved in synaptic function have been identified, their genes cloned, and function examined by many different approaches. In parallel, it has become clear that there are a variety of inherited or acquired diseases that can affect neuromuscular transmission resulting in either muscle weakness, or less often muscle hyperactivity. At the same time, a number of different neurotoxins, from a variety of species, have been identified which bind strongly to these molecules. This article discusses the genetic and autoimmune diseases that affect neuromuscular transmission and includes mention of some of the neurotoxins that have helped to make this knowledge possible.

Investigating Neuromuscular Transmission in Human Disease

Much of what we know about the diseases of neuromuscular transmission results from *in vivo* and *in vitro* examination of the neuromuscular junction. Typically, patients with a defect in neuromuscular transmission will complain of muscle weakness or excessive fatigue during repeated effort. The nature of this weakness can be identified by use of electromyography. This involves stimulating a peripheral nerve (e.g., in the forearm) while recording from the muscle it innervates (e.g., the abductor of the thumb). When the nerve is stimulated at low frequency (3 Hz), the amplitude of the compound muscle action potential should remain within 10% of the initial amplitude; any defect in transmission will tend to cause a decrease ('decrement') in the amplitude. An alternative and more sensitive technique is to use single-fiber electromyography in which the time intervals between the responses of two endplates from one motor unit are measured during voluntary activity; defects in transmission at the two endplates will cause excessive variation in this interval ('increased jitter').

In vitro techniques to assess the response of the acetylcholine receptors (AChRs) to released acetylcholine (ACh) include microelectrode recordings from the muscle fibers to look at the amplitude of the miniature endplate potentials and of the endplate potentials (under artificial conditions where the muscle does not fire action potentials). The amount of ACh released per impulse can be assessed by measuring the quantal content (the number of packets released) or by biochemical measurements from isolated muscles. Binding of ^{125}I-α bungarotoxin can be used to measure the numbers of AChRs on the muscle surface. It is also possible to record extracellular potentials from the motor nerve terminals or to place a voltage-clamp pipette on the muscle surface to record the number and characteristics of single AChR openings.

In addition, histochemistry can be used to demonstrate the localization and distribution of acetylcholinesterase (AChE), and immunolocalization studies to identify other autoantibodies and complement bound to the neuromuscular junction in the autoimmune disorders. Finally, electron microscopy and freeze-fractures microscopy have been performed on the neuromuscular junctions to quantify abnormalities in the synaptic vesicles, the active zone particles, or the postsynaptic membrane and secondary folds.

Treatment of Neuromuscular Junction Disorders

In the majority of cases in which the defect is a reduction in neuromuscular transmission, the symptoms can be improved substantially by use of two types of drugs that increase the amount of ACh available to the AChRs. AChE inhibitors are the mainstay of treatment, and diamino-pyridine, which blocks potassium channels and causes prolonged and increased ACh release from the motor nerve terminal, can also be helpful.

In the rare conditions in which neuromuscular transmission is enhanced, notably in neuromyotonia, sodium channel blockers such as the anti-epileptic drugs can help to stabilize the motor nerve and prevent hyperexcitability. In the slow-channel syndrome, quinidine and the serotonin reuptake inhibitor, fluoxetine, both of which block the AChR channel when open, have been found to be helpful.

Congenital Myasthenic Syndromes

The congenital myasthenic syndromes (CMS) are a group of heterogenous inherited disorders that are

Table 1 Targets for autoimmune and genetic disorders of neuromuscular transmission

Target	*Disease*	*Pathogenetic mechanism*
Genetic		
AChR	Acetylcholine receptor deficiency	Recessive mutations in AChR genes causing reduced AChR expression
	Acetylcholine receptor deficiency	Recessive mutations in RAPsyn genes causing reduced anchoring of AChR on the postsynaptic membrane
	AChR kinetic abnormalities	Dominant or recessive mutations in AChR genes causing kinetic defects – 'slow' and 'fast' channel syndromes
AChE	Acetylcholine esterase deficiency	Recessive mutations in the collagen tail that anchors AChE at the NMJ causes absence of AChE
Choline acetylase	Choline acetylase deficiency	Recessive mutations in the gene for choline acetylase that synthesizes ACh causes reduced Ach release
Autoimmune		
AChR	Myasthenia gravis	Antibodies to AChR in 85% reduce AChR numbers
MuSK	Myasthenia gravis	Antibodies to MuSK in 5–10% – mechanism not known
AChRs, MuSK	Transient neonatal myasthenia	Maternal antibodies cause transient disease in neonate; not seen commonly if mother receiving treatment
Fetal AChR	Arthrogryposis (multiple joint contractures in babies)	Maternal antibodies that inhibit function of fetal AChR paralyse baby *in utero* leading to joint contractures; very rare
VGCCs	Lambert Eaton myasthenic syndrome	Antibodies to VGCC in 90% reduce VGCC numbers and ACh release and EPP amplitude
VGKCs	Acquried neuromyotonia	Antibodies to VGKCs in 40% probably lead to spontaneous ACh release

caused by mutations in the genes coding for different molecules at the neuromuscular junction. Most of the conditions are recessively inherited, but one is due to a dominant mutation that causes a toxic gain of function. The main conditions are listed in Table 1 and the targets illustrated in Figure 1.

AChR Deficiency

In this condition the patient is normally born with mild weakness or develops weakness within the first 2 years of life, although in a few cases the diagnosis might not be made for many years. The AChRs at the neuromuscular junction are reduced in number. The result is that the miniature endplate potentials and endplate potentials are reduced in amplitude and neuromuscular transmission fails making the patient weak. The area of neuromuscular contact is typically elongated, possibly as the result of a compensatory sprouting of the motor nerve terminals.

There are two main causes of this syndrome. In one case there are mutations in the AChR epsilon gene (see Figure 2 for the subunit structure of the AChR) which generally cause complete loss of this subunit. This means that the adult form of the AChR cannot be made, and the patient survives by persistent expression of the fetal AChR. In the other case, which is increasingly recognized, the loss of AChRs is due to a defect in the receptor aggregating protein at the synapse (RAPsyn) molecule that is essential for clustering the AChRs during development and for maintaining these clusters in mature muscle. These conditions are usually treated with AChE inhibitors and sometimes also with 3,4-diaminopyridine.

Kinetic Abnormalities of the AChR

There are two disorders in which the AChR is present in normal or near-normal amounts but functions abnormally. In the slow-channel syndrome, dominant mutations in any of the AChR subunit genes lead to abnormally prolonged AChR channel openings. This means that a single nerve impulse results in a grossly prolonged endplate potential. If this endplate potential persists after the refractory period of the muscle action potential, a second action potential will occur and typically this can be recorded *in vivo* by electromyography as a double response to a single impulse. The patients complain of weakness and the condition is progressive often leading to marked wasting of some muscles. It is thought that the prolonged openings allow excess calcium to enter the muscle resulting in 'excitotoxic' damage. This can be prevented by using quinidine or fluoxetine, which block the open AChR channel and help to reduce calcium entry.

The converse situation exists in the AChR fast-channel syndrome, in which mutations lead to reduced duration of each channel opening. The miniature endplate potential amplitudes are very small and the symptoms are very similar to AChR-deficiency syndromes; the treatments are also the same.

AChE Deficiency

This is a recessive disorder and the patients suffer from a progressive disease, not unlike the slow-channel syndrome; this is because loss of the endplate form of the AChE leads to prolonged exposure of the postsynaptic membrane to released ACh. The endplate potentials

Figure 1 Diagram of the neuromuscular junction illustrating the main enzymes, ion channels, and anchoring proteins involved in genetic (left) or autoimmune (right) diseases.

Figure 2 General structure of the AChR in the membrane (top left) showing the topology of each subunit (top right). From above, the AChR consists of five subunits, including two α subunits which are the main sites of antibody binding (main immunogenic regions). The ACh-binding sites are at the interface of the α subunits with their adjacent subunits. There is a site on the γ subunit which binds maternal antibodies that can paralyze the fetus *in utero*.

are prolonged and a double compound muscle action potential is common on *in vivo* testing. This is the most severe of the CMS, and no useful treatments are available at present. Interestingly, the genetic defect is not in the AChE gene itself, but in the collagen molecule, ColQ, that anchors AChE at the neuromuscular junction.

Choline Acetylase Deficiency

A few patients with CMS have reduced ACh release from the motor nerve terminal that may only be evident during repetitive high-frequency nerve stimulation. The patients often present during neonatal life with respiratory problems or choking, but if the syndrome is recognized these can be adequately treated with small doses of AChE inhibitors. The gene defect is in the gene for choline acetylase, the enzyme that synthesizes ACh from acetate and coenzyme A.

Limb Girdle Myasthenia

A recently recognized syndrome is a form of myasthenia that may occur in families and causes weakness of the trunk and limb muscles, with some facial involvement. The neuromuscular junctions in this condition are reduced in size with small motor nerve terminals, reduced area of AChE staining, and reduced AChR numbers; as a result the miniature endplate potentials are only marginally reduced in amplitude but the endplate potentials are small due to reduced numbers of packets of ACh released. It is not clear why the neuromuscular junction does not increase in size to try to compensate for the defective transmission as it appears to do in some of the other syndromes. Mutations in a postsynaptic cytoskeletal protein Dok-7 have recently been identified in this syndrome, but how these affect both pre- and postsynaptic morphology and function is not yet clear.

Autoimmune Disorders

The autoimmune disorders are caused by the immune system reacting against self-proteins at the neuromuscular junction. The humoral immune system has the capacity to react against foreign microbes or parasites, producing immunoglobulin antibodies that bind specifically to the foreign proteins. These immunoglobulin (antibody) molecules are produced by specific B (bone-marrow-derived) lymphocytes. For these antibodies to be made, other lymphocytes, called T (thymus-derived) helper cells, have to recognize the antigen and help the antibody response. New antibodies are being made all the time in response to different environmental, or internal, stimuli. Sometimes the antibodies are able to bind to self-proteins resulting in autoimmune disease. Thus, these diseases are not inherited but are acquired during life. The environmental, or possibly internal stimuli, that initiate the self-reactive immune response are only known in a few diseases. Although they are often chronic conditions, they can be treated by removing the antibodies from the circulation or by suppressing the immune system so that it produces less of the pathogenic antibodies.

The reason that we understand so well the diseases of the neuromuscular junction depends, in large part, on its accessibility to circulating factors. Quite large molecules like antibodies (MW 160 000) can diffuse out of the blood and find their way to the neuromuscular junction which is not protected by a 'blood–nerve barrier.' As a result, many venomous animals have taken advantage of this accessibility to develop neurotoxins that, when absorbed into the circulation, can access the neuromuscular junction, block the crucial ion channels, and paralyze their prey. These neurotoxins have been of great value in the study of the diseases described.

Myasthenia Gravis

Myasthenia gravis (MG) is an acquired autoimmune disease caused in most cases by autoantibodies to the AChR. It was probably first described by Thomas Lewis in 1676. The patients first notice the disease at any age, but childhood cases are rare, young female adults are common, and older patients (after 50 years) are increasingly being identified. They complain of muscle weakness and fatigue. The eye muscles are often involved first causing double vision and drooping of the eyelids (ptosis). There is usually limb weakness and it is common to have weakness of facial and pharyngeal and respiratory muscles (bulbar weakness), which can be life threatening when breathing is impaired. However, some patients remain with only ocular muscle weakness (ocular MG).

The story of how MG was shown to be autoimmune and due to antibodies to the AChR is one of the best examples of how basic science can lead to understanding of clinical disease. It was known for many years that the defect in MG was at the neuromuscular junction, and in the 1960s it was shown that the miniature endplate potential amplitudes were very small – often almost undetectable. However, it was not clear whether the defect was in the amount of ACh in each packet or the number of AChRs. Two findings in the 1960s and 1970s were crucial. First, Lee and his collaborators working on the venom of *Bungarus multicinctus*, the banded krait, found that it contained a neurotoxin, α-bungarotoxin, that blocked neuromuscular transmission completely and irreversibly. They showed that this toxin binds highly

specifically to the endplate region of normal and denervated muscles (when AChRs appear over the entire muscle surface), and prevented the response of the muscles to ACh. This indicated that the toxin was blocking the AChRs themselves rather than interfering with release of ACh. Drachman and his colleagues at Johns Hopkins University were then able to use radioactively tagged α-bungarotoxin to identify and measure AChRs in human muscle biopsies, and they found that the number of binding sites was reduced in MG biopsies. Almost concurrently with these observations, Patrick and Lindstrom working at the Salk Institute, purified AChRs from the electric eel and immunized rabbits against AChR in order to raise antibodies for use in immunolocalization studies. The rabbits developed antibodies to the AChRs and also became very weak. These two observations together strongly suggested that MG could be the result of autoimmune response to self-AChRs in the patients, as was shown by Lindstrom a couple of years later.

For the last 30 years the diagnosis of MG has been confirmed by measuring the level of antibodies to AChR in the patients' serum or plasma. The diagnostic test relies on immunoprecipitation of human AChRs that have been radioactively tagged with ^{125}I-α-bungarotoxin. Normal healthy individuals do not have antibodies to the AChR and their serum antibodies do not therefore immunoprecipitate the AChRs; in 85% of patients with MG, the AChR antibody levels are much higher, although quite variable.

Autoantibodies that bind to self-protein may not always be pathogenic This is the case if the protein is not accessible to the circulating antibodies, or the antibodies do not bind to the native conformation of the protein. It was therefore important to demonstrate that these antibodies were causing the disease, rather than perhaps developing as a secondary immune response resulting from other abnormalities at the neuromuscular junction. This was done in three main ways: first, the antibodies to the AChR in MG were shown to be directed against the extracellular, exposed, domains of the AChR and they were bound to the AChRs in animal models of MG and in the patients' muscle biopsies. Second, if the patient is treated by plasma exchange, which removes large amounts of the patients' own antibodies and replaces them with substitute healthy antibodies, they almost always improve substantially. The improvement is only maintained for as long as the AChR antibody levels remain low – when the levels rise again, due to resynthesis, the patients' symptoms return. Third, signs and experimental evidence for myasthenia can be induced in experimental animals by injecting them with the serum or purified immunoglobulin antibodies of the patients. Thus, the AChR antibodies in MG are pathogenic.

In general, the serum antibodies in MG patients do not block directly the function of the AChR, although such antibodies are present in some patients. The antibodies, particularly those directed toward the main immunogenic region (see Figure 2), can bind divalently to the AChRs at the neuromuscular junction, and this causes increased internalization and degradation of the AChRs. In addition, and perhaps most importantly, serum complement components can bind to the antibodies, activate the membrane attack complex, and lead to lysis and morphological damage to the postsynaptic membrane (Figure 3). The reduction in the postsynaptic folds may enhance the defect in transmission by reducing the number of VGKCs. On the other hand, there is some evidence that both the motor nerve and the muscle try to compensate for the loss of AChRs by increasing ACh release, and increasing AChR synthesis, respectively.

An obvious question is why do the patients develop antibodies to their own AChRs? There are a few clues. One is the presence of abnormalities in the thymus gland. This gland is responsible for educating the cells of the immune system, and it expresses many self-proteins so that those cells of the immune system that might react against 'self' can be deleted. Small muscle-like cells called myoid cells express AChRs and other muscle proteins. In some patients at least, an immune response toward these myoid cells seems to initiate myasthenia. This is supported by the fact that lymphocytes cultured from the thymus gland produce AChR antibody, and if the gland is removed the patients tend to improve over the following year with decreases in their AChR antibody levels. However, this applies mainly to patients under the age of 50 years. A proportion of slightly older patients (usually between 30 and 60 years) will have a thymic tumor, which is also likely to be involved in sensitizing the immune system to the AChR protein, but the cause of the disease in those who develop symptoms later in life without a thymic tumor is not at all clear.

Ocular MG

Only about 50% of the patients whose symptoms do not progress beyond the ocular muscles (causing ptosis and double vision) have AChR antibodies. It is still a mystery as to why the disease is so restricted. One possible explanation is that neuromuscular transmission in the extraocular muscles that control eye movements is subtly different from that in other muscle groups; this is partly the case as some of the muscle fibers are multiply innervated and muscle contraction depends directly on the endplate potentials generated at each junction, rather than on a propagated action potential. It has also been suggested that the extraocular muscles express more of the fetal

Figure 3 The neuromuscular junction in myasthenia gravis (left) and the Lambert–Eaton myasthenic syndrome (right).

AChR, but this has been disputed by subsequent studies. Another possibility is that these muscles do not express sufficient complement inhibitors. Whatever the explanation, it should be realized that these muscles are often the first to be affected in systemic neurotoxicity such as with botulinum or snake envenomation. Thus, the basis of their susceptibility to fatigue must lie partly in the physiology of their neuromuscular junctions.

MG without AChR Antibodies

Only about 85% of patients with generalized MG have AChR antibodies, and for many years there was controversy about whether the remaining 15% had a different disease. It turns out that some of the 15% have antibodies to another protein at the neuromuscular junction. This is the muscle-specific kinase (MuSK). MuSK is expressed in muscle during development and is essential for orchestrating the RAPsyn-induced clustering of the AChRs at the developing neuromuscular junction. It is not yet clear what role(s) MuSK plays in mature muscle when the AChRs are already clustered, and when the high density of AChR is maintained by endplate-specific synthesis.

Only up to 50% of the patients without AChR antibodies have MuSK antibodies, and it is not clear how these antibodies cause a neuromuscular junction defect. However, these patients often have mild limb weakness with marked facial and bulbar symptoms, relatively frequently leading to muscle atrophy or wasting which is not a marked feature of typical MG. It is possible that the MuSK antibodies interfere not only with MuSK's function at the neuromuscular junction, leading to the myasthenic symptoms, but also to some downstream functions involved in the trophic support of the muscle itself.

Maternal Antibodies and Development

It has long been recognized that some mothers with MG give birth to babies who have a transient form of the disease. This results from the transfer of the AChR antibodies across the placenta, which is a normal event that occurs during the latter half of pregnancy. In very rare cases, a mother has high levels of antibodies that are mainly directed against the fetal form of the AChR (Figure 2). When these transfer to the fetus they can lead to neuromuscular junction failure and fetal paralysis. The baby may survive but has multiple joint contractures and other abnormalities as a result of lack of movement *in utero*.

The Lambert–Eaton Myasthenic Syndrome

In 1957 Lambert and Eaton described a myasthenic syndrome that was distinct from MG. The distribution

of weakness usually affects the legs first with relatively little ocular muscle involvement. Also, muscle reflexes which are normal in MG are absent or depressed but may become stronger after voluntary contraction. Autonomic symptoms (dry mouth, constipation, impotence) are present in many patients, suggesting that the defect may be one that is common to autonomic neurons.

The difference from MG was most obvious on electromyography. When the motor nerve was stimulated *in vivo*, the compound muscle action potential (CMAP) amplitude was small and became smaller at low rates of stimulation ($<10\,s^{-1}$), but during stimulation at higher rates, or following a few seconds of voluntary contraction, the amplitude increased substantially ('increment'). These findings contrasted with those in MG where the CMAP fails to show an increase during high-frequency stimulation (see above).

The basis for these changes was examined in patients' muscle biopsies. These showed that the miniature endplate potentials were normal but the endplate potentials were very small, indicating a reduction in the number of packets of ACh released per impulse. The endplate potentials increased during repetitive stimulation, and also in response to increases in extracellular calcium concentration. It seems that increasing the buildup of intracellular calcium, either by increasing the amount of extracellular calcium or by high-frequency nerve stimulation, increases ACh release and improves neuromuscular transmission. Moreover, freeze-fracture electron microscopic studies showed that the active zone particles, which are thought to be the voltage-gated calcium channels (VGCCs) (Figure 1), were reduced in numbers and the normal double parallel arrays of these particles were mainly absent.

The approaches used to prove that Lambert–Eaton myasthenic syndrome (LEMS) was autoimmune, relied on those established in MG. Plasma exchange was found to lead to clinical improvement and the patients also improved clinically when given long-term immunosuppressive drugs. Moreover, daily injection of LEMS plasmas, or IgG fractions, into mice led to reduced endplate potentials and quantal content in the mouse muscles, with changes in the active-zone particles similar to those found in the patients' biopsies.

These observations suggested VGCC as a target for antibodies in LEMS. The VGCCs are a family of transmembrane proteins consisting of $\alpha1$, β, and $\alpha2/\delta$ subunits. The VGCC at the neuromuscular junction is the $\alpha1$A (P/Q-type) and binds a particular cone snail-derived toxin, ω-Conotoxin (ω-CmTx) MVIIC. It was relatively easy therefore to use ^{125}1-ω-Conotoxin (ω-CmTx) MVIIC to tag solubilized VGCCs and test the patients' sera for antibodies to the VGCC (in a method analogous to that used for AChR antibodies in MG). Further studies showed that the antibodies were highly specific for this VGCC. Indeed, in mice injected with the patients' antibodies, there is upregulation of another VGCC, the $\alpha1$B (N-type) which seems to be an attempt of the motor nerve to compensate for loss of the $\alpha1$A (P/Q-type) VGCC.

Similarly, the $\alpha1$A (P/Q-type) VGCCs play a role at autonomic synapses, although this role is much more subtle. For instance, multiple subtypes of VGCC are involved in the release of neurotransmitter at mouse bladder and vas deferens smooth muscles, including P-, Q-, N-, and R-types. Injection of LEMS IgG into mice causes a reduction in the proportion of release that is dependent on the $\alpha1$A (P/Q-type) without in general interfering with the release dependent on the other subtypes.

Paraneoplastic Neurological Disorders

The cause of LEMS in half the patients is unknown, but about 50% of the patients have a small cell lung cancer (SCLC). This tumor is aggressive and generally has a poor prognosis. Only 3% of the patients with SCLC develop LEMS, but it is highly likely that the tumor is responsible because SCLC cells express VGCC on their surface. Therefore, the VGCC antibodies are a byproduct of the body's attempt to get rid of the tumor, but the antibodies bind to the VGCCs on the motor nerve terminals, causing the neurological symptoms. From this it follows that if the tumor is successfully removed or treated, the stimulus decreases and the patient tends to improve. Moreover, the antibody response against the SCLC VGCCs may inhibit tumor growth, so that patients with the autoimmune disease may have a better prognosis than those who do not have LEMS.

There is a family of diseases in which the tumor initiates a neurological condition. The recognition of these 'paraneoplastic neurological syndromes' is important because in many cases the onset of the neurological disease ensures early detection of the relevant tumor. However, not all of these conditions are due to autoantibodies and in many the patients do not improve with immunological or tumor treatments.

Acquired Neuromyotonia

Neuromyotonia (NMT), or Isaacs' syndrome, is a syndrome of muscle hyperactivity with muscle stiffness and cramps most prominent in the limbs and trunk. Increased sweating is also very frequent. In this condition, the electromyograph (EMG) shows spontaneous motor activity. Muscle biopsies have not been studied in NMT, but the muscle hyperactivity is initiated in the motor nerves because it can be

blocked by curare which is an AChR antagonist (given locally in the arm).

NMT may be associated with other autoimmune diseases or other autoantibodies suggesting an autoimmune basis, and cerebrospinal fluid analysis may show an increase in IgG or 'oligoclonal bands', suggesting that there is an immune response to neuronal antigens. Like MG, NMT can be associated with a thymoma. Moreover, plasma exchange results in clinical improvement, and passive transfer of the patients' serum antibodies to mice results in increased motor nerve and sensory nerve activity and an increase in the number of AChR packets released. These results were very similar to those obtained with low concentration of the potassium channel blockers, 4 amino-pyridine or 3,4-diaminopyridine.

The most likely target for the autoantibodies, therefore, was a potassium channel. Aminopyridines or specific toxins such as α dendrotoxin block certain types of VGKCs and cause the nerve to generate repetitive or spontaneous bursts of action potentials A functional VGKC consists of four transmembrane α subunits that combine as homomultimeric and heteromultimeric tetramers. α-Dendrotoxin binds to VGKCs of the subtypes Kv1.1, 1.2, and 1.6: 1.1 and 1.2 are highly expressed at nodes of Ranvier and are therefore important for controlling motor nerve excitability. The subtype expressed at the motor nerve terminal, however, is not known, and dendrotoxin has only quite modest effects on neuromuscular transmission *in vitro*.

Antibodies to VGKCs can be detected in about 40% of NMT patients by immunoprecipitation of ^{125}I α-dendrotoxin-labeled VGKCs. Antibodies to Kv1.2 probably dominate in most patients, but antibodies to Kv11 or Kv16 may be important in determining some of the clinical effects. The antibodies, or IgG fractions, can reduce potassium channel currents in a neuroblastoma cell line, Nb-1, and this does not require complement but does require divalent (Fab)2 antibodies. Thus the antibodies probably act mainly by cross-linking the VGKCs in the membrane.

Some patients with NMT also have autonomic and central nervous system disease with cardiac and gastrointestinal problems, memory loss, and sleep disorder (Morvan's syndrome). Stemming from studies on these very rare patients, high levels of antibodies to VGKCs have also been found in individuals who present with memory loss and seizures without (for unknown reasons) the peripheral or autonomic disturbance (usually called nonparaneoplastic limbic encephalitis). Both these diseases improve with immunological treatments that reduce the VGKC antibody levels.

Miller–Fisher Syndrome

There is another condition that can be considered with disorders of the neuromuscular junction, although it is strictly classified as an immune-mediated neuropathy. Miller–Fisher Syndrome (MFS) is an acute, monophasic disease in which the patients suffer from ophthalmoplegia (ocular muscle paralysis), ataxia (incoordination of movements), and areflexia (loss of muscle reflexes). It usually gets better spontaneously and is not life threatening although sometimes there is overlap with the Guillain–Barre syndrome. The condition often follows an infection with a bacterium, *Campylobacter jejunii*, and the patients' sera almost always contain antibodies to a ganglioside (glycolipid molecule) called GQ1b. It appears that these antibodies are formed primarily against similar structures on the bacterial cell wall, and that this is a prime example of molecular mimicry in which autoimmunity arises as a result of cross-reactivity between microbial and self-antigens.

The relevance to the neuromuscular junction was recognized when serum from patients with this condition was applied to mouse neuromuscular preparations *in vitro*. The MFS serum produced a massive release of ACh from the motor nerve terminals which began about 10 min after application, and continued until transmission failed altogether. This has been shown to result from the binding of the GQ1b antibodies to the glycolipid on the motor nerve terminal, and activation of complement leading to influx of calcium and release of the transmitter. How these *in vitro* findings relate to the patients only neuromuscular junctions *in vivo* is not yet clear.

Neuromuscular Junction (NMJ): Mammalian Development

C R Slater, University of Newcastle, Newcastle upon Tyne, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The neuromuscular junction (NMJ) is an example of a highly specialized, asymmetric, cell-cell junction. The speed with which fast chemical transmission occurs requires that the specializations of the postsynaptic muscle cell surface that allow it to respond to the transmitter released from the nerve are less than a micrometer from the presynaptic release sites. An important question concerning the development of the NMJ is therefore, what are the mechanisms that account for the alignment and proximity of the distinctive specializations of its pre- and postsynaptic components? A second important question concerns the specificity of the mature nerve-muscle contacts. What part does the process of NMJ formation play in achieving functional matching of individual motor neurons to the muscle fibers they innervate?

This article gives an overview of the way mammalian NMJs develop. Most of the information has come from rats and mice, in which the most detailed studies of NMJ formation in vertebrates have been made. The article starts with the origin of motor neurons and skeletal muscle fibers and then considers how the NMJ itself is formed.

Development of Motor Neurons

Birth

Motor neurons are among the earliest nerve cells to be born, that is, to complete their final round of DNA synthesis. Soon after cell birth, the motor neurons begin to extend an axon that leaves the spinal cord in the nascent ventral roots. In mammals, the motor neurons that innervate an individual muscle are usually grouped into a longitudinally oriented column that extends over two to three spinal segments.

Axon Outgrowth and Motor Neuron Identity

The immature motor axons leave the spinal cord even before their target muscles have formed. As they grow, the axons select paths that lead to the muscles they are destined to innervate. The ability of an immature motor neuron to make such decisions indicates that it has some knowledge of its identity, and that different motor neurons therefore have different identities. In adults, motor neurons that innervate slowly contracting nonfatigable muscle fibers tend to be rich in oxidative enzymes that can be visualized by appropriate histochemical techniques. Well before the first NMJs are formed, embryonic motor neurons already differ in their oxidative enzyme profiles. This supports the idea that the motor neurons that innervate a single muscle differ in their properties and that those differences arise before any interaction with the muscle occurs.

Once contact with the appropriate premuscle mass has been established, but not before, the axons branch extensively. In rats and mice, functional contacts with newly formed limb muscles are first present around embryonic day 14 (E14), a week before birth. A similar stage occurs in humans at about week 9 of gestation.

Release of Acetylcholine from Growth Cones

The terminals of cultured motor neurons can release acetylcholine (ACh), the chemical transmitter at neuromuscular junctions, even before they make contact with muscle. This suggests that motor neurons *in vivo* also synthesize ACh and have the necessary specializations for its activity-dependent release at an early stage of their development.

Development of Skeletal Muscle Fibers

Myotube Formation

Most vertebrate skeletal muscle fibers arise during development from the fusion of many mononucleated postmitotic myoblasts. These spindle-shaped cells line up and fuse to form the primitive myotubes. As the myotubes grow and mature into muscle fibers, they incorporate additional myoblasts. In adult muscle fibers, there is typically one nucleus for every 10 μm of length. Thus, a single fiber in a large human muscle, such as *vastus lateralis*, which has fibers up to 20 cm long, has up to 20 000 nuclei.

Kinetics of Primary and Secondary Myotube Formation

In mammalian muscles, myotube formation occurs in two phases. The first involves the formation of an initial cohort of relatively few primary myotubes. As the muscle elongates, further myoblasts line up along the primary myotubes and eventually fuse to form secondary myotubes. These form initially roughly midway between the ends of the primary myotubes and then grow rapidly in length as they add new myoblasts. The two populations of myotubes, and the mature muscle fibers that form from them, have

somewhat different functional properties. The great majority of fibers in the adult muscles are derived from secondary myotubes.

Origin of Muscle Fiber Types

Most adult mammalian muscles contain fibers of different functional types. Some are specialized for relatively slow, sustained contraction whereas others are specialized for fast, high-powered contractions. At birth, the muscle fibers in rats and mice contract uniformly slowly. Differentiation into faster and slower contracting fibers begins soon after birth and is well established 2–3 weeks later. Most of the muscle fibers that develop from primary myotubes end up as slow in the adult, while secondary myotubes give rise to both fast and slow fibers. These distinctive properties arise from the pattern of genes expressed by the fibers. Most of the nuclei in each fiber express the same set of genes, raising the as yet unanswered question of how that homogeneity of gene expression comes about.

Early Appearance of Delocalized Postsynaptic Properties

Even before they are innervated, immature muscle fibers begin to express the receptor proteins that allow them to respond to ACh (acetylcholine receptors, or AChRs). AChRs of the fetal form, containing $\alpha_2\beta\delta\gamma$ subunits, are initially present over the whole fiber surface at a density of about 500 μm^{-2}. Other molecules that play roles in AChR localization and gene expression, such as rapsyn and muscle specific kinase (MuSK; see 'AChR aggregation' below), have a similar pattern of expression. As the muscle fibers become increasingly active, their activity suppresses the expression of all these proteins away from the NMJ.

Early Development of the NMJ

Initial Nerve–Muscle Encounters

Muscle fibers become innervated very soon after they first form. In rats and mice, signs of functional innervation can be detected within a day or two of the earliest myotube formation at about E12–14, depending on the muscle. The early nerve-muscle contacts lack many of the structural features of mature NMJs but are characterized by a high density of AChRs in the muscle fiber membrane. Whether the AChR clusters form before or after nerve contact is a matter of continuing debate (see below). Indeed, there is evidence that NMJs in different muscles in the same species form by different sequences of events.

Polyaxonal Innervation

A distinctive feature of the early motor innervation of vertebrates is that several motor neurons initially innervate each muscle fiber. This innervation occurs at a single postsynaptic site that is thus contacted by the terminal axons of several motor neurons (Figure 1). Myotubes cultured *in vitro* can acquire polyneuronal innervation, but such multiple inputs are normally distributed over the myotube surface rather than focused on a single site. The forces that initially restrict the immature nerve terminals to this single site *in vivo* are not known.

AChR Accumulation

A high density of AChRs is a hallmark of the postsynaptic membrane of the vertebrate NMJ. A distinct cluster of AChRs, detectable after labeling with fluorescent conjugates of the snake toxin α-bungarotoxin, is present from a very early stage of NMJ formation (Figure 2). Within the immature cluster, AChRs are often gathered into microclusters less than 1 μm across. The mean density of AChRs within the plaque

Figure 2 Structural maturation of mouse neuromuscular junctions (NMJs). Nerve terminals in postnatal mouse extensor digitorum longus muscles were labeled with zinc iodide-osmium, and acetylcholine receptors (AChRs) were labeled with R-α-bungarotoxin. Arrows point to the preterminal motor axon(s). Several axons are present at birth, but between 1 and 2 weeks after birth, all but one are withdrawn. The surviving axon becomes myelinated 2–3 weeks after birth. As the axon terminal enlarges, the initially uniform granular distribution of AChRs breaks up, leaving areas with low AChR density that come to match the branches of the nerve terminals. NB, newborn.

is about $3000\,\mu m^{-2}$. How the AChR cluster forms initially and is subsequently maintained are topics of extensive current research. There appear to be at least two components of this process: the aggregation of AChRs within the membrane of the muscle fiber and the enhanced expression of the genes encoding the AChR subunits by the myonuclei closest to the site of nerve contact.

AChR aggregation AChRs can exist in a form that is mobile in the plane of the cell membrane. In the case of cultured immature frog muscle precursor cells, such mobile AChRs aggregate at sites of contact with motor axons, suggesting that the nerve induces aggregation of AChRs in the muscle cell. Much evidence suggests that it is a protein, agrin, which is made by and released from motor axons, that triggers AChR aggregation. Agrin function is associated with its activation of a muscle specific kinase (MuSK), which triggers downstream signaling cascades in the muscle. A second key player in the process of agrin-induced AChR aggregation is the 43 kDa protein rapsyn. Rapsyn links AChRs to the plasma membrane and to components of the membrane skeleton. In the absence of rapsyn, no aggregation of AChRs occurs.

There is also much evidence that AChRs can self-aggregate, and on suitable substrates they can form clusters similar to those at mature NMJs. Some recent

studies have shown that in some species and muscles, AChR clusters form in the region of presumptive NMJs before nerve-muscle contacts are made. In these cases, neuromuscular contacts may form selectively on the presumptive postsynaptic sites. On balance, it seems likely that while the muscle fiber surface has an inherent tendency to form AChR clusters, agrin released from the nerve can either trigger clustering *de novo* or stabilize preexisting clusters.

Upregulation of postsynaptic gene expression The second process that contributes to AChR accumulation at the mature NMJ is the enhanced expression of the genes that encode the AChR subunits. This process is discussed below.

Within a few days of nerve contact, acetylcholinesterase (AChE), the enzyme that terminates ACh-action, accumulates in the synaptic basal lamina that forms between the nerve and muscle cells. As for AChRs, this accumulation is associated with upregulation of the genes encoding AChE.

Schwann Cells: The Motor Neurons' Companion

Throughout most of their life, motor axons are closely accompanied by Schwann cells. There is increasing evidence of a mutual dependency of motor axons and their companion Schwann cells during NMJ development. Thus, if the motor axons are cut at birth, the Schwann cells associated with their degenerating distal portion die. This can be prevented by addition of neuregulin, a growth factor normally produced by the motor neuron. Consistent with a role for neuregulin in promoting Schwann cell survival is a reduction of Schwann cell numbers in mice in which neuregulin expression is reduced by genetic manipulation.

NMJ Maturation: Presynaptic

At birth, both the pre- and postsynaptic components of the NMJ of rats and mice are immature in structure, function, and molecular makeup. Nonetheless, neuromuscular transmission is adequate for the simple movements of the neonate. The adult form of the NMJ arises in concert with increasing motor activity during the next 3–4 weeks as the result of a program of coordinated events affecting the presynaptic nerve terminal and the postsynaptic surface of the muscle fiber.

Myelination of the Axon

In rats and mice, myelination of the peripheral nerves begins a day or two after birth. Within a further week or so, the extramuscular parts of the nerves are well myelinated. By contrast, although the fine intramuscular branches leading to individual muscle fibers remain in close contact with Schwann cells, they remain unmyelinated until the elimination of supernumerary innervation is complete.

Synapse Elimination

During the first 2 weeks or so after birth, all but one of the axons that initially innervate each muscle fiber withdraws, leaving a sole survivor (Figure 1). A similar process occurs at most of the vertebrate NMJs that have been investigated. In humans, synapse elimination is complete by about 14 weeks of gestation. This important process has been extensively investigated, both at the NMJ and in the CNS.

A very different pattern of muscle innervation occurs in the muscle of fish, some muscles in other lower vertebrates, and in a few muscles of mammals. In these muscles, the mature muscle fibers are innervated at multiple sites by numerous axons. Although the development of the innervation pattern in these multiply innervated muscles has not been studied in detail, it is clear that the immature nerve–muscle contacts are not restricted to a single site and that the local competition that occurs in most mammalian muscles does not occur. A common feature of these muscle fibers is that instead of generating action potentials, the contraction is triggered by the summed effects of the local depolarizations at the multiple sites of innervation.

Maturation of the Nerve Terminal

Once synapse elimination is complete, the terminal of the sole surviving motor axon expands significantly. This involves a broadening of the regions of contact with the muscle and an overall increase in the area of synaptic contact (Figure 2(a)). As the nerve terminal expands, it retains its close contact with the terminal Schwann cells, which increase in number as a result of continuing cell divisions.

The factors that limit or determine the size of the mature terminal are poorly understood. Zones of postsynaptic specialization can be induced in a variety of experimental conditions and may adopt a size and appearance remarkably similar to those at mature NMJs. This suggests that factors within the muscle play an important role in determining NMJ size and its well-established correlation with muscle fiber caliber. This view has found recent support from the discovery that a class of mutations of the gene encoding Dok-7, a postsynaptic protein that regulates MuSK activity, causes a reduction in human NMJ size without significant alteration in muscle fiber size or the local density of AChRs. It remains to be seen whether neuromuscular synaptic size–strength homoestasis in vertebrates is regulated by mechanisms

similar to those recently shown to operate in *Drosophila* larvae.

Transmitter release While growing motor axons may be able to release ACh in response to depolarization (see above), evidence from *in vitro* studies indicates that contact of the nerve terminal with muscle cells greatly increases the efficacy of quantal release. The structural basis of this enhanced release is unclear since active zones, the sites of nerve-induced quantal release at mature NMJs, have not been described until the NMJs acquire their mature form.

Even at immature NMJs, stimulation of any of the several axons innervating each muscle fiber is often adequate to trigger muscle contraction. However, the quantal content (the number of ACh quanta released by a single nerve impulse) is very low, initially about 5% of the adult value. During the 2–3 week period of synapse elimination, quantal release increases at some of the terminals at each NMJ while it declines at others. In general, greater quantal release is associated with a greater chance of a terminal's surviving the competitive process. Since transmitter release correlates strongly with synaptic size, and it is the smallest synapses that are ultimately eliminated, this association is perhaps not surprising. After synapse elimination is complete, the quantal content of the sole surviving input increases progressively, reaching its adult value at about 2 months of age. Part of this increase reflects the increasing size of the nerve terminal. In addition, there is an increase in the quantal release per unit area of membrane. This may be related to the maturation of the population of active zones.

Ca^{2+} Channel Switch

The changes in the effectiveness of quantal release are accompanied by a change in the type of calcium channels that trigger release. At adult mammalian NMJs, release is mediated by P/Q-type channels, as can be shown using selective blockers. In contrast, at the NMJs of newborn mice, both P/Q-type and N-type channels contribute to release. The contribution of the N-type channels is lost within 1–2 weeks after birth.

NMJ Maturation: Postsynaptic

Maturation of the nerve terminal is paralleled by numerous changes in the postsynaptic region of the muscle fiber that contribute to an increase in the speed and efficacy of neuromuscular transmission. This occurs in the context of a substantial increase in muscle fiber diameter. Immature muscle fibers typically have a diameter of 8–10 μm and relatively high electrical input resistance. As a result, relatively little ACh-induced current is required to depolarize them to the action potential threshold. This helps ensure effective neuromuscular transmission even when ACh output from the nerve is still low. As the muscle grows, the diameter of the fibers also grows, and their input resistance falls. A variety of changes in the postsynaptic region help to ensure and enhance the efficacy of transmission in spite of this.

Remodeling of the Postsynaptic Zone

As synapse elimination proceeds, important changes take place in the distribution of key synaptic molecules and in the conformation of the postsynaptic membrane.

Redistribution of AChRs and AChE At birth, the AChRs and AChE occupy more or less uniformly the oval plaque that defines the NMJ. With time, holes in this plaque appear where the density of postsynaptic molecules is relatively low. As synapse elimination is completed and the one surviving terminal begins to expand, the regions with a high density of postsynaptic molecules become closely associated with the nerve terminals, mirroring their pretzel-like shape (Figure 2(b)). In the case of AChRs, this redistribution is associated with a substantial increase in the local density, rising to about 10 000 μm^{-2}. A number of molecules associated with the AChRs, including rapsyn, utrophin, and syntrophin, undergo a similar redistribution. This suggests that there are close links between them and that these molecules may help to stabilize the AChR cluster by cross-linking to the cytoskeleton.

Appearance of voltage-gated sodium channels channels and postsynaptic folds At the mature NMJ, the postsynaptic membrane is highly folded, with the folds extending into the muscle fiber. The voltage-gated sodium channels that account for the action potential, of a type termed Na_V1, are highly concentrated in the depths of these folds and in a perijunctional zone a few micrometers wide (Figure 3(a)). During development in rats, these channels are first detectable around the time of birth, about a week after the AChRs. At this time, the Na_V1 channels are present in highest density in a diffuse band some 200–300 μm^2 wide, centered on the AChR cluster but extending well beyond it and lacking its distinct boundary (Figure 3(b)). Thus, the two types of ion channel that are central to the postsynaptic response to the nerve have very different developmental patterns of expression.

Formation of the folds The postsynaptic folds begin to develop soon after birth (Figure 4). The factors that

Figure 3 Voltage-gated sodium channels (Na$_V$1) at the mammalian neuromuscular junction (NMJ). (a) Adult rat. Na$_V$1s, shown in red, occupy the depths of the folded postsynaptic membrane and in the light microscope (left panel) appear as a red fringe surrounding the acetylcholine receptors (AChRs), shown in green. (b) Newborn rat. AChRs are concentrated in discrete spots at the immature NMJs while the Na$_V$1s, which are first detected at this age, have a much more diffuse distribution. (a) Reproduced from Slater CR (2003) Structural determinants of the reliability of synaptic transmission at the vertebrate neuromuscular junction. *Journal of Neurocytology* 32: 505–522, with the permission from Springer.

control their distribution and growth are poorly understood. It has been suggested that the opening of the fold represents a site of reduced nerve-muscle adhesion, possibly related to the presence of the active zones in the nerve terminal. However, folds also form in a variety of situations in which AChRs form clusters in the absence of the nerve. These include both denervated and regenerating muscle and muscle exposed to exogenously applied agrin, where AChR clusters associated with folds form at sites away from the NMJ.

From an early stage in fold formation during normal development, while AChRs are concentrated at the crests of the folds, nearest the nerve, the Na$_V$1 channels occupy the depths of the folds. This is likely to result from a high concentration of Na$_V$1 channels in the new membrane added during the process of fold formation combined with a barrier to diffusion of Na$_V$1 channels into the region of high AChR density.

Molecular Differentiation of the Postsynaptic Zone

The remodeling of the postsynaptic region is accompanied by changes in the patterns of isoforms of the ion channels expressed within it. These come about as a result of the combined effects of increasing muscle activity and signaling molecules released from the nerve on gene transcription in the subsynaptic myonuclei.

Changes in AChR expression After birth, the density of AChRs away from the NMJ declines so that in the adult it is generally undetectable. This is the result of suppression of AChR subunit gene transcription by muscle activity, mediated by the binding of myogenic regulatory factors to an E-box sequence in the genes of several AChR subunits. It raises a central question: How is it that AChRs remain at the NMJ itself? In brief, the answer is that agrin released from the nerve and bound to the synaptic basal lamina, through its activation of MuSK, induces activity-resistant transcription of the genes encoding both AChR subunits and a number of other postsynaptic proteins, by the myonuclei in the vicinity of the NMJ (see below).

In addition to the activity-mediated suppression of AChR expression away from the NMJ, there is a change in the type of AChRs expressed at the NMJ

Figure 4 Ultrastructural maturation of mouse neuromuscular junctions (NMJs); development of postsynaptic folds at NMJs in postnatal mouse extensor digitorum longus muscles. (a) In the newborn, few folds are present. Solid arrows, subjunctional cytoplasm rich in coated vesicle and coated pits; open arrows, multivesicular bodies. (b) At 2 weeks, folds are present but less well developed than in adult. (c) In the adult, folds are well formed and closely packed. itself. At birth the predominant fetal form of the AChR has a subunit composition of $\alpha_2\beta\delta\gamma$. During the first 2 weeks after birth, the γ subunit is replaced by an ε subunit to produce the adult form. Expression of the ε subunit is not suppressed by muscle activity. The two forms of AChR differ in their channel properties: The immature form has a longer mean open time (typically 7–8 ms) and a lower conductance (40–50 pS) than the adult form (1–2 ms; 50–60 pS). As a result, a single opening of average duration of a fetal AChR channel allows 3–4 times as much charge to enter the cell as an adult channel. This makes the fetal channels more efficient at converting bound ACh to charge entry. However, the slower kinetics of the currents mediated by fetal AChRs mean that immature NMJs are poorly suited to transmit the high-frequency repetitive activity that occurs in the mature animal. It is thus relevant that the changes in AChR properties occur at about the same time as the speeding up of the firing patterns of the motor neuron (see below) and the myelination of the most distal axons that allows those patterns to reach the NMJ.

Changes in Na_V1 expression An analogous change in isoform expression occurs for the Na_V1 channels. The first Na_V1 channels to appear are of an immature form, designated $Na_V1.5$. These differ from the adult form ($Na_V1.4$) in that they open at more-negative membrane potentials. As a result, less depolarization is required to trigger an action potential in an immature muscle than in a mature one. Expression of the gene encoding $Na_V1.5$, like that of the γ-AChR subunit gene, is suppressed by muscle activity, both at the NMJ and away from it. As a result, expression of $Na_V1.5$ declines to an undetectable level during the first 2–3 weeks after birth. Expression of the gene encoding $Na_V1.4$ is not sensitive to activity. Its expression first becomes detectable at birth and increases during the next few weeks, both away from the NMJ and at a higher level at the NMJ. The factors that control the onset of $Na_V1.4$ expression and its enhancement at the NMJ are not known.

mRNA accumulation The developmental increases in the concentration of AChR and Na_V1 at the NMJ are accompanied by localized increases in the levels of the mRNAs that encode them. At the mature NMJ, there is an increase in the concentration of mRNA encoding a number of critical postsynaptic proteins, including AChR subunits, AChE, and $Na_V1.4$, as well as supporting proteins including rapsyn and utrophin. These increases are apparent soon after birth and are probably induced by agrin acting via MuSK.

Accumulation of Myonuclei

The upregulation of expression at the NMJ of the genes encoding important components of the postsynaptic membrane is now believed to be induced by agrin acting via MuSK. At the NMJ, agrin is fixed in place by association with the synaptic basal lamina. This ensures that the effects of agrin are confined to the vicinity of the NMJ. The effective sphere of influence of this immobilized agrin is not more than about 100 μm, so myonuclei further than this from the NMJ do not have a synaptic profile of gene expression. At many NMJs, there is an accumulation of 5–10 myonuclei within this sphere of influence.

This amplifies the effect of the agrin–MuSK signaling system. The clustering of myonuclei begins soon after birth and is complete by about 1 month of age. The events leading to myonuclear accumulation are not yet understood.

Mammalian Motor Unit Maturation

The formation and maturation of the mammalian NMJ occurs in the context of the development of the motor unit as a whole. The maturation of the motor neuron, and in particular its pattern of firing, has an effect on the development of the NMJ itself. In turn, the increasing ability of the NMJ to transmit faithfully the patterns of activity arising in the motor neuron to the muscle fibers plays an important part in the acquisition of mature muscle properties. It may also lead to retrograde regulation of motor neuron properties.

Firing Patterns

In adult mammals, motor neurons vary considerably in their functional properties. Most notably, some fire action potentials in long trains at a frequency of 10–20 Hz while others fire in short bursts of 5–10 action potentials at frequencies of up to 100 Hz. Motor neurons in neonatal rats and mice fire at a uniformly low frequency and are often synchronized as a result of electrical coupling by gap junctions. The first evidence of faster, more adultlike firing patterns, and of differences between the firing patterns of different motor neurons, is seen about 2 weeks after birth, by which time electrical coupling is lost. The onset of these more adult firing properties coincides with the time of myelination of the most distal intramuscular nerve branches. It is likely that before this happens, these small branches would be unable to fire at high frequencies and could therefore not transmit the features of activity that distinguish different motor neurons in the adult.

Efficacy of Neuromuscular Transmission

During the early stage of polyaxonal innervation, more than one input to the muscle fiber is often capable of triggering contraction. As the competitive process unfolds, some inputs, and ultimately only one, come to have a much stronger impact on the muscle fiber than others. There is evidence that each branch of a motor axon competes locally at a given NMJ and that axons with the strongest input to a given NMJ are more likely to survive the competitive process than weaker ones. However, the evidence on this point is not clear cut, and neither of these findings fully explains the final outcome of the competition, in which a single motor axon, with appropriately matched properties, innervates each muscle fiber.

As the NMJ matures, both the pre- and postsynaptic components increase in size. For the muscle fiber, this results in a decrease in input resistance and therefore the need for a greater synaptic current to reach the action potential threshold reliably. This is achieved by the parallel increase in the size of the motor nerve terminal and with it, the quantal content. This, together with the folding of the postsynaptic membrane, results in the great reliability of neuromuscular transmission in the adult. The nature of the feedback mechanisms that regulate synaptic size and strength is intriguing, however, because one hallmark of the normal adult neuromuscular junction is a three- to fivefold excess of transmitter release over that required to trigger an action potential in the muscle fiber. This high safety factor ensures that every action potential entering a motor nerve terminal will normally trigger an action potential in all the muscle fiber it innervates.

Development of Muscle Fiber Homogeneity

An important consequence of the process of synapse elimination is that each motor neuron ends up innervating muscle fibers with very similar properties. Clear signs of increasing functional homogeneity of the muscle fibers within motor units are seen in mice 1–2 weeks after birth, as synapse elimination nears completion but before the distinctive patterns of activity of different motor units are well developed. It therefore seems unlikely that differences in activity patterns between motor neurons play a decisive role either in selecting which input survives at a given NMJ or in matching the properties of motor neurons to the muscle fibers they innervate. A possible alternative is that the matching of nerve and muscle cells is achieved by a molecular recognition system that involves activity-dependent expression of surface and/or diffusible molecules that interact so that during the process of synapse elimination, the most compatible nerve-muscle pairs survive at each developing NMJ. Such a mechanism could depend on activity as a driving force without the pattern of activity determining the specific outcome of the competition. As yet, however, no likely candidates for such a molecular recognition scheme have been identified.

It is also not yet clear how the properties of a mature muscle fiber are determined. There is good evidence for at least two very different, though not mutually exclusive, mechanisms. On the one hand, there is evidence that myoblasts are predetermined to make fast and slow muscle fibers even before myotube formation occurs. If correct, this mean that myoblasts of the same predisposition may fuse more or less selectively to make myotubes containing nuclei with intrinsically similar properties. On the other

hand, there is very strong evidence, particularly in mammals, that the properties of adult muscle fibers are sensitive to the patterns of activity they experience. This is consistent with the idea that the properties of a muscle fiber are modified after innervation by the pattern of activity of the motor neuron that innervates it. Both schemes raise important questions about how the muscle fibers innervated by a single motor neuron come to have the same properties.

Conclusions

The many changes in the structural, functional, and molecular properties of the NMJ that occur during its maturation adapt it for reliable high-frequency activation of mature muscle fibers. These changes are matched to complementary changes in the nerve and the muscle. Their overall effect is the conversion of an immature system that is good at generating slow muscle contractions in response to low-frequency activity in the nerve to a much faster system, adapted to the needs of a freely moving and increasingly independent animal.

The events that give rise to the mature NMJ are part of a coherent developmental program that defines the patterns of expression of a number of proteins, such as ion channels, that play central roles in neuromuscular transmission. In addition, it determines the size and conformation of the NMJ. Both aspects of the program have important consequences for the efficacy and reliability of the mature NMJ.

Neuromuscular Junction (NMJ): Postsynaptic Basal Lamina

M J Werle, University of Kansas Medical Center, Kansas City, KS, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The primary function of skeletal muscle is to produce force. This force is controlled by the motor neuron that contacts the cell. This cell-to-cell contact was best described by Ramón y Cajal as a 'protoplasmic kiss.' The synapse between the motor neuron and the skeletal muscle cell has many names, including motor endplate, neuromuscular synapse, and neuromuscular junction. We will refer to this synapse as the neuromuscular junction. There are three cellular components of the neuromuscular junction – the skeletal muscle cell, the motor neuron terminal (NT), and the terminal Schwann cell (SC) (Figure 1).

Surrounding the muscle cell is an extracellular matrix. The extracellular matrix also covers the Schwann cell. The focus of this article is the specialized extracellular matrix that is found between the nerve terminal and the skeletal muscle cell; this specialized extracellular matrix is called the synaptic basal lamina. The synaptic basal lamina contains many molecules that are commonly found in all basal laminae throughout the organism, but it also contains many molecules that are unique to the neuromuscular junction.

The extracellular matrix is a vital and regulated extension of the cell. The fact that the extracellular matrix is part of the cell is easily understood by the fact that the matrix attaches to a number of membrane-bound structures. These membrane-bound structures in turn attach to the cytoskeleton of the cell. The matrix thus provides mechanical support for the cell. This is particularly important when considering the fact that the muscle fiber is twitching and moving large distances. The motor neuron is very well attached to the surface of the muscle cell that it is innervating. For example, in Figure 1 the motor nerve terminal innervates the muscle cell seen at the bottom of the image. On top of the motor neuron sits the terminal Schwann cell. On top of the Schwann cell is another muscle cell that is regulated by another motor neuron. Thus, the two muscle cells in this image will twitch and move at different times. The extracellular matrix keeps the motor neuron precisely aligned with the muscle cell it innervates.

The precision at which the extracellular matrix aligns the motor neuron and muscle cell is astounding. The active zone is the site on the motor nerve terminal, where the synaptic vesicles fuse with the cell membrane to release the contents of the synaptic vesicle. This active zone is also the site where the voltage-gated calcium channels are concentrated in the membrane of the nerve terminal. The active zones are found precisely opposite the junctional folds in the skeletal muscle cell. The junctional folds are the invaginations in the membrane of the muscle cell. The acetylcholine receptors (AChRs) are concentrated on the crests of the junctional folds, immediately adjacent to the active zones from which ACh is released. The molecules in the synaptic basal lamina lie between these two membranes, and undoubtedly are intimately involved in both the mechanical linking of the two cells, and the cell-to-cell signaling that is essential for maintaining the structure and function of this synapse.

To provide a basis for understanding the synaptic basal lamina, in the following sections we first discuss the molecules that are found in all basal lamina. An important point to emphasize is that in a functional sense, the synaptic basal lamina extends across the nerve and muscle cell membranes to make contact with the cytoskeletons of both cells, thus accounting for the strong mechanical coupling between them. After considering all the extracellular molecules, we therefore discuss the multimolecular complexes that are found in the cell membrane and how they, in turn, are attached to the intracellular cytoskeleton. Finally, we discuss how the synaptic basal lamina is altered by the activities of proteases that cleave the matrix components. Altogether, these features reveal that the synaptic basal lamina is a dynamic cellular component that plays a critical role in the structure and function of the synapse.

Synaptic Basal Lamina Components

Collagen IV

The type IV collagens are critical components of basal laminae throughout the organism, and particularly of the synaptic basal lamina. There are features of collagen IV that are common to all basal laminae, and also specializations that are unique to the synaptic basal lamina.

The α chains of collagen IV have a long collagenous tail that has a glycine at every third amino acid. Characteristic of other collagen proteins there is a non-collagenous domain at the C-terminus; this region is called the NC1 domain. There are six genes that code for collagen IV α chains (*COL4A1* to *COL4A6*). These α chains can form either homo- or heterotrimers.

Figure 1 Electron micrograph of a neuromuscular junction from a mouse diaphragm. The left panel is an electron micrograph of a normal mouse neuromuscular junction. The right panel is the same image with the structures colorized and labeled. There are two muscle cells (red and light red). The muscle cell on the bottom is the cell that is innervated by the nerve terminal (green; NT). There is a separate muscle cell that sits on top of the nerve terminal; on top of the nerve terminal is a Schwann cell (yellow; SC). Also seen are the subsynaptic nucleus of the muscle cell (dark red; N) and the mitochondria (blue) in the muscles and in the nerve terminal. Also within the nerve terminal are clusters of synaptic vesicles (dark green). These synaptic vesicles are focused on the active zones (dark black). The active zones are found opposite the mouths of the junctional folds (JF). The synaptic basal lamina (SBL; red) is found in the area between the nerve terminal and the muscle cell on the bottom.

There could therefore be a large number of different combinations, but the only identified groupings are (two α1 and one α2); (α3, α, α5), and (two α5 and one α6). α1 and α2 are found everywhere in the basal laminae, but α3, α4, α5, and α6 are concentrated at the synaptic basal lamina.

The type IV collagens form a meshwork that is critical to the structure of the basal lamina. Three individual collagen IV α chains will combine to form a flexible trimer. The trimer is organized such that the NC1 domains are bundled together at one end, and the N-terminal 7S domains are bundled at the other end. These collagen IV trimers can further associate into larger structures. The N-terminal 7S domains from four trimers will bind to form an X-shaped structure, with the NC1 domains pointed outward (Figure 2). The NC1 domains on collagen IV trimers can then bind head to head with the NC1 domains on a separate collagen IV trimer. The resulting structure is a well-organized and regular meshwork of collagen IV.

The type IV collagens can also associate with other components of the synaptic basal lamina, and with proteins on the surface of the muscle, nerve terminal, and Schwann cell. In the synaptic basal lamina, the most common binding partners are the nidogens, which link the collagen IV meshwork to the laminins. On the cell surfaces, the NC1 domains can interact with integrins, proteoglycans, and the dystroglycan complex. Matrix metalloproteinases can cleave the type IV collagen, and this cleavage results in the release of the NC1 domains. The soluble NC1 domains are known to have potent effects on vascular formation, but the role of the NC1 domain at the neuromuscular junction is still largely unknown.

Figure 2 Highly schematic diagram of the type IV collagen meshwork in the basal lamina. Each collagen IV protein has an NC1 domain that is depicted as an oval, and a long collagenous tail. Three subunits assemble into a trimer, with the NC1 domains grouped together, and the collagenous tails intertwined. The NC1 domains from two trimers will interact head to head, and the 7S domains from four trimers will interact to form an X-shaped structure. The individual collagen IV proteins are depicted as either red, green, or blue. This diagram is overly simplified to show a single sheet of the collagen IV matrix.

Laminins

Laminins are heterotrimeric glycoprotein structures. Each laminin is composed of one α subunit, one β subunit, and one γ subunit. There are five genes

that code for α subunits, four genes that code for β subunits, and three genes that code for γ subunits. Of the myriad of possible combinations, currently there are 15 identified laminins. The laminins are important components of basal laminae throughout the organism, and play a special role at the neuromuscular junction.

The skeletal muscle cell produces the laminins found surrounding the skeletal muscle cell in the extrajunctional regions, and also the laminins found in the synaptic cleft. There are strong differences in the distribution of the various laminin subunits, revealing that the release of the laminins by the muscle cell is controlled. The subunits produced by the skeletal muscle cell are predominantly the $\alpha2$, $\alpha4$, or $\alpha5$, plus the $\beta1$, $\beta2$, and $\gamma1$ subunits. Of particular importance to the neuromuscular junction is the $\beta2$ subunit. The $\beta2$-containing laminins are highly concentrated at the synaptic cleft. Since the skeletal muscle cell produces the laminins, the production and release of the $\beta2$ subunit must be tightly controlled. The mechanism is still unknown. The $\beta2$-containing laminins do play an important role in the structure and function of the synapse. Mice that lack the $\beta2$ subunit have defects in synaptic release. The mice die at an early age due to a combination of problems associated with the loss of synaptic function, and also the loss of kidney function. One of the main features observed is the infiltration of the Schwann cell into the synaptic cleft. Thus one of the cellular mechanisms performed by the $\beta2$ subunit may be to stop the Schwann cell from wrapping the nerve terminal. In addition, the $\beta2$ laminin null mutants have disrupted active zones. Thus, the $\beta2$ subunit plays an important role in both the structure and function of the synapse.

The distribution of the α subunit is also controlled by the skeletal muscle cell. The $\alpha2$ subunit is predominantly found in the extrasynaptic basal lamina. The $\alpha5$ subunit is found concentrated at the neuromuscular junction, and it extends into the junctional folds. The $\alpha4$ subunit is found concentrated in a small, specialized region of the synaptic basal lamina. Of particular interest are recent findings that the $\alpha4$ subunit will bind to the voltage-gated calcium channels on the nerve terminal. The distribution and binding of the $\alpha4$ subunit reveal that this laminin chain is likely to play an important role in the communication between the muscle and the nerve terminal.

Nidogens (Entactins)

There are two nidogens in mammalian species. Nidogen-1 is a 150-kDa glycoprotein. It is a common component of all basal laminae, where it acts as a link by binding to both type IV collagens and laminin. Nidogen-2 is found in the basal lamina of skeletal muscle and its distribution mirrors that of nidogen-1. Nidogen-2 will bind to perlecan and collagen IV. Nidogen-2 also weakly binds to laminin-1. Interestingly, mice deficient in nidogen-1 have an apparently normal phenotype, and nidogen-2 is upregulated in the skeletal muscles of these animals. At the neuromuscular junction there is a uniquely glycosylated form of entactin. The size (150 kDa) and the activity of this uniquely glycosylated form of entactin are consistent with its identification as nidogen-1. There is also recent evidence revealing that nidogen can play a role in central nervous system (CNS) synaptic release, thus it is likely that the nidogens play a role at the neuromuscular junction.

Fibronectin

Fibronectin is a large glycoprotein that plays an important role in linking integrins to the extracellular matrix. Fibronectin will bind to a large number of matrix components, and substrates. The important binding partners in the synaptic basal lamina are the collagens and heparan sulfate proteoglycans (predominantly agrin). Fibronectin will then bind to the integrins on the surface of either the muscle cell or the nerve terminal. Fibronectin binding has been shown to alter synaptic release from the motor nerve terminal in culture, and to influence AChR aggregation in cultured myotubes. This activity has been shown to be dependent upon the activation of protein kinases in the cells. Thus, fibronectin acts as a mechanical link between matrix proteins in the extracellular matrix. It also acts as a mechanical link between the matrix and the cell cytoskeleton via the integrin. The binding to integrin also serves as a cell-signaling ligand that increases protein kinase activity. The protein kinase activity has been shown to work predominantly through protein kinases A and C, but it is likely that other protein kinases are also implicated in this signaling.

Heparan Sulfate Proteoglycans

Heparan sulfate proteoglycans (HSPGs) are a family of glycoproteins that share unique features. The molecules contain a protein core with large carbohydrate chains. The carbohydrate chains are sensitive to heparitinase. HSPGs are negatively charged. In their native forms the HSPGs run in bands as an extremely large smear (>200 kDa) when separated by apparent molecular mass in polyacrylamide gels. After heparitinase treatment the core protein is much smaller in size. HSPGs are found in all basal laminae and also associated with the cell surfaces. The three

major HSPGs found in skeletal muscle extracellular matrix are perlecan, agrin, and collagen XVIII.

Perlecan Perlecan has a widespread distribution. It is found in all basal laminae, and plays an important role in the storage and release of growth factors. There are three glycosaminoglycan (GAG) side chains extending form the N-terminal region.

Collagen XVIII Collagen XVIII has been recently shown to be a HSPG and to be present in the basal lamina of skeletal muscle. Loss of collagen XVIII in *Caenorhabditis elegans* has been shown to disrupt neuromuscular junction formation. There are no reports showing that collagen XVIII is concentrated at the vertebrate neuromuscular junction, so it remains unclear whether it has a function there.

Agrin Agrin is the most extensively studied HSPG at the neuromuscular junction, and it plays a pivotal role in the structure and function of the neuromuscular junction. Early experiments performed by UJ McMahan and colleagues were instrumental in revealing the fact that cell-signaling molecules were found in the extracellular matrix. When muscle fibers were damaged, in a way that left the extracellular matrix intact, the damaged portions of the muscle cells would be removed. In addition, the nerve terminal could be removed, leaving behind an empty basal lamina sheath. When the muscle cell regenerated by the proliferation and fusion of skeletal muscle satellite cells, the skeletal muscle would reform within the basal lamina sheath. The regenerated muscle cells would aggregate AChRs on their surfaces precisely at the spot that they contacted the previous synaptic site on the basal lamina. These experiments clearly showed that molecules stably bound to the synaptic basal lamina could direct the aggregation of AChRs on the surface of the muscle cell. Subsequent experiments revealed that the protein agrin could direct the aggregation of AChRs in culture. Mice that lack agrin do not develop neuromuscular junctions, and these mice die at birth.

Agrin is a multifunctional component of the synaptic basal lamina. The C-terminal region of agrin has been most extensively studied, since this is the region that is sufficient to induce the aggregation of AChRs. The number of other molecules that interact with agrin at the neuromuscular junction is extensive. The N-terminal region of agrin has been shown to bind to laminin. Agrin will also bind to α-dystroglycan and thus helps to link the dystroglycan complex to the extracellular matrix. Agrin will also bind to integrins, and to neural cell adhesion molecules (N-CAMs) on the surface of the motor neuron and muscle cell. In addition to these interactions, agrin will also bind to nidogen and collagen. Agrin clearly plays an important role in the structure and function of the neuromuscular junction, and this role is both structural (linking other proteins in the intracellular matrix together) and functional (acting as a cell-signaling molecule).

AChE

The main form of acetylcholinesterase (AChE) at the neuromuscular junction and the synaptic basal lamina is the collagen-tailed form of AChE, ColQ-AChE. ColQ-AChE is bound to the heparan sulfate proteoglycan perlecan and will also interact with the muscle-specific tyrosine kinase receptor. Its main function is to remove ACh from the synaptic cleft. In fact, the ACh released from the nerve terminal must first run the gauntlet of AChE that is bound to the synaptic basal lamina, before it can bind to the AChR concentrated on the crests of the junctional folds.

Cell Surface and Membrane Receptors

Dystroglycan Complex

The main components of the dystroglycan complex are α- and β-dystroglycan. These two forms are from a single gene, but have very different sizes and properties. The α-dystroglycan is 156 kDa in size; it is an extracellular protein that binds noncovalently to β-dystroglycan in the dystroglycan complex, on the one hand, and to laminin and/or agrin in the extracellular matrix, on the other. β-Dystroglycan is a 43 kDa glycoprotein and is an integral membrane protein. Numerous other proteins associate with the dystroglycans and together they form a large structure called the dystroglycan complex. The other members of the dystroglycan complex are the sarcoglycans (α-, β-, δ-, and γ-sarcoglycans), α-dystrobrevin, neuronal NO synthase (nNOS), and the syntrophins (α, β1, and β2). In addition, and of critical importance, the dystroglycan complex will bind to dystrophin or utrophin.

On the intracellular side, the dystroglycan complex will bind to the proteins dystrophin or utrophin. In turn, dystrophin and utrophin will bind to the actin cytoskeleton. The protein utrophin is shorter than dystrophin, and utrophin is concentrated at the neuromuscular junction. The dystroglycan complex is found throughout the entire length of the skeletal muscle cell and is particularly concentrated at the neuromuscular junction and the myotendinous junction. The dystroglycan complex is greatly reduced in Duchenne muscular dystrophy patients, who suffer from muscle fiber breakdown and degeneration. Thus, the dystroglycan complex plays an important

role in linking the intracellular actin cytoskeleton to the extracellular matrix. This link is undoubtedly important in the structural integrity of the muscle cell membrane and is probably critical to protect the membrane from tears that would result from the contractions of the skeletal muscle cell. At the neuromuscular junction the dystroglycan complex may also play an important role in cell-to-cell signaling. The binding of agrin to dystroglycan may be an important feature of the processes that regulate the induction and maintenance of the postsynaptic apparatus in muscle. The exact role of the agrin/dystroglycan complex interaction in postsynaptic signaling is still unknown.

MuSK

The aggregation of AChRs induced by agrin depends absolutely on the presence of a muscle-specific tyrosine kinase (MuSK). MuSK is clearly a downstream mediator of agrin, and MuSK knockout mice have virtually the same phenotype as those lacking agrin. However, the direct binding of agrin to MuSK has not been demonstrated, and the exact choreography of the events that start with agrin and end with the activation of MuSK has not been determined. MuSK has a large extracellular domain and an intracellular kinase domain. More recently it has been found that MuSK is required for the anchoring of the ColQ-AChE complex to the synaptic site. It is also been shown that the Abl kinases (Abl1 and Abl2) are downstream of activated MuSK. Thus, MuSK plays a central role in the events leading to the proper formation of the neuromuscular junction.

Integrins

Integrins are transmembrane protein complexes that form from heterodimers of α and β chains. Both chains are important for ligand binding. There are 18 α subunits and eight β subunits known, and currently 24 unique combinations of these have been identified. In addition, many of the subunits are alternatively spliced so that there are multiple variants of many subunits. Of particular interest is the $\alpha7$ subunit, since it is found concentrated at the neuromuscular junction. The $\alpha7$ subunit interacts with the $\beta1$ to form the $\alpha7\beta1$ integrin. This integrin binds to laminin via the RGD (arginine-glycine-aspartate) domain on the $\beta2$ arm of the synaptic laminin. The $\alpha7$ subunit is alternatively spliced, and there are at least six variants of the $\alpha7$ integrin.

While the binding of the $\alpha7\beta1$ integrin to laminin is a structural link between the matrix and the cell, the integrins also participate in intracellular signaling. On the intracellular side the integrins play a key role in linking to the actin cytoskeleton. This linkage is very similar to the molecular linkage found in a focal adhesion. Namely, the integrin binds to vinculin, α-actinin, and talin. All of these components are found aggregated at the postsynaptic site. In addition, integrins play an important role in regulating the activities of kinases. Of particular interest are the Src kinase family members Abl and Fyn, which have been shown to play a role in the assembly and maintenance of the postsynaptic apparatus. Thus, the integrins play an important structural and signaling role in the postsynaptic apparatus.

Integrins also are likely to play a presynaptic role, since treatment of frog muscles with RGD-containing peptides will reduce the increase in miniature endplate potential release upon muscle stretch. In addition to the $\alpha7\beta1$ integrins, the $\alpha3\beta1$ integrins are found at the presynaptic active zones. The $\alpha3\beta1$ integrins also interact with laminins in the synaptic basal lamina and can activate intracellular kinases. The precise role of the $\alpha3\beta1$ integrin is still largely unknown, but it is clear, at least in frogs, that the binding of integrin to matrix also has an important presynaptic cell-signaling function.

Cadherins

Cadherins are membrane-bound proteins that require calcium for their activity. They play an important role in the early development of the skeletal muscle cell. There are many cadherins, but the main ones produced in adult skeletal muscle are neural (N)-cadherin and muscle (M)-cadherin. Immunolabeling studies have revealed that both N-cadherin and M-cadherin are concentrated at the neuromuscular junction. The role of cadherins at the neuromuscular junction has been largely uninvestigated. N-Cadherin promotes neurite outgrowth *in vitro* and it is of interest that this effect is blocked by agrin. Both N-cadherin and M-cadherin play an important role in the formation of multinucleated muscle cells. They also may play a role at the synapse. The cadherins will form calcium-dependant bonds with cadherins on adjacent cells. Cadherins also interact on the intracellular surface with catenins. The α-, β-, and δ-catenins have been detected at the neuromuscular junction. In other systems it is known that the α- and β-catenins form a link with the actin cytoskeleton. In addition, the liberation of β-catenin from cadherins can result in nucleocytoplasmic shuttling to alter gene transcription via the interaction of β-catenin with T cell factor (TCF). Similarly, δ-catenin has also been shown to be present at the neuromuscular junction and interacts with the promoter region of rapsyn. Altogether, these results argue that the cadherin system functions at the neuromuscular junction to regulate cell structure and function.

Proteases at the Neuromuscular Junction

Matrix Metalloproteinases

The matrix metalloproteinases (MMPs) are a large family of enzymes whose main function is to degrade the extracellular matrix. There are over 25 metalloproteinases, each with preferred matrix substrates. Most MMPs are released from cells in a pro form and must be first activated by other proteases. While it is clear that the MMPs play a role in matrix development and remodeling, it is clear that they also have an influence on cell-to-cell signaling. For example, cleavage of the NC1 domain from type IV collagens is known to play a major role in the signaling of vascular development and remodeling. The strongest evidence for the involvement of MMPs at the neuromuscular junction is the fact that mice that lack MMP3 have increased junctional folds and have AChR receptors on their surface. This likely results from an accumulation of matrix molecules that would normally be removed by MMP3, particularly agrin. MMP2 and MMP9 have been shown to play an important role in the reinnervation of muscle following nerve damage. The fact that MMPs are present at the neuromuscular junction is not a surprise, since it is clear that the matrix must be remodeled to allow synaptic growth. The mechanisms that control MMP activation at the neuromuscular junction are still unknown.

Tissue Inhibitors of Metalloproteinases

Balancing the activity of the MMPs are the tissue inhibitors of metalloproteinases (TIMPs). There are four TIMPs, and one of these, TIMP2, has been shown to be present at the neuromuscular junction. Mice that lack TIMP2 have altered neuromuscular junctions. TIMPs inhibit MMPs, but are also required for the activation of some MMPs. Thus, there is a delicate balance between the activity of MMPs and TIMPs. The control of matrix structure and function is likely to be central to the mechanisms that control synaptic structure and function.

Conclusion

The synaptic basal lamina contains molecules that are common to all basal laminae throughout the body, and also a number of unique molecules. The synaptic basal lamina has both a structural role that links the cytoskeletons of the synaptic components, and a cell-to-cell signaling role. The organization of the synaptic basal lamina is extremely precise, and the maintenance of this structure is undoubtedly important in the organization of the synapse. The synaptic basal lamina is a dynamic structure, and proteases are constantly sculpting this complex matrix. The control of matrix structure and function is likely to be central to the mechanisms that control synaptic structure and function.

Neuromuscular Junction (NMJ): Postsynaptic Events in Neuromuscular Transmission

Essentials of Neuromuscular Transmission in Vertebrates

The neuromuscular junction (NMJ) is the interface between the central nervous system and the muscles it controls. The contraction of muscle fibers is activated by depolarization of the muscle fiber membrane. When motor neuron firing is triggered, action potentials (APs) are initiated near the nerve cell body and then travel along the motor axon to the NMJ. There, the AP causes the release of neurotransmitter molecules that act locally to depolarize the postsynaptic muscle fiber. The ultimate effect of the transmitter is to make the muscle contract. In most vertebrate muscle fibers, an essential intermediate step in the process of neuromuscular transmission is the generation of an AP in the muscle fiber. This AP travels rapidly along the muscle fiber, activating contraction of the whole fiber at nearly the same time. This article describes how vertebrate muscles respond to transmitter released from the nerve and how the APs that activate muscle contraction are generated. In the invertebrates, most muscles do not generate APs and the details of muscle activation are therefore somewhat different. This is also true of a distinct class of electrically inexcitable muscle fibers in vertebrates, discussed briefly at the end of this article.

Most vertebrate twitch muscle fibers are innervated at a single site, often roughly midway along the length of the fiber, by a single motor axon. Following a nerve AP, transmitter released from the nerve causes a local reduction in membrane potential, or depolarization, of the muscle fiber. This brief event (~10 ms) is referred to as the endplate potential (EPP; **Figure 1**), since the NMJ is sometimes called the motor endplate. The EPP is a local event that has its maximum amplitude at the NMJ and declines to a low level within 1–2 mm along the fiber (see later). Since muscle fibers may be more than 10 cm long, some other event must account for the depolarization that activates contraction. This event is the AP (**Figure 1(a)**), which can propagate rapidly in an all-or-none fashion from the NMJ to the ends of the muscle fiber.

APs are generally triggered when the membrane potential of the muscle fiber becomes less negative than about −60 to −55 mV. Thus, from a resting potential of −90 to −70 mV, the membrane must be depolarized by at least 25 mV. In most vertebrates, the EPP is substantially larger than required to reach the AP threshold. This results in very reliable and complete activation of the contractile apparatus, leading to an 'all-or-none' twitch contraction, in each muscle fiber, by every motor nerve impulse.

The postsynaptic events of neuromuscular transmission occur within the highly specialized region of the muscle fiber known as the postsynaptic apparatus. This region contains very high concentrations of the ion channels that mediate the response of the muscle fiber to the transmitter released from the nerve. In many vertebrates, there are also striking structural features of this region, including a highly folded surface membrane and an accumulation of specialized myonuclei with distinctive patterns of gene expression.

AChRs and the Generation of the Endplate Current

The neurotransmitter acetylcholine (ACh) is released from the vertebrate motor axon terminal in multimolecular quanta. The ACh causes a depolarization by binding to, and thus opening, cation-selective ion channels in the muscle fiber membrane known as ACh receptors (AChRs; **Figures 2(a) and 2(b)**). When these channels open, the internal negativity of the muscle fiber drives the net entry of positive ions into the cell. It is this effect that gives rise to the depolarizing phase of the EPP.

The AChRs present at the vertebrate NMJ are pentameric complexes of four types of subunits (**Figure 2(a)**). While the structures of these subunits are broadly similar there are also important differences and each subunit is encoded by a different gene. In the muscles of some lower vertebrates, and in immature or paralyzed mammalian muscles, each AChR molecule has two α-subunits and one each of β-, δ-, and γ-subunits. In many vertebrates, including mammals, the γ-subunit is largely replaced by an ε-subunit. Each subunit has a molecular mass of about 50 kDa, so the entire complex has a molecular mass of about 250 kDa. Every AChR molecule has two ACh binding sites, each of which includes part of one α-subunit.

When no ACh is bound, the AChR channel is closed and no current flows through it. To open the channel, two ACh molecules must bind, one to each binding site. When this happens the channel opens rapidly (**Figure 2 (b)**). The open channel has a conductance of about 30–50 pS. In the ionic conditions found in an intact mammal, the entry of positive charge through this

Figure 1 Electrical events associated with transmitter action at the vertebrate NMJ. (a) Intracellular recordings of endplate potentials (EPP) and action potentials (AP). When the EPP fails to reach the AP threshold (horizontal dashed line) no AP is generated. The smaller EPPs illustrated were recorded during partial block of AChRs by curare. The larger EPPs illustrated were recorded during block of Na_V1 channels in the muscle fiber by a cone snail toxin. These EPPs would normally trigger an AP. (b) Miniature endplate currents (mEPC) result from the flow of current into the muscle fiber induced by a single quantum of ACh. The nerve impulse causes the release and action of many quanta, resulting in the much larger endplate current (EPC). The electrical properties of the muscle fiber convert these currents into equivalent changes in membrane potential, the miniature endplate potential (mEPP) and the larger endplate potential (EPP). Note that the potential changes are slower than the currents that give rise to them, a result of the membrane capacitance.

conductance represents an 'inward' current of about 2.5–4 pA (Figure 2(c)). After being opened, each channel closes spontaneously and abruptly, on average after about 1 ms (for AChRs containing an ε-subunit). However, the duration of open times, even of the same channel on different occasions, varies considerably and randomly, with brief openings being the most common and long open times the least common.

At the vertebrate NMJ, each ACh quantum consists of 5000–10 000 molecules. Each quantum causes the opening of 1000–2000 ACh-gated channels, resulting in a brief influx of a current of about 3–5 nA into the muscle fiber. The current induced by a single quantum is known as a miniature endplate current (mEPC; Figure 1(b)). Although all the channels activated by a single quantum of ACh open almost simultaneously, the variability of the open times means that some close very quickly and others remain open for several milliseconds. As a result, the shape of the mEPC differs from that of the individual channels, having an abrupt rise to a maximum value and a slower exponential decay with a time constant of 1–1.5 ms (Figures 1(b) and 2(d)). In the case of AChRs containing a γ-subunit (see earlier), the time constant is severalfold longer.

Figure 2 Acetylcholine receptors (AChRs) mediate permeability changes in the postsynaptic membrane. (a) The five subunits of the AChR associate to form a pore that spans the plasma membrane. (b) A model of the open and closed states of the AChR as viewed looking along the pore axis. Small relative movements of the subunits, induced by ACh binding, result in changes in the diameter of the ion pore that have a big impact on permeability. (c) Record of current flowing through a single AChR channel. Each event has an abrupt start and finish. Although the duration of the open states varies, the intensity of the current in different events is very similar. (d) Scheme of how single channel openings sum to give rise to a mEPC. In the upper part, each of six channels is shown to open simultaneously. Each channel stays open for a time that varies randomly about a mean value. Thus the six channels close at different times. In the lower part is shown a model mEPC consisting of the sum of the currents flowing through the six channels. It decays exponentially from the initial peak with a time constant equal to the duration of the mean open time of the individual channels. (b) Diagram provided by Nigel Unwin. (c) Reprinted by permission from Macmillan Publishers Ltd: [Nature] Mishina M, Takai T, Imoto K, et al. (1986) Molecular distinction between fetal and adult forms of muscle acetylcholine receptor. *Nature* 321: 406–411, copyright (1986).

At the NMJ of vertebrate twitch muscles, between 20 and 200 quanta are typically released by a single nerve AP. In general, the sites of release of these quanta are distributed randomly over the entire NMJ. The AChR channels opened by a single quantum do so within less than 100 μs. During this time ACh molecules, on average, can diffuse about 0.3 μm. Each quantum thus acts on about 0.25 μm^2 of postsynaptic membrane. For most vertebrate NMJs, this is less than 0.1% of the membrane containing AChRs. As a result, the sites of action of individual quanta on the muscle fiber membrane are effectively separated from each other, allowing the effects of the individual quanta to sum to produce the much larger endplate current (EPC; Figure 1(b)). In different vertebrate species, the EPC may vary in amplitude from 200 to 2000 nA. Since the quanta released by a single nerve AP act almost simultaneously on the muscle, the time course of the EPC is usually very similar to that of the mEPCs.

From EPCs to EPPs

The passive electrical properties of the muscle fiber determine how the current of the EPC is converted into the depolarization that is the EPP. A brief account of these properties is given in the following sections.

Passive Cable Properties of Muscle Fibers

The flow of current in muscle fibers is governed by the so-called cable properties of the cell. These derive from the relatively high electrical conductivity of the cytoplasm and the low conductivity (or high resistivity) of the plasma membrane. Current entering the cell at a point, such as the NMJ, may flow longitudinally in the cytoplasm or transversely through the membrane (Figure 3(a)). Only the latter pathway leads to a change in the membrane potential. The fraction of the current that takes each route depends on the relative resistance each pathway presents. In practice, the conductivity of the cytoplasm is roughly the same in most cells and the resistivity of the membrane is similar in many (but not all) skeletal muscle fibers. As a result, the dominant factor determining the distribution of current flow in different muscle fibers is their diameter. When the diameter is large, current can flow much more easily along the muscle fiber than across the membrane, and there is relatively little voltage change across the membrane at the site of current entry. In contrast, if the diameter is small, the resistance to longitudinal current flow is high and more current crosses the membrane close to the site of entry, giving rise to a larger local change in voltage.

The peak amplitude of the potential change caused by a given intensity of current flow entering the cell at a single point is determined by the so-called input resistance of the muscle fiber. Typical vertebrate skeletal muscle fibers have 'input resistances' of

Figure 3 The passive electrical properties of the muscle fiber shape the voltage change caused by current flowing across the membrane. (a) Diagram of a typical experiment. Two electrodes are placed within the muscle fiber, one to pass current into the cell (*i*) and the other to measure the resulting change in transmembrane potential (*V*). Arrows show flow of current. The current across the membrane is greatest near the site of current injection and decreases with distance from that site. (b) Decay of transmembrane potential (*V*m) with distance from the site of injection. The space constant (λ) is the distance at which the potential has fallen to 36% (1/*e*) of its maximum (*V*o). (c) Changes in membrane potential (upper part) in response to rectangular current pulses. Note the slower change in voltage due to the capacitance of the membrane. Horizontal dashed line shows AP threshold: depolarizations greater than this trigger an AP. (d) Potential changes in response to injection of current with a time course similar to that of the postsynaptic mEPC and EPC that occur during neuromuscular transmission. Note that the passive properties of the membrane convert these currents into potential changes very similar to mEPP and EPP. The action potential threshold is very similar to that observed with rectangular pulses. (c) Reproduced from Wood SJ and Slater CR (1995) Action potential generation in rat slow- and fast-twitch muscles. *Journal of Physiology* 486: 401–410, with permission from Blackwell Publishing. (d) Reproduced from Wood SJ and Slater CR (1997) The contribution of postsynaptic folds to the safety factor for neuromuscular transmission in rat fast- and slow-twitch muscles. *Journal of Physiology* 500: 165–176, with permission from Blackwell Publishing.

0.2–1 MΩ (see later). If the full amplitude of the EPC (e.g., 250 nA) were instantly converted into a depolarization, its value (for a resistance of 0.4 MΩ) would be 100 mV.

Spatial factors The decay of potential from a site of current injection (e.g., the NMJ) can usually be approximately described by a single exponential (Figure 3(b)). For many vertebrate muscle fibers, the

space constant of the decay – that is, the distance required for the potential to drop to 37% (1/*e*) of its value at the origin – is 0.5–2 mm. It is because of this that the ACh released from the nerve has little direct effect on the membrane potential more than a few millimeters away from the NMJ.

Effects of membrane capacitance Like all cell membranes, the muscle fiber membrane has electrical capacitance as well as resistance. When positive charge enters the cell through the opened AChRs, it must bring about a reorientation of the charge stored in the molecular dipoles in the membrane before a potential difference develops across the membrane. This takes time. For an instantaneous change in current flow across the membrane of a mammalian muscle fiber, the voltage typically takes 3–5 ms to reach 84% of that, a measure of the so-called time constant of the muscle fiber (Figure 3(c)).

For a flow of current which is brief relative to the membrane time constant, such as the mEPC, the capacitance distorts the time course of the resulting voltage change (Figure 3(d)). In addition, because the mEPC is short relative to the time constant of the membrane, the potential never reaches the maximum value that corresponds to the current at the peak of the mEPC. In practice, the distorting effect of the membrane capacitance means that the observed peak amplitude of the EPP is typically about 30–40 mV.

Initiation of the Muscle AP

Most vertebrate skeletal muscle fibers, like neurons, have voltage-gated sodium channels in their membranes. The specific forms of these channels present in vertebrate skeletal muscle are of the class designated as Na_V1 and are very similar in their structure and function to those in other excitable tissues. However, they differ in detail and are encoded by different genes which are normally expressed only in muscle cells. Each Na_V1 channel contains a major pore-forming α-subunit with a molecular mass of about 250 kDa and a smaller accessory β-subunit. Like most voltage-gated ion channels, Na_V1 channels are largely closed at the normal resting membrane potential and open when the membrane potential becomes sufficiently less negative. In the case of Na_V1 channels in mammalian muscle fibers, opening begins at a membrane potential of about −60 mV and is maximal at about −30 mV.

In a vertebrate twitch muscle fiber, the action potential is normally initiated at a single point along its length, the NMJ. In order for this to happen, the charge entering at that point, and the depolarization it gives rise to, must open sufficient nearby Na_V1 channels so that the inward current entering through them outweighs the flow of longitudinal current away from the NMJ and thus brings the surrounding membrane to threshold. In muscle fibers, this threshold is conventionally measured away from the NMJ using two closely spaced (<100 μm) intracellular electrodes, one to pass current and the other to record the resulting change in membrane potential (Figure 3(a)). In rat skeletal muscle fibers in which the resting potential is maintained at −80 mV, the threshold recorded in this way, using a current pulse that is long relative to the AP, is about −55 mV (Figure 3(c)). In other words, a depolarization of about 25 mV is required to initiate an AP. A similar threshold depolarization is observed when a current pulse which has a time course and amplitude similar to that of an EPC is used (Figure 3(d)).

A number of observations in mammalian muscle suggest that the effective threshold at the NMJ is significantly less than in the extrajunctional region. For example, when the amplitudes of the EPP and EPC are progressively decreased by adding the AChR blocker curare, EPPs as small as 12 mV (starting from a resting potential of −80 mV) can just trigger an AP. To understand the basis of this effect, it is necessary first to consider the structure and molecular organization of the postsynaptic region.

Structure of the Postsynaptic Apparatus

A striking feature of the postsynaptic region at many, but by no means all, vertebrate NMJs is the presence of infoldings of the muscle fiber membrane (Figure 4). These are typically 0.5–1 μm deep, 0.1 μm wide, and spaced 0.5–2 μm apart. Detailed investigation of mammalian NMJs, where the folds are particularly prominent, has shown that there is a remarkable degree of segregation of ion channels within the postsynaptic membrane.

At the crests of the folds, close to the overlying motor nerve terminal, AChRs are clustered at a density of approximately 10 000 μm^{-2}. This means that the individual AChR molecules are virtually in contact with each other in a near-crystalline array. The region of high AChR density typically extends about one-third of the way down the fold, where it ends abruptly. Outside this region, the density of AChRs is generally no more than a few per square micrometer.

In contrast to the membrane at the crests of the folds, that in the depths of the folds, and in a perijunctional zone extending about 20–30 μm away from the NMJ, contains a high density of Na_V1 channels. While the absolute density of these channels is not known accurately, it is estimated to be about

Figure 4 The postsynaptic apparatus and its amplifying effect. (a) A schematic diagram of a mouse NMJ. Note particularly the highly folded postsynaptic membrane and the nonoverlapping distributions of acetylcholine receptors (AChRs) and Na_V1 molecules. AChRs are concentrated near the sites of transmitter release from the nerve while the Na_V1 channels are concentrated in the depths of the folds. (b) Current flow in the muscle fiber induced by the action of ACh. Positive charge enters the muscle fiber through opened AChR channels at the crest of the folds. The resulting current flows in the narrow space between the folds into the cytoplasm and then out across the nonsynaptic membrane. (c) Equivalent circuit of an active fold at a rat NMJ. Note that the resistance of the interfold cytoplasm (4.8 MΩ) is an order of magnitude greater than that of the input resistance of the fiber (0.5 MΩ). (d) AP threshold during neural activation of a rat muscle fiber. The EPP was reduced in amplitude by partially blocking AChRs with curare so that only occasional EPP are big enough to trigger an AP. The AP threshold determined this way (dashed line, about −60 mV) is substantially less than when determined when current is injected away from the NMJ (solid line, about −50 mV; see **Figure 2(a)**). This is a result of the combined effects of the high concentration of Na_V1 channels and the high interfold resistance.

$2000\,\mu m^{-2}$. This is some 10 times greater than in the remainder of the muscle fiber membrane.

These features of the postsynaptic membrane of the mammalian NMJ have an important impact on the current flows initiated by ACh released from the nerve. The current flowing through the opened AChRs enters the cell at the crest of the folds (**Figure 4(b)**). Because the effective resistance of the folded membrane

is very high, the path of least resistance for this current is through the thin sheet of cytoplasm between the folds. However, the resistance of this pathway is some 10 times greater than the input resistance of the muscle fiber as a whole (Figure 4(c)). As a result, there is a steep potential gradient within the cytoplasm between the top of the folds and that in the bulk of the muscle fiber. This results in a similar spatial gradient of the transmembrane potential. At NMJs in the rat, it has been estimated that a single quantum of ACh depolarizes the membrane at the crest of a fold by more than 10 mV, while in the bulk of the fiber the depolarization recorded by an intracellular electrode is only 0.5–1 mV.

The functional significance of this local amplification of the depolarizing effect of ACh is enhanced by the high density of Na_V1 channels in the depths of the folds. To initiate an AP, a minimum number of Na_V1 channels at the NMJ must be opened. As a result of the high density of these channels in the postsynaptic membrane, a smaller fraction of the channels needs to open to generate an AP than if the density were as low as it is in the extrajunctional region of the fiber. In addition, the amplifying effect of the geometry of the folds means that a larger fraction of those channels is opened by a quantum of ACh than if the membrane was not folded. As a result, the effective threshold for AP generation at the NMJ is about half of that in the extrajunctional region (Figure 4(d)).

Safety Factor for AP Generation

The pattern of muscle innervation varies in different species and muscles. In some cases, multiple axons innervate each muscle fiber and no AP is generated (see later). However, in most higher vertebrates, and in mammals in particular, an important principle of the functional organization of muscle innervation is that each AP in a motor neuron causes contraction of every muscle fiber that its axon innervates. This requires that neuromuscular transmission is very reliable, even during intense high-frequency activity when fewer quanta are released per impulse. This reliability results from the release of substantially more quanta of ACh than are necessary to reach the threshold for AP generation in the muscle. Neuromuscular transmission is thus said to have a high 'safety factor.' In rat limb muscles, where it has been studied in most detail, the safety factor is about 4.

It is clear that the postsynaptic specializations just described make an important contribution to the safety factor in mammalian muscle fibers. By lowering the effective threshold they reduce the number of quanta that must be released from the nerve to ensure reliable transmission.

Termination of ACh Action

The action of ACh is terminated by the enzyme acetylcholinesterase (AChE), which is bound to the basal lamina located in the space between the nerve and the muscle. AChE cleaves the ACh into choline and acetate. Although the AChE lies on the diffusion path taken by ACh molecules on the way to their targets, there are many fewer AChE molecules than ACh or AChRs. As a result, most ACh molecules released from the nerve reach the postsynaptic membrane and bind to AChRs. However, when they subsequently dissociate from the AChRs, the ACh molecules are bound and cleaved by the AChE, thus preventing them from rebinding to a second AChR. AChE thus acts to limit both the spatial extent and temporal duration of ACh action.

How Different Species Achieve Reliability

Not all vertebrate species achieve an adequate safety factor in the same way. While mammals rely on the amplifying effect of the postsynaptic folds, many fish and birds have few or no folds. Comparison of the quantal content and intensity of folding in several species suggest that there is often a reciprocal relationship between these two properties of the NMJ (Figure 5). In frogs, the nerve terminals are very big and release many quanta, but the folding is less prominent than in mammals. At the other extreme are human NMJs, which are relatively small and release relatively few ACh quanta (20–50 vs. 100–200 in the frog) but have very extensive folding. The NMJs of rats and mice are of intermediate size and intensity of folding. There is little reliable information about the number of quanta released at avian NMJs. It is also possible that the safety factor is not as high in birds as in some other species.

It is unclear why some species rely more on presynaptic release and others on postsynaptic amplification to achieve an adequate safety factor. In large animals such as humans, each motor neuron innervates many more muscle fibers than in small animals. It may be that cellular economy dictates that the total volume of nerve terminals supported by a single motor neuron should be kept to a minimum. The postsynaptic specializations that increase the efficiency of transmitter action may have evolved in response to such pressures.

Some Special Cases

In the great majority of vertebrate muscle fibers, APs are generated as part of the process by which contraction is activated. However, there are some important exceptions to this rule. In many species, muscle fibers

Figure 5 Inverse relationship between the extent of folding and the amount of transmitter release. (a) Light micrographs of NMJs in the indicated species. The muscle fiber is shown in black and the NMJ in white. Note small size of the human NMJs relative to those in frogs. (b) Electron micrographs of NMJs in the same species. Note that human NMJs have much greater postsynaptic folding than do frog NMJs. (c) In these species, the extent of folding (reflected by the folding index) is inversely related to the number of transmitter quanta released from the nerve. This provides the structural basis for the postsynaptic amplification of ACh action that is particularly prominent in humans.

are present that appear to be incapable of generating APs. These fibers tend to have small diameters and very high membrane resistance, and to contract relatively slowly. A common feature of these fibers is that they are innervated at multiple sites along their length, typically at intervals of 1–2 mm. Contraction is activated by the summed effect of the local depolarizations caused by transmitter quanta acting at these sites. These fibers are referred to by a number of terms, the most common being 'slow' and 'tonic.' Unfortunately, both of these terms are used in a number of different ways, leading to much confusion in the literature. The term 'nonEx-MIF' (nonexcitable, multiply innervated fibers), though cumbersome, is more precise.

Frog 'Slow' Fibers

In lower vertebrates, nonEx-MIFs are found in many skeletal muscles. In frogs, the vertebrates in which this type of NMJ was first studied in detail, stimulation of the nerve elicits junction potentials, analogous to EPP. Analysis of the properties of these potentials with intracellular electrodes is greatly complicated by the presence of multiple sites of innervation of individual muscle fibers, and the contamination of recordings at one site by events at others. Nonetheless, it seems that AChRs with kinetics and pharmacology similar to those in twitch fibers are concentrated at these junctions and account for the increased

conductance that underlies the junction potentials. A common feature of electrically inexcitable muscle fibers, both in frogs and in mammals (see later), is that they have a very high input resistance. This is probably a result of a low resting permeability to chloride ions. An important consequence of this is that the depolarization caused by the action of a quantum of ACh is much greater than it would be in a typical twitch fiber. This is of obvious importance in the activation of contraction in the absence of APs.

Mammalian Extraocular Fibers

In higher vertebrates, including mammals, non-Ex-MIFs are mainly restricted to a few specialized types of muscles. The extraocular muscles include fibers that receive innervation from several motor neurons. In contrast to the analogous fibers in frogs, these fibers contract very rapidly in response to the graded stimulus provided by their multiple innervations. Many of these fibers appear unable to generate APs, although a subclass shows some degree of excitability *in vitro*. In these intermediate fibers, the level of excitability seems to vary along the length of the fiber, being greatest in the central region. Very little is known in detail about the quantitative aspects of ACh action or voltage-gated sodium channel activation in these very small diameter muscle fibers.

Intrafusal Fibers

The second main class of non-Ex-MIF in higher vertebrates is the intrafusal fibers of the muscle spindles. The motor innervation of these fibers is complex, arising mainly from specialized γ-motor neurons, but in some cases from collateral branches of the α-motor neurons that also innervate extrafusal fibers. Very little is known in detail about neuromuscular transmission in these fibers, which are even more challenging to investigate than those of the extraocular muscles.

Conclusions

At vertebrate NMJs, the postsynaptic response to ACh quanta released from the nerve is determined primarily by two key ion channel species and the geometry of the postsynaptic region. AChRs mediate the initial influx of excitatory depolarizing current in response to ACh binding. This current is converted into a depolarization by the passive electrical properties of the muscle fiber. In the case of those species in which there are prominent postsynaptic folds, these focus the depolarizing effect on the folded membrane, in a manner analogous to the isolating effect of the neck of dendritic spines on central neurons. The depolarization acts to open Na_V1 channels that are concentrated in the postsynaptic region. When enough of these channels open, a regenerative AP is initiated.

Neuromuscular Junction (NMJ): Presynaptic Non-Quantal Release of Transmitter

F Vyskočil, Charles University, Prague, Czech Republic

© 2009 Elsevier Ltd. All rights reserved.

Introduction

During neuromuscular transmission in vertebrates, acetylcholine (ACh) is released from the nerve in multimolecular 'quanta.' Each quantum is believed to represent the 5000–10 000 ACh molecules contained within a single synaptic vesicle. In addition to this quantal release, there is considerable evidence for a form of continuous molecular leakage of ACh from the nerve terminal. The evidence for this nonquantal release (NQR), and for its possible physiological significance as a regulator of muscle fiber excitability at the neuromuscular junction (NMJ), is the subject of this article.

Early Observations

The first electrophysiological evidence for NQR was obtained from cat muscles. A depolarization of the endplate zone of several millivolts was observed after injection of an anticholinesterase (anti-AChE) into the jugular vein. This depolarization developed as soon as 70–80 s after anti-AChE treatment and extended most of the way along the muscle (Figure 1(a)), with peaks in the regions of the NMJs. It was abolished after denervation, suggesting that it was of neural origin. The depolarization was not accompanied by muscle twitching, which seems to exclude the participation of action potentials in the nerve terminal or increased quantal release. Similar observations were subsequently made by us on isolated strips of mouse diaphragm (Figure 1(b)), where the depolarization arises in the region of the muscle corresponding to the single narrow band of NMJs. Subsequent studies found that the amount of ACh released into the bath by an isolated muscle that had been pretreated with an anti-AChE far exceeded the amount that could be accounted for by the quantal leakage due to spontaneous miniature endplate potentials (MEPPs). In mammals, NQR represents most (50–98%) of the total ACh release at rest.

Depolarization of the nerve and muscle by high K^+ increased both total and quantal release, but in different degrees. Further, nerve stimulation increased the total release 1.4-fold but the quantal release 45-fold. This implied that the major part of the resting release results from leakage from the axon, the nerve terminal, or the muscle. Experiments with denervated muscles supported the nerve terminal as the main, but not the only, source of the ACh. These early data were thus largely consistent with the proposal that there are two principal mechanisms of release at resting motor nerve terminal: quantal and nonquantal, or vesicular and nonvesicular, and that the former is only a small fraction of the total.

The H-Effect

The first direct evidence for NQR was obtained by using intracellular microelectrodes to record the muscle fiber membrane potential. This approach revealed a small hyperpolarization (0.04 mV in the frog and 2 mV in the mouse) in the region of the endplate area after applying the ACh antagonist (+)tubocurarine (TC) to muscles previously treated with an anti-AChE (Figure 2). This hyperpolarization, the so-called H-effect, is believed to be due to inhibition of the depolarizing effect of ACh released by NQR. In muscles in which the NQR is absent, for example, several hours after denervation, a similar H-effect can be produced by approximately 10^{-7} M ACh. This suggests that the level of ACh in the synaptic cleft of the mouse or rat muscles is on the order of hundreds of nanomoles. It is interesting to note that in frog muscles, the magnitude of the much smaller H-effect is matched by about 10^{-9}–10^{-8} M ACh.

To learn more about the factors controlling the proposed NQR, the effects of various modifications of the ionic contents of the bath on the NQR have been investigated.

Increasing the K^+ concentration in the bath from 0.5 to 15 mM and exposure to hypertonic solutions, both procedures that increase the frequency of MEPPs at normal NMJs, has little influence on the H-effect. In contrast, lowering the Ca^{2+} from its normal value of 2 mM reduces the H-effect, which becomes undetectable in preparations incubated in Ca^{2+}-free solution for more than 60 min. The H-effect also decreases if the Ca^{2+} level is increased from 2 mM and disappears in 15 mM Ca^{2+}, although the frequency of MEPPs shows the expected dependence on the Ca^{2+} level in parallel recordings. A similar dependence on Ca^{2+} is observed at embryonic neuromuscular synapses in the frog, *Xenopus*. The H-effect has an opposite dependency on the external level of Mg^{2+}. In the absence of Mg^{2+}, the H-effect is maximal; 1 mM Mg^{2+} reduces the H-effect by one-third, and it is virtually absent at 3 mM Mg^{2+}.

Figure 1 Distribution of potential along the cat gracilis muscle (a) and mouse hemidiaphragm (b). In (a), the control tracing was taken at zero time, after which the AChE tetraethylpyrophosphate (560 mg kg^{-1}) was injected into the jugular vein. The distribution of the electrical potential along the length of the muscle was measured by traversing two endplate regions of a muscle in a paraffin bath with a scanning electrode In (b), a mouse hemidiaphragm was hung vertically and immersed slowly in a vessel in which the liquid-air interface served as a recording electrode. The lower trace shows a small positivity in the endplate area, reflecting the slight hyperpolarisation regularly observed in muscles with intact synaptic cholinesterase (surplus hyperpolarization). After treatment of the same muscle with the irreversible AChE paraoxon, there was a local depolarization (upward inflection) apparently due to nonquantal leakage of the ACh (upper trace). The reference electrode (Ag/AgCl wire) was placed on the top of muscle. (a) Adapted from Douglas WW and Paton WMD (1954). The mechanism of motor end-plat depolarization due to a cholinesterase-inhibiting drug. *Journal of Physiology* 124(2): 325–344.

Figure 2 The effect of curare on the membrane potential in the mouse diaphragm endplate with AChE inhibited by paraoxon. At the time of the arrow 0.1 mM TC in saline was applied by pressure from a pipette with a tip diameter 10 μm. It caused the MEPPs (rapid upward deflections, left part of the record) to disappear and endplate to hyperpolarize (slow downward deflection, the H-effect). Intracellular recording by standard glass microelectrode filled with 1M KCl.

A number of compounds abolish the H-effect. These include Botulinum toxin type A; aconitin; and toosendanin, a triterpenoid derivative extracted from the bark of *Melia toosendan*. All abolished the H-effect, suggesting that the quantal and nonquantal components of the ACh release are regulated differently. This is also supported by differing temperature dependencies of quantal release and NQR. The maximal H-effect is observed at 20 °C while the frequency of MEPPs continues to increase with temperature above 20 °C.

The VAChT Hypothesis

It was proposed originally by Charles Edwards that the vesicular ACh transporters (VAChTs) may play a role in NQR of ACh. Synaptic vesicles have been shown to take up ACh by an active process. The VAChT responsible for this uptake is incorporated into the plasma membrane during exocytosis and removed by endocytosis. If these transporter molecules were to retain their orientation following the incorporation of the vesicle membrane into the axon membrane, they would then continue to move ACh out of the axoplasm, but now into the extracellular space instead of the vesicle lumen.

To test the VAChT hypothesis, the effects on the H-response of agents and treatments which act on the transport of ACh into vesicles have been examined. The most potent inhibitors of ACh transport into synaptic vesicles are vesamicol, quinacrine, and

tetraphenylborate. These compounds inhibit the H-effect at concentrations similar to those that block ACh transport in vesicles. The local application of vesamicol from a micropipette hyperpolarizes the muscle fiber membrane within seconds without changes in the amplitude of the MEPPs. This indicates that the reduction of the H-effect is of presynaptic origin.

The transport of ACh into the vesicles is coupled with a proton concentration gradient, in which the vesicle interior is more acidic. If the NQR requires a similar proton gradient, an increase in the bath pH should inhibit the release. Consistent with this, the H-effect is largely abolished at pH higher than 8. Furthermore, the H-effect is potentiated by ouabain, a blocker of the Na^+-K^+ ATPase. This block could remove a source of protons within the nerve terminal that would tend to make the cytoplasm more alkaline. Such a change in the proton gradient across the membrane might facilitate the ACh–proton exchange via the VAChT transport system. Another possibility is based on the finding that ouabain interferes with vesicle endocytosis and can thus prolong the time for which the VAChTs are incorporated into the nerve membrane. Other interpretations are also possible, however.

The H-effect, measured just after the addition and washout of an anti-AChE, is usually in the range of 7–9 mV. This value declines with time, presumably as the VAChTs are taken up by endocytosis. Consistent with this, stimulation of the motor nerve at 50 Hz, which causes extensive exocytosis, can restore the NQR.

There is thus considerable evidence, albeit indirect, that is consistent with the hypothesis that the VAChT is a source of NQR.

Modulation of NQR

A number of factors can influence the size of NQR. These include the activity of AChE in the synaptic cleft as well as substances released from the nerve, such as ACh itself and ATP and its breakdown product adenosine.

AChE Activity and NQR

An immediate question raised by the early studies of the H-effect was, How could ACh released from the nerve by NQR at normal NMJs survive breakdown by AChE in the synaptic cleft? One possible answer is that the AChE is not sufficiently activated by the low concentration of ACh resulting from NQR. This idea is supported by the demonstration that the velocity of ACh hydrolysis decreases sharply when the concentration of ACh is less than 10^{-4} M. As noted earlier, the H-effect can be produced by ACh concentrations as low as 5×10^{-8} M.

Purinergic Regulation of NQR

The role of ATP as a neurotransmitter or cotransmitter at the NMJ is now generally accepted. ATP is present in the synaptic vesicles at the neuromuscular junction in concentrations only several times smaller than that of ACh. Stimulation of the motor nerve releases ATP, together with ACh in a Ca^{2+}-dependent manner. ATP at the relatively low concentration of 10^{-5} M, but not adenosine, depresses NQR whereas both purines reduce the frequency of MEPPs. ATP reduces the amplitude of the H-effect substantially, but not completely, unless Rp-cAMP (an inhibitor of protein kinase) or a guanylyl cyclase inhibitor such as ^{1}H-[1,2,4]oxadiazolol[4,3-a]quinoxalin-1-one (ODQ) is also present. This suggests that more than one pharmacologically distinct mechanism contributes to NQR. The intracellular metabolic route or routes involved in the inhibition of NQR mediated by ATP are unknown. Metabotropic P2Y receptors might be coupled to multiple intracellular cascades. Pretreatment by staurosporine completely prevents the depressant action of ATP on the NQR, suggesting involvement of protein kinase C in the cascade.

The inhibitory influence of a continuous supply of ATP on a substantial fraction of NQR is consistent with the finding that hypoxia increases both MEPP frequency and NQR in solutions with normal extracellular Ca^{2+} (2.0 mM). The effect on MEPP frequency is virtually absent in low Ca^{2+} solution ($(Ca^{2+})_o = 0.4$ mM) whereas there is still a significant increment of NQR. This suggests that these two processes are influenced by different oxygen-sensitive mechanisms. The rise of MEPP frequency during the onset of hypoxia apparently requires the Ca^{2+} entry into the nerve terminal, whereas the NQR can be increased by other factors, such as the lower level of the ATP when its oxidative production is hindered.

The differing effects of ATP and adenosine allow a further test of the VAChT hypothesis. The reduction of NQR is prevented by the P2-receptor inhibitor suramin and by the protein kinase C inhibitor staurosporine. This further supports the ideas that there are two pharmacologically and functionally distinct types of ATP-binding receptors at murine motor nerve terminals and that there are different pathways for regulation of the two types of release.

An intriguing question is whether NQR is itself accompanied by release of ATP, as occurs during quantal release. The finding that a P2 antagonist increases the level of nonquantal ACh release favors such a tonic action of endogenous ATP. Apparently there is a

feedback inhibition of NQR mediated by accumulation of endogenous purines.

Biological Aspects of NQR

Studies of the changes in NQR and quantal release during degeneration and regeneration of the nerve and during the relative inactivity associated with mammalian hibernation have further supported the notion that although these two forms of ACh release are functionally related through the insertion of VAChT into the nerve membrane, they are regulated in somewhat different ways.

Denervation

After motor nerve section, the biochemically measured reduction in the total amount of ACh released from a mammalian muscle precedes the loss of MEPPs, suggesting that NQR declines before quantal release. Biochemical estimates, however, cannot distinguish between ACh of axonal, nerve terminal, or muscle origin. Direct measurements of the decline and recovery of MEPPs and the H-effect in the mouse diaphragm after nerve crush and during regeneration showed that the H-effect drops to 50% within 1 h of denervation and is undetectable 4 h later. In contrast, MEPPs are still present for another 5–10 h. The preferential disappearance of the NQR might be due to rapid inhibition of ACh synthesis in the terminal and exhaustion of cytosolic ACh. Even more rapid disappearance of the H-effect (within minutes) occurs after inhibition of the fast choline uptake by hemicholinium-3 or when Li^+ is substituted for Na^+.

Reinnervation

During reinnervation, the H-effect is detectable 3 days before the reappearance of MEPPs. The H-effect develops first on day 8 in the proximal endplates and then with delays of 3 and 6 days as the nerve reaches the central and distal areas of the diaphragm. Early MEPPs are less than 0.2 mV in amplitude and often slow and K^+ independent. Full recovery of the MEPP frequency and K^+ and Ca^{2+} dependency is achieved 20 days after the nerve crush in proximal parts, and 30 days in distal parts, of the diaphragm. These observations show that NQR can exist in the absence of quantal release. This might mean either that empty vesicles have fused, adding VAChT to the membrane without ACh release (invisible MEPPs) or that quantal release and VAChT incorporation are not absolutely necessary for NQR. Alternatively, early in reinnervation, VAChTs might be synthesized and incorporated into the terminal membrane but not incorporated into vesicles. They might then form a pathway for NQR which precedes vesicle maturation and quantal release. Whatever the explanation, NQR closely follows the morphological restoration of neuromuscular contact and can thus be considered as an early manifestation of the ability of the nerve terminal to synthesize and release ACh during axonal regeneration.

Hibernation

If NQR depends on the quantal release, then the H-effect should be related to the frequency of MEPPs. In muscles from golden hamsters, the frequency of quantal MEPPs is lower than in mouse or rat, particularly in hibernating animals. The H-effect is substantially lower in awake hamsters than in mice and is very small in hibernating hamsters (Figure 3) and is proportional to the rate of spontaneous quantal release. This supports the idea that NQR depends on the number of vesicles fused with the presynaptic membrane during quantal release.

Physiological Implications

What, if any, might be the effects of NQR on neuromuscular transmission in normal muscles with intact AChE activity? One possibility is that it contributes to the maintenance of the negative resting membrane potential (RMP) in the vicinity of the NMJ in the face of continuous inward leakage of Na^+. This, in turn, may influence the excitability of the postsynaptic membrane and hence the reliability with which action potentials can be generated in the muscle fiber.

Figure 3 Time course of early postdenervation depolarization in diaphragms of rat, active and hibernating hamster, and decline of the surplus hyperpolarization in rat.

Surplus Polarization of Muscle Fibers at the NMJ

There is normally a small but consistent difference in the RMP of mammalian muscle fibers between the region of the NMJ and the extrajunctional area. At mouse or rat NMJs with intact cholinesterase, the RMP is more negative (by 2–3 mV at 22 °C, 4–5 mV at 37 °C) than in the extrajunctional area. The hyperpolarization is insensitive to the nicotinic antagonist *d*-tubocurarine chloride (dTC) making a direct role of postsynaptic nicotinic receptors unlikely.

Role of Na^+-K^+ATPase The addition of 10^{-6} M ouabain, an inhibitor of the electrogenic Na^+-K^+ pump, abolishes this local hyperpolarization in less than 5 min. This suggests that it is caused by the activity of the electrogenic Na^+-K^+ pump in the junctional region (Figure 1(b)). This activity can be potentiated by ACh when the muscle fibers are loaded with Na^+ and the pump activity is high. Thus it may be that the Na^+-K^+ pump at the NMJ is modulated by ACh. In addition to direct potentiation by ACh, the electrogenic activity of the pump might also be promoted by a high resting Na^+ influx through spontaneous openings of the sodium channels concentrated in the postsynaptic folds. In the presence of ACh, this Na^+ might be removed from the cell more rapidly, thus hyperpolarizing the subsynaptic membrane.

In muscles excised 4 h after denervation, the H-effect has disappeared and the surplus hyperpolarization is replaced by a local depolarization. It is interesting to note that the addition of 5×10^{-8} M ACh (an amount simulating the NQR) causes a reappearance of the hyperpolarization at the endplate zone.

Early Postdenervation Depolarization (EPD)

Within a few hours of nerve section, mammalian muscle fibers undergo a partial depolarization which affects their excitability and contraction. Muscle fibers of the rat diaphragm maintained *in vitro* are depolarized by about 8–10 mV (10–12% of the control RMP) within 3–4 h of denervation. This EPD coincides with the onset of an inward-directed, furosemide-sensitive Cl^- transport which may trigger other changes in the muscle fiber, such as the loss of its ability to control its volume in hypertonic solutions. The appearance of the EPD also coincides with, and may result from, the loss of NQR. If the ACh receptors (AChRs) are kept active by exposing the denervated muscles to ACh or carbacholine (Carb), the EPD is substantially reduced. This reduction is largely prevented by adding Ca^{2+} inhibitors such as verapamil or Cd^{2+}. Thus activation of AChRs, whether by NQR or exogenous cholinergic agonists, exerts a protective effect on the RMP of denervated muscles that appears to be influenced by Ca^{2+} influx (Figure 4).

In many cell types, the entry of Ca^{2+} into the cytoplasm activates nitric oxide synthase (NOS), leading to the generation and release of NO. NO can activate

Figure 4 Possible pathways involved in regulation of the resting membrane potential and early postdenervation depolarization in skeletal muscle fibers. Nonquantal and quantal ACh indicated in reddish. M1, muscarinic acetylcholine receptors; ACh, acetylcholine; RMP, resting membrane potential; NOS, nitric oxide synthase; NMDA, *N*-methyl-D-aspartate; ODQ, ^{1}H-[1,2,4]oxadiazolol[4,3-a]Quinoxlin-1-one; cGMP, cyclic guanoline monophosphate; APV, α-(−)-2-amino-5-phosphoxo valeterate, an NMDA receptor antagonist; MEPCs, miniature endplate currents. For more details see text.

soluble guanylyl cyclase to produce cyclic guanosine monophosphate (cGMP), which activates specific protein kinases and results in the phosphorylation of various proteins. Inhibitors of NOS prevent cholinergic agonists from inhibiting EPD, suggesting that ACh released by NQR may enhance Ca^{2+}-dependent NO synthesis and the following phosphorylation cascade.

Muscarinic AChRs (mAChRs) and EPD ACh and Carb appear to delay the EPD by activating M1-cholinergic receptors. Thus while the nicotinic antagonists dTC and α-bungarotoxin have no effect on the action of Carb, oxotremorine (Oxo), a highly specific muscarinic agonist, and atropine both diminish the EPD in a similar way to Carb. This inhibition is present in 5×10^{-9} M atropine and is prevented by M1 antagonists such as pirenzepine. It remains to be determined whether these mAChRs are coupled to Ca^{2+} channels directly or via a NO-cGMP cascade (Figure 4). Consistent with the view that NQR normally suppresses EPD by activating mAChRs, muscarinic antagonists facilitate the development of EPD by protecting fibers from the action of Ach, which is still released for several hours after nerve section. In the presence of both atropine and pirenzepine, the EPD is already detectable within 30 and 60 min.

Hypertonicity and EPD Hypertonicity activates Cl^- transport in muscle fibers. Both sucrose and NaCl (in the presence of tetrodotoxin), when used to increase the osmolarity to 500 mosmol/l, significantly potentiate EPD, whereas Carb completely loses its ability to delay EPD onset. The inhibition of Cl^- transport by furosemide or Cl^-free incubation medium in hypertonic solutions effectively prevents osmotically augmented EPD.

Summary These experiments give some insight into the possible physiological significance of NQR (Figure 4). They support the view that ACh suppresses EPD by activating the furosemide-sensitive inward transport of Cl^- which starts to operate when NQR diminishes after nerve section. The NQR can apparently stimulate the Ca^{2+} influx, NO production and NO cascade-mediated phosphorylation that normally suppress the inward Cl^- current and helps to maintain the RMP at a high level. After nerve section, this protection from depolarization disappears, and the dephosphorylated transporter begins to move Cl^- into the muscle fiber, making the equilibrium potential Cl^- more positive and the muscle membrane more depolarized.

Glutamate

There is some evidence that glutamate, the most common excitatory transmitter in the CNS, may also act on the RMP of muscle fibers at the NMJ. Glutamate is the most common amino acid in most cells, and glutamate-like immunoreactivity has been reported at rat motor nerve terminals. Glutamate is secreted and taken up at the frog neuromuscular junction, and mRNA coding for a glutamate transporter is present in rabbit motor neuron perikarya. On the postsynaptic side, an accumulation of *N*-methyl-D-aspartate receptor-1 (NMDAR-1) glutamate receptor subunits has been demonstrated by immunolabeling in the rat diaphragm.

It has been suggested that glutamate participates in the regulation of muscle fiber RMP through a pathway similar to that activated by ACh. Like ACh and Carb, glutamate and *N*-methyl-D-aspartate (NMDA) induce Ca^{2+}-dependent synthesis of NO in the sarcoplasm, which delays the EPD. The influence of glutamate on RMP appears to be mediated by the NMDA subtype of Glu receptors which are enriched at NMJ. There is thus potential for interaction between the effects of ACh released by NQR and glutamate in the regulation of the RMP, and hence excitability, at the NMJ.

Conclusions

There is considerable evidence for a continuous release of ACh from motor nerve terminals associated with the activity of VAChT inserted into the nerve membrane during exocytosis. Early experiments implied the existence of NQR from the hyperpolarization of the muscle (the H-effect) at the NMJ in response to block of mAChRs in muscles in which the AChE activity had also been blocked. Normal AChE activity would prevent this effect but appears to allow enough ACh to reach the muscle to activate mAChRs. This in turn appears to trigger a postsynaptic phosphorylation cascade that involves both Ca^{2+} and NO as second messengers. This cascade suppresses the activity of an inward Cl^- transporter and activates the electrogenic sodium pump. This supports the local hyperpolarization of the muscle in the region of the NMJ, thus helping maintain muscle excitability. A number of factors including AChE activity and purines released from the nerve appear to influence the magnitude of NQR and the effects resulting from it.

Although the full physiological significance of NQR is not yet clear, it seems that it should not be considered simply a by-product of the quantal

exocytosis of ACh but rather a fundamental aspect of the release process that may play a significant role in regulating synaptic efficacy at the NMJ.

Neuromuscular Junction (NMJ): Presynaptic Schwann Cells and Modulation of Neuromuscular Transmission

E-L Bélair and R Robitaille, Université de Montréal, Montreal, QC, Canada

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The concept of the neuromuscular junction (NMJ) as a tripartite structure, consisting of a nerve terminal (presynaptic component), a muscle fiber and its endplate (postsynaptic component), and a few perisynaptic Schwann cells (PSCs; glial component), has gained general acceptance over the past decade. Indeed, Schwann cells that were first described as passive cells, implicated in homeostasis functions and NMJ stability, are now believed to actively modulate synaptic transmission. The discoveries that led to the evolution of this concept, mainly evidence that PSCs can detect and respond to synaptic activity and, in return, have the ability to increase or decrease transmitter release, are discussed in this article.

An Advantageous Position

PSCs lie on top of nerve terminals and extend processes that run along and wrap around them in the vicinity of transmitter release sites (active zones). Although this is true for all vertebrates, differences exist among species. At amphibian NMJs, for example, these processes intrude into the synaptic cleft. In contrast, at mammalian NMJs, PSC processes remain at the edge of the synaptic cleft. Interposition of Schwann cell processes between presynaptic and postsynaptic membranes appears to be negatively correlated with synaptic efficacy, suggesting that glial coverage of synaptic clefts may regulate information processing. Moreover, because of their proximity to active zones, PSCs are well positioned to sense synaptic activity and exert a modulating role on pre- and/or postsynaptic elements.

Detectors of Synaptic Transmission

A Cocktail of Presynaptically Released Molecules

During presynaptic activity, many neurotransmitters and neuromodulators can be released from nerve terminals. In fact, at some NMJs, adenosine triphosphate (ATP) is released synchronously together with the neurotransmitter acetylcholine (ACh) following a single nerve impulse and is subsequently degraded by enzymatic activity into ADP, AMP, and adenosine. In addition, immunoreactivity for peptides (calcitonin gene-related peptide and substance P) was found in large dense core vesicles of amphibian and mammalian motor nerve terminals and the release of these peptides is elicited by high-frequency nerve stimulation. Synaptic activity also regulates the release of diverse neurotrophins – namely, brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4 (NT-4) – that, in turn, act as synaptic regulators. Therefore, according to the level of synaptic activity, a cocktail of molecules can be released into the synaptic environment and the message received by the three synaptic partners varies as a function of the receptors they express.

A Variety of Receptors

Using calcium imaging and immunocytochemical techniques, functional receptors for all of the aforementioned molecules have been found on PSCs. The presence of functional receptors on PSCs *in situ* was first revealed at amphibian NMJs, where PSCs responded to nerve stimulation with an elevation of intracellular Ca^{2+}. This Ca^{2+} rise was greatly reduced by blockade of presynaptic Ca^{2+} entry, was independent of the presence of muscle fibers, and could be reproduced by direct application of ATP, adenosine, and ACh. This suggests that neurotransmitters released from presynaptic nerve terminals mediated the glial Ca^{2+} responses. Also, because Ca^{2+} responses still occurred in the absence of extracellular Ca^{2+}, intracellular Ca^{2+} stores were involved. The use of specific antagonists later allowed the identification of the receptors mediating ATP and adenosine responses on frog PSCs. ATP triggered Ca^{2+} rises via P2Y and P2X receptors; P2YR activation led to the release of Ca^{2+} from internal stores through recruitment of a pertussis toxin-sensitive G-protein and P2XR activated L-type Ca^{2+} channels. Adenosine acted on A1 receptors also coupled to a pertussis toxin-sensitive G-protein. The blockade of A1 receptors did not alter calcium rises evoked by nerve stimulation, suggesting that they are not involved in neuron–glia communication during normal neurotransmission. Conversely, blockade of ATP receptors led to delayed Ca^{2+} elevations with smaller amplitude, indicating that endogenous ATP participates in synapse–glia signaling. The identity of the receptors mediating cholinergic responses in PSCs is, however, less clear. An unconventional muscarinic receptor, insensitive to the general antagonist atropine but inhibited by the nonspecific blocker gallamine, has

been identified. These receptors are coupled to internal Ca^{2+} stores via a pertussis toxin-insensitive G-protein mechanism. Hence, owing to the presence of receptors for the neurotransmitters normally released during presynaptic activity, PSCs are well adapted to sense this activity and ultimately to respond to it.

An Evolutionarily Conserved Property

The ability of PSCs to respond to synaptic activity is well conserved among vertebrates, although some evolutionary differences exist. For example, at the skate neuroelectrocyte junction, which has a neuromuscular embryonic origin, receptors for ATP and ADP, but not for adenosine and AMP, were identified on PSCs. This preparation also receives a cholinergic innervation where ATP is co-released with ACh. Application of ATP was found to trigger a biphasic calcium elevation in PSCs, involving P2Y receptor stimulation and, most likely, activation of phospholipase C, generation of inositol 1,4,5-trisphosphate (IP_3), and subsequent Ca^{2+} release from IP_3-sensitive stores. In mammals, ATP-mediated Ca^{2+} responses do not involve P2 receptors, suggesting that ATP acts through its metabolites, mainly adenosine. Moreover, as opposed to frog PSCs, A1 receptors for adenosine participate in nerve-evoked Ca^{2+} rises, but to a lesser extent than receptors for ACh. In addition, the latter are of a conventional muscarinic type, since atropine blocks ACh-evoked Ca^{2+} responses. Regardless of the interspecies variability in receptor expression, which might contribute to physiological differences between species, the ability of PSCs to respond to the release of transmitters is common to all, reflecting their functional importance. Also, the variety of receptors for a given neurotransmitter and their relative sensitivity will undoubtedly color the signal received by PSCs and adapt their response as a function of synaptic activity.

Adapted Ca^{2+} Responses

In addition to their receptors for neurotransmitters, PSCs possess receptors for molecules that are preferentially released during elevated synaptic activity. For example, substance P induces the release of Ca^{2+} from intracellular stores of frog PSCs, most likely through its metabolites. These Ca^{2+} elevations are mediated by neurokinin-1 receptors (NK-1Rs) coupled to pertussis toxin (PTX)-sensitive G-proteins. NK-1R activity seems to be involved in the modulation of ATP and ACh signaling in PSCs, since their previous activation reduces the amplitude of Ca^{2+} responses evoked by nerve stimulation or local application of muscarine and ATP. Some neurotrophin receptors may play similar roles in specific conditions. In fact, NT-3 and BDNF trigger Ca^{2+} elevations in mouse PSCs, through tyrosine kinase B (BDNF) and tyrosine kinase C (NT-3) receptors. An application of BDNF prior to nerve stimulation increases the duration of the evoked Ca^{2+} response. These molecules may be important for the fine-tuning of PSC Ca^{2+} responses and may enlarge their scale of responsiveness to ACh and ATP, allowing them to discriminate different degrees of synaptic activity.

Presence of Voltage-Gated Ion Channels

In addition to the various receptors for neurotransmitters and neuromodulators, PSCs possess voltage-gated ion channels that also allow them to sense synaptic activity. Depolarization-activated L-type Ca^{2+} channels are found on frog PSC processes, close to the synaptic cleft, while N-type Ca^{2+} channels are presumed to be present on mammalian PSCs. However, the persistence of PSC calcium responses in the absence of extracellular Ca^{2+} suggests that only a small proportion of the response can be accounted for by the activation of Ca^{2+} channels. Hence, PSCs are kept aware of synaptic activity mainly through G-protein-coupled receptor activation and intracellular Ca^{2+} signaling, with Ca^{2+} being released from intracellular stores and, to a lesser extent, entering the cell via voltage-gated ion channels. Therefore, a direct manipulation of G-protein or Ca^{2+} signaling would lead to a modulation of the message received by PSCs, which could, in turn, modulate synaptic transmission.

Modulators of Synaptic Transmission

G-Protein Signaling

The first direct evidence of PSCs modulating synaptic transmission came from a study of the frog NMJ, where PSC G-proteins were specifically activated or inactivated via intracellular injection of guanosine 5′-3-*O*-(thio)triphosphate (GTPγS) and guanosine 5′-*O*-(2-thiodiphosphate) (GDPβS), respectively. This method avoids the complication of bath-applied drugs acting on cells other than PSCs. GTPγS injection into PSCs decreased the amplitude of nerve-evoked endplate currents, but had no effect on the frequency, amplitude, or kinetics of spontaneous events (Figure 1). Furthermore, paired-pulse facilitation was not altered by the injection, suggesting that the modulation of synaptic efficacy by PSCs does not affect the basic mechanisms required for vesicular fusion but rather involves the synchronization mechanisms that are necessary for quantal release. Moreover, the effect of

Figure 1 Injection of guanosine 5′-3-*O*-(thio)triphosphate (GTPγS) in perisynaptic Schwann cells depresses synaptic transmission. (a) Endplate current (EPC) amplitude recorded focally from a nerve terminal branch and evoked by a single stimulus at 0.2 Hz before, during, and after injection of GTPγS in the PSC covering the same terminal branch. The injection of GTPγS into the PSC produced a reduction in the amplitude of EPC. (b) Average of four EPCs recorded before (control) and 20 min after the injection of GTPγS in the PSC. Reproduced from Robitaille R (1998) Modulation of synaptic efficacy and synaptic depression by glial cells at the frog neuromuscular junction. *Neuron* 21(4): 847–855, with permission from Elsevier.

GTPγS injection into PSCs was only partially occluded by pretreatment with pertussis toxin, revealing a dual effect of PTX-sensitive and -insensitive G-protein activation on the modulation of synaptic efficacy. On the other hand, inhibition of G-proteins, via GDPβS injection, had no effect on transmitter release evoked by 0.2 Hz stimulation. While an increase of synaptic efficacy would have been expected if PSC G-proteins were tonically active, the observed lack of effect is suggestive of an absence of tonic activity. This is consistent with the absence of detectable Ca^{2+} signaling in PSCs with low-frequency nerve stimulation and reflects an activity-dependent modulation of transmitter release by PSCs.

In addition to their modulation of transmitter release, PSCs also participate in short-term plasticity of synaptic transmission. Indeed, inhibition of PSC G-proteins decreased synaptic depression in response to high-frequency stimulation. Moreover, the depression induced by PSC G-protein activation occluded 75% of high-frequency-triggered depression. These results suggest that PSC G-protein might modulate the presynaptic mechanisms causing the depression of transmitter release (Figure 2).

Calcium Signaling

The effect of PSC Ca^{2+} elevations on transmitter release was later investigated in the same system, using thapsigargin, an inhibitor of Ca^{2+}-ATPase pumps of internal stores. Bath application of thapsigargin induced a transient rise of Ca^{2+} in PSCs as a result of the gradual leak of Ca^{2+} from the internal stores and the incapacity to replenish them. Thapsigargin also prolonged Ca^{2+} responses in presynaptic nerve terminals following single action potentials and caused Ca^{2+} accumulation during high-frequency stimulation without altering resting levels of Ca^{2+}. Therefore, presynaptic internal stores were assumed to be empty at rest and to participate to Ca^{2+} clearance during synaptic activity. Correlated with the prolonged Ca^{2+} signal in presynaptic nerve terminals was a rapid increase in transmitter release. After a delay, transmitter release was further increased, transiently and with a slower rate. This delayed and transient increase of transmitter release was associated with PSC Ca^{2+} rise, since it was occluded by specific injection of the Ca^{2+} chelator 1,2-bis(2-aminophenoxy)ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid (BAPTA) into PSCs. Moreover, the release of Ca^{2+} from PSC internal stores, triggered by the injection of inositol 1,4,5-trisphosphate, mimicked thapsigargin-induced potentiation of transmitter release (Figure 3). This potentiation was associated with an increase in the frequency of miniature endplate potentials (mEPPs). This, together with the lack of effects of thapsigargin on mEPP amplitude and time course, implies that this potentiation is presynaptic in origin.

Because Ca^{2+} signaling is undetectable in PSCs at low frequencies of stimulation, their Ca^{2+}-dependent potentiation of transmitter release is likely to occur mainly during elevated synaptic activity. Decreasing the availability of free Ca^{2+} by increasing the Ca^{2+} buffering capacity of PSCs should inhibit this potentiation. As expected, specific BAPTA injection into PSCs, prior to high-frequency stimulation, enhanced the depression of synaptic transmission, confirming the potentiating role of PSC Ca^{2+} responses (Figure 4). Therefore, PSCs can modulate

Figure 2 Perisynaptic Schwann cells modulate endogenous high-frequency depression. (a) Endplate current (EPC) amplitude expressed as a percentage of control value before, during, and after a train of stimuli (10 Hz, 80 s) recorded before (black trace) and 25 min following guanosine 5′-*O*-(2-thiodiphosphate) (GDPβS) injection in the PSC covering the nerve terminal branch recorded by the focal electrode (gray trace). EPCs were evoked at a frequency of 0.2 Hz before and after the train of stimuli. (b) Average depression in control (black) and following GDPβS injection in PSCs (gray) ($n = 5$). Note that the amount of synaptic depression was significantly reduced (asterisk, $p < 0.05$; Student's *t* test). (c) EPC amplitude expressed as a percentage of control value before, during, and after a train of stimuli (10 Hz, 80 s) recorded before (black trace) and 35 min following GTPγS injection (gray) in the PSC covering the nerve terminal branch recorded by the focal electrode. EPCs were evoked at a frequency of 0.2 Hz before and after the train of stimuli. (d) Average depression in control (black) and following GTPγS injection (gray) in PSCs ($n = 4$). Note that the amount of synaptic depression was significantly reduced (asterisk, $p = 0.02$; paired Student's *t* test), suggesting that nerve-evoked synaptic depression was occluded by the depression induced by PSC G-protein activation. Adapted from Robitaille R (1998) Modulation of synaptic efficacy and synaptic depression by glial cells at the frog neuromuscular junction. *Neuron* 21(4): 847–855, with permission from Elsevier.

short-term plasticity either by increasing or decreasing transmitter release, via Ca^{2+} signaling and G-protein activation, respectively. As a result, the balance between potentiation and depression by PSCs may vary according to the state of the synapse and the level of its activity.

Glutamate Carboxypeptidase II

N-Acetylaspartylglutamate (NAAG) is a widely distributed neuropeptide in the mammalian central nervous system (CNS). The presence of its hydrolyzing enzyme on PSC membranes and its neuromodulatory role at the rat NMJ have raised the possibility of its release by motor neuron terminals. Indeed, NAAG was found to inhibit nonquantal release of ACh, through the activation of postsynaptic *N*-methyl-D-aspartate (NMDA) receptors and synthesis of the retrograde messenger nitric oxide (NO). This effect was mimicked by glutamate application and blocked by the inhibition of the PSC membrane-associated ectoenzyme, glutamate carboxypeptidase II (GCP II), which hydrolyzes NAAG into glutamate. Therefore, PSCs could modulate transmitter release indirectly through the metabolism of presynaptically released neuropeptides. This function may be tightly regulated by synaptic activity, as activation of glial type II metabotropic glutamate receptors has been shown to upregulate GCP II activity in crayfish nervous tissue. Thus, previous synaptic activity could provide an important reciprocal modulation of synaptic activity by PSCs.

The variety of mechanisms by which PSCs can modulate neurotransmission strongly suggests that the ultimate effect on the synapse is a balance of potentiation and depression. The equilibrium may be displaced according to the state of the synapse and its previous activity, favoring one or another pathway and leading to the release of appropriate gliotransmitters (Figure 5).

Figure 3 Potentiation of synaptic transmission by perisynaptic Schwann cells (PSCs). (a) Experimental model of the three-electrode recording method. Intracellular recordings of synaptic activity generated by the whole neuromuscular junction were performed simultaneously with extracellular recordings, using a focal electrode, which monitored the portion of the presynaptic terminal covered by a PSC injected via the third electrode. (b) Endplate current (EPC) and endplate potential (EPP) amplitude expressed as a percentage of change relative to control before and during bath application of an inhibitor of the Ca^{2+}-ATPase pumps, thapsigargin (Tg; 2 μM), after the injection of the PSC covering the portion of the nerve terminal recorded by the focal electrode with the vehicle solution (500 mM K^+-acetate and 10 μM Ca^{2+}-green-1). Changes in EPC amplitude represent the activity of the nerve terminal covered by the injected PSC, whereas changes in EPP amplitude represent changes occurring at the whole neuromuscular junction. Note that Tg induced a similar increase in EPP amplitude (whole neuromuscular junction activity) and in EPC amplitude (portion of the terminal covered by the injected PSC). (c) EPC amplitude recorded by a focal electrode located near the portion of a nerve terminal covered by a PSC before, during, and after the injection of the calcium chelator 1,2-bis(2-aminophenoxy)ethane-*N,N,N′,N′*-tetraacetic acid (BAPTA; 10 mM in the electrode) in the PSC. EPCs were evoked by nerve stimulation at 0.2 Hz. Note that BAPTA injection had no effect on synaptic transmission. (d) EPC and EPP amplitude expressed as a percentage of changes relative to control before and during bath application of Tg (2 μM) after the injection of BAPTA (10 mM in the electrode) in the PSC covering the portion of the nerve terminal recorded by the focal electrode. Note that Tg induced a rapid rise, followed by a second, slower increase in EPP amplitude (whole neuromuscular junction activity) but induced only a small and rapid rise in EPC amplitude (portion of the terminal covered by the injected PSC). (e) EPC amplitude before and after the injection of inositol 1,4,5-trisphosphate (IP_3; 10 mM in the electrode) in the PSC covering the portion of the nerve terminal recorded by the focal electrode. EPCs were evoked by motor nerve stimulation at 0.2 Hz. Note that the injection of IP_3 in PSCs potentiated transmitter release. Reprinted from Castonguay A and Robitaille R (2001) Differential regulation of transmitter release by presynaptic and glial Ca^{2+} internal stores at the neuromuscular synapse. *Journal of Neuroscience* 21(6): 1911–1922. Copyright 2001 by the Society for Neuroscience.

Putative Gliotransmitters

In order to achieve reciprocal communication, PSCs need to release some neuroactive substances that can diffuse to, and activate signaling cascades in, its synaptic partners, just as presynaptic nerve terminals do when releasing neurotransmitters and neuropeptides. Many molecules have been cited as putative gliotransmitters, suspected to be

Figure 4 Synaptic depression is modulated by perisynaptic Schwann cells. (a) Changes in endplate current (EPC; gray trace) amplitude and endplate potential (EPP; black trace) amplitude expressed as a percentage of control before, during, and after the induction of high-frequency depression (10 Hz/80 s) at the frog neuromuscular junction. Note that the focal and intracellular recordings show the same amplitude of depression. After the injection of calcium chelator 1,2-bis(2-aminophenoxy)ethane-*N,N,N′,N′*-tetraacetic acid (BAPTA) into a PSC (break in *x*-axis), the focal electrode (gray trace), which records synaptic transmission under the injected PSC, shows a bigger depression than the intracellular on does, thus suggesting that the presence of BAPTA in the PSC blocked the potentiating effect on synaptic transmission. (b) Mean ± SEM of the difference between intracellular and extracellular depression in control and after BAPTA injection into PSCs. Note that, after BAPTA injection, the difference between the amplitude of depression recorded by the intracellular and focal electrodes was significantly greater. Reprinted from Castonguay A and Robitaille R (2001) Differential regulation of transmitter release by presynaptic and glial Ca^{2+} internal stores at the neuromuscular synapse. *Journal of Neuroscience* 21(6): 1911–1922. Copyright 2001 by the Society for Neuroscience.

involved in depression or potentiation of transmitter release.

Possible Mediators of Synaptic Depression

Nitric oxide NO is a ubiquitous neuromodulator of the nervous system. At the frog NMJ, exogenous application of NO causes a reduction of EPP amplitude that is presynaptic in origin. NO is also endogenously produced in a tonic fashion and is implicated in synaptic depression via a cyclic guanosine monophosphate (cGMP)-dependent mechanism. Furthermore, NO is synthesized during elevated synaptic activity and contributes to high-frequency depression independently of soluble guanylate cyclase activation. A form of neuronal NO synthase (NOS) has been found in PSCs of the frog NMJ. Many NOS enzymes are Ca^{2+} dependent, therefore it is likely that activity-dependent Ca^{2+} elevations in PSCs could trigger NO production and mediate synaptic depression. This would, however, be inconsistent with the greater synaptic depression observed with specific injection of BAPTA into PSCs, unless Ca^{2+} activates two different pathways leading either to potentiation or depression, with potentiation prevailing in normal conditions. As an alternative, NOS could be activated through a G-protein pathway, consistent with the effect of G-protein activation in PSCs.

Glutamate Like NO, glutamate and (1*S*,3*R*)-aminocyclopentanedicarboxylic acid (ACPD), a metabotropic glutamate receptor (mGluR) agonist, decrease transmitter release at the frog NMJ. Glutamate also modulates synaptic transmission in an activity-dependent manner, since blockade of mGluRs by (*S*)-α-methyl-4-carboxyphenylglycine (MCPG) during high-frequency stimulation reduces synaptic depression. This frequency dependence of glutamatergic modulation of transmitter release resembles the frequency dependence of glial regulation of synaptic depression. Therefore, glutamate was suggested to be glial in origin. This proposition is consistent with the observation of glutamate-like immunoreactivity in

Figure 5 Perisynaptic Schwann cell (PSC) modulation of neurotransmission. Schematic representation of synapse–glia interactions at the neuromuscular junction. (a) Upon arrival of an action potential at the nerve terminals (NT; 1), voltage-gated calcium channels open and Ca^{2+} enter the nerve terminals, triggering the release (2) of neurotransmitters acetylcholine (circles) and ATP (triangles) into the synaptic cleft. (3) Acetylcholine (ACh) binds to nicotinic receptors (nAChR) on muscle fiber (MF) endplate, leading to an influx of Na^{+} and Ca^{2+} (4) that causes a depolarization (endplate potential). (b) Neurotransmitters also bind to PSC metabotropic receptors (1; ACh → mAChR, ATP → P2R), which activate G-proteins. (c) Calcium signaling pathway: potentiation. (1) G-proteins activate phospholipase C (PLC), which (2) cleaves membrane lipid phosphatidylinositol bisphosphate into diacylglycerol and inositol trisphosphate (IP_3). (3) IP_3 then binds to its receptors on endoplasmic reticulum. (d) Activation of IP_3 receptor triggers the release of Ca^{2+} (1) from internal stores. (2) Calcium elevation in PSCs induces the release of gliotransmitters (prostaglandins, neurotrophins, and/or unidentified molecules) into the synaptic cleft. These molecules, in turn, act on nerve terminals (3). (e) At the nerve terminals (1) following the arrival of an action potential, the molecules (2) increase the release of transmitters through unknown mechanisms. (3) This greater transmitter release results in a stronger activation of nAChRs and (4) a larger endplate potential. (f) G-protein pathway: depression. (1) G-protein activity in PSCs also activates a signaling cascade (2) that leads to the release of depressing gliotransmitters (nitric oxide (NO), endocannabinoids, arachidonic acid (AA), glutamate, and/or unidentified molecules) into the synaptic cleft. (3) These molecules, in turn, act on nerve terminals. (g) At the nerve terminals (1) following the arrival of an action potential, the molecules (2) decrease the release of transmitters through unknown mechanisms. (3) This reduction in transmitter release results in a weaker activation of nAChR and (4) a smaller endplate potential.

rat PSCs and the presence of functional glutamate uptake machinery on these cells at the frog NMJ, thus providing an economical mechanism to recycle glutamate. By releasing glutamate, likely in a Ca^{2+}-dependent manner, or by regulating the rate and capacity of glutamate reuptake, PSCs may thus modulate short-term plasticity through postsynaptic mGluR activation and possibly NO synthesis by muscle fibers.

Endocannabinoids Endocannabinoids have been found to decrease cholinergic transmission by reducing the release of ACh in several smooth and skeletal muscle preparations. In addition, in the CNS, glial cells express some enzymes of the endocannabinoid metabolism, both *in vitro* and *in situ*, suggesting that they may synthesize these molecules. Thus, a role of glial cells in the cannabinergic modulation of synaptic transmission at the NMJ could be envisioned.

Arachidonic acid As with endocannabinoids, arachidonic acid (AA), an important component of membrane lipids, and also a degradation product of the endocannabinoid 2-arachidonoylglycerol (2-AG), has been shown to inhibit presynaptic Ca^{2+} currents at the frog NMJ. Moreover, AA has a depressive effect on transmitter release. Cultured Schwann cells present an agonist-dependent regulation of AA release, and therefore AA could be envisaged as a gliotransmitter implicated in synaptic depression. The effects of AA on synaptic transmission at the frog NMJ have been shown to be dependent on cyclooxygenase activity and are believed to be mediated by prostaglandin E_2. Depressive effects on synaptic transmission have also been described for prostaglandins E_1 and $F_{2\alpha}$ at the frog NMJ.

Possible Mediators of Synaptic Potentiation

Prostaglandins In addition to their depressive effect, prostaglandins can also potentiate synaptic transmission. Indeed, at the frog NMJ, inhibition of a prostaglandin-synthesizing enzyme, cyclooxygenase, decreased quantal release. This decrease was partially restored by subsequent exposure to prostaglandin E_2. However, when applied on untreated preparations, prostaglandin E_2 decreased the amplitude of evoked EPPs, suggesting that its potentiating effect depends on the state of the synapse and may be unmasked in synapses that are already depressed. Therefore, one could hypothesize a role of prostaglandin E_2 in the modulation of high-frequency induced synaptic depression, and an appealing possibility would be an activity-dependent release by PSCs. This seems very likely since rat Schwann cells produce different prostanoids *in vitro*. In addition, AA- and prostaglandin E_2-synthesizing enzymes, phospholipase A_2 and cyclooxygenase, are found in frog PSCs.

Neurotrophic factors: BDNF At developing NMJs, acute exposure to BDNF rapidly potentiates spontaneous and evoked synaptic activity. BDNF also enhances synaptic transmission in the adult rat diaphragm muscle. Because cultured Schwann cells produce molecules with BDNF-like activity and possess the mRNA coding for BDNF, this neurotrophic factor may be involved in PSC potentiation of transmitter release.

Thus, many molecules could modulate synaptic transmission and therefore act as gliotransmitters. They may be recruited in different conditions, according to the specific needs of the synapse. For example, activation of a certain pathway following G-protein activation could favor the release of depressing molecules, while the activation of a Ca^{2+} cascade could encourage the release of potentiating molecules. The two pathways may act independently, causing the release of both types of molecules, with the resulting influence on synaptic transmission being a balance of depression and potentiation. As another possibility, the G-protein pathway and the Ca^{2+} pathway may interact such that, downstream of G-protein activation, Ca^{2+} signaling modulates the activity of proteins that are involved in the release of depressing molecules.

Long-Term Modulation by PSCs

In an attempt to elucidate the role of PSCs in synaptic transmission, techniques have been developed to specifically ablate these cells at the NMJ. Using the monoclonal antibody 2A12, specific for PSCs *in vivo*, complement-mediated lysis was performed to eliminate PSCs from adult frog NMJs without damaging nerve terminals, muscle, or myelinating Schwann cells along axons. Acute ablation of PSCs resulted in no obvious defects in evoked synaptic transmission, while the frequency of spontaneous release was slightly increased. Paired-pulse facilitation and synaptic depression of NMJs lacking PSCs were also comparable to these functions in control NMJs. Similar results were obtained in mammals: PSCs were acutely ablated using antibodies specific for disialosyl epitopes on gangliosides (preferentially GD3), which are enriched in the PSC membrane.

In contrast to these acute effects, chronic absence of PSCs leads to long-term morphological and physiological transformations of frog NMJs. After 1 week of PSC ablation, 10% of nerve terminals were retracted, although they were not detached from the muscle. Active zone length, vesicle density, and ACh

receptor distribution were not altered, ruling out degenerative changes in the nerve terminal or postsynaptic fiber. In contrast, the lack of PSCs altered synaptic transmission, decreasing evoked EPP size and average mEPP frequency, without affecting mEPP amplitude. Thus, synaptic efficacy was decreased in PSC-ablated NMJs, but postsynaptic function remained unchanged. Paired-pulse facilitation and synaptic depression were also decreased, supporting a role for PSCs in the maintenance of synaptic function. These results thus raise the possibility of a role for PSCs in long-term synaptic plasticity.

Conclusion

Taken together, studies on PSCs have revealed the importance of synapse–glia interactions on NMJ stability and have proved the necessity of considering these cells as major players in short-term and long-term modulation of neuromuscular activity. The ability of PSCs to detect and respond to synaptic activity and to modulate neurotransmission likely allows them to regulate activity levels with the effect of maintaining optimal nerve–muscle communication. Future work will undoubtedly shed light on the patterns of synaptic activity that most efficiently recruit PSCs in physiological conditions and that prompt glial modulation of synaptic transmission. Further insights on PSC function will also arise from comparative studies linking PSC activation and modulation properties to functional differences between NMJs of mammals and lower vertebrates.

Introduction

Short-term stimulation-induced changes in transmitter release have been characterized in terms of various underlying components. Facilitation, augmentation, and potentiation are components of increased transmitter release that differ from one another on the basis of their kinetic properties and time courses of decay. Depression is a component of decreased transmitter release. The properties and possible mechanisms of these components of variable synaptic efficacy are described in the following sections.

Techniques of Study

Variable synaptic efficacy has been studied extensively at many different synapses, including the neuromuscular junction. The frog neuromuscular junction will form the basis for much of the material presented herein. In a typical experiment the sartorius muscle is placed in a small chamber and bathed with a simple salt solution containing 114 mM NaCl, 2 mM KCl, 0.1–2 mM $CaCl_2$, 0–15 mM $MgCl_2$, and a pH buffer. The motor nerve leading to the muscle is stimulated with a train of impulses, and the resulting change in transmitter release after each impulse is determined from changes in the amplitude of successive postsynaptic responses. Postsynaptic responses are determined either from endplate potential (EPP) amplitudes measured using a microelectrode placed in the muscle cell at the region of an endplate, or by measuring the current that flows through the endplate (endplate current) using a two-microelectrode voltage clamp. For experimental conditions in which the EPP amplitudes exceed threshold for generation of action potentials in the muscle, the postsynaptic receptors can be partially blocked with tubocurare to prevent the muscle from contracting. Since the purpose of these studies is to examine stimulation-induced changes in synaptic efficacy, the response to the first impulse in the train serves as a control for the changes that occur during and after the train. Sufficient time is allowed between each train of impulses so that the synapse returns to its unstimulated (control) state.

Stimulation-induced changes in synaptic efficacy have been found to involve a number of different processes or components. To facilitate the study of the individual components, it is advantageous to modify the external media by reducing or increasing the concentration of Ca^{2+} or Mg^{2+}. Reducing Ca^{2+} or increasing Mg^{2+} decreases the amount of transmitter released so that depression due to depletion of synaptic vesicles no longer masks the processes that act to increase transmitter release. An example of variable synaptic efficacy under conditions of decreased transmitter release is shown in Figure 1. Transmitter release was decreased by reducing the amount of extracellular Ca^{2+} available for entry into the nerve terminal and by increasing the amount of extracellular Mg^{2+} which inhibits Ca^{2+} entry. Each record presents EPPs recorded during 5 s of repetitive stimulation at the indicated stimulation rate. Because of the slow time base, each EPP appears as a vertical line. The amplitudes of the EPPs, which are a good measure of transmitter release under the conditions of this experiment, increase during the trains, with the greatest increase at the higher stimulation rates. The enhancement in transmitter release shown in Figure 1 is due to an increase in the number of synaptic vesicles that release their contents of transmitter from the presynaptic nerve terminal into the synaptic cleft for each impulse. This increased release under conditions of low Ca^{2+} can be accounted for in terms of four components: potentiation, augmentation, and the first and second components of facilitation. Each component of increased transmitter release is defined in a similar manner, as the fractional increase in transmitter release over the control level in the absence of the other components, such that

$$y(t) = (\mathrm{EPP}(t) - \mathrm{EPP}_0)/\mathrm{EPP}_0 \qquad [1]$$

where $y(t)$ is the magnitude of the specified component of increased transmitter release at time t, EPP $(t) - \mathrm{EPP}_0$ is the increase in EPP amplitude at time t due to the component, and EPP_0 is the control EPP amplitude when the component equals zero. The components have been distinguished from one another on the basis of widely separated decay rates and differential sensitivities to Sr^{2+} and Ba^{2+}. The time courses of decay of the components are determined by placing test impulses at various intervals after one or more conditioning impulses. Since the decay of each component can be approximated by a single exponential, decay rates are characterized in terms of time constants – the time required to decay to 37% ($1/e$) of the initial magnitude. The properties of each component are summarized in the following sections.

Figure 1 Variable synaptic efficacy at the frog sartorius neuromuscular junction under conditions of low levels of transmitter release. Each record presents endplate potentials recorded with a surface electrode when the nerve was stimulated at the indicated rate. Each vertical line represents an endplate potential. The amplitude of the endplate potentials is proportional to the amount of transmitter released by each nerve impulse. Transmitter release increased during the trains, and the increased release was greater for higher stimulation rates. Vertical bar = 0.5 mV; horizontal bar = 0.5 s. Reproduced from Magleby KL (1973) The effect of repetitive stimulation on facilitation of transmitter release at the frog neuromuscular junction. *Journal of Physiology (London)* 234: 327–352, with permission.

Facilitation of Transmitter Release

Facilitation includes two components of increased transmitter release. Each nerve impulse adds a first and second component of facilitation. The first component increases transmitter release about 80% above the control level and then decays with a time constant of about 50 ms. The second component increases release about 12% and then decays with a time constant of about 300 ms. The facilitation added by a single nerve impulse can be described by

$$f(t) = 0.8e^{-t/50\,\mathrm{ms}} + 0.12e^{-t/300\,\mathrm{ms}} \qquad [2]$$

where $f(t)$ is the fractional increase in transmitter release at time t following the conditioning impulse.

During repetitive stimulation, the facilitation added by each release combines with that remaining from previous impulses, so that facilitation builds up during the train, reaching a steady-state level after approximately 1 s of stimulation. The greater the frequency of stimulation, the greater the combined facilitation. Because of their large magnitudes and rapid time courses of decay, stimulation-induced changes in the two components of facilitation can lead to large and rapid changes in transmitter release following step changes in stimulation rate. Facilitation decays to insignificant levels within about 1 s after a conditioning train ends. Replacing Ca^{2+} in the bathing solution with Sr^{2+} leads to a selective increase in the magnitude and time constant of the second component of facilitation.

Augmentation of Transmitter Release

Each nerve impulse adds an increment of augmentation which increases transmitter release about 1% above the control level. Augmentation then decays with a time constant of about 7 s. The augmentation added by each impulse can be described by

$$a(t) = 0.01\,e^{-t/7\,\mathrm{s}} \qquad [3]$$

where $a(t)$ is augmentation at time t. The increment of augmentation added by each impulse typically increases above the 0.01 level during trains of several hundred impulses. Because of its slow 7 s decay rate and the progressive increase in the increment of augmentation added by each impulse, augmentation can build up to large levels during several hundred impulses in the absence of depression, acting to increase the transmitter released by each nerve impulse several fold in the absence of depression (see later). Addition of small amounts of Ba^{2+} to the bathing solution leads to a selective increase in the magnitude of augmentation while having little or no effect on its time constant of decay.

Potentiation and Posttetanic Potentiation of Transmitter Release

Each nerve impulse adds an increment of potentiation that increases transmitter release about 1% above the control level. Potentiation then decays with a time constant that ranges from tens of seconds to minutes. The time constant of decay, which is about 60 s after the end of a 300-impulse conditioning train, increases with the number and frequency of conditioning impulses. Potentiation after a train can develop with a delay if depression (see later) occurs during the conditioning train. Under these conditions potentiation is often called posttetanic potentiation (PTP), because

it becomes apparent with a delay after the tetanus due to the slow recovery from the masking depression. The potentiation added by each impulse may be approximated by

$$p(t) = 0.01\,\mathrm{e}^{-t/60\,\mathrm{s}} \qquad [4]$$

where $p(t)$ is potentiation at time t. Potentiation builds up during repetitive stimulation, often increasing release for each impulse two times the control level after several hundred impulses.

Relationship between the Components of Increased Transmitter Release

Potentiation, augmentation, and the two components of facilitation retain their kinetic properties during and following repetitive stimulation. The relationship between these four components is not entirely clear, but their effects do not add linearly to one another. Instead, there appears to be a multiplicative relationship among the components. This is expressed as

$$\mathrm{EPP}(t)/\mathrm{EPP}_0 = (F(t)+1)(A(t)+1)(P(t)+1) \qquad [5]$$

where $\mathrm{EPP}(t)/\mathrm{EPP}_0$ is the increase in transmitter release at time t over the control level in the absence of repetitive stimulation, and $F(t)$, $A(t)$, and $P(t)$ are the magnitudes of facilitation, augmentation, and potentiation at time t.

The combined properties of the four components of increased transmitter release are sufficient to account for stimulation-induced changes in transmitter release under conditions of low quantal release (e.g., low extracellular Ca^{2+}). The four components build up during repetitive stimulation and decay thereafter, with their characteristic time constants. Under conditions of low quantal release the combined effects of the four components can increase the transmitter released by each impulse an order of magnitude over the control level after several hundred impulses of repetitive stimulation at 10–20 impulses per second.

Comparison of the Components of Increased Transmitter Release at Three Different Preparations

Even though the time constants of decay of the four components of increased transmitter release are temperature dependent in reptiles and mammals, the decay rates of the components in mammalian sympathetic ganglion at 34 °C and in fascia dentata of rat hippocampus at 35 °C are similar to those stated in the previous sections for the frog neuromuscular junction at 20 °C. The general kinetic properties of facilitation, augmentation and potentiation appear to be similar at frog neuromuscular junction and fascia dentata of rat hippocampus. In contrast, the increments of the second component of facilitation and augmentation added by each impulse in the mammalian sympathetic ganglion are about 6 to 10 times larger than at the frog neuromuscular junction.

Mechanisms for the Components of Increased Transmitter Release

Depolarization of the presynaptic nerve terminal by an action potential opens voltage-sensitive channels in the nerve terminal that are permeable to Ca^{2+}. It is the influx of Ca^{2+} into the nerve terminal through these Ca^{2+} channels that leads to evoked transmitter release. Since Ca^{2+} triggers transmitter release, it might be expected that increases in the amount of Ca^{2+} in the nerve terminal would lead to increases in transmitter release, and it has been suggested that all four components of increased transmitter release are related to increased Ca^{2+} in the nerve terminal. Such a hypothesis is attractive since Ca^{2+} does accumulate in the nerve terminal during repetitive stimulation, and the time course of Ca^{2+} accumulation and removal can be similar to the combined time courses of the components of increased transmitter release.

An increase in intracellular Ca^{2+} during repetitive stimulation could arise from several different mechanisms, including incomplete removal of the Ca^{2+} entering through Ca^{2+} channels with each nerve impulse, saturation of the buffering capacity of the nerve terminal, increased Ca^{2+} entry through the Ca^{2+} channels, or release of Ca^{2+} from intracellular stores. While all of these processes may act to increase Ca^{2+} under some conditions, facilitation appears to be associated with residual Ca^{2+} remaining from preceding impulses. Augmentation follows a similar time course as Ca^{2+} decay in the nerve terminal and therefore may be due to delayed extrusion of residual Ca^{2+} by pumps such as the Na^+/Ca^{2+} exchanger, where a reduction in the Na^+ gradient due to continual stimulation will slow or even reverse the rate of exchange between Na^+ and Ca^{2+}. Potentiation follows a time course similar to the efflux of the Ca^{2+} accumulated in the mitochondria during prolonged stimulation. On this basis, the different time courses of the components of increased release may reflect the time course of diffusion, buffering, and multicompartment uptake and extrusion of Ca^{2+} from the nerve. A residual Ca^{2+} model for the components of increased transmitter release can give an approximate multiplicative relationship between the components if the residual Ca^{2+} is expressed as a power, such that the transmitter release is proportional to the third or fourth

power of Ca^{2+} acting at one or a combination of proteins involved in release.

Additionally, the components of increased Ca^{2+} release could also reflect the time course of binding and release of Ca^{2+} from Ca^{2+} binding sites on proteins involved in synaptic release; an example is synaptotagmin, a vesicle membrane protein which has multiple binding sites for Ca^{2+}. The differential effects of Ba^{2+} and Sr^{2+} could reflect different kinetic properties of these ions on one or more of the multiple proteins involved in vesicle release and/or on the various uptake mechanisms for Ca^{2+}.

There are a number of difficulties with a simple residual (free) Ca^{2+} hypothesis for stimulation-induced increases in transmitter release. The correlation between free Ca^{2+} and facilitation does not always follow the expected properties for such a hypothesis, and the expected concentrations of residual free Ca^{2+} calculated from the observed increases in transmitter release predict that the rate of transmitter release between nerve impulses, measured as the frequency of miniature endplate potentials seen, should be many times higher than is observed.

However, release evoked by an action potential and residual release from miniature endplate potentials may involve different release sites/mechanisms, so such correspondence might not be expected, and such calculations typically ignore the complexity of a multistep release process. It has also been proposed that one reason why residual free Ca^{2+} does not produce the predicted high level of transmitter release is because of a hypothesized voltage component that directly enhances release at the time of the action potential in the presynaptic nerve terminal, although effective release models have been developed without such a voltage-dependent component.

Residual Ca^{2+} could alter a number of factors involved in the transmitter release, giving rise to the components of increased transmitter release. Such factors could include an increase in the number of sites with vesicles available for release and an increase in the probability that a primed site will release the contents of its synaptic vesicle. The mechanism for the multiplicative relationship between the components is less clear, but if release is determined by the joint probability of multiple factors, such as sites and probability, then these factors could have a multiplicative relationship. Release would then be given by the product of these factors.

Studies of the mechanism of transmitter release suggest that a number of Ca^{2+}-dependent steps with different affinities for Ca^{2+} precede exocytosis. On this basis, the time course of decay of some of the components of increased transmitter release may reflect the time course of Ca^{2+} unbinding associated with the various Ca-dependent steps, as well as the time course of removal of Ca^{2+}.

At least nine families of proteins associated with synaptic vesicles and the presynaptic membrane, many of which are expressed in multiple isoforms, have been implicated in the release of transmitter. These proteins are involved in synaptic vesicle turnover, docking of the vesicles at the release sites, priming to enable the vesicles to be released, and the release process itself that leads to the exocytosis of the vesicle contents. When the functions of all these proteins are clearly defined, as well as the properties of the systems involved in the uptake, sequestration, and extrusion of Ca^{2+}, then the precise molecular mechanisms of facilitation, augmentation, and potentiation may also become clear.

Depression of Transmitter Release

Depression is a decrease in postsynaptic potential amplitude due to a decrease in the number of synaptic vesicles that release their contents into the synaptic cleft by each nerve impulse. Depression is typically insignificant under conditions of low levels of transmitter release (low Ca^{2+}) and becomes more pronounced the greater the level of release. Depression typically develops during prolonged or high-frequency repetitive stimulation under physiological conditions. The magnitude of depression, measured as the fractional decrease in transmitter release, increases with higher stimulation rates or increased duration of stimulation. In physiological Ca^{2+}, the higher the stimulation rate, the greater the resulting depression of transmitter release.

Figure 2 presents an example of depression during repetitive stimulation of the rat diaphragm neuromuscular junction (Figure 2(a)) and the frog sartorius neuromuscular junction (Figure 2(b)) under conditions of normal levels of transmitter release. The postsynaptic response recorded in each case was the endplate current (EPC); inward current through the endplate is plotted downward. Shown in Figure 2(a), EPC amplitudes are successively decreased during a short train of 150 stimuli per second. In Figure 2(b), successive EPC amplitudes first increase and then decrease during a train of 100 stimuli per second. The decrease in amplitude, which results from a decrease in transmitter release, is referred to as depression. Depression is typically superimposed on or masks facilitation, augmentation, and potentiation, which also develop during repetitive stimulation, even under conditions of normal or increased quantal release. The increase in EPC amplitudes in Figure 2(b), before depression becomes prominent, is due to the components of increased transmitter release. Depression is pronounced in Figure 2 over what would be

Figure 2 Depression of transmitter release at rat diaphragm (a) and frog sartorius (b) neuromuscular junctions under physiological levels of transmitter release. Each record presents endplate currents recorded under voltage clamp from a neuromuscular junction. The nerve was stimulated at 150 impulses per second in (a) and 100 impulses per second in (b). Inward current through the endplate is plotted downward, and the absolute endplate current amplitude gives a measure of the amount of transmitter released. The decrease in transmitter release that occurs after the first impulses in (a) and after 5 impulses in (b) results from depression. The first endplate current amplitude in (a) is 100 nA and the endplate currents were evoked every 6.67 ms. The first endplate current amplitude in (b) is 140 nA and endplate currents occur every 10 ms. Reproduced from Magleby KL, Pallotta BS, and Terrar DA (1981) The effect of (+)-tubocurarine on neuromuscular transmission during repetitive stimulation in the rat, mouse, and frog. *Journal of Physiology (London)* 312: 97–113, with permission.

observed under physiological stimulation rates because of the high stimulation rates used in this experiment.

Depression can be divided into two components under physiological levels of transmitter release: a fast component depression that decreases transmitter release about 15% below the control level after a single impulse and recovers with a time constant of about 5 s, and a slow component depression that decreases transmitter release about 0.1% for each impulse and recovers with a time constant of tens of seconds to minutes. The slow component depression is only apparent after prolonged stimulation, and its time course of recovery is slowed as the duration of stimulation increases. At the frog neuromuscular junction, the fast component of depression has been shown to conceal an underlying component of augmentation and the slow component of depression masks the onset of potentiation (posttetanic); the components of augmentation and potentiation increase incrementally during successive impulses of stimuli, but under normal levels of transmitter release the components of depression dominate the response.

The relative amount of depression that develops under physiological levels of transmitter release depends on the synapse and stimulation pattern. At some synapses, such as those in fascia dentata of rat hippocampus, depression does not appear to be significant, and facilitation, augmentation, and potentiation dominate the response. On the other hand, depression is more prominent at rat diaphragm neuromuscular junctions, and tends to mask augmentation and the onset of potentiation.

Mechanisms of Depression

The observation that the magnitude of depression is related to the amount of transmitter released from the nerve terminal has led to the suggestion that depression is due to a depletion of the transmitter immediately available for release. On this basis, the fast component depression might reflect a depletion of the synaptic vesicles at the release sites (the readily releasable pool of vesicles), with a 5 s time constant of recovery reflecting the time required for depleted synaptic vesicles to be replaced from the larger pool of synaptic vesicles in the nerve terminal. A number of factors could give rise to the slow component depression: it may reflect a more general depletion of a larger pool of synaptic vesicles; vesicle release and membrane recycling could decrease the number of functional sites available for transmitter release or decrease their release probability; the coupling between Ca^{2+} channels and release sites may decrease with prolonged release. The depression associated with prolonged, slow (0.5–10 Hz) nerve stimulation in the frog occurs without changes in the entry of Ca^{2+} into the nerve terminal. Thus, decreases in Ca^{2+} entry into the nerve terminal with each impulse do not appear to be the major mechanism for depression in the frog. At some synapses, however, a decrease in Ca^{2+} entry through Ca^{2+} channels may also contribute to depression.

Mobilization is often used to refer to the replacement of depleted synaptic vesicles. The rate of mobilization may be modified by the level of intracellular Ca^{2+}, the activation of second messengers acting on the mobilization machinery, the size of the mobilization pool, and also the fractional depletion of vesicles at the release sites. If the mobilization process overshoots the original level, then mobilization might lead to an increase in transmitter release, or, conversely, if mobilization cannot keep up with release, the result would be a depression of transmitter release. Second messengers acting presynaptically may also be involved in depression and recovery from depression. For example, transmitter release at the neuromuscular junction can be inhibited by the ATP that is co-released from the nerve terminal with acetylcholine, and also by adenosine, a by-product of ATP hydrolysis. These agents may act at some presynaptic site to induce

depression without altering Ca^{2+} entry into the nerve terminal. It is not known whether ATP or adenosine induces depression by slowing mobilization of transmitter or by acting through some other mechanism.

Developing Models to Describe Mechanisms Consistent with Short-Term Plasticity

Given the number of components of increased and decreased transmitter release and their overlapping time constants, together with the large numbers of factors that contribute to transmitter release, such as the numbers of release sites, the fraction of release sites with docked vesicles, the fraction of docked vesicles that are primed for release, the changes in release probability based on Ca^{2+} concentrations at multiple sites, possible cooperativity of multiple binding sites for Ca^{2+} on proteins involved in release, the localization of Ca^{2+} channels and their relationship to release sites, the diffusional microdomains of Ca^{2+}, the intracellular Ca^{2+} buffers, the uptake and storage of Ca^{2+} by the mitochondria, the extrusion of Ca^{2+} by Na^{+}/Ca^{2+} exchangers, and the multiple pools of synaptic vesicles with different rates of replenishment and recycling (just to name some of the factors), models of transmitter release must be formulated and tested in terms of solutions of simultaneous differential equations, as the interactions among the various factors make it difficult if not impossible to study a single factor in isolation. Considerable progress has been made using this approach to develop realistic physical models of short-term synaptic plasticity that include many of the complex features of transmitter release.

Short-Term Synaptic Memory

Facilitation, augmentation, potentiation, and depression are different components of short-term synaptic memory (synaptic plasticity). These components act to integrate information about previous synaptic activity over time, and the synapse indicates its memory of the previous activity by releasing a different amount of transmitter to subsequent nerve impulses. This short-term synaptic memory provides a ready means for the nervous system to store information about previous synaptic activity for a period of milliseconds to several minutes. The multiplicative relationship between the components would provide a means for low-frequency input to a synapse to modulate higher frequency input. It is not known, however, to what extent the nervous system makes functional use of this short-term synaptic memory, or whether the nervous system is designed to operate reliably in spite of it, but such short-term synaptic plasticity is present in the central nervous system and has been shown to have profound effects on the efficacy of synaptic transmission.

Neuromuscular Junction (NMJ): Presynaptic Stretch Effects on Neuromuscular Transmission

A D Grinnell, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

How Muscle Stretch Influences Neuromuscular Transmission

One of the most robust forms of synaptic plasticity described to date is the modulation of neurotransmitter release from frog motor nerve terminals by muscle stretch. Fatt and Katz, in their classic paper first describing the quantal nature of neurotransmission, noted that "Stretching a muscle 10–15% beyond its resting length reversibly increased the rate by a factor of 2.5–3, and pulling on the motor nerve sometimes caused a similar 'speeding up' of the discharge." Indeed, subsequent research has shown that over the physiological range of muscle length, from about 5–10% below rest length to 15–20% muscle stretch, miniature endplate potential (mEPP) frequency increases by about 10% for each 1% change in length. The effect is fully reversible. Following partial curarization, or at a reduced [Ca^{2+}] where quantal content can be measured, EPP amplitude shows comparable enhancement (Figure 1).

The Kinetics of Stretch-Induced Enhancement of Release

In the 1990s, Grinnell and his associates turned their attention to the kinetics and possible mechanisms of the stretch effect. Using 'floating electrodes' and a computer-driven stretching/shortening apparatus that could change the length of a 30 mm-long frog sartorious muscle linearly by as much as 4 mm at rates up to 1 mm/5 ms, they confirmed that the enhancement of EPP amplitude is linear with length, maintained constant at a new length, and fully reversible. Remarkably, there is virtually no delay between the change in length and the corresponding change in EPP amplitude (Figure 2).

Lack of Dependence on Ca^{2+} Influx or Release of Ca^{2+} from Internal Stores

Given the importance of Ca^{2+} in triggering neurotransmitter release, an obvious hypothesis is that stretch increases Ca^{2+} influx or causes release of Ca^{2+} from internal stores. Neither appears to be the case. The enhancement of spontaneous release is not blocked by ω-conotoxin GVIA, which blocks N-type Ca^{2+} channels and EPPs in frog muscle, and it persists in a Ringer containing only 0.1 mM Ca^{2+} and 10 mM Mg^{2+}. Even after an hour's incubation in a Ringer containing 0 mM Ca^{2+}, 2 mM Mg^{2+} and 1 mM ethylene glycol tetracetic acid (EGTA), which blocked EPPs and reduced the mean resting mEPP frequency by about 50%, the stretch effect was not blocked, although it too was reduced by about 50%. Thus, Ca^{2+} influx through stretch-activated or any other kind of channel is not required for the stretch enhancement of spontaneous release, although some Ca^{2+} in the external environment appears to enhance the effect.

Several experiments also ruled out the possibility that nerve terminal stretch somehow causes the release of Ca^{2+} from internal stores. When junctions were incubated in 25 μM 1,2-bis-(o-aminophenoxy)-ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid tetraacetoxy methyl ester (BAPTA-AM) to clamp the intraterminal [Ca^{2+}] at ~100 nM and further treated with 10 μM thapsigargin to block the endoplasmic reticulum Ca^{2+}-ATPase, disabling a major compartment for sequestering or releasing Ca^{2+}, stretch still produced about half the normal enhancement of release. Moreover, the rapidity and linearity of the modulation, the lack of 'overshoot', and the equally rapid and linear reversal of the phenomenon are inconsistent with internal Ca^{2+} release, or indeed with any mechanism on involving biochemical reactions or a second messenger cascade. Finally, when the effects of stretch on mEPP frequency and EPP amplitude were compared at 13° and 22°, the degree of modulation was the same, that is, the temperature effect (Q_{10}) of the effect is ~1. These findings are compelling evidence that the modulation is a purely mechanical phenomenon.

Several hypotheses have been proposed to explain the modulation on the basis of physical phenomena. Frog motor terminals consist of multiple branches, often up to 100–200 μm in length and running parallel to the muscle fiber, slightly invaginated into gutters in the muscle fiber surface. As a muscle fiber is stretched, the nerve terminal branches are proportionately elongated. This could slightly decrease the terminal diameter, arguably forcing water out and causing an increase in the internal Ca^{2+} concentration. However, calculations suggest that a possible change in [Ca^{2+}] due to decrease in volume per unit length of terminal, if it occurs, would be much too small to explain the large change in release efficacy.

Alternatively, stretch of the terminal might expose release sites that, at the shorter length, are cryptic, for example, hidden by folding of the presynaptic membrane or by Schwann cell processes and exposed by

Figure 1 Modulation of neurotransmitter release by stretch. (a) mEPP frequency in a sartorius muscle fiber before, during, and after a 22% stretch of the muscle from a rest length of 2.59 μm/sarcomere. Each point represents the mean ± SE of frequency calculated from the time required for occurrence of 100 mEPPs. (b) Histograms of mEPP amplitude during the prestretch, stretched, and poststretch periods in the same preparation. There was no change in mean mEPP amplitude. (c) Average change in EPP amplitude as a function of changes in muscle length in six sartorius muscle junctions (mean ± SE). The EPP quantal content was reduced in a low-Ca^{2+} frog Ringer containing 0.56 mM Ca^{2+} and 4 mM Mg^{2+}. Inset: EPPs obtained in one preparation at 95%, 100%, 110%, and 120% of rest length. (At rest length, the sarcomere spacing was ~2.25 μm.) (a, b) Reproduced from Turkanis SA (1973) Effects of muscle stretch on transmitter release at end-plates of rat diaphragm and frog sartorius muscle. *Journal of Physiology (London)* 230: 391–403, with permission from Blackwell publishing (c) From Chen B-M and Grinnell AD (1997) Kinetics, Ca^{2+} dependence, and biophysical properties of integrin-mediated mechanical modulation of transmitter release from frog motor nerve terminals. *Journal of Neuroscience* 17(3): 904–916.

stretch. However, many studies of the ultrastructure of frog motor terminals have failed to find any evidence of significant Schwann cell occlusion or folding of the presynaptic membrane that could account for a large increase in exposed active zones with stretch. Thus, the likely mechanism is one that affects the configuration or distance between interacting molecules (or membranes) involved in release, thereby altering release probability.

Integrins as Mediators of the Stretch Modulation

The magnitude and rapidity of the stretch modulation of release suggest that release is influenced by stretch-imposed mechanical stress on the presynaptic membrane near active zones. Because Ca^{2+} influx is not necessary but the effect is reduced in zero-Ca^{2+} Ringer, Ca^{2+}-dependent adhesion interactions with one or more ligands in the extracellular matrix (ECM) are implicated. Obvious candidate adhesion molecules are cadherins and integrins, both of which occur widely at synapses throughout the nervous system. The role of cadherins, if any, has not been investigated, but integrins play a major role in the stretch effect.

Integrins are nearly ubiquitous heterodimeric transmembrane molecules that are the principal receptors connecting the cytoskeleton, intracellularly, to different ligands in the ECM. Ligand bonding can trigger profound changes in cells, including activation of protein kinase C (PKC) and phospholipase C, initiation of tyrosine phosphorylation cascades, induction of nitric oxide (NO) synthase, cytoplasmic alkalinization, and changes in gene expression. Integrins are also capable of transducing mechanical tension in both directions across the cell membrane, potentially bringing reactant molecules closer together or changing reaction equilibria by altering protein–protein conformation or stress on noncovalent bonds.

A large fraction of the extracellular binding by integrins is to ligands containing a specific triplet of amino acids: arginine, glycine, and aspartic acid (RGD). Short peptides that contain the RGD sequence reduce the stretch enhancement of mEPP frequency and EPP amplitude by 40–50%, presumably by displacing

Figure 2 Kinetics of stretch/shortening modulation of EPP amplitude. Average of six experiments in low-Ca^{2+} Ringer containing 0.56 mM Ca^{2+} and 4 mM Mg^{2+}. The muscles were attached at either end to a pair of modified chart recorder arms that moved in opposite directions in response to a command signal from a computer. The stretch began at 0 ms, reached 2 mm (~6%) stretch at 50 ms, was held at that length for 45 ms, and shortened in another 50 ms (thin solid line at bottom). Upper records show the actual measured change in length of this muscle (noisy solid line from phototransistor) and the EPP amplitude evoked by nerve stimulation timed to generate EPPs at 36 different times during the lengthening/shortening cycle. Each point is the average of 50 or more EPPs, each evoked in a single lengthening/shortening cycle. There was virtually no delay between change in muscle length and change in release efficacy. From Chen B-M and Grinnell AD (1997) Kinetics, Ca^{2+} dependence, and biophysical properties of integrin-mediated mechanical modulation of transmitter release from frog motor nerve terminals. *Journal of Neuroscience* 17(3): 904–916.

Figure 3 Suppression of the stretch enhancement by RGD peptides, but not the inactive control RGE peptide, at frog sartorius neuromuscular junctions. mEPP frequency (a) was recorded in normal frog Ringer and EPP amplitude in 3–6 μM D-tubocurarine chloride. (b) Muscles were incubated for 1 h or more in 0.2 mM peptide before commencing recording. From Chen B-M and Grinnell AD (1997) Kinetics, Ca^{2+} dependence, and biophysical properties of integrin-mediated mechanical modulation of transmitter release from frog motor nerve terminals. *Journal of Neuroscience* 17(3): 904–916.

many of the integrin–ECM bonds. Inactive control peptides containing the sequence RGE have no effect (Figure 3). Moreover, a function-blocking polyclonal antibody against the $\beta 1$ subunit of *Xenopus* integrin also reduces the stretch enhancement, while the preimmune serum has no effect. The remaining stretch effect in the presence of RGD peptides might indicate that integrins mediate only part of the phenomenon. However, integrin binding is dependent on the presence of Ca^{2+}. By lowering the concentration of Ca^{2+} to 50 μM or less, integrin bonds to native ligands are broken and the suppression of the stretch effect by RGD-containing peptides is much greater.

Although the effect of reducing integrin binding to native ligands with RGD-containing peptides in a low-Ca^{2+} Ringer did not totally block the stretch effect, this can be explained by the probability that many of the native ligand bonds survived the treatment. Other experiments, moreover, support the conclusion that virtually all of the stretch effect can be attributed to integrins. These experiments also help explain the reduction in the stretch enhancement in zero-Ca^{2+} Ringer. When frog nerve–muscle preparations are treated with Ringer containing zero-Ca^{2+} and 0.2 mM Mn^{2+}, the effect of stretch on mEPP frequency is close to that in normal Ringer. Manganese is a potent Ca^{2+} channel blocker but equally potent stabilizer of integrin–ligand bonds. Hence, Mn^{2+} apparently stabilizes integrin bonds that would otherwise be broken in the absence of extracellular Ca^{2+}. On the other hand, in the presence of Mn^{2+} integrins have been shown to bind more avidly to small RGD-containing peptides than to native ligands. Under these conditions,

RGD-containing peptides virtually totally block the stretch modulation of release at the frog neuromuscular junctions (Figure 4). It appears, therefore, that integrin binding to native ligands in the ECM can explain most or all of the stretch effect.

Interfering with integrin–ECM binding does not alter the appearance of frog motor nerve terminals or their elongation with muscle stretch; other connective tissue components are still intact and attach the terminal tightly to the muscle fiber surface. Thus, the effect of reducing integrin–ligand binding appears to be specific to a subset of connections, probably attaching close to the presynaptic release sites, that are not needed for terminal elongation as a muscle is stretched but which profoundly regulate release probability.

The Intracellular Mechanism of Modulation of Release

The nature of the mechanical link between integrins and the release apparatus is still unknown. Integrins attach to the internal cytoskeletal via a number of linking proteins, and tension on integrins can transmit a mechanical stimulus almost instantly over many micrometers distance within the cell. To date, integrins have not been shown in any preparation to be connected, directly or indirectly, to any of the recognized vesicle or membrane soluble NSF attachment protein receptors (SNARES) or other docking/fusion apparatus. It is surely relevant, however, that treatment of frog junctions with okadaic acid, a broad-spectrum

Bath solution	Resting mEPP frequency
1. NFR	1.47 ± 0.06
2. 0 Ca^{2+}	0.69 ± 0.08
3. 0 Ca^{2+} + 0.5 mM Mn^{2+}	1.75 ± 0.20
4. 0.2 mM RGD + 0 Ca^{2+} + 0.5 mM Mn^{2+}, n = 36 (1 mm stretch)	1.63 ± 0.17
5. 0 Ca^{2+} + DM-BAPTA	0.64 ± 0.09
6. 0 Ca^{2+} + DM-BAPTA + 0.5 mM Mn^{2+}	1.64 ± 0.14
7. DM-BAPTA + 0.2 mM RGD + 0 Ca^{2+} + 0.5 mM Mn^{2+} n = 45 (1 mm stretch), n = 36 (2 mm stretch)	0.99 ± 0.14

Figure 4 Stretch enhancement of mEPP frequency at sartorius neuromuscular junctions is not dependent on Ca^{2+} influx and is mostly blocked by 0.2 mM RGD. The stretch enhancement was reduced in 0 Ca^{2+} Ringer (column 2) and severely reduced by loading with BAPTA (column 5). 0.2 mM Mn^{2+}, which stabilizes integrin–ligand bonds, largely restored the stretch effect (columns 3 and 6). Further incubation with 0.2 mM RGD virtually eliminated the stretch effect (columns 4 and 7). From Chen B-M and Grinnell AD (1997) Kinetics, Ca^{2+} dependence, and biophysical properties of integrin-mediated mechanical modulation of transmitter release from frog motor nerve terminals. *Journal of Neuroscience* 17(3): 904–916.

phosphatase inhibitor which causes 'untethering' of synaptic vesicles in the cloud around each active zone, also blocks the stretch effect, and that this effect of okadaic acid can be prevented by preincubation with the kinase inhibitor staurosporine (Figure 5). It would appear that one or more proteins in the mechanical chain between integrins and the release apparatus must be in the unphosphorylated state for the connection to be functional.

Functional Importance and Generality of the Phenomenon

The stretch effect on release probability has been studied almost exclusively in the frog sartorius, in which it is clearly of functional significance. About 30% of the fibers in this muscle, at rest length in normal Ringer, do not generate suprathreshold EPPs to a single stimulation of the nerve. When a muscle is stretched, however, as it would be by contraction of an antagonist muscle, a single nerve impulse can excite most or all of the fibers, that is, the stretch effect is a strong peripheral amplifier of the spinal stretch reflex. Other frog muscles that have been tested, such as the cutaneous pectoris and some toe muscles, also exhibit a stretch effect, even though most or all of their fibers receive suprathreshold input at rest length.

Integrins have been found at a wide variety of synapses and may be present in almost all. In *Xenopus* motor terminals, active zones contain $\alpha 3\ \beta 1$ interins, while at rat neuromuscular junctions, the $\beta 1$ subunit is associated with $\alpha 1$ presynaptically and with α_V and with three different isoforms of $\alpha 7$ postsynaptically. Whether there is stretch enhancement of release in rat junctions is uncertain, however. Studies of rat diaphragm muscle have found no stretch effect, but the motor nerve boutons in most mammalian muscles are on top of distinct postsynaptic pads ('endplates') and might not undergo significant mechanical stretch or distortion when a muscle is stretched. Moreover, EPPs at mammalian neuromuscular junctions normally are suprathreshold at rest length, with a large safety margin, so there would be no obvious advantage in having peripheral amplification of release. Smooth muscle, with multiple innervation and contraction graded in response to EPP amplitude would seem a better candidate for this form of modulation.

The widespread presence of integrins at synapses throughout the central nervous system (CNS) suggests that they may play important roles in nonneuromuscular connections. Evidence is accumulating that this is the case. Integrins are implicated in memory formation and in the consolidation of long-term potentiation (LTP) in hippocampal slices, perhaps stabilizing activity-related change in spine architecture; RGD peptides also cause abnormalities in kindling behavior in hippocampal slices, suggesting changes in

Figure 5 Stretch enhancement of sartorius EPP amplitude and mEPP frequency are severely reduced by ≥ 1 h incubation at 0.3 μM okadaic acid (OA), a broad-spectrum phosphatase inhibitor. This effect of OA was largely prevented by 1–1.5 h preincubation in 0.5 μM staurosporine, a broad-spectrum kinase inhibitor. From Grinnell AD, Chen B-M, Kashani A, Lin J, Suzuki K, and Kidokoro Y (2003) The role of integrins in the modulation of neurotransmitter release from motor nerve terminals by stretch and hypertonicity. *Journal of Neurocytology* 32: 489–503.

excitability. Interference with integrin binding prevents a developmental increase in glutamate release and expression of *N*-methyl-D-aspartate (NMDA)-receptor subunits. In *Drosophila*, mutations in the *volado* gene, which encodes two forms of an α-integrin subunit, cause defective consolidation of olfactory memory. These mutants also exhibit abnormalities in neuromuscular neurotransmitter release and short-term presynaptic plasticity, while mutations of the β-subunit lead to changes in motor nerve branching and neuromuscular morphology.

Thus integrins may play a variety of important roles at synapses – roles that are only beginning to be elucidated. It is noteworthy that RGD peptides that disrupt integrin bonds sharply reduce the enhancement of spontaneous release by hypertonic solutions in both frog and *Drosophila* neuromuscular junctions. Since hypertonicity causes increased spontaneous release in almost all chemical synapses, integrins may play a role in regulating synaptic effectiveness at most synapses.

Neuromuscular Junction Plasticity in Mammals and Botulinum Toxins

C R Slater, University of Newcastle, Newcastle upon Tyne, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The highly coordinated activation of skeletal muscles that underlies most animal movement depends on reliable transmission of signals from motor neurons to their target muscle fibers at the neuromuscular junction (NMJ). An important component of this reliability is the release by each nerve impulse of more transmitter than is required to activate muscle contraction. In many species and muscles, the amount of transmitter released from the nerve is approximately proportional to the area of synaptic contact at the NMJ. As a result, an important structural determinant of transmitter output is the size of each junction.

NMJs are distinguished from most synapses in the central nervous system (CNS) by their very large size. This makes physiological sense because the postsynaptic muscle fiber is much larger than most neurons and, accordingly, requires much more synaptic current to activate it. As animals grow, the size of the NMJ keeps up with the increasing dimensions of the muscle fibers to ensure that transmission remains effective. However, in animals such as mammals, in which there is relatively little growth after maturity is reached, the form and size of the NMJs reach a stable state: when repeated observations of the same NMJ are made *in vivo*, there is little change in size or form on a time scale of weeks or months. Although this suggests that the mature mammalian NMJ is relatively static, other evidence belies this impression and reveals an inherent plasticity that plays a vital part in ensuring that effective neuromuscular transmission remains, or is restored, after even severe disruption. The first part of this article describes this plasticity and the evidence for it.

Important insights into plasticity of the NMJ have been gained from observing the response to botulinum toxins, which block transmission by interfering with the release of transmitter from the nerve. These toxins are among the most poisonous substances known. Yet in recent years they have been used increasingly in a clinical context to weaken the contraction of specific muscles in conditions in which the patterns of muscle activation are abnormal, such as the spasticity associated with cerebral palsy. Even more common is the cosmetic use of botulinum toxins to paralyze the facial muscles that cause wrinkling of the skin, in the hope of maintaining a youthful appearance. The latter part of this article deals with a number of issues associated with such uses of these toxins and their impact on NMJ form and function.

Natural Plasticity of the NMJ

Plasticity During Aging

When the NMJs of elderly human subjects are compared with those of younger people, consistent changes in structure are seen. Most obvious is an increase in branching of the terminal motor axon and the presence of numerous small acetylcholine receptor (AChR) clusters associated with the terminals of those branches (Figure 1). In some cases, such branches may come to innervate adjacent muscle fibers. In spite of these structural changes, there is little evidence of any deterioration in the efficacy of neuromuscular transmission. Similar structural changes are seen in old rats and mice in which there may even be an increase in transmitter release. The causes of age-related remodeling of the NMJ are not well established. It is likely that several factors contribute.

The Response to Muscle Damage

One possible trigger of NMJ remodeling is mechanical damage to muscle fibers resulting from mild injury or overexertion. When skeletal muscles are experimentally damaged, for example, by exposure to a myolytic toxin, the muscle fibers may regenerate and become innervated by the surviving nerve terminal. In such cases, the NMJs that reform at the original sites often differ in structural detail from the original ones. As during aging, they tend to consist of numerous small synaptic spots rather than the bands of synaptic contact present normally. An example of this kind of change is seen in muscles of *mdx* mice, which have a form of muscular dystrophy that results in the degeneration and regeneration of most muscle fibers (Figure 2). In spite of the altered form of the restored NMJs, neuromuscular transmission is essentially normal, indicating that changes in overall structure of the NMJ may not necessarily have an important impact on the efficacy of transmission.

Figure 1 Changes in the structure of human neuromuscular junctions (NMJs) with age: (a) three classes of NMJs based on extent of branching of preterminal motor axon; (b) decrease with age in fraction of NMJs with an unbranched terminal axon (T1 (%)). From Oda K (1984) Age changes of motor innervation and acetylcholine receptor distribution on human skeletal muscle fibres. *Journal of the Neurological Sciences* 66: 327–338.

Figure 2 Mouse neuromuscular junction (NMJ) reorganization after muscle damage (a) in control; (b) in *mdx* mouse NMJs following muscle degeneration and regeneration. Upper panels show nerves visualized after silver impregnation. Lower panels show the distribution of acetylcholine receptors (AChRs) visualized by R-α-bungarotoxin labeling. Images are from four different NMJs. Note that following muscle fiber regeneration, the NMJ consists of a cluster of spotlike synaptic regions instead of the continuous bands of contact seen normally. Reproduced from Lyons PR and Slater CR (1991) Structure and function of the neuromuscular junction in young adult mdx mice. *Journal of Neurocytology* 20: 969–981, with permission.

The Response to Nerve Injury

A second likely trigger of NMJ modification with age is the death of some motor neurons. It is well established in humans that the number of functional motor units (a single motor neuron and the muscle fibers it innervates) declines steeply after the age of 60. Death of a motor neuron leaves the muscle fibers it used to innervate in a state of denervation. Experimental studies in which some of the axons innervating a muscle have been destroyed intentionally have shown that such partial denervation is a potent sprouting stimulus for the intact motor axons. This sprouting may originate either from the nerve terminal itself or from the most distal nodes of Ranvier.

Partial denervation When some of the motor axons innervating a rat or mouse muscle are damaged, the muscle fibers so denervated are often reinnervated by newly formed branches of the surviving axons. Within a few days of partial denervation, axonal sprouts grow out from the intact nerve terminals and/or nodes of Ranvier. If such sprouts make contact with denervated NMJs, they are likely to form new synaptic contacts with them. As a result, the size of the surviving motor units gradually increases. In humans, an increase of this kind can be detected by single-fiber electromyography (EMG) as an increase in 'fiber density' (FD). In elderly patients, in whom changes in NMJ structure are common, there is a parallel increase in FD, consistent with the view that some of the changes in NMJ structure may be associated with cycles of partial denervation and reinnervation (Figure 3).

Complete denervation Some forms of injury may lead to the disruption of the entire nerve supply to a muscle. If the nerve is cut through, the axons are likely to grow out from the cut end; however, they may never grow back to the muscle they used to innervate. On the other hand, if the nerve is crushed so that the sheaths of connective tissues and extracellular matrix

Figure 3 Motor axons forming sprouts after nerve injury: (a) normal; (b) regeneration; (c) sprouting; (d) sprouting and regeneration. In (a), in normal mouse NMJs, the motor axon ends in a highly branched arborization in which each branch remains within the roughly oval region representing the NMJ. In (b), during nerve regeneration, such as after a crush injury of the entire nerve, axons make their way back to the original NMJs, but thin sprouts may also continue to grow beyond the NMJ. In (c), when only some of the axons are damaged, leading to partial denervation, axonal sprouts grow from the intact terminals and may reinnervate denervated muscle fibers. In (d), when damaged axons regenerate after partial denervation, both forms of sprouting may occur. NMJ, neuromuscular junction. surrounding each axon remain intact, the outcome is more successful. Then many axons may grow back within their original sheaths and eventually reach precisely the same muscle fibers they innervated previously. When the regenerating axons reach the site of the original NMJs, they often reoccupy those sites and effective transmission is rapidly restored.

In some cases, regenerating axons overshoot the original synaptic site. The result is that fine sprouts extend beyond the original NMJ and may even establish some new sites of synaptic contact with the muscle fiber (Figure 3(b)). As a rule, these escaped sprouts regress after a number of weeks. Why the newly made synaptic contacts are less stable than those made at the sites of the original NMJ is not known.

The ability of motor axon sprouts to form new synaptic contacts with adult muscle fibers is a particularly striking aspect of NMJ plasticity. This process of ectopic NMJ formation involves the localized induction by the nerve of all the key components of the postsynaptic apparatus that allow increases in acetylcholine (ACh) concentration to excite the muscle fiber.

The Role of the Schwann Cell

The molecular events associated with the initiation and growth of the axonal sprouts that form the structural basis of NMJ plasticity are generally poorly understood. At a cellular level, however, an important discovery was that within a few days of denervating a mammalian muscle, the Schwann cells that cap the nerve terminal at the NMJ extend sprouts similar to those that grow out from the nerve. These Schwann cell sprouts can become very extensive, forming a dense network over the surface of the muscle. Following reinnervation of the muscle and renewed contractile activity, the Schwann cell sprouts regress and a more or less normal arrangement is restored. When muscles are partially denervated, only those Schwann cells at the denervated NMJs extend sprouts. Thus, the control of Schwann cell sprouting is mediated very locally.

The real significance of the Schwann cell sprouts for NMJ plasticity was revealed by careful examination of the relationship of axon and Schwann cell sprouting in partially denervated muscles (Figure 4). This has shown that axon sprouts generally grow along Schwann cell sprouts, which apparently serve as guides. When an NMJ is denervated, its Schwann cells extend sprouts in all directions but particularly in the direction of intact NMJs on muscle fibers that are still active. If one of those sprouts makes contact with an innervated NMJ, it apparently induces the outgrowth of axonal sprouts that follow the Schwann cell processes back to the denervated NMJ. Thus, the Schwann cell plays a central role in the events that account for the adaptive plasticity of the NMJ.

How Is Nerve Terminal Sprouting Regulated?

The events that account for Schwann cell and axon sprouting during adaptive plasticity of the NMJ are not known with any certainty. It seems likely that both the rearrangement of cytoskeletal proteins and the directed insertion of membrane into growing sprouts are involved. Whatever the mechanisms of

Figure 4 Schwann cells guiding axonal sprouts to denervated neuromuscular junctions (NMJs): (a) normal NMJ (rat); (b) Schwann cells forming sprouts after damage to a motor axon terminal; (c) sprouts growing away from damaged NMJ; (d) sprouts contacting intact NMJs; (e) intact axons growing back along the Schwann cell sprouts; (f) intact axons making contact with the denervated NMJs and reestablishing synaptic contact. Axons are shown in red and Schwann cells are shown in blue in all diagrams. From Son YJ, Trachtenberg JT, and Thompson WJ (1996) Schwann cells induce and guide sprouting and reinnervation of neuromuscular junctions. *Trends in Neuroscience* 19: 280–285.

sprout formation and growth, additional questions remain concerning the factors that trigger these events.

The role of activity The search for factors that induce sprouting has generally started from observations that axonal sprouting is influenced by muscle activity. There is evidence that both increased and reduced levels of activity may induce changes in NMJ structure and function. For example, increased activity associated with exercise training caused an increase in the length and extent of branching of rat NMJs without altering the total area of synaptic contact. In contrast, reduction of activity by unloading muscles caused a reduction in total area without altering nerve branching. The basis of these rather subtle changes is unknown.

In contrast, a complete block of muscle activity, whether by long-term application of local anesthetics to the nerve or by exposure to botulinum toxin to block neuromuscular transmission, induces extensive sprouting. Direct stimulation of muscles in which axonal sprouting has been triggered by exposure to botulinum toxin reduces sprouting from motor axon terminals. It thus seems that the amount of activity can have a long-term regulatory effect on the NMJ plasticity.

Growth factors Many features of muscle fiber biochemistry are influenced by activity. An obvious possibility is that nerve sprouting is triggered by the action of one or more diffusible substances that are released from inactive (but not from active) muscles. A candidate for which there is considerable evidence is insulin-like growth factor (IGF-)1. The expression of IGF-1 by muscle is suppressed by normal electrical activity, but increases following denervation. When muscles are exposed to IGF-1 *in vivo,* it has a sprout-promoting effect. Furthermore, natural sprouting in response to botulinum toxin is reduced if the muscles are exposed to an IGF-1 binding factor IGF-BP4, known to inactivate IGF-1 in *in vitro* assays. The effect of these experimental procedures on the Schwann cells is not known.

Although these observations are intriguing, it is not clear that a single factor could control the entire sprouting response of the nerve at the NMJ in a wide variety of situations. Although various other factors have been reported to have sprout-promoting activity, the evidence that they play a role in the sprouting response *in vivo* is not strong.

Botulinum Toxins and How They Block Neuromuscular Transmission

Natural History of Botulism and Botulinum Neurotoxins

Botulism (from the Latin *botulus,* sausage) is a paralytic disease often caused by eating inadequately preserved food. Since the classic studies of van Ermengem in the 1890s, it has been recognized that the pathogens are neurotoxins synthesized by the bacterium *Clostridium botulinum*. These toxins cause a block of ACh release from motor nerve terminals, leading to muscle weakness or paralysis. It was recently found that the toxins are peptidases that specifically cleave one or more of the proteins that play a central part in synaptic vesicle exocytosis.

Several forms of botulism, varying in the mode of infection, are recognized clinically. In the classic food botulism, the toxins are ingested and reach the NMJs via the bloodstream. In infant botulism, the most common form in some countries, bacterial spores (often present in honey) are ingested and then germinate in the intestinal tract, leading to the proliferation of the pathogenic bacteria and production of the active toxin. The susceptibility of infants to this form of botulism is believed to result from the absence of protective bacterial flora and bile acids that inhibit the proliferation of the bacteria in the adult digestive tract. A third form, wound botulism, arises from the bacteria *C. botulinum* in abscesses and is particularly common in drug abusers.

Clinical features of the disease The main features of botulism are weakness and paralysis. When this involves the respiratory muscles, it is potentially fatal. Indeed, botulinum toxin is one of the most toxic substances known, with an estimated fatal dose of as little as 0.1 μg. However, even in severe cases, recovery is often possible with appropriate management, although it may take weeks before the patient can breathe unassisted, months before ambulation is possible, and years before fully normal movement recovers.

It is clear that clinical botulism results from a block of neuromuscular transmission. Evidence for this comes from both EMG studies and electrophysiological investigations of NMJs in biopsy samples from patients.

Botulinum neurotoxin structure and serotypes There are seven distinct serotypes of botulinum neurotoxin (BoNT/A–G) (Table 1). These are the products of distinct but closely related genes. All are also closely related in structure to tetanus toxin produced by the bacterium *Clostridium tetani,* suggesting that all these toxins arose from a common ancestor. Each toxin has a molecular mass of approximately 150 kDa and consists of a heavy (H) chain of approximately 100 kDa and a light (L) chain of approximately 50 kDa.

Overview of Botulinum Neurotoxin Action

All forms of BoNT are zinc peptidases. Their natural substrates are one or more of the soluble *N*-ethylmaleimide-sensitive factor attached protein receptor (SNARE) proteins that play a central part

Table 1 Botulinum neurotoxin serotypes[a]

Serotype	*Extracellular protein binding target*	*Intracellular enzymatic target*	*Duration of action*		*Sources*[b]
			Mouse/rat NMJ	*Human NMJ*	
A	SV2	SNAP-25	30–90 days	>3 months	[2, 4, 11, 12, 13]
B	Synaptotagmins	Synaptobrevin	21 days	~2 months	[3, 5, 7, 10]
C	?	SNAP-25, syntaxin	~2 months	~2 months	[1, 3]
D	?	Synaptobrevin			[11]
E	?	SNAP-25	4–5 days	< 1 month	[4, 6, 11, 13]
F	?	Synaptobrevin	7 days	1–2 months	[3, 6, 8]
G	Synaptotagmins	Synaptobrevin			[7, 9]

[a]?, unknown; NMJ, neuromuscular junction; SNAP-25, synaptosomal-associated protein of 25 kDa; SV2, synaptic vesicle protein 2.

in the process of quantal release of ACh from the motor nerve terminal (Figure 5). Because these proteins are all intracellular, the toxins can gain access to them only by crossing the plasma membrane to enter the cytoplasm of the nerve terminal.

Binding and Activation of Botulinum Neurotoxins

Binding targets The first step in the action of BoNT at the NMJ is binding to a specific site on the extracellular surface of the nerve terminal. This binding is achieved by the C-terminal region of the H chain. The binding sites on the nerve appear to consist of two parts: a protein and a ganglioside. It was recently found that the protein component of the binding site for BoNT/A is the extracellular domain of SV2, an integral protein of the synaptic vesicle membrane that is exposed on the surface of the nerve terminal by vesicle exocytosis during neuromuscular

Figure 5 BoNT/A acting on the neuromuscular junction (NMJ): (a) the NMJ target of botulinum neurotoxins (BoNTs); (b) the crystal structure of BoNT serotype A (BoNT/A); (c) the mode of action of BoNTs; (d) cleavage sites of the various BoNT serotypes (A–G) on vesicle-associated membrane protein (VAMP)/synaptobrevin (blue). As shown in (a), the cell body of the motor neuron is located in the spinal cord, and the myelinated axon projects to the muscle fiber, making contact at the motor endplate, the prime target of BoNTs. In (b) and (c), the three distinct domains of BoNT/A are color coded. As shown in (c), the mode of action of BoNTs comprises (i) binding to a proteinaceous BoNT acceptor and gangliosides, (ii) internalization into an endocytic compartment, (iii) translocation of BoNT into the cytosolic compartment following endosomal acidification and the subsequent release of the light chain from the heavy chain by reduction of the disulfide bridge, and (iv) soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) cleavage via zinc-endopeptidase activities possessed by the light chains. As shown in (d), the VAMP)/synaptobrevin protein is located on synaptic vesicles; by contrast, synaptosomal-associated protein of 25 kDa (SNAP-25; yellow) and syntaxin 1 (pink) are situated predominantly on the nerve terminal plasmalemma. ACh, acetylcholine. From Foran PG, Davletov B, and Meunier FA (2003) Getting muscles moving again after botulinum toxin: Novel therapeutic challenges. *Trends in Molecular Medicine* 9: 291–299.

transmission. In contrast, BoNT/B and BoNT/G bind to the extracellular domain of synaptotagmin, a component of the nerve membrane. The ganglioside components of the binding sites have not been fully characterized.

Uptake, translocation, and activation Once bound to the nerve terminal surface, the BoNT is translocated into the cytoplasm by endocytosis. The lumen of the endocytotic vesicles is acidic, and this causes a conformational change in the H chain that enables the toxin to pass through the vesicle membrane into the cytoplasm. There the L chain, and the enzyme activity associated with it, separates from the H chain.

Enzyme activity The L chains of the seven BoNT serotypes are all zinc-dependent metalloproteases, but they differ in their substrate specificities (Table 1). BoNT/A and BoNT/E both attack synaptosomal-associated protein of 25 kDa (SNAP-25) but at different sites; BoNT/B, /D, /F, and /G all attack synaptotagmin but again different cleavage sites are involved. Finally, BoNT/C attacks both syntaxin and SNAP-25. In each case, cleavage of the target protein causes the cessation of Ca^{2+}-dependent vesicular ACh release and hence the failure of neuromuscular transmission. The particular pattern of cleavage associated with each serotype has an important influence on the duration of its toxic effect.

Response of the Neuromuscular Junction to Botulinum Neurotoxin

Block of Transmission

Following an intramuscular injection of BoNT/A, a block of neuromuscular transmission usually occurs within 1–4 days. Both spontaneous miniature endplate potentials (mEPPs) and evoked EPPs are affected. In a clinical context, the decline in the electrical signs of muscle activation may continue for up to 2 weeks. By contrast, when isolated nerve–muscle preparations are exposed to BoNT/A *in vitro*, both spontaneous and evoked quantal release may cease within 1–2 h. It thus seems that the main determinant of the rate of onset of the blocking effect *in vivo* is the time required for an active concentration of BoNT to build up in the vicinity of the NMJs. Clearly in the cases of wound and infant botulism, in which the bacteria must first proliferate in the gut and then produce and release the toxin, the delay between contact with the source of the pathogen and the onset of symptoms is likely to be longer than for food botulism.

Recovery of Transmission after Block by BoNT/A

The recovery of transmission takes place on a time scale of days to months, depending on the BoNT serotype involved and the dose (Table 1). The longest acting serotype is BoNT/A, and for this reason it is used most often in the clinical context. It is also the serotype whose action has been studied in greatest detail.

Axon sprouting Blockade of neuromuscular transmission by BoNT/A in rats and mice is followed within a week or less by the initiation of sprouting by the terminal motor axons (Figure 6). The fine unmyelinated sprouts extend away from the parent NMJ, and in mice grow at a rate that increases from approximately 3 μm day^{-1} at the outset to 15 μm day^{-1} after several weeks. Individual sprouts may ultimately attain lengths of several hundred micrometers. The axonal sprouts are accompanied by Schwann cell sprouts, as following partial denervation.

A poorly understood aspect of the sprouting induced by BoNT/A is the mechanism of insertion of the new membrane that forms the sprouts. Evidence from some studies suggests that the normal activity of SNAP-25, the target of BoNT/A action, is required for axon growth, presumably as part of the process by which new membrane is added to the growing sprouts. During the early stages of motor axon sprouting induced by BoNT/A, the exocytosis associated with the quantal release of ACh is fully blocked, whereas that associated with sprouting is active. One possible explanation is that BoNT/A is inactivated soon after the initial SNAP-25 cleavage. Another is that the SNAP-25 molecules targeted by BoNT/A are not required for sprout formation.

Formation of new synapses The muscle paralysis induced by BoNT/A leads to the generalized expression of numerous postsynaptic molecules within the muscle fiber. Among these are the AChRs. Within approximately a week after sprout formation begins, clusters of AChRs start to form along the growing axons. This process has been followed using fluorescent conjugates of the AChR-binding protein α-bungarotoxin, together with antibody labeling of the axons and their sprouts. Within days of the appearance of the first AChR clusters, lateral branches of the axons form. Individual branches often end in a swollen bouton 1–3 μm in diameter. Most, if not all, new AChR clusters are associated with these boutons. The new synaptic spots also acquire a high density of AChE. Thus, two of the most distinctive components of the NMJ, and probably many more, come to be specifically associated with the newly formed axonal boutons.

Figure 6 BoNT/A inducing axon sprouting and AChR clustering: (a) normal mouse NMJ; (b) 4 days after a blocking dose of BoNT/A; (c) 8 days after dose; (d) 16 days after dose; (e) graph of quantal content of ACh over time. As shown in (a), at a normal mouse NMJ, the branches of the terminal axon (green) occupy regions of high AChR density (red).As seen in (b), 4 days after a blocking dose fine axonal sprouts can be seen; these sprouts grow and branch over the surface of the muscle. As seen in (c), they often end in swollen boutons. In (d), after approximately 2 weeks, AChRs begin to accumulate in the vicinity of the terminal boutons. ACh, acetylcholine; AChR, acetylcholine receptor; BoNT/A, botulinum neurotoxin serotype A; NMJ, neuromuscular junction; QC-EDL, quantal content of the extensor digitorum longus muscle; QC-SOL, quantal content of the soleus muscle.

Recovery of Quantal Release

The first signs of renewed quantal release of ACh are detected approximately 2 weeks after exposure of the rat/mouse NMJs to a fully blocking dose of BoNT/A. There is then a period of several months during which both spontaneous and evoked release gradually return to near normal values.

It has generally been assumed that the initial recovery of quantal release after BoNT/A intoxication occurs at new synaptic contacts formed by the sprouts. Support for that view comes from studies in which a membrane-soluble fluorescent dye, FM1–43, was used to visualize sites of membrane cycling associated with nerve activity. At normal NMJs, FM1–43 is taken up into the nerve terminal during activity. During the period of complete block following exposure to BoNT/A, this activity-dependent labeling is abolished. The first sites where labeling is again seen during recovery are associated with the sprouts. Eventually, FM1–43 labeling returns in the region of the original NMJ and that associated with the sprouts is lost (Figure 7(b)).

Although these observations are consistent with the view that newly formed synaptic spots account for the initial function recovery after BoNT/A, release was not measured directly. Other studies, made on different muscles of the mouse, suggest that recovery of release at the original NMJ may occur as early as that associated with the sprouts. In both cases, however, it is clear that the new contacts contribute to the initial recovery.

Withdrawal of sprouts In the original description of axonal sprouting following BoNT/A intoxication, it was noted that many of the sprouts were eventually withdrawn (Figure 7(a)). This has been subsequently confirmed by other studies (Figure 7(b)). The withdrawal occurs after neuromuscular transmission has recovered sufficiently to generate appreciable muscle activity. This suggests that, as during nerve regeneration, the sprouts and their newly formed synaptic contacts are less stable than the contacts formed at the original synaptic sites. The basis for this differential stability is not yet known.

It has generally been observed that, even after sprout withdrawal, the appearance of the surviving NMJs differs substantially from normal. Because the reformed NMJs appear to function well, the situation is similar to that following muscle damage in that essentially normal function may be restored even though the structure of the NMJs remains abnormal.

Serotypes other than BoNT/A The rate of recovery from BoNT intoxication depends greatly on the serotype. Although it takes several months to recover from BoNT/A, recovery from BoNT/E is largely complete in less than 1 week. Recovery from other serotypes occurs at intermediate times (Table 1). Here note that the time course of recovery depends on the dose and that in Table 1 typical, but not always directly comparable, values are given. The other factors that determine the duration of functional block associated with the different serotypes are only partly understood. Of particular interest is the comparison between the longest-acting serotype, BoNT/A, and the shortest, BoNT/E, because both cleave SNAP-25. The difference between them is in the site of cleavage. Whereas BoNT/E removes a 26-amino-acid peptide from the C-terminus, the peptide removed by BoNT/A is only 9-amino-acids long. It has been suggested that the removal of 9 amino acids from SNAP-25 is enough to completely inactivate the enzyme activity of the

Figure 7 Reorganization of BoNT/A-induced sprouting: (a) drawings of a hypothetical motor axon terminal in a mouse soleus NMJs at different stages in the response to BoNT/A; (b). Experimental results from studies using repeated observation of the same NMJ *in vivo*. In (a), normal NMJ with no fine sprouts present (stage 1). During the early response to BoNT/A, fine sprouts appear (stage 2, 4 days; cf. Figure 6). More extended sprouts as seen during the recovery of functional transmission (stage 3). Enlarged terminals of new synaptic contacts are present along with persisting sprouts when transmission has recovered (stage 4). Note that original NMJ is no longer recognizable. In (b), the nerve terminal is labeled green, representing the mitochondrial dye 4-di-2-asp. The regions of the terminal which take up the membrane dye FM1–43 appear red; these are assumed to be regions of activity-dependent quantal release of ACh. Scale bars = 20 μm. ACh, acetylcholine; BoNT/A, botulinum neurotoxin serotype A; d0, d53, d91, day 0, day 53, day 91; NMJ, neuromuscular junction. Panel (a) Reproduced from Duchen LW (1970) Changes in motor innervation and cholinesterase localization induced by botulinum toxin in skeletal muscle of the mouse: Differences between fast and slow muscles. *Journal of Neurology, Neurosurgery and Psychiatry* 33: 40–54, with permission from BMJ Publishing Group; panel (b) Reproduced from de Paiva A, Meunier FA, Molgó J, Aoki KR, and Dolly JO (1999) Functional repair of motor endplates after botulinum neurotoxin type A poisoning: Biphasic switch of synaptic activity between nerve sprouts and their parent terminals. *Proceedings of the National Academy of Sciences of the United States of America* 96: 3200–3205, with permission from proceeding of the National Academy of Sciences, USA.

toxin while still leaving it in a sufficiently normal state to prevent it from being recognized as defective and hence being rapidly broken down and replaced. Thus, its continued presence as an inactive protein may account for the long duration of the functional blocking effect of BoNT/A.

The rate of recovery has a substantial influence on the extent of axonal sprouting and new synapse formation. Following exposure to BoNT/E, which blocks neuromuscular transmission for less than a week, there is little if any sprouting. Thus functional recovery in this case must occur by recovery of release at the original nerve terminals.

BoNT/F blocks transmission for approximately 1–2 weeks. Sprouting occurs after BoNT/F, but is withdrawn soon after the block is overcome.

Differences Related to Muscle Type and Species

The response to BoNTs also varies both between species and between muscles in the same species. For example, axonal sprouting and functional recovery are much slower in frogs than in mammals. A number of studies on mammalian muscles found that the extent of sprouting is greater in slow-twitch than in fast-twitch muscles. This has sometimes been interpreted to mean that slow motor neurons are more plastic and therefore more successful at recovering from impaired function. Alternatively, it may be that fast motor neurons make new synaptic contacts more rapidly and effectively than slow ones and that the muscle activity resulting from those contacts limits more extensive sprouting in fast muscles.

Effects on muscle When mammalian skeletal muscles are paralyzed for more than a few days, they generally undergo significant atrophy. This loss of volume is part of a complex response to inactivity that has among its effects a facilitation of the restoration of adequate innervation. As the NMJs in a muscle recover from a BoNT-induced block, activity resumes and the muscle fibers regain their normal size. It is a common finding that, during recovery from BoNT intoxication, the variation in muscle fiber diameters is greatly increased. This results from the presence of both abnormally small- and abnormally large-diameter fibers. The former presumably reflects disuse atrophy of the muscle fibers that are functionally denervated, whereas the latter may reflect hypertrophy due to overuse of the fibers. This situation presumably reflects different rates of recovery at different NMJs, possibly related to the functional type of the motor neuron.

Clinical and Cosmetic Uses of BoNT/A

It is a remarkable fact that BoNT/A, one of the most toxic substances known, is currently used clinically to manage patients with abnormal patterns of muscle activation, (e.g., spasticity and dystonias). Even more

Figure 8 BoNT/A inducing sprouting at human NMJs: axonal sprouts (small arrows), visualized after silver impregnation, can still be seen in the human orbicularis oculi muscle 3 years after treatment with BoNT/A. Reproduced from Holds JB, Alderson K, Fogg SG, et al. (1990) Motor nerve sprouting in human orbicularis muscle after botulinum A injection. *Investigative Ophthalmology & Visual Science* 31: 964–967, with permission from Association for Research in Vision and Ophthalmology.

remarkable is the elective use of BoNT/A as a cosmetic reagent to reduce facial wrinkling by selective weakening of facial muscles. These uses are made possible by the fact that, when injected intramuscularly, BoNT/A binds tightly to the binding sites at the NMJ. Unbound toxin is rapidly broken down. As a result, the diffusion of active toxin away from the site of injection in the extracellular environment may be limited. By keeping doses and injection volumes small, it is therefore possible for experienced and careful operators to use BoNT/A to achieve localized weakening of muscles with minimal risk. At the same time, it is clear that the risks of adverse side effects exist, particularly when repeated injections over a long period of time are used.

The initial use of BoNT/A in a clinical context was to weaken muscles involved in various focal dystonias. These include blepharospasm, strabismus, hemifacial spasm, cervical dystonia, and both juvenile and adult forms of spasticity. More recently, it is also used to treat a variety of autonomic disorders (e.g., hyperhidrosis) and pain syndromes.

Effects of Botulinum Neurotoxins on Human Neuromuscular Junctions and Muscle

Remarkably little is known about the effects of therapeutically administered BoNTs on human NMJs. There are no detailed studies of the short-term effects on NMJ structure and function and only one serious study of the long-term effects on NMJ structure, made on muscles of the eyelid. By far the most common serotype used in clinical practice is BoNT/A because of its long-lasting effects. What follows, therefore, concerns the response to this form.

Time course of action The development of detectable muscle weakness after the administration of BoNT/A is usually reported to take several days. Because the toxin acts within hours on isolated muscles, it is likely that the longer time course seen in practice reflects the low doses used and the spread of the toxin through the extracellular spaces.

Some recovery of muscle strength is usually reported to be detectable 1–3 months after an injection. Here it must be recalled that there is a high safety factor for neuromuscular transmission. As a result, some muscle fibers can be activated when the quantal release of ACh from the nerve is still much lower than normal. Because the aim of the therapeutic use of BoNT/A is to cause muscle weakness, even slight recovery may be considered disadvantageous and viewed as a signal for repeated treatment. It is, therefore, common practice to repeat injections at intervals of several months to maintain the therapeutic effect.

Effects on nerve It is clear from clinical EMG studies that the muscle weakness caused by injections of BoNT/A results from a block of neuromuscular transmission. Almost nothing is known in detail about the process or true extent of recovery of neuromuscular

transmission after BoNT/A injections. Studies of eye muscles from 6 weeks to 3 years after cessation of BoNT/A treatment reveal abundant axonal sprouts (Figure 8). It is therefore likely that the initial recovery, as in animals, is associated with the formation of such sprouts and new synaptic contacts, but there is no direct evidence to support or refute this possibility. What is clear is that, even several years after ending BoNT/A treatment, the nerve terminals may retain strikingly abnormal features.

Effects on muscle The muscle paralysis resulting from BoNT/A treatment generally leads to muscle-fiber atrophy and muscle wasting. Muscles that have been studied at various times after treatment show a striking increase in variability of fiber diameters, similar to that seen in animal muscles. It is not yet known whether normal muscle-fiber diameters are ever fully restored. However, there is some evidence that increased fiber-diameter variation may persist for more than 1 year in human muscles. Whether this reflects a very prolonged period of reinnervation or a stable situation in which some muscle fibers remain permanently functionally denervated is not clear.

Conclusion

The adequate functioning of the NMJ is essential for survival. It is therefore not surprising that very effective mechanisms have evolved to maintain reliable transmission even after severe mechanical trauma or toxic assault. Most notable of these mechanisms are the regeneration of motor axons and effective reinnervation of muscles after damage and the formation of axonal sprouts and new synaptic contacts following partial denervation or BoNT/A intoxication. In these processes, the nerve, the muscle, and the Schwann cell, and interactions among them, all play important parts.

The Vertebrate Neuromuscular Junction: An Excellent System for Studying Neurotransmitter Receptor Accumulation in the Postsynaptic Membrane

Synapse formation in the nervous system is an example of highly coordinated subcellular differentiation driven by localized reciprocal interactions between the synapsing cells. These interactions result in the apposition of the molecules that mediate transmitter release in the nerve terminal and the ligand-gated ion channels that are opened by the transmitter in the target cell. To enable synaptic transmission to operate sufficiently rapidly, these two features of the synapse must be located within less than 100 nm of each other. This raises the question, what are the mechanisms that coordinate the appearance and spatial alignment of these crucial aspects of pre- and postsynaptic differentiation?

The vertebrate neuromuscular junction (NMJ) has served as a valuable model system for formulating and testing ideas regarding the cell–cell communication that governs synapse formation. Compared with synapses in the brain, which are small and are made by different neuronal types at different stages of development, the NMJs are large, have qualitatively similar properties, develop at a similar time, and are easily accessible for experimental manipulation. Moreover, new NMJs can be surgically induced to form in adult muscle. Furthermore, the electrical impulse activity which influences the expression of genes involved in synapse formation can be experimentally controlled independently in the pre- and postsynaptic cells forming these *de novo* synapses. Finally, combinations of transgenes can be readily transferred into the myofibers, allowing examination of their function for subsynaptic differentiation.

At NMJs, action potentials in the nerve cause acetylcholine (ACh) to be released from the nerve terminals. This ACh then binds to acetylcholine receptors (AChRs) in the postsynaptic muscle membrane. The muscle AChRs are ligand-gated ion channels which open on binding ACh. The flow of cations through the open channels causes a depolarization that induces an action potential which propagates along the muscle membrane, triggering muscle contraction. So that each action potential in the motor neuron is transmitted to the muscle fiber, AChRs must accumulate in the postsynaptic muscle membrane during development and be maintained there at high concentration throughout life.

Vertebrate skeletal muscle fibers are very large, multinucleated cells. The region of nerve contact at the NMJ occupies about 0.01% of the surface area of a typical muscle fiber. Two complementary processes account for the high density of AChRs in this region. First, in immature muscle, AChRs that are mobile in the plane of the cell membrane aggregate at sites of nerve–muscle contact. This aggregation is mediated by AGRIN, a protein which is released from the nerve terminal. Like all proteins, the clustered AChRs are constantly degraded and need to be continuously replaced. However, the electrical activity associated with muscle activation suppresses transcription of *AChR* subunit genes by muscle fiber nuclei. A second key process therefore exists to ensure that new AChRs continue to be synthesized near the NMJ in active muscles. Signals released by the motor neuron act to maintain a high level of *AChR* subunit gene expression by the small number of muscle nuclei in the immediate vicinity of the synapse. This article discusses the signals and molecular pathways by which the motor nerve maintains *AChR* gene transcription at the synapse despite its suppression in nonsynaptic regions. It should be noted, however, that in addition to *AChR* genes, nuclei at the synapse also express genes coding for other synaptic components at elevated levels (see Table 1).

Recent experiments have dramatically reshaped our understanding of the mechanisms regulating the accumulation of AChRs in the postsynaptic membrane of the vertebrate NMJ. Recent genetic studies *in vivo* have demonstrated convincingly that major conclusions drawn from earlier *in vitro* (muscle culture) studies were incorrect. The data from these *in vitro* studies (some of which are reviewed below) strongly suggested that neuregulin (NRG)/ARIA was the principal molecule stimulating synapse-specific synthesis of AChRs but had little effect on clustering AChRs whereas AGRIN, which clearly induced clustering, had no stimulating effect on synapse-specific synthesis of AChRs. However, the current evidence supports the conclusion that *in vivo*, AGRIN plays an essential role in both clustering of AChRs and their synapse-specific synthesis. In contrast, NRG/ARIA has only a minor role in postsynaptic AChR accumulation (but does

Table 1 Genes for which elevated expression levels by subsynaptic nuclei of the adult neuromuscular junction have been demonstrated

Gene	*Function*
AChRα	AChR subunit
AChRβ	AChR subunit
AChRδ	AChR subunit
AChRε	AChR subunit
Ache	Acetylcholinesterase, rapidly terminating ACh action by hydrolysis
Rapsyn	Membrane associated protein required for synaptic AChR clustering
Utrophin	Cytoskeletal protein involved in synaptic AChR clustering
Musk	Component of Agrin receptor complex, required for all aspects of postsynaptic differentiation
Dok-7	MuSK-interacting cytoplasmic protein, essential for MuSK activation
Na_v1.4	Voltage-activated sodium channel, expressed in adult muscle
Erbb2	NRG receptor
Erbb3	NRG receptor
Laminin–β2	Component of synaptic basal lamina, involved in presynaptic differentiation
Ncam	Neural cell adhesion molecule thought to be involved in neuromuscular adhesion

Data based on elevated transcriptional activity or on synaptic levels of respective mRNAs.

have other essential roles in the development of the neuromuscular system). The reader is asked to keep these points in mind while reading this article.

Expression of AChRs throughout Uninnervated Differentiating Myotubes Is Replaced by Synapse-Specific Expression in Innervated Fibers

The pattern of AChR expression along muscle fibers and cultured myotubes was initially resolved by electrophysiological mapping of ACh sensitivity, that is, changes in membrane potential in response to localized application of short pulses of ACh to the fiber surface. Later, application of labeled α-bungarotoxin (α-BTX), a snake venom protein that binds with very high affinity to AChRs, was used to visualize and quantify AChR distribution. Both methods revealed that AChRs are distributed along the full length of uninnervated and denervated muscle fibers, often grouped in small clusters, but that in mature innervated muscle, almost all surface AChRs are aggregated in the postsynaptic muscle membrane immediately opposite the nerve terminal. These findings indicated that there is a mechanism that tightly traps (clusters) AChRs at the synapse but left open the question as to whether in innervated muscle (1) *AChR* subunit genes are expressed by nuclei throughout the muscle, with the assembled receptors or unassembled subunit proteins or subunit mRNAs subsequently transported to the synapse, or if instead, (2) the *AChR* subunit genes are expressed primarily by subsynaptic nuclei. Molecular biological studies over the period ≈1985–93, applying techniques of increasing sophistication, definitively demonstrated synapse-specific transcription by subsynaptic nuclei.

Muscle AChRs are heteropentameric transmembrane proteins composed of α, β, δ, and either a γ or an ε subunit, each encoded by a separate gene. The AChRs present in immature muscle have the subunit composition $\alpha_2\beta\gamma\delta$ and are sometimes referred to as fetal while those in mature muscles have the composition $\alpha_2\beta\delta\varepsilon$ and are known as adult. The AChR α, β, γ, and δ subunits are expressed by differentiating myoblasts as part of their developmental program. Mammalian myoblasts fuse to form myotubes in two waves. In the first wave, myoblasts fuse to form a relatively small population of 'primary' myotubes that extend to both ends of the developing muscle. In a second wave, a few days after the first, other myoblasts that have undergone further proliferation line up along the primaries, generally in the central innervated region, and then fuse to form a much larger population of 'secondary' myotubes that make up the majority of fibers in adult muscle. During and after myoblast fusion, the expression of fetal AChR subunits along the entire length of the myotube (called global expression) is greatly increased relative to the levels expressed in unfused myoblasts.

It is at the developmental stage when primary myotubes are being formed that nerve processes, later followed by Schwann cells, appear in the developing muscle and begin to form neuromuscular contacts. These are characterized by clusters of fetal AChRs in the muscle membrane. Though the contacts at this stage lack many morphological and physiological characteristics of mature synapses, single quanta of ACh released from the nerve and activating the fetal AChRs are sufficient to generate action potentials in the myotubes, a process that is facilitated by their high input resistance and the long open time of fetal AChR channels. Thus, from the earliest stages of synapse formation, action potentials in the nerve induce muscle action potentials and contraction. Muscle action potentials repress *AChR* subunit gene expression by nuclei along the full length of the muscle fiber, and thus the consequence of innervation is that expression of *AChR* subunit genes by extrasynaptic nuclei becomes almost completely repressed as the muscle matures. An important exception is the

small group of muscle nuclei (termed 'synaptic' nuclei) that underlie the synaptic contact and continue to express high levels of *AChR* α-, β-, and δ-subunit genes in electrically active muscle. In the same nuclei, expression of the γ-subunit gene is replaced by that of the ε-subunit gene. This occurs during the early postnatal period in the rodent. The switch in subunit composition of the AChRs from $\alpha_2\beta\gamma\delta$ to $\alpha_2\beta\varepsilon\delta$ at the synapse results in channels with shorter open times but increased conductance for Na^+, K^+, and Ca^{2+} ions.

Do Motor Neurons Produce Signals That Induce Clustering of AChRs at the Synapse, Stimulate Synapse-Specific AChR Synthesis, or Both?

The central question addressed in this article is, what are the mechanisms that account for the production of AChR subunits at the synapse (synapse-specific expression) in the face of the global repression caused by muscle electrical activity? One possibility is that the synaptic nuclei differentiate independent of (and prior to) innervation to a state in which electrical activity does not suppress their expression of AChR subunits (discussed further in the section titled 'Myocentric model'). However, evidence from two experimental models of NMJ formation, nerve–muscle cocultures and the induction *in vivo* of ectopic synapses by surgical transplantation of foreign motor nerves onto nonsynaptic muscle regions, indicated that motor neurons produce signals that are capable of inducing activity-resistant accumulations of AChRs in the muscle plasma membrane opposed to the nerve terminal. Three hypotheses for the mechanism by which these nerve-derived signals cause AChR accumulation in the postsynaptic membrane were considered: that the signals induce clustering (aggregation) of AChRs, that they induce synapse-specific transcription of *AChR* subunit genes, or both. Using *in vitro* assays of AChR clustering and AChR synthesis rate, investigators set out to identify candidate signaling molecules.

A Nerve-Derived Factor Inducing AChR Aggregation: AGRIN

In a series of elegant experiments, McMahan and colleagues pursued the hypothesis that components of the basal lamina at the NMJ induce aggregation of AChRs. The basal lamina is the layer of extracellular matrix that ensheathes each skeletal muscle fiber and each myelinated axon. At the NMJ, a single layer of 'synaptic' basal lamina is present in the synaptic cleft between the nerve and the muscle. When adult muscles are damaged and allowed to regenerate within the persisting basal lamina sheath, AChRs aggregate at original synaptic sites (marked by the activity of acetylcholinesterase (AchE) that survives muscle fiber breakdown), even if the nerve is cut and its terminals degenerate. Material that could cause AChR aggregation in cultured chick muscle cells was found to be present in the extracellular matrix of the electric organ of the electric fish *Torpedo*, a modified NMJ of great size. This material was purified, found to be based on a protein, and named AGRIN. Antibodies against AGRIN label the synaptic basal lamina at frog and mammalian NMJs and prevent the AChR-aggregating activity of motor neurons. AGRIN is synthesized by motor neurons and released from motor nerve terminals (see also below). In mice in which expression of *Agrin* has been knocked out, nerve-induced AChR clustering fails to occur and nerves wander across the entire muscle, as they do in mice lacking the AGRIN receptor MUSK (Figure 1). There is thus very strong evidence that AGRIN released from the nerve mediates clustering of AChRs at developing NMJs. As pointed out above, AGRIN was not found to affect AChR synthesis rate in cultured myotubes. This is not the case *in vivo*, however, as discussed below.

Candidate Nerve-Derived Factors Inducing *AChR* Gene Transcription

Several molecules have been implicated in inducing the expression of *AChR* subunit genes by synaptic

Figure 1 Deletion of AGRIN or of the AGRIN receptor MUSK prevents AChR clustering and neuromuscular synapse formation. Instead, nerve fibers grow along muscle fibers, suggesting that an AGRIN/MUSK-dependent stop signal is required for neuromuscular synapse formation.

nuclei. They include products of four genes, *Nrg1*, *Nrg2, Agrin*, *αCgrp*, as well as ATP. We very briefly discuss αCGRP, and ATP, and then turn to NRG1, NRG2, and AGRIN.

αCGRP and ATP

αCalcitonin gene-related peptide (αCGRP; acting via a G-protein-coupled receptor) and ATP (acting via P2YX receptors enriched in the synaptic membrane) are present in motor nerve terminals and enhance AChR subunit mRNA in cultured myotubes. ATP also affects the rate of AChR desensitization by high concentrations of cholinergic agonist. In contrast to AGRIN and NRG1, however, they have not been shown to be essential for NMJ formation *in vivo*. Specifically, ablation of the *αCgrp* gene in mice does not affect NMJ development, nor does abolishing presynaptic αCGRP and ATP delivery by sectioning the motor nerve abolish synapse-specific *AChR* transcription. However, this does not exclude a redundant role of these factors in this process.

Neuregulins

***In vitro* studies implicating NRG1 as a motor neuron-produced signal regulating postsynaptic *AChR* gene expression** Fischbach and colleagues reasoned that if motor neurons produce a signal that locally stimulates the synthesis of AChRs, an extract of spinal cord (where the cell bodies of motor neurons are located) would increase the rate at which receptors are inserted into the surface membrane of cultured muscle. They found that chick spinal cord and chicken brain extracts did accelerate the rate of new AChR insertion and that this 'acetylcholine receptor-inducing activity' (ARIA) had the biochemical characteristics of a protein. Peptide sequence of ARIA purified from chick brain revealed that this protein is encoded by the gene now designated *Nrg1*.

The NRG1 proteins are ligands for the receptor tyrosine kinases ERBB2, ERBB3, and ERBB4. Several features of NRG1 support the hypothesis that NRG1 is a signal used by motor neurons to induce the synthesis of the muscle postsynaptic specializations. These features include the following: (1) NRG1 is produced by motor neurons and transported along motor axons to the motor nerve terminals; (2) NRG1 receptors are expressed by muscle and become concentrated in the postsynaptic membrane; (3) NRG1 treatment of cultured muscle increases the amount of AChRα, AChRδ, and AChRε mRNAs; and (4) NRG1 activates signal transduction pathways and *cis*-acting DNA sequences implicated in regulating synapse-specific gene transcription (see discussion below of pathways involved in AGRIN-activated gene transcription). It is noteworthy that NRG1 has little effect on AChR clustering. Thus, a widely accepted view in the 1990s was that motor neurons induced postsynaptic differentiation via two signals: NRG1, which stimulated synapse-specific gene transcription, and AGRIN, which caused clustering and anchoring of AChRs and other synapse-specific proteins.

***In vivo* genetic studies have revealed relatively normal NMJ development in mice lacking neuromuscular NRG signaling** A role of NRG/ErbB was difficult to test *in vivo* by genetic approaches because mice homozygous for *Nrg1* or *Erbb* null alleles die due to defects in heart development at an embryonic stage before neuromuscular synapse formation begins. This difficulty has been circumvented through production of mice with tissue-specific mutations of the *Nrg1*, *Erbb2*, and *Erbb4* genes. Synapses begin to develop normally in mutants lacking *Nrg1* selectively in motor and sensory neurons. However, because neural *Nrg1* mutants die at birth (see below), that is, before the developmental time when nerve-induced electrical activity causes marked global suppression of AChR expression, the dispensability of *Nrg1* from neurons for synapse-specific *AChR* gene transcription cannot be tested in the adult in these genetic models. NMJ phenotypes in *Nrg2* mutants have not been analyzed, but mutants are viable, suggesting formation of functional NMJs.

The recent analysis of mice with muscle-specific deletion of both *Erbb2* and *Erbb4* genes has allowed clear assessment of the requirement for NRG-mediated nerve to muscle signal in neuromuscular synapse formation and maintenance. Ablation of both *Erbb2* and *Erbb4* rendered fibers insensitive to NRG, thus abolishing NRG signaling selectively to muscle (ERBB3 homodimers are inactive as they lack a kinase domain) while leaving ERBB2 and ERBB4 expression by Schwann cells and motor neurons unaffected. Synapses developed normally in these mutants (Figure 2). They were viable for months past birth, and synapse-specific *AChRε* and *AChRδ* transcription in the adult was only marginally affected. Therefore, NRG signaling from nerve to muscle is not essential for formation and maintenance of the subsynaptic apparatus. The function of muscle ERBB receptors in the postsynaptic membrane remains unclear.

Essential functions of NRG1 in neuromuscular development While the biological significance of muscle ERBB receptors, and possible *Nrg1*-mediated neuron-muscle, Schwann cell-muscle, and muscle autocrine signaling, remains unclear, there is no uncertainty that NRG1 signaling is essential for neuromuscular system development. First, mice homozygous for a targeted

Figure 2 NRG signaling to muscle is not essential for neuromuscular synapse formation. Endplates develop normally in mouse mutants in which NRG/ErbB signaling to muscle is genetically abolished by Cre-induced recombination. (a) Muscle-specific *Erbb* deletion was induced by crossing a mouse line carrying a Cre transgene expressed under the control of a human skeletal actin promoter fragment (HSA-Cre) with a mouse line in which *Erbb* alleles were flanked by loxP sites. Endplates in (b) wild-type and (c) *Erbb*-deficient muscles appear similar (*en face* views (left), bar: 10 μm). Also shown are cross-sections after hybridization with a radiolabeled cRNA probe specific for the detection of *AChR* ε mRNA and development of photo emulsion. Note that accumulations of silver grains reflecting *AChR* ε mRNA co-localize with synaptic AChR clusters marked by fluorescent α-BTX (bar: 20 μm).

mutation that prevents production of Type III NRG1 protein die at birth because of respiratory paralysis and lack neuromuscular synapses because of degeneration of peripheral nerves. Analysis of these and other genetically altered mice, as well as cell culture studies, has demonstrated critical roles of NRG1 in proliferation, survival, migration, and myelination by Schwann cells. Second, targeted ablation of *Nrg1* in motor and sensory neurons (including γ-motor neurons and muscle spindle proprioceptive afferents) or of *Erbb2* in muscle prevents normal development of muscle spindles, causing abnormal gait.

AGRIN

AGRIN molecular variants and the AGRIN receptor MUSK AGRIN is secreted by muscle, nerve, and Schwann cells. As a consequence of differential mRNA splicing, multiple AGRIN proteins are produced by muscle, nerve, and Schwann cells (Figure 3). An N-terminal splice variant, NtA, binds to laminins, thus anchoring AGRIN to the synaptic portion of the muscle fiber's basal lamina. Another variant, TM, is a type II membrane protein with unknown function, expressed throughout the nervous system. NtA–AGRIN in turn is expressed in several C-terminal variants. The isoforms expressed by motor neurons include an 8, 11, or 19 amino acid insert (termed *B*- in chicken and *z*- in mouse) that is required for its function at the NMJ. While the three B/z variants differ somewhat in biological activity, they all act through a receptor tyrosine kinase (RTK) in muscle, MUSK, which is concentrated in the postsynaptic membrane. In contrast, AGRIN proteins lacking the B-/z-insert are expressed by terminal Schwann cells, along the entire length of muscle fibers, as well as in other tissues. The function of this AGRIN is poorly understood. In muscle, it does not activate MUSK, but it is involved in the organization of the muscle fiber's cytoskeleton.

***In vivo* genetic studies of AGRIN'S roles in synapse-specific gene expression** Consistent with the classical function of clustering AChRs, deletion of *Agrin* or of *Musk* genes abolishes synapse formation. It is interesting to note that in fetal muscle of mice lacking MUSK, no nerve-associated elevation of AChR subunit mRNA levels is seen, consistent with the idea that MUSK may be necessary for synapse-specific transcription (see also the section titled 'Models of neuromuscular synapse formation'). In these mice,

Figure 3 Structural domains of AGRIN and sites of alternative *Agrin* messenger RNA splicing (NtA vs. TM; A/y (0 vs. 4 amino acids); B/z (8 vs. 11 vs. 19 amino acids).) A miniAGRIN generated by fusion of an N-terminal fragment of Agrin (NtA), mediating binding to the basal lamina, to a C-terminal 21 kDa fragment comprising the B/Z-insert and LG3 is sufficient to activate MUSK and can induce ectopic nerve-free postsynaptic membranes, but with less potency than longer C-terminal fragments. SS: signal sequence required for secretion; LG: laminin globular domain. Binding regions to other partners (potentially) involved in NMJ formation are discussed in Bezakova G and Ruegg MA 2003 New insights into the roles of agrin. *Nature Reviews Molecular Cell Biology* 4: 295–308.

the growing motor neurons fail to make terminals but instead grow along the myotubes toward their ends. This suggests that a reciprocal signal from the muscle, in response to the AGRIN/MUSK interaction, is required for the induction of presynaptic terminals (Figure 1).

Positive evidence for a major physiological role of AGRIN in mediating synapse-specific *AChR* gene transcription comes from gain of function experiments in adult muscle. Recombinant neural AGRIN applied to nonsynaptic regions of normally innervated adult muscle fibers *in vivo* can induce the formation of functional ectopic, nerve-free, and Schwann cell-free postsynaptic membranes. These membranes contain accumulations of AChRs and all known molecules involved in AChR aggregation and anchoring and in *AChR* gene induction (muscle-derived NRG1, MUSK, and ERBBs) as well as the type of voltage-gated sodium channels concentrated at adult NMJs, $Na_v1.4$. The AChRs at these ectopic sites have the physiological properties of adult $\alpha_2\beta\varepsilon\delta$channels present at mature NMJs. Finally, the nerve-free ectopic membranes show synaptic folds characteristic of normal NMJs.

A striking feature of this inductive effect of AGRIN is that the ectopic postsynaptic membrane differentiation occurs in regions of the muscle where ongoing activity would normally suppress expression of *AChR* genes. Just as at normal NMJs, ectopically applied AGRIN induces the accumulation of a number of muscle nuclei. These nuclei, but not those elsewhere in the muscle fiber, express the genes *AChRε*, *Musk*, and, as implied from the activity-resistant AChR clusters, *AChRα*-, *β*-, and *δ*-subunits (Figure 4). In addition, these nuclei express higher levels of the gene *$Na_V1.4$* than do the nonsynaptic nuclei. Thus, the ectopic postsynaptic membranes induced by AGRIN are, at least qualitatively, similar to those

Figure 4 Ectopically applied AGRIN induces nerve-free, ectopic acetylcholine receptor (AChR) clusters and *AChRε*-subunit gene expression. Note that this occurs in spite of electrical impulse activity in the muscle fibers, which is maintained through the original synapses. Left: Ectopic expression of neural AGRIN by muscle fibers is induced by intracellular injection of AGRIN expression plasmid (pAgrin) into single muscle fibers. X- - - X denotes plane of cross-section shown on the right: (a) AGRIN-induced ectopic AChR clusters marked by fluorescent α-BTX; (b) same section after hybridization with a radiolabeled cRNA probe specific for the detection of *AChRε*-mRNA. Note that accumulations of *AChRε*-mRNA (arrowheads) co-localize with ectopic AChR clusters. Scale bar = 70 μm. (a, b) Reproduced from Jones G, Meier T, Lichtsteiner M, Witzemann V, Sakmann B, and Brenner HR (1997) Induction by agrin of ectopic and functional postsynaptic-like membrane in innerrated muscle. *Proceedings of the National Academy of Sciences of the United States of America* 94: 2654–2659, copyright (1997) National Academy of Sciences, USA.

induced by transplanted motor neurons. It is interesting to note that recombinant AGRIN induces nerve-free ectopic AChR clusters and *AChRε* transcription in electrically active muscle, even in *Erbb*-deficient fibers. Therefore, AGRIN alone is sufficient for targeting *AChR* gene transcription to the synapse in electrically active muscle fibers.

Signaling Pathways by Which MuSK Regulates Postsynaptic Gene Expression

***Musk* expression in the postsynaptic membrane: A positive feedback loop?** AGRIN induces synapse-specific *AChR* gene transcription via MUSK. Whereas *Musk* is expressed throughout fetal muscle cells, it is downregulated later in development by electrical muscle activity. But if electrical activity suppresses *Musk* expression, how is MUSK maintained at synapses of active fibers? In adult fibers, forced expression of *Musk* mutants that are constitutively active activates endogenous *Musk*. This implies that MUSK protein is able to autoactivate the expression of the *Musk* gene. Thus synaptic *Musk* expression is stabilized in electrically active fibers by AGRIN/MUSK in a positive feedback signaling loop.

Signaling pathways AGRIN-induced *Musk* transcription is mediated, at least in part, by a regulatory sequence, CCAAGG, termed *N-box*, in the first intron of *Musk*. The same motif is also found in the promoters of *AChRε*- and *δ*-subunit genes, for which it mediates transcription induced by NRG1*β* in cultured myotubes as well as that induced by the nerve at synapses *in vivo*. Thus, the pathways activated by AGRIN, NRG1*β*, and the nerve converge. The AGRIN-dependent pathway has been examined by overexpression of constitutively active and inactive signaling components. AGRIN is known to activate the small GTPases Rac, Cdc42, and Rho. Forced expression of the active mutant RacV12 strongly activates *Musk* and *AChRε*, as does overexpression of active MKK7, an effector of Rac. In contrast, in muscle fibers *in vivo*, induction of *AChRε* and *Musk* by AGRIN is barely affected by overexpression of inactive ERBBs, consistent with the findings on *Erbb*-deficient muscles. However, overexpression of the inactive mutant RacN17, of the MAP kinase JNK, an effector of MKK7, and of inactive GAPB*β*, an effector of JNK, strongly inhibit transcription of *AChRε* and *Musk* both *in vivo* and *in vitro*. In combination, these data are consistent with a pathway at the synapse in which AGRIN/MUSK, activating in turn small GTPases RAC, MKK7, JNK, and GABP and ERM, members of the Ets family of transcription factors, converge on the same N-box in the *AChRε* and *Musk* genes that mediates their activation by the nerve and by NRG/ERBB (Figure 5).

It should be noted that the levels of AChRs and of *Musk* mRNA at ectopic sites induced by AGRIN or constitutively active MUSK are lower than at original synapses. Therefore, full transcriptional activation at the synapse may require synapse-specific signaling components acting downstream of MUSK and essential for its function (e.g., DOK-7), or neural signals in addition to AGRIN, such as NRGs or ATP, which may also target regulatory sequences other than the N-box. For example, NRG1*β* has been found *in vitro* to activate strongly *AChRε* via the transcription factor EGR1, and ATP via Elk-1. Moreover, *in vivo*, forced expression in muscle of a general Ets-dominant negative mutant competing for binding to N-box regulatory elements reduces *AChRδ*- and *ε*-without an obvious effect on *Musk* mRNA levels. Finally, the *AChRα* gene lacks an N-box in its promoter. Alternative pathways are further suggested for another synaptic component, UTROPHIN, which is part of the synaptic cytoskeleton anchoring the AChRs in the synaptic muscle membrane. Specifically, synaptic levels of *Utrophin* mRNA are not regulated by transcriptional activation alone but also by RNA stabilization.

MUSK and synaptic nuclei One factor thought to be important for synapse-specific transcription is the clustering of 5–8 nuclei underneath the synaptic muscle membrane, thus exposing them optimally to signals from the nerve terminal, such as AGRIN. The mechanisms governing this clustering process are not known. Hints come from studies of the control of cell migration, in which crucial roles of small GTPases of the Rho family, in particular of Cdc42, in defining cell polarity with respect to extracellular cues, are well established. Given that (1) recombinant AGRIN and constitutively active MUSK accumulate muscle nuclei in adult fibers, (2) subsynaptic nuclei are embedded in a rich and elaborate microtubular network, (3) efficient and persistent long-range migration requires stabilization of cell polarity, a process achieved through reorganization of the microtubule cytoskeleton, and (4) AGRIN activates Rho GTPases, it is plausible that nuclear translocation to the synapse is mediated through modifications of the cytoskeleton driven by AGRIN-activated Rho GTPases.

A number of proteins in addition to AChRs and MUSK display synapse-specific expression Although the role of neuromuscular NRG/ErbB signaling for synapse formation remains unclear, it is worth mentioning that synapse-specific expression of ERBBs is linked to the AGRIN/MUSK pathway. Both ERBB receptors and their mRNAs as well as *Nrg1β* precursors are observed at the synapse and at ectopic sites induced by AGRIN/MUSK. This indicates that the nerve, at

Figure 5 AGRIN from the nerve induces synaptic expression of acetylcholine receptors (AChRs) by targeting the expression of the *Musk* gene to the synaptic muscle region and aggregating AChRs in the synaptic muscle membrane. By activating MUSK in the muscle fiber, AGRIN induces (1) accumulation of muscle nuclei under the synapse via unknown mechanisms and (2) synapse-specific expression of (a) *Musk*, via a positive feedback loop (black solid arrows), as well as of other synaptic genes, including *AChRε*- and δ-subunits (indicated in yellow), all sharing the same regulatory sequence (N-box) in their promoters, and (b) *Erbb*s (broken gray arrows; pathways unknown). The activation of ErbB receptors by neuregulins (NRGs) from the nerve and muscle fiber can also stimulate transcription of genes with N-boxes and thus may strengthen the MUSK-induced expression level. Note that they may be enhanced further by other pathways (not shown). AGRIN also induces synapse-specific expression of (c) *AChR*α- and β-subunit genes (not shown, pathways unknown) and (3) subsynaptic accumulation of AChRs, MUSK, and ERBBs by anchoring them to the synaptic cortical cytoskeleton of the muscle fiber (broken black arrows). PKC is protein kinase C. ERK, RAC, MKK7, JNK are components of the respective signaling pathways; P denotes phosphorylation, mf is myogenic factor, E is promoter sequence binding mf.

least in part by secreting AGRIN, stimulates synaptic nuclei to express *Erbb* genes and to aggregate their products in the synaptic muscle membrane (see also Table 1).

Models of Neuromuscular Synapse Formation

Neurocentric Model

The simplest model to explain the induction and maintenance of synapse-specific gene transcription by the motor neuron in fetal muscle is that *Musk*, expressed constitutively in developing myotubes, is activated locally by AGRIN released from a motor neuron growth cone. This MUSK activation, in turn, stabilizes the expression of *Musk* in myonuclei closely adjacent to the site of contact (subsynaptic nuclei) against the downregulation of *Musk* expression throughout the muscle fiber caused by the electrical muscle activity which begins soon after the neuromuscular contact is established. Via a similar pathway, AChR expression is stabilized by AGRIN/MUSK, ensuring high synaptic ACh sensitivity in electrically active fibers. While NRG/ERBB signaling is not essential for postsynaptic membrane formation and maintenance, induction of genes by AGRIN/MUSK may be augmented by NRG from the nerve and/or the muscle converging on common regulatory elements, as well as by other hitherto unknown alternative pathways, perhaps mediated via NRG2, αCGRP, and/or ATP from motor neurons, muscle fibers, and/or Schwann cells, respectively. As the synapse further differentiates, the number and density of subsynaptic nuclei increase. The accumulation of extrasynaptic nuclei expressing *AChR* genes in response to ectopic AGRIN indicates that any nucleus can be reprogrammed by AGRIN to become a subsynaptic nucleus. Implicit in this model and the supporting data is the idea that during development, motor neuron terminals have the capability of inducing synapse formation anywhere along the length of the muscle fiber.

Myocentric Model

This alternative to the neurocentric model postulates that in fetal muscle, AChRs first cluster independently of neural influence and only later are stabilized by AGRIN from motor neurons contacting them. Conversely, AChR clusters not stabilized by AGRIN would be dispersed. The model is based on the observation that in fetal diaphragms of mouse

mutants lacking phrenic nerves, a central band of AChR clusters and of elevated level of *AChR* α-mRNA is seen in the area where synapses are normally made (although co-localization of nerve-free AChR clusters with focally elevated *AChR* mRNA has not been established at the subcellular level). As noted above, neither the central AChR clusters nor elevated AChR mRNA is seen in *Musk* mutant muscles, indicating an essential role of MUSK in this process. The myocentric model is supported by the observation that in certain muscles of the zebra fish, AChR clusters form prior to innervation and are then preferentially contacted by nerve processes. However, such 'prepatterning' is not generally required for fetal zebra fish neuromuscular synapse formation: AChR clusters follow, rather than precede, the appearance of motor neurons in other zebra fish muscles. A plausible explanation for the 'synaptic zone' in nerve-free mouse muscle is that (1) at high concentrations, MuSK auto-activates, and (2) high MuSK spatially coincides with developing myotubes elongating from the central muscle region and expressing elevated levels of MUSK and, as a consequence of auto-activated MuSK, high AChR levels.

A Unifying Model?

It is possible that the two models represent extreme states of an equilibrium between active and inactive MuSK. MuSK is activated not only by AGRIN but also by itself, depending on its abundance and that of other proteins (e.g., DOK-7) with which it interacts. The number of nerve-free AChR clusters in any particular situation is therefore likely to depend on the levels of expression of MUSK and these other proteins. For example, in myotubes expressing high MUSK levels, the number of nerve-free AChR clusters, and therefore the likelihood of a nerve process to encounter and stabilize a preformed AChR cluster, would be high. Conversely, in myotubes expressing low levels of MUSK, delivery of AGRIN by motor neurons would be required for initial MUSK activation and subsequent AChR cluster formation.

Conclusion

Among the candidates mediating the neural control of neuromuscular synapse formation, AGRIN and NRGs have for more than two decades commanded the widest attention. New genetic studies *in vivo* have dramatically redefined their roles in this process. The key pathways regulating the expression of synaptic AChRs, as well as their aggregation in the synaptic muscle membrane, are activated by AGRIN/MUSK. Synapse-specific transcription of several key synaptic genes appears to be regulated, at least in part, via a common pathway. In contrast, the neuregulins, which had been considered the primary candidates regulating *AChR* gene transcription, have turned out to be dispensable for this process. They are, however, essential for normal development of Schwann cells and muscle spindles.

Neuromuscular Junction: Synapse Elimination

Introduction

Motor neurons supply the last outposts of the motor system, where volition finally interfaces with and influences the material world. In higher vertebrates, the axon of an adult somatic motor neuron projects to a single anatomically defined muscle target. The motor axon then divides into several tens to hundreds of intramuscular collateral branches, each terminating on a muscle fiber at a neuromuscular junction (NMJ) to form its sole innervation. A high margin of safety for neuromuscular transmission ensures that every action potential generated in the motor neuron reliably triggers an action potential and contraction of all the muscle fibers it supplies. Thus, a motor neuron and its muscle fibers function together in a unitary fashion: The combined set is referred to as a motor unit. The number of muscle fibers in one unit is termed the motor unit size. Motor units are activated in an orderly fashion during voluntary movements, often sequentially by size. The variation in motor unit sizes (more than tenfold in some muscles and more than 1000-fold between other muscles) confers a remarkable dynamic range on the motor system as a whole.

All historic and contemporary images of adult NMJs reveal a remarkable and stereotyped pattern of the motor nerve supply to skeletal muscle fibers, found throughout the vertebrate subphylum but particularly well represented in mammals: Each well-defined motor junctional area, also called the 'endplate,' is supplied by the axon of one and only one motor neuron. However, this pattern is not formed *de novo*. Rather, the motor endplates of individual muscle fibers are initially supplied by terminals derived from several motor neurons. This state is called polyneuronal innervation. The transition from polyneuronal to mononeuronal innervation during development occurs by a process commonly known as synapse elimination, the subject of this article. The reduction in motor unit convergence (overlap) has another important consequence: Since in most cases the number of muscle fibers does not increase during synapse elimination, the degree of motor divergence also decreases; that is, synapse elimination also brings about a reduction in motor unit size, therefore ultimately limiting the maximum force a motor unit can produce.

Three main physiological factors regulate motor unit force production in vertebrate muscle. In addition to motor unit size, these are the frequency of activation and the functional 'type' of the muscle fiber. In rodents, where these factors have been studied in greatest detail, they all change during development. It is interesting to note that the three properties appear to be linked: Frequency of activation and intrinsic properties such as motor neuron and muscle fiber type play roles in steering the process of synapse elimination to its conclusion, thus determining the motor unit size.

Different rules govern the maturation of innervation patterns in smooth, cardiac, and some specialized types of voluntary striated muscle fibers that contract relatively slowly. Persistent, stable polyneuronal innervation is the norm in these muscle types, and they are therefore not discussed here. Synaptic remodeling also occurs during development of invertebrate muscles, and this plasticity is increasingly studied in the fruit fly, *Drosophila melanogaster*, mainly because of the power and pace of molecular genetic analysis in this species. However, although pruning of motor axon branches occurs during metamorphosis, neuromuscular synapse elimination comparable to that in mammalian muscles does not normally take place in *Drosophila*. The present discussion is therefore mainly restricted to mammalian skeletal muscle.

From π to μ

Neuromuscular synapses form about halfway through gestation in mice and rats. In some muscles, axonal growth cones appear to contact random points on the membrane of the immature muscle fibers (myotubes) and to induce specialized synaptic features in them. In other muscles, it appears that growth cones contact preformed postsynaptic sites. Either way, axons from other motor neurons then add to the first neuromuscular inputs. Thus, by birth, virtually all muscle fibers are innervated by terminals of several motor neurons, that is, polyneuronal innervation (π). The first evidence of polyneuronal innervation in mammalian muscle was obtained in 1916–17 in a study of fetal human tissue by Tello. Contemporaneously, Boeke reported polyneuronal innervation in reinnervated intercostal muscles after nerve injury in hedgehogs. Skeletal muscles of mice and rats are presently the tissues of choice for descriptive and mechanistic studies of neuromuscular synapse elimination both in neonates and in reinnervated muscles in adults.

More-recent interest in synapse elimination began with two electrophysiological exposés, one on neonatal

rat diaphragm muscle and the other on reinnervated adult rat hind limb muscles. Both studies showed that when the muscle nerves were stimulated with electric pulses of gradually increasing strength, discontinuous, stepwise increments occurred in the amplitude of the endplate potentials recorded with intracellular electrodes from individual muscle fibers. This is in contrast to the one-step response normally observed during graded nerve stimulation in adults. The simplest explanation of these observations is that multiple axons converging on the same endplate, and having distinct electrical excitation thresholds, are progressively recruited as the stimulating current is increased.

Polyneuronal innervation was also demonstrated using electrophysiological techniques at about the same time in other immature vertebrates, including tadpoles and chick embryos. These studies were complemented by physiological evidence of polyneuronal innervation in skeletal muscles of neonatal kittens by recording isometric tension. These studies showed that the force produced in response to the simultaneous stimulation of two immature motor axons is usually less than the arithmetic sum of the responses to stimulating both separately. This is also most simply explained by convergent innervation of muscle fibers.

More recently, direct histological evidence of polyneuronal innervation and synapse elimination has been obtained by confocal microscopy analysis of three- and four-dimensional image stacks (X,Y,Z +/− T), for example in preparations immunostained for neurofilament protein in axons (Figure 1) or expressing different fluorescent proteins. Such images have provided unequivocal confirmation of the convergence of several axon terminals on individual motor endplates at birth in rodents and synapse elimination during the first 3 postnatal weeks.

One early study has since achieved iconic status in the field: a comprehensive analysis of polyneuronal innervation and synapse elimination carried out by Jansen, Brown, and Van Essen. These investigators brought to bear a powerful combination of tension measurements, intracellular recordings, and histology. All contemporary studies and analysis of polyneuronal innervation and neuromuscular synapse elimination can be traced back to this study. Its main findings and conclusions were the following:

- Motor unit size is maximal at birth and declines roughly exponentially during the first 3 postnatal weeks, during which time there is no reduction in the total number of motor neurons. Therefore, synapse elimination is due to withdrawal of motor nerve terminals and pruning of axon collateral branches rather than to complete degeneration of individual motor neurons.

Figure 1 Polyneuronally innervated neuromuscular junctions in an 8-day-old mouse skeletal muscle, stained for neurofilament proteins in axons (green) and acetylcholine receptors on muscle fibers at motor endplates (red). Two axons can be seen projecting in the same motor endplate on several of these muscle fibers.

- The rate of synapse elimination is highest during the first postnatal week. However, virtually all muscle fibers remain innervated by at least two inputs during this period. Mononeuronally innervated muscle fibers emerge rapidly during the second to third postnatal weeks.
- Partial denervation at birth leads to reduced synapse loss in the surviving motor units but does not prevent synapse elimination completely. Mononeuronal innervation therefore arises partly by competition between the terminals of different motor neurons converging on the same endplate and partly by an intrinsic tendency of motor neurons to withdraw a proportion of their terminal branches.
- Implanting the cut end of a nerve that normally innervates one neonatal muscle into another, at some distance away, can result in stable polyneuronal innervation. The distance between converging synaptic inputs therefore mitigates elimination of polyneuronal connections: The further apart two inputs are, the more likely they are to persist and become stable.

A striking feature of the process of synapse elimination at the developing NMJ revealed by these studies is that the great majority of NMJs end up innervated by one and only one motor neuron μ. Although the response to partial denervation at birth suggests that there is a limit to the number of supernumerary branches that can be maintained, it is clear that the

usual result of synapse elimination is not consistent with a random loss of a fraction of the branches formed initially. This would leave some NMJs innervated by several axons and others by none. Rather, the observations point to some sort of local competition at each NMJ that results in a single 'winner.' (Whether synapse formation by motor axon branches is initially random is another unresolved matter.)

Comparable findings were subsequently reported by several groups using similar combinations of histological and electrophysiological methods in studies of reinnervated muscles in adults. Following certain forms of nerve injury, particularly crushing the nerve so that the surrounding connective tissue sheaths remain intact, the damaged motor axons grow back into the target muscle. Regeneration of damaged axons may restore some or all their original neuromuscular connections, in some cases leading to excellent functional recovery. When axons regenerate into partially denervated muscles, they often polyneuronally innervate endplates already occupied by intact motor nerve terminals. In such cases, a form of competition takes place between the original and the regenerated axons. The many similarities between synapse elimination in neonatal muscles and reinnervated adult muscles led to the working hypothesis that the underlying mechanisms are the same.

Synapse Elimination versus Synapse Degeneration

Ultrastructural analysis of NMJs established that the characteristics of synapses and axon collaterals undergoing elimination and withdrawal are quite unlike those of the orthograde (Wallerian) degeneration that occurs when axons are damaged. Wallerian degeneration is rapid and involves radical breakdown of cytoplasmic integrity and organelles within intramuscular axons and motor nerve terminals. By contrast, synapse elimination results in regression of a subset of the collateral branches in a motor neuron's axonal arbor. It is protracted over several days, and for the most part it involves gradual retraction of synapses and resorption of the affected branches into the parent axon trunk with no overt loss of integrity of the cytoplasm and organelles (e.g., mitochondria and synaptic vesicles appear to remain healthy).

Real-Time Visualization of Synapse Elimination *In Vivo*

An improvement in the basic description of the neonatal remodeling of motor units has followed the development of transgenic mice expressing fluorescent proteins in motor neurons. This enables all the connections made by individual motor neurons to be visualized at all stages of development. These transgenic mice have been made by inserting variants of the fluorescent jellyfish protein Green Fluorescent Protein into the mouse genome under the control of a chemically modified promoter, thy1.2, that has the effect of selectively driving protein expression mainly in neurons. Collectively, the members of this family of fluorescent transgenic mice are referred to below as XFP mice (X = R for red, Y for yellow, G for green, or C for cyan). Recently, via Cre-Lox floxed-stop tamoxifen induction, variants have been generated that express variable amounts of YFP. In all these cases, expression of the fluorescent proteins in neurons appears to be completely harmless: The transgenic mice are indistinguishable from their littermates until their brains, spinal cords, and peripheral nerves are viewed in a fluorescence microscope. Use of XFP mice has already revealed interesting new insights into the process of synapse elimination and is likely to continue to do so for some time.

Is competition local? Visualization of XFP-labeled NMJs during postnatal synapse elimination has confirmed and extended previous interpretations based on the more indirect methods applied for the first time by Jansen, Brown, and Van Essen. Studies of motor nerve terminal size, number, and disposition at different stages in the elimination process show that synapses and collateral branches retract into their parent nerve trunks such that during early stages, a dwindling fraction of each NMJ is occupied by the withdrawing synapses. The local competitions experienced by each of the numerous terminals of an immature motor neuron do not occur simultaneously but by an asynchronous process protracted over several days. At any given time, some of the terminals of a single neuron are 'victorious,' fully occupying the endplate, while others show variable fractional occupancies, giving way to or taking over the space occupied by the terminal synapses of other motor neurons. Takeover of endplates during synapse elimination has now been observed directly, by repeated visualization of polyneuronally innervated junctions whose axonal inputs are labeled by selective expression of YFP and CFP in different motor neurons. These direct observations appear to refute the hypothesis previously favored by some, that the main route to mononeuronal innervation was via elimination of acetylcholine receptors and their overlying synaptic boutons, with no takeover by the remainder. The routine takeover of endplates by one terminal, with simultaneous retraction of others, is now a generally accepted account of the normal process leading from polyneuronal to mononeuronal innervation. This view also accords with the progressive recovery

of synaptic area observed in partially denervated muscles following regeneration of injured axons, as suggested by static images of vital staining of regenerating and intact axons.

Expression of different fluorescent proteins (CFP and YFP) in different motor neurons has also been used to study unusual behavior at some NMJ. A few synapses show oscillating 'flip-flop,' in which first one of two inputs occupies most of the endplate at the expense of the other, but then the second gains the upper hand and the most fractional occupancy. It is unknown what determines this remarkable dynamic interaction or its ultimate outcome in favor of one of the two inputs, with complete elimination of the other.

At first glance, it is tempting to conclude that asynchronous retraction and flip-flop behavior suggest that synapse elimination is driven locally, entirely by competitive interactions between converging terminals. However, experiments show that asynchronous synapse loss also occurs when global properties such as axonal transport are interrupted. For example, axonal injury in adult mutant mice with the 'Wallerian degeneration, slow' mutation (Wld^S), in which orthograde degeneration is delayed, also results in protracted, asynchronous synapse retraction. Thus, observations of asynchronous synapse loss constitute insufficient evidence to conclude that local interactions drive synapse elimination (see below).

The fate of the losers Finally, detailed descriptions have been obtained by time-lapse imaging *in vivo* of the last stages of synaptic retraction. These have confirmed that removal of the losing synapse partly involves retraction of a collateral nerve branch into the parent axon trunk, identified by characteristic end bulbs (retraction bulbs) on the withdrawing axon branch. In addition, combined confocal and ultrastructural (electron microscopic) analysis has also shown that some retracting synapses and axon branches undergo fragmentation, with sequestration of the cellular residues, named axosomes, into Schwann cells and other phagocytic cells in the vicinity of the NMJ. Collectively, the retraction and axosomal fragmentation of synapses undergoing elimination appear remarkably similar to the loss of synapses following axotomy in some forms of neuromuscular pathology. This includes neuromuscular synaptic degeneration in Wld^S mutant mice after nerve injury; mouse models of some forms of motor neuron disease, such as in the SOD1G93A transgenic mouse model of amyotrophic lateral sclerosis (ALS); and in *smn* mutant models of spinal muscular atrophy (SMA; see below). However, it remains to be seen whether these remarkable morphologically similarities are caused by similar underlying molecular mechanisms.

Are There Intrinsic Hierarchies Among Motor Neurons?

A recent study by Kasthuri and Lichtman seems set to reignite debate over the forces that establish which synapses persist when two motor nerve terminals belonging to different motor neurons vie for exclusive occupancy of the same motor endplates. Transgenic mice expressing YFP in a small subset of motor neurons and CFP in a different subset were examined. Sometimes only two motor neurons supplying the same muscle were labeled, one yellow and the other cyan. Thus, the investigators were able to identify all the polyneuronally innervated motor endplates where both axons contributed a motor nerve terminal. They found that while both axons innervated variable fractions of the endplates they did not share, the same member of the pair nearly always occupied a greater fraction than the other at all endplates that they did share. This suggests that while competitive interactions take place locally at motor endplates, a pecking order or dominance hierarchy may operate within motor neuron pools, intrinsically biasing the outcomes of all their interactions with others during synapse elimination. An important prediction of this hypothesis is that all the branches of the motor neuron with the highest ranking should be 'winners.' By contrast, the lowest-ranked motor neurons should lose virtually all competitions and have either all or nearly all their terminals eliminated.

The suggestion of a fixed hierarchy among motor neurons needs to be viewed in the context of several previous studies. First, time-lapse observations of flip-flop (made by the same research group) made over several days *in vivo* suggest that if there is a hierarchy, then either it may be a dynamic one or the differences that determine the hierarchical rank could be very small and subtle. Second, indirect evidence based on isometric tension recordings in the watershed study by Jansen et al. suggests that some motor neurons withdraw their terminals from motor endplates in the absence of competitors, albeit this observation has been challenged by other studies and the issue remains unresolved. Third, axons regenerating into partially denervated muscles fail to displace sprouts from most of the terminals they previously innervated. Fourth, high levels of stable, persistent polyneuronal innervation are found following recovery from muscle paralysis. However, all but the first of these caveats are based on indirect evidence that predated the availability of transgenic XFP mice. It is to be hoped that the general availability of these mice will eventually allow clarification of the possibility of an intrinsic hierarchy among motor neurons.

The Role of Activity in Synapse Elimination

One of the questions examined in the immediate wake of the Jansen, Brown, and Van Essen study was whether activity plays an obligatory and decisive role in synapse elimination. In rats and mice, synapse elimination occurs in hind-limb muscles as the animals are first beginning to use those limbs to bear weight. By analogy in the visual system, use of the eye during a critical period when the precision of adult connectivity is being established plays a vital part in determining the outcome of that process. It therefore seemed plausible that something similar might happen at the NMJ. Several studies have explored the effect of changes in neuromuscular activity on both the timing and the outcome of synapse elimination, either in development or during reinnervation of adult muscle. The various studies have led to the following conclusions:

- Reducing activity delays elimination of polyneuronal innervation.
- Increasing activity makes synapse elimination occur sooner.
- Selectively altering activity levels in motor nerve terminals at NMJs supplied by convergent motor neurons frequently biases the outcome of synapse elimination in favor of the more active axons.
- Polyneuronal innervation is not an inherently unstable state: it persists indefinitely in active muscle under some experimental conditions.
- Activity is not strictly necessary for synapse elimination since it can occur at some NMJs even when they are experimentally paralyzed.
- Activity-dependent competitive vigor correlates with the synaptic strength of convergent inputs, that is, the amount of neurotransmitter release per unit area.

The overall conclusion from these studies is that activity is strongly influential but not strictly decisive in determining the outcome of synapse elimination. Other variables likely to mitigate competitiveness include intrinsic limits on the numbers of peripheral connections any one motor neuron can support, sensitivity to neurotrophic factors, and selective recognition or adhesion of motor neurons to specific muscle fibers based on either topographic or histochemical markers.

Muscle Fiber Type Specificity and Selective Synapse Elimination

Skeletal muscle fibers are metabolically heterogeneous. For example, some are specialized for brief, faster and others for prolonged, slower contractions. In addition, many are segmentally or compartmentally organized with axonal inputs constrained to arborize within the segmental or compartmental boundaries. Synapse elimination in development therefore occurs largely within rather than between segments or compartments. Occasionally, however, it appears that mistakes are made and editing of these occurs by axon branch pruning.

In rats and mice, some muscle fiber subtypes are already specified at birth: specifically, type I fibers expressing myosin isoforms characteristic of slow-twitch muscles. In contrast, fast-twitch type II muscle fibers develop mainly postnatally. In adults, these subtypes of fibers are selectively innervated by motor neurons whose activity patterns match the muscle fiber type characteristics. There is some evidence for nonselective innervation of muscle fiber types before synapse elimination occurs. Thus in mice in the first week after birth, individual motor units contain both fast and slow muscle fibers. By the time synapse elimination is complete, the homogeneity of the units has increased to nearly its adult level. This suggests that specific matching of motor neuron type to functionally appropriate muscle fiber types plays a role in synapse elimination. However, as yet there are no selective molecular markers for different motor neuron types, so this hypothesis awaits a stringent test.

Molecular Mechanisms of Synapse Elimination and Axonal Pruning

Progress toward understanding the molecular mechanisms that induce and execute synapse elimination has been exasperatingly slow. Neuromuscular synapses are virtually inaccessible to systematic biochemical analysis, because they comprise such a small fraction of the volume of skeletal muscles (unlike the brain, where synapses are the main constituent). However, several studies have used the incidence of polyneuronal innervation as a bioassay for the effects of pharmacological blockers, growth factors, and other treatments on synapse elimination. Virtually all these studies show only transient effects and have thus far provided no clear understanding at a molecular level of the causal events leading to mononeuronal innervation.

Neurotrophic Influences on the Rate of Synapse Elimination

Neurotrophic factors play a crucial role in maintaining the size of neuronal populations and the number and disposition of their connections. For instance, survival and growth of autonomic and sensory

neurons depend on maintenance of physiological levels of nerve growth factor. Some cortical neurons show similar requirements for the related neurotrophin, brain-derived neurotrophic factor (BDNF). Members of another class, the neurotrophic cytokines, have potent effects on motor neuron survival. The effects of different families of these cell-survival molecules have been tested on neonatal muscles to see whether they may play similar regulatory roles in synapse elimination. The results have been largely equivocal and/or negative. For example, administration of either BDNF or ciliary neuronotrophic factor delays synapse elimination in mice, but only by about a day. Remarkably, however, transgenic expression of glial cell line-derived neurotrophic factor (GDNF) in mouse muscle delays synapse elimination by about 1–2 weeks. Unfortunately, GDNF is unlikely to be a physiological regulator because many muscle fibers in normal mice do not express it at the right stage of development.

Role of Proteases and the Ubiquitin-Proteasome System

Some studies have focused on the possibility that regulated proteolysis of extracellular components of the NMJ might be involved in the elimination of supernumerary nerve terminals. There is some evidence that inhibition of either Ca-activated or serine proteases delays synapse elimination. Likewise, it has been reported that activation of protein kinase C delays synapse loss. At present, however, there is no detailed model of how these effects might operate during normal NMJ development.

Recently, there has been interest in the possible role of the ubiquitin-proteasome system (UPS), the mechanism within cells for targeted breakdown of proteins. Proteins tagged with a chain of ubiquitin monomers are recognized by chaperone proteins that convey them to proteasomes, organelles that execute protein degradation. Interest in this system stems partly from the role of the UPS in several forms of neurodegenerative disease, including ALS. There is evidence that the UPS plays a significant role in both Wallerian degeneration and axon pruning. For instance, synaptic degeneration is delayed in Wld^S mutant mice, in which there is expression of a chimeric protein, part of which contains the N-terminal 70 amino acids of a ubiquitination cofactor, Ube4b. Axotomy induces asynchronous synaptic retraction and fragmentation in these mice. Inhibitors of the UPS also delay axon pruning in *Drosophila* and axon degeneration in the SOD1G93A mouse model of ALS. However, there are as yet no published data on the role of the UPS in neonatal synapse elimination.

Role of Other Nonneural Cell Types at Immature and Adult NMJs

Parts of three cell types are thought to constitute the normal NMJ: muscle fiber, motor nerve terminal, and one or more perisynaptic (terminal) Schwann cells. These structures are bonded to one another by synaptic basal lamina. Nerve injury in adults triggers, after a latent period of about 3 days, proliferation and branching of terminal Schwann cells, which then form a scaffold of bridges between motor endplates. These appear to facilitate reformation of synapses by regenerating motor axons. The average number of Schwann cells per NMJ increases postnatally, but there is no compelling evidence that this process plays a role in selective elimination of inputs during synapse elimination. However, Schwann cells engulf degenerating nerve terminals after axotomy, during Wallerian degeneration, and appear to fulfill a similar function in synapse elimination, with formation of axosomal fragments. Recent availability of transgenic mice expressing fluorescent proteins in these terminal Schwann cells will permit longitudinal studies that should help establish whether they have a role in synapse elimination. NMJs also appear to be a favorable local environment for a population of so-called perisynaptic fibroblasts. These cells have been observed at most NMJs in frogs, chickens, rodents, and human muscle. They lie outside the basal lamina, but although they react by spreading and expression of specific cell adhesion molecules, their precise functions at NMJs remain intriguing but unknown.

Synapse Elimination and Neurodegenerative Disease

Most neurodegenerative diseases show an increased likelihood of onset with age. This applies to most adult forms of motor neuron disease (MND), such as ALS. Most adult forms of MND (more than 90%) are sporadic, the remainder inherited. About 20% of the inherited forms (i.e., less than 2% overall) are due to mutations in genes coding for superoxide dismutase (SOD). However, the availability of good animal models of SOD-dependent ALS has led to this form's being the most widely studied. Overexpression of SOD genes in transgenic mice leads to defective axonal transport and motor neuron degeneration, with clinical signs resembling the human disease. Other forms of MND are neonatal and juvenile. These include SMAs of various types, the most aggressive and earliest onset being type I (Werdnig-Hoffman disease), which is lethal within the first few months of life. In contrast to ALS, most forms of SMA are inherited, and in more

than 95% of cases, the mutations responsible have been pinpointed to the *smn* (survival of motor neurons) gene. There are good animal models of these forms of motor neuron disease as well.

Recent studies of neuromuscular pathology in mouse models of ALS and SMA, as well as other mutants, such as *pmn* and *wasted*, have revealed some remarkable common features. Specifically, neuromuscular synapses within some motor units in all these models degenerate or retract into their parent axons at early stages in the disease process, in advance of axonal or motor neuron cell body degeneration. This has led to three views: first, that these motor neuron disease variants may represent a form of dying-back neuropathy, beginning with primary pathology at neuromuscular synapses; second, that neurodegenerative processes in general may be compartmentalized, with independent mechanisms regulating the degeneration of synapses, axons, and cell bodies; and third, that degeneration of synapses in circumstances like MND may share some common molecular mechanisms with normal forms of synaptic plasticity, including synapse elimination in postnatal development.

These views are not universally held and remain open to stringent experimental validation. For instance, although there may be strong morphological and physiological similarities between developmental synapse elimination and MND pathology in SOD-dependent ALS, recent data suggest that synaptic degeneration in SOD1G93A mouse variants shows loss of synaptic vesicle proteins in advance of degeneration, which synapses undergoing elimination in development do not. Moreover, synapses in SOD1G93A mice degenerate synchronously in some muscles, suggesting a primary axonopathy (consistent with the disruptive effect of the SOD-1 mutation on axonal transport).

Synapses are known to be especially vulnerable to defects in axonal integrity, perhaps partly due to the high metabolic and energetic demands placed on them by the exigencies of synaptic transmission. Thus, it is perhaps not surprising that early loss of synapses could lead to the erroneous conclusion that these foci are the primary loci of disease. On the other hand, primary synaptic pathology has not been conclusively ruled out, either for SOD1-related ALS or for any other form of MND. Synapses contain abundant mitochondria, so these foci of oxidative metabolism may be especially vulnerable to direct, primary effects of oxidative stress. Either way, genetic or pharmacological strategies aimed directly at inhibiting synaptic degeneration could prove highly effective in mitigating disease progression. For instance, *pmn* mutant mice cross-bred with Wld^S mice showed strong evidence of mitigation of disease progression. However, transferring the Wld^S gene to SOD1G93A mice has, at best, only a weak neuroprotective effect. This may be partly explained by the weakening of the protective effect of the Wld^S gene on synapses as mice age. Screens of mutations induced by ethylnitrosourea are currently under way in a search for novel mutations that may protect synapses as effectively as Wld^S protects axons. Such mutations could ultimately be exploited so as to mitigate disease progression in several forms of motor neuron disease.

Summary

We still do not know precisely what genetic, environmental, or even stochastic factors determine whether a synaptic bouton should persist or be removed from a π-junction or indeed whether there is a single deciding factor. Activity levels and sensitivity to neurotrophic factors, selective recognition between motor neurons and muscle fibers, and other intrinsic properties of motor neurons and the muscle fibers they innervate may all help to establish the size of motor units, shaping their organization and orderly recruitment, as we accumulate repertoires of behavior during development that we carry with us into adulthood. Ultimately, all these potential regulators may individually play influential rather than decisive roles. For example, perhaps inactivity induces and sustains polyneuronal innervation merely by stimulating and maintaining nerve branching, enhancing the opportunities for competitive interactions to occur between synaptic terminals. Intrinsic determinants of synaptic strength, differential sensitivity to neurotrophic factors, and differential adhesion may then bias the outcome of the subsequent interplay as motor terminals advance or retreat over endplate territory defined by the boundaries of postsynaptic receptor clusters they require to mediate their primary function. But the final outcome could also be generated by chance, through some fundamentally stochastic process. By analogy, reliable chemical synaptic transmission is produced by an underlying stochastic mechanism in which action potentials elevate the probability of exocytosis rather than determining precisely how many vesicles fuse with release sites in presynaptic active zones. Perhaps chance and necessity, an apt epithet for the forces regulating molecular evolution, may also prove to be a fitting summary of the interplay between environment andgene expression leading to development of functionally appropriate innervation patterns, not only at NMJs but throughout the developing nervous system, thereby individualizing all voluntary behavior.

Neuromuscular Transmission Modulation at Invertebrate Neuromuscular Junctions

General Features of Modulation at Invertebrate Neuromuscular Junctions

Modulation of neurotransmission in its broadest sense refers to alterations in preexisting synaptic efficacy due to engagement of pre- or postsynaptic modifying mechanisms by altered activity at the synapse or by influences of other cells that impinge upon the synapse. Modulation of neuromuscular transmission in muscles subserving locomotion and posture has been investigated in detail in the decapod crustaceans, and to a lesser extent in three orders of insects (Orthoptera, Diptera, and Lepidoptera). Apart from sporadic observations, little is known about mechanisms of modulation in other groups of invertebrates. However, the major invertebrate phyla share features of neuromuscular structure with arthropods: motor neurons form small individual synapses, often very numerous in large muscles. In the present account, we define 'synapse' as the closely apposed and tightly adhering pre- and postsynaptic membranes containing presynaptic structural specializations for transmitter release and postsynaptic arrays of receptors for released transmitter substances. The relatively small and discrete synapses of invertebrate neuromuscular junctions stand in contrast with the large consolidated neuromuscular junctions (end plates) typically found in many vertebrate muscles. In most cases, altered effectiveness of invertebrate neuromuscular transmission involves changes in the presynaptic nerve terminal rather than modification in responsiveness or number of postsynaptic receptors. The probability of transmitter release at individual synapses, or changes in the number of responsive synapses, or both, may change during modulation. Most likely, what has been found in arthropods will apply in other groups of invertebrates and also, at least to some extent, to central and peripheral synapses of vertebrates.

Modulation of neuromuscular transmission includes several different processes:

1. Altered synaptic transmission resulting from changes in steady-state membrane potential in the presynaptic nerve terminal.
2. Modulations of synaptic response properties arising from changes in impulse activity in the motor neuron (activity-dependent modulation).
3. Rapid changes imposed by other neurons synapsing on the neuromuscular junction. The best-known case is presynaptic inhibition in crustaceans.
4. Changes effected by nearby glial cells. This action is known to be significant at vertebrate neuromuscular junctions, but little is known about comparable actions at invertebrate neuromuscular junctions. It should be noted, however, that many invertebrate neuromuscular junctions, especially among dipteran insects, lack accompanying glial cells along most of the presynaptic terminal.
5. Changes in neurotransmission mediated by neurohormones released at a distance and carried to the neuromuscular junction by circulation, or by neuromodulators which diffuse from nearby nerve cells to target neuromuscular junctions. Amines and peptides are known to act as neuromodulators or neurohormones in invertebrates.
6. Reverse (retrograde) transmission or transport from muscle to motor neuron. Processes of this type are thought to underlie certain forms of long-term potentiation at mammalian central synapses. Strong indirect evidence implicates retrograde processes at invertebrate neuromuscular junctions. However, on present evidence most of these processes apparently act over a long period of time during development, and can be more usefully considered as processes of neuromuscular formation and development. The present account focuses on modulation of neurotransmission in fully formed neuromuscular junctions.

Presynaptic Membrane Potential

Steady-state membrane potential of the presynaptic nerve terminal exerts a modulatory effect on the release of neurotransmitter, as illustrated by studies of the single excitatory motor axon supplying the opener muscle of the crayfish leg (**Figures 1(a) and 1(b)**). When depolarizing current is applied to the terminal, asynchronous transmitter release is observed at membrane potentials close to –60 mV. Stimulated action potentials are reduced in amplitude by steady-state depolarization (due to reduction of the electrical driving force for Na^+ entry), yet synaptic transmission is enhanced; the converse scenario is apparent with steady-state hyperpolarization. Similar effects have been reported more recently for the mammalian calyx of Held synapse, and for amphibian retinal rod photoreceptors. In these cases, small changes in background levels of intracellular Ca^{2+} ($[Ca^{2+}]_i$), initiated by an increase in Ca^{2+} entry

Figure 1 Modulation of neurotransmission by presynaptic membrane potential. (a) Intracellular recordings at a crayfish excitatory neuromuscular junction from presynaptic axon terminal (trace labeled 'a'), showing the presynaptic action potential (AP), and from postsynaptic muscle fiber (m), showing the excitatory junction potential (EJP). Current was injected into the presynaptic axon terminal to hyperpolarize (ii) and depolarize (iii) the presynaptic membrane. Hyperpolarization resulted in a larger AP than seen normally (i), and a smaller EJP; depolarization produced the opposite result. (b) Presynaptic action potentials in panel a shown at higher temporal resolution. (c) Enhancement of synaptic transmission by presynaptic conditioning pulses at a crayfish inhibitory neuromuscular junction. Inhibitory junction potentials (IJP) were recorded in response to three test pulses before conditioning stimulation (IJP(1)) and after eight subthreshold pulses of conditioning stimulation (IJP(2)). Conditioning pulses which do not cause neurotransmitter release enhance the IJPs evoked by test pulses; the enhancement decays with a time constant (737 ms) equivalent to that of the F2 component of short-term facilitation. (b) Reproduced from Wojtowicz JM and Atwood HL (1984) Presynaptic membrane potential and transmitter release at the crayfish neuromuscular junction. *Journal of Neurophysiology* 52: 99–113, with permission from The American Physiological Society. (c) Reproduced from Vyshedskiy A and Lin J-W (1997) Activation and detection of facilitation as studied by presynaptic voltage control at the inhibitor of the crayfish opener muscle. *Journal of Neurophysiology* 77: 2300–2315, with permission from The American Physiological Society.

through voltage-dependent Ca^{2+} channels, were shown to be responsible for modulating neurotransmitter release.

A related finding from a crayfish inhibitory neuromuscular junction is enhancement of neurotransmission by brief subthreshold depolarizing pulses which release no transmitter but augment subsequent release by suprathreshold pulses (Figure 1(c)). The enlarged synaptic response has the decay kinetics of short-term facilitation (F2 phase). Thus, membrane potential changes can activate a process of facilitation without releasing neurotransmitter. It is thought that $[Ca^{2+}]_i$, elevated by these pulses, acts on a Ca^{2+} receptor that has higher binding affinity than do the receptors that activate transmitter release. The most likely interpretation for these collective findings is that membrane potential modulates neurotransmitter release through regulation of the number of open presynaptic Ca^{2+} channels, with possible secondary mobilization of intracellular Ca^{2+} stores at some synapses.

Activity-Dependent Modulation

Short-Term Modulation

Invertebrate neuromuscular junctions, like most other synapses, are sensitive to previous neural activity, which sets in motion processes leading to enhancement or to depression of neurotransmission. Both forms of response are strikingly displayed at neuromuscular junctions of crustaceans, which consequently have been heavily utilized for descriptive and analytical studies. Neuromuscular junctions of tonic motor neurons, which are active during normal locomotion, exhibit dramatic facilitation at many terminals. In contrast, those of phasic neurons, which normally fire briefly to produce fast responses, exhibit synaptic depression.

Synaptic enhancement The features of the major categories of short-term enhancement that have been analyzed at crustacean neuromuscular junctions (NMJs) are summarized in Table 1. The buildup in amplitude of the excitatory junction potential (EJP) proceeds during maintained activity, and is modulated by the frequency of nerve impulses and by the duration of the impulse train. When a train of impulses ends, the EJP declines in amplitude. For analytical purposes, the time course of decline in EJP amplitude is measured; from this, three or four processes with distinct time courses are discerned, as shown in Table 1.

Short-term facilitation (STF), which is often described as having two components – F1, which is over in less than a second, and F2, which decays in 1–10 s – appears after one impulse, but often increases further with more impulses. Crustacean examples are illustrated in Figure 2. These show variable responses often seen at different NMJs of a single motor axon (Figure 2(a)), and an extremely long-lasting enhancement produced by a single impulse (Figure 2(b)).

The slower processes, augmentation and potentiation, require more stimulation to become evident, and decay more slowly. These processes were

Table 1 Activity-dependent synaptic enhancement of transmission in the crayfish opener motor neuron

Process	*Life span*	*Regulators*	*Sites of regulation*
Short-term facilitation (STF)	Up to a few seconds after one impulse	Ca^{2+} residue from previous impulse	Binding site for Ca^{2+} (synaptic vesicles?)
Augmentation (AUG)	Tens of seconds after a train of impulses	Ca^{2+} and Na^{+}	Surface membrane
Tetanic and posttetanic potentiation (POT)	Up to a few minutes after a train of impulses	Ca^{2+} and Na^{+}	Surface membrane, mitochondria
Long-term facilitation (LTF)	A few hours or longer after a train of impulses	Ca^{2+}, Na^{+}, cAMP, protein synthesis	Surface membrane, active zone

Figure 2 Manifestations of short-term synaptic facilitation at crustacean neuromuscular junctions. (a) Variation at different endings of one neuron. Excitatory junction potentials (EJPs) recorded from three different muscle fibers of the spider crab *Hyas* to show the range in excitatory junction potential amplitude and facilitation that occurs in this singly motor-innervated muscle. Initial stimulation frequency was 1 Hz; it was changed from 1 to 10 Hz and then to 1 Hz again (shown at lower temporal resolution in the right-hand records). During the 10 Hz trains, progressive enhancement of EJPs (frequency facilitation) occurs in fibers 1 and 2, but is not apparent in fiber 3. EJP amplitude and duration were smallest in fiber 1, intermediate in fiber 2, and largest in fiber 3. The extent of facilitation was in the reverse order (i.e., largest in fiber 1 and smallest in fiber 3). Enhancement of evoked EJPs after the 10 Hz train (posttetanic potentiation) is also inversely related to initial EJP amplitude. Vertical calibration: 7.5 mV, fiber 1; 15 mV, fibers 2 and 3. Horizontal calibration: 30 ms, fibers 1 and 2; 75 ms, fiber 3; 750 ms for 10 Hz trains. (b) Twin-pulse facilitation of EJPs at the neuromuscular junction of a stomach muscle in the crab *Callinectes sapidus*. Two pulses were separated by successively longer intervals: 20 ms (i), 250 ms (ii), and 4000 ms (iii). Facilitation of the second EJP persisted for approximately 10 s. Calibration: amplitude, 10 mV; times were 40 ms (i), 100 ms (ii), and 1 s (iii). (c) Frequency facilitation of synaptic currents recorded with an external macro-patch electrode at a crayfish excitatory neuromuscular junction. Averaged responses were obtained at frequencies of 2, 3, 4, 5, and 10 Hz from a recording site in the central region of the crayfish opener muscle. Averages of 200 sweeps are shown for each frequency. Transmitter release increased progressively with frequency of stimulation. (a) Reproduced from Sherman RG and Atwood HL (1972) Correlated electrophysiological and ultrastructural studies of a crustacean motor unit. *Journal of General Physiology* 59: 586–615. Copyright 1972 The Rockeyeller University Press. (b) From Atwood HL, Govind CK, and Jahromi SS (1977) Excitatory synapses of the blue crab gastric mill muscles. *Cell and Tissue Research* 177: 145–158. originally distinguished at the amphibian neuromuscular junction, but were then found at many other synapses. At some crustacean neuromuscular junctions, stimulation for several minutes at frequencies of 10 Hz or more induces a much longer-lasting process referred to as long-term facilitation (LTF; similar to certain forms of long-term potentiation in the vertebrate CNS).

All of these processes are attributed to changes in the amount of neurotransmitter released by the nerve impulse, and not to postsynaptic modulation of receptors. At the crayfish neuromuscular junction, entry of Ca^{2+} during voltage clamp of the presynaptic terminal does not increase during STF; thus, the Ca^{2+} trigger for exocytosis remains unchanged (Figure 3). The size of the quantal units (each representing exocytosis of one synaptic vesicle) remains constant, while the number of quantal units that compose an EJP increases. Recordings with extracellular electrodes at individual varicosities (Figure 2(c)) yield counts of the number of quantal units released by each impulse at several synapses on the varicosity. These data can be fitted to binomial distributions which incorporate two factors contributing to enhancement at the recording site. The binomial model is based upon the principle that quantal content, or quantal units released per impulse (m), is a product of the number of responding units (n) and the probability of response of each unit (p): in simplest form, $m = np$.

Numerous statistical analyses have shown in general that both n and p increase during short-term facilitation. Although several interpretations have been offered to explain the physical identities of n and p, the available evidence best supports the idea that n represents the number of responding synapses, since values for n are always similar to, but lower than, the number of morphologically discerned synapses. The value for p would then reflect an increase in response probability for the responding units. An extension of this model for crustacean neuromuscular junctions allows individual synapses on a varicosity to have different response probabilities, with recruitment of more synapses during higher frequencies of activity. Evidence in support of this view comes from statistical analyses and from experiments in which terminals exposed to the fluorescent vesicle-accumulated dye FM1–43 exhibit more bright spots (putative active synapses) after stimulation at higher frequencies.

Although best-fitted binomial distributions provide a formal description of changes in the presynaptic terminal, they do not in themselves reveal the underlying cellular mechanisms. The most commonly accepted proximate mechanism for STF is a persistent elevation of presynaptic $[Ca^{2+}]_i$. Another possibility, increased entry of Ca^{2+} with successive impulses, has been ruled out at the crustacean neuromuscular junction (Figure 3). On the other hand, persistent elevation of presynaptic $[Ca^{2+}]_i$ after impulse activity has been directly demonstrated in crustaceans with imaging techniques for intracellular Ca^{2+} (Figure 4(a)). Thus, action of Ca^{2+} on specialized receptors is most likely to account for increased probability of transmitter release (p) during STF, and probably also for increased n (additional active synapses), since general enhancement of p could bring initially silent synapses into play. (Direct

Figure 3 Calcium entry into crayfish inhibitory presynaptic terminal during short-term synaptic facilitation. Twin-pulse facilitation of inhibitory junction potentials (IJPs) occurs without increased entry of Ca^{2+}. Facilitation was induced by paired action potentials, with duration prolonged by potassium channel blockers to enhance Ca^{2+} entry. A_1 A_2, and A_3 illustrate IJPs, presynaptic Ca^{2+} transients, and presynaptic action potentials, respectively. The first (dotted line) and second (solid line) IJPs (B_1), Ca^{2+} transients (B_2), and action potentials (B_3) are superimposed and displayed at a higher time resolution. Although the second IJP is facilitated, the duration of the second action potential is shorter than that of the first one. The second Ca^{2+} transient has a lower amplitude than the first. Each trace represents the average of 100 trials. From Vyshedskiy A, Allana T, and Lin J-W (2000) Analysis of presynaptic Ca^{2+} influx and transmitter release kinetics during facilitation at the inhibitor of the crayfish neuromuscular junction. *Journal of Neuroscience* 20: 6326–6332.

Figure 4 Residual presynaptic calcium and synaptic potentiation at crayfish neuromusclar junctions. (a) $[Ca^{2+}]$ in three synaptic boutons and an axon branch of the excitatory motor axon of the crayfish leg 'opener' muscle, observed with ratiometric fluorescence imaging, using the Ca^{2+}-sensitive dye fura-2. Images were taken at rest, during stimulation at 20 Hz, and during recovery after cessation of stimulation at the times indicated. Colors indicate $[Ca^{2+}]$ values: blue, 50–100 nM; yellow, 300–600 nM; orange, 600–1000 nM; red, 1000–1200 nM; violet, 1200–1600 nM. The small branches and boutons exhibit a larger and more rapid increase in Ca^{2+} than does the larger axon branch. Scale bar = 4 μm. (b) Decay of $[Ca^{2+}]_i$ (squares) and enhancement of synaptic transmission (circles) after tetanic stimulation (50 Hz for 4 s) in crayfish excitatory presynaptic terminals. The solid line is an exponential fit to excitatory junction potential (EJP) data, and the dashed line is an exponential fit to the $\Delta[Ca^{2+}]_i$ data, both beginning about 1.5 s after tetanic stimulation. The kinetic features of the two recovery processes match closely. (c) Relationship between $[Ca^{2+}]_i$ and synaptic enhancement after tetanic stimulation as in panel b (solid circles) and during elevation of $[Ca^{2+}]_i$ (dots) following application of the Ca^{2+} ionophore bromo-A23187 (0.5 μM). In both cases, there is a nearly linear relationship, and the amount of synaptic enhancement associated with $\Delta[Ca^{2+}]_i$ is comparable. EJP enhancement is the ratio of EJP amplitude during treatment to EJP amplitude prior to teatment. (a) After Zucker RS, Delaney KR, Mulkey R, et al. (1991) Presynaptic calcium in transmitter release and posttetanic potentiation. *Annals of the New York Academy of Sciences* 635: 191–207. (b, c) From Delaney KR and Tank DW (1994) A quantitative measurement of the dependence of short-term synaptic enhancement on presynaptic residual calcium. *Journal of Neuroscience* 14: 5885–5902.

evidence for addition of active synapses at crayfish excitatory NMJs has been provided by imaging a fluorescent dye, FM1-43, taken up in synaptic vesicles during exocytotic activity. More fluorescent spots are added with STF. Additional compelling evidence for the importance of residual Ca^{2+} derives from experiments with caged buffers which rapidly remove Ca^{2+} upon photolysis. This procedure abruptly decreases enhanced release of neurotransmitter.)

Short-term enhancement of transmitter release after nerve impulses appears to be linearly related to residual $[Ca^{2+}]_i$ (Figures 4(b) and 4(c)). This linear Ca^{2+}–EJP relationship for enhancement of transmission was initially an embarrassment for the residual Ca^{2+} concept, because the magnitude of the synaptic response to a single nerve impulse is a third- or fourth-order function of intracellular Ca^{2+}. Exocytosis of a single synaptic vesicle is therefore considered to require binding of three to five Ca^{2+} ions, and the vesicle-associated synaptotagmin molecule with five Ca^{2+}-binding sites is currently the preferred candidate for the Ca^{2+} receptor. Thus, it was not possible to account for both evoked release and facilitation with a single Ca^{2+}-binding site leading to release; instead, at least two binding sites, one for exocytosis (low affinity) and one or more for enhancement (high affinity), are implicated. Evidence for a separate high-affinity receptor for enhancement is presented in Figure 1(c). One possibility emerging from recent work is that Ca^{2+}-dependent priming of synaptic vesicles is promoted by residual Ca^{2+}, and then the high Ca^{2+} concentration of the nanodomain which appears at the active zone after a nerve impulse preferentially selects primed vesicles for exocytosis (Figure 5). A version of this model can also explain the dominance of STF at crustacean tonic synapses (more vesicle priming is required) and the depression at phasic synapses (vesicle priming is more complete, and docked vesicles have a higher

Figure 5 Diagram to illustrate that two separate Ca^{2+}-binding sites are needed to explain short-term facilitation and exocytosis of synaptic vesicles. Low-affinity sites activated by a relatively high Ca^{2+} concentration formed near calcium channels of the active zone are thought to trigger fusion of docked and primed synaptic vesicles, with rapid release of their contained neurotransmitter(s). One or more high-affinity sites that react at low concentrations of Ca^{2+} are thought to be responsible for facilitation, augmentation, and posttetanic potentiaton. The number and molecular identity of these sites, and the sequence of priming reactions, remain unknown at present.

probability of exocytosis). As yet, a good molecular candidate for the priming site (or sites) has not been discovered, although candidate molecules have emerged in recent work on *Drosophila* (Table 2).

Enhancement processes that usually require multiple impulses and longer initiation periods – augmentation and potentiation – also depend on residual Ca^{2+} (Figure 4). Their time courses are affected by impulse-mediated Na^{+} accumulation, which acts to slow the extrusion of Ca^{2+} by the surface membrane's Na^{+}–Ca^{2+} exchange. The plasma membrane Na^{+}–Ca^{2+} exchanger actually operates in reverse mode to accelerate buildup of presynaptic Ca^{2+} during intense tetanic stimulation. In addition, the slower process of potentiation is apparently prolonged by leakage of Ca^{2+} from mitochondria, where it is sequestered during periods of elevated presynaptic Ca^{2+} and released thereafter at a slow rate, sustaining the enhanced transmission. Whether different low-affinity Ca^{2+} receptors are responsible for STF, augmentation, and potentiation remains unresolved.

Synaptic depression On initial stimulation, crustacean phasic neuromuscular junctions typically generate large EJPs which depress dramatically as the stimulus is repeated (Figure 6). Tonic neuromuscular junctions, in contrast, show little depression at normal operating frequencies; depression can be induced only with very high nerve impulse frequencies, or when release is abnormally elevated by pharmacologically broadening the presynaptic action potential. Part of the explanation for the phasic–tonic differences lies in the much higher fraction of the readily releasable vesicles that undergo exocytosis at phasic synapses. This, in turn, is linked to the greater sensitivity of the phasic exocytotic machinery to Ca^{2+} and the higher priming rate postulated for synaptic vesicles in phasic terminals (Figure 5).

Depression occurs with very low frequencies at many phasic synapses (low-frequency depression; Figure 6). This type of depression cannot be attributed to depletion of readily releasable synaptic vesicles. Recent work on this obscure phenomenon has shown that low-frequency depression is relieved by blocking calcineurin and other phosphatases (Figure 6(c)). Phosphorylation of specific proteins attached to synaptic vesicles or the presynaptic membrane appears to counteract depression. The molecular targets of phosphorylation and dephosphorylation are as yet unknown.

With high frequencies of stimulation, a different form of depression appears which is linked to loss of readily releasable vesicles (high-frequency depression). The phasic–tonic disparity is partly explained by the smaller size of the vesicle pool, lower concentrations of cytoplasmic glutamate (GLUT), and higher fractional release of available vesicles per impulse in phasic neurons. All of this is most likely related to the supply of ATP by mitochondria, which is less robust in phasic than in tonic terminals, and is required to counteract high-frequency depression. There is good evidence from various invertebrate studies to support this view. Electron microscopic observations have shown loss of vesicles around synapses when fixation is carried out during high-frequency depression. Inhibiting mitochondrial ATP production accelerates depression in both phasic and tonic neuromuscular junctions. In fact, tonic junctions assume phasic characteristics: enlargement of the EJP (due to elevation of cytosolic Ca^{2+}) occurs soon after incapacitation of mitochondria, and rapid depression ensues. Another line of evidence comes from recent studies of *Drosophila* mutants

which lack mitochondria at the neuromuscular junction. These mutants exhibit rapid synaptic depression when repeatedly stimulated, even though initial EJP amplitude is close to normal; the defect can be rescued by supplying exogenous ATP directly through the motor axon to the neuromuscular junction.

Both forms of depression are presynaptic in origin. However, a small postsynaptic contribution due to desensitization of glutamate receptors has been described at *Drosophila* neuromuscular junctions: quantal size is reduced slightly as a result of prior glutamate exocytosis. Despite this, it is currently thought that the major cause of high-frequency synaptic depression at invertebrate neuromuscular junctions is the inability of presynaptic mechanisms to sustain continuous release of neurotransmitter at the required rate.

Long-Term Modulation

Long-term facilitation Activity-dependent enhancement of synaptic transmission lasting many hours or longer occurs in some facilitating motor neurons of crustacean limb muscles. After several minutes of tetanic stimulation at frequencies of 5–10 Hz or greater, and following the decay of posttetanic potentiation, EJPs tested with low-frequency stimulation remain stably enhanced at 150–200% of normal amplitude (long-term facilitation; LTF). The enhancement is entirely presynaptic – quantal size is unaltered, while quantal content increases – and does not involve changes in amplitude or duration of the presynaptic action potential (Figure 7). In many of its general features, LTF resembles a form of long-term potentiation described in the mammalian central nervous system (CNS) at hippocampal mossy fiber synapses on CA1 pyramidal neurons.

Binomial statistical analyses have indicated that the enhancement is entirely due to an increase in number of responding units (n), and not to a change in mean response probability (p). In this, LTF differs from STF. Evidence from electron microscopy suggests that some individual synapses acquire additional presynaptic densities, indicating the presence of more active zones for these synapses. No detectable change in number or disposition of synaptic vesicles was detected. These observations support a model in which a few synapses become modified structurally or functionally to respond more effectively to low-frequency stimulation (Figure 7). In a parallel case of presynaptic modification, direct evidence for addition of new synapses during long-term potentiation has been obtained from optical studies of dendritic spines of pyramidal cells in CA3 region of the mammalian hippocampus, using cultured slice preparations.

Recent experimental work on induction and expression of LTF has implicated several Ca^{2+}-activated kinases and phosphatases, including calcineurin. In addition, surprisingly, local protein synthesis contributes to establishment of LTF, as its expression is sensitive to translation inhibitors (cycloheximide and anisomycin). Collectively, these processes may be involved in synaptic modification, perhaps in structural modification of active zones; but the proteins and structures involved in synaptic modification are not yet defined.

Induction of LTF has been linked to activation of hyperpolarization-activated and cyclic nucleotide-activated (HCN) channels by hyperpolarization of the presynaptic membrane, which results from electrogenic surface extrusion of accumulating Na^+ by the Na^+/K^+-ATPase (sodium pump). HCN channels may be linked in turn to actin polymerization, which leads to enhancement by an unknown process. There is, however, conflicting evidence on the need for Na^+ accumulation in LTF induction, as earlier experiments demonstrated induction of LTF by depolarizing pulses in neurons treated with tetrodotoxin (TTX) to block action potential-mediated entry of Na^+. Thus, the details of the pathways and mechanisms for LTF remain to be confirmed and further elucidated, and the model for this process is presently incomplete.

The cellular components involved in short-term enhancement and long-term facilitation are diagramed in Figure 8, and candidate molecules (emerging from recent work in *Drosophila*) which are likely components of the mechanisms of synaptic modulation are presented in Table 2.

Experience-dependent strengthening At *Drosophila* larval neuromuscular junctions, a form of long-term plasticity that requires coordinated pre- and postsynaptic modification has been described. When larvae are forced to be more active, their neuromuscular junctions exhibit enhanced synaptic transmission within 2 h. Correlated with this, subsynaptic protein synthesis apparently increases, and soon extra glutamate receptors (DGluR-IIA subunits) start to accumulate around synapses. Additional boutons and synapses with active zones and postsynaptic receptor patches are added to the neuromuscular junctions. Similar changes are induced by genetic manipulation of genes for two glutamate receptor subunits (*dGluR-IIA* and *dGluR-IIB*), showing a link between increased expression of the DGluR-IIA subunit and recruitment of additional presynaptic active zones. Thus, increased activity may initiate a process resembling LTF (presynaptic enhancement). At the *Drosophila* neuromuscular junction, postsynaptic protein synthesis is then induced, which in turn feeds back to the presynaptic neuron,

Table 2 Learning, memory, and synaptic plasticity mutants in *Drosophila*

Gene product/protein	*Mutant or gene name*	*Cytogenetic positions*	*General physiological role*	*Effect of mutation on synaptic transmission and structure at larval NMJ (reduced function unless otherwise stated)*	*Effect of mutation on modulation at larval NMJ (reduced function unless otherwise stated)*	*Learning/memory phase affected*
Transmitters PACAP38	*amnesiac*	18F4–19A2 (X)	Neuropeptide activity: activates AC (*rutabaga*) through G-protein-coupled receptor; activates Ras/Raf pathway; induces slow depolarization during high-frequency stimulation; ↑ K^+ current		Eliminates both ↑ K^+ current and slow depolarization	MTM
Dopa decarboxylase (Ddc)	*Ddc*	37C1 (2L)	Catalysis of dopamine and 5-HT: ↑ dopamine and 5-HT			Associative memory deficit
Receptors G-protein sα	*Gsα60A*	60A12–A13 (2R)	Stimulatory G-protein: activates AC (*rutabaga*); most severe learning and memory mutant (complete abolishment)	↑ Post Gsα: ↑ amplitude mini's	↓ F acilitation; ↓ PTP	Acq
Metabotropic glutamate receptor subunit	*DmGluRA*	102C5–6 (4)	Metabotropic glutamate receptor subunit: modulatory effect requires G-protein β13F subunit	Asynchronous release; ↑ bouton size; ↓ bouton number	↑ Short-term facilitation; ↑ augmentation	
Ionotropic glutamate receptor subunit	*DGluRIIA*	25E6 (2L)	Ionotropic glutamate receptor subunit: involved in CaMKII-dependent retrograde synaptic strengthening pathway	↓ Quantal size; ↑ quantal content; ↑ rate of desensitization		
Notch	*Notch*	3C7–9 (X)	Surface receptor: ultrastructural remodeling			LTM
Channels Shaker cognate b	*shab*	63A1–2 (3L)	Delayed rectifier K^+ channel subunit		↑ Augmentation; ↑ facilitation	
Ether-a-go-go	*eag*	13A2–5 (X)	K^+ channel subunit: modulated by CaMKII; mutants have hyperexcitable nerves and muscles	↑ Mini's after discharge		Nonassociative memory deficit
Slowpoke	*slowpoke*	96A14–17 (3R)	Ca^{2+}-activated K^+ channel: large conductance			ARM
Shaker	*Shaker*	16F3–5 (X)	K^+ channel subunit: involved in shaping action potentials; controls basal transmitter release; possible point of converging pathways activated by PACAP32; adults shake in ether	↓ Presynaptic K^+ current; action potential widening; ↑ EJP amplitude due to ↑ transmitter release	↑ Facilitation; augmentation lost and depression ensues	STM: nonassociative memory deficit
Slowpoke-binding protein	*Slob*	28C1 (2L)	Binding protein: ↑ voltage sensitivity of slowpoke; CaMKII regulates binding to *slowpoke* and *leonardo*	↓ Channel open prob.; ↓ peak current		

Second-messenger kinases cAMP-dependent protein kinase 1 regulatory subunit of PKA	PKA-RI	77E8–F1 (3L)	Protein phosphorylation: inhibits function of kinase when associated with catalytic subunit; mutant causes constitutively active PKA	↑ PKA activity; ↓ EJC amplitude; ↓frequency of mini's; ↓ quantal size	Loss of large vesicle recruitment during periods of high activity; loss of retrograde modulation of transmitter release	MTM
cAMP-dependent protein kinase 1 catalytic subunit of PKA	PKA-CI/DCO	30C5 (2L)	Protein phosphorylation: becomes active when freed from regulatory subunit; phosphorylates proteins in the cAMP/PKA pathway, including CREB, which then induces 'learning and memory' genes; modulates L-type Ca^{2+} channel and Ca^{2+}-dependent K^+ channel; recruits vesicles from reserve pool	↓ PKA activity; ↓ EJC amplitude; no Δ in frequency of mini's; ↑ quantal size (requires DGluRIIA)	Loss of large vesicle recruitment during periods of high activity; loss of retrograde modulation of transmitter release	MTM
PKB	*Akt*	89B3 (3R)	Protein phosphorylation: insulin receptor signal transduction		Disrupts LTD; normal facilitation and PTP	
PKC	*PKC 98E* *PKC 53E* *PKC 51D*	98F6 (3R) 53E2 (2R) 51D5–6 (2R)	Protein phosphorylation: regulates structural formation of synapse			ARM
PKG	*Foraging*	24A2–4 (2L)	Protein phosphorylation: regulates polymorphic foraging behavior (rover vs. sitter)	For(r): ↑ PKG, ↑ K^+ current; for(s): ↓ PKG, ↓ K^+ current; ↑ mini's; ↑ transmitter release		Nonassociative memory deficit
Calcium/calmodulin-dependent kinase	*CamKII*	102D1–3 (4)	Protein phosphorylation: coordinates responses to neuroactive substances; part of retrograde synaptic strengthening pathway requiring bone morphogenetic protein; pre- and postdevelopment/maturation; activates *ether-a-go-go*, *slob*, *naylot*	↓ Post-CaMKII; ↑ bouton number; ↑ presynaptic T bars; ↑ quantal content	↓ Facilitation; ↓ augmentation; ↓ PTP	LTM
Ras oncogene at 85D	*Ras85D/Ras1*	85D19 (3R)	GTPase: converges with AC path to modulate K^+ channels at larval NMJ; part of MAPK/ERK path; PACAP38 effect eliminated in mutant		Eliminates modulatory effect of PACAP38 on K^+ current	Associative memory deficit
Raf/polehole	raf^{HM7}/*phl*	3A1 (X)	Protein phosphorylation: converges with AC path to modulate K^+ channels at larval NMJ; part of MAPK/ERK path; PACAP38 effect eliminated in mutant		Eliminates modulatory effect of PACAP38 on K^+ current

Gene product/protein	*Mutant or gene name*	*Cytogenetic positions*	*General physiological role*	*Effect of mutation on synaptic transmission and structure at larval NMJ (reduced function unless otherwise stated)*	*Effect of mutation on modulation at larval NMJ (reduced function unless otherwise stated)*	*Learning/memory phase affected*
Second-messenger pathway components Adenylyl cyclase–Ca^{2+} CaM sensitive	*rutabaga*	12F4 (X)	Converts ATP to cAMP: cAMP activates PKA, recruits vesicles from reserve pool; *rutabaga* mutation → ↓ cAMP and ↓ PKA activity	↓ Bouton number; ↑ bouton size; ↑ T-bars/synapse; ↓ ratio of docked/undocked vesicles; ↓ transmission; ↑ asynchronous release	↓ Facilitation; ↓ PTP; normal LTD	STM
cAMP phosphodiesterase	*Dunce*	3C9–D1 (X)	Degradation of cAMP: *dunce* mutation → ↑ cAMP and ↑PKA activity	Poorly defined synaptic specialization; ↑ T-bars/synapse; ↑ ratio of docked/undocked vesicles; ↑ asynchronous release	↓ Facilitation; ↓ PTP; Ca^{2+} dependence of transmitter release; normal LTD	STM
Calmodulin	*Cam*	48F1 (2R)	Calcium-binding protein: activates adenylyl cyclase (*rutabaga*); altered Ca^{2+} transport, NO regulation, and cytoskeletal regulation; muscular hypercontraction; disrupted locomotion	↑ Transmitter release; deregulation of muscle Ca^{2+} fluxes	Disrupted facilitation and PTP	
Neurofibromin 1	*Nf1*	96F9 (3R)	Guanosine triphosphatase-activating protein: role in PACAP38-induced ↑ K^+ current (through AC/cAMP path)		Eliminates modulatory effect of PACAP38 on K^+ current	STM
14–3-3	*leonardo*	46E6–8 (2R)	Hydroxylase: MAPK and PKA regulation; Ca^{2+}-induced transmitter release; mutants have↓ voltage sensitivity of Ca^{2+}-act. K^+ channel (*slowpoke*)	↓ Transmission	↑ Facilitation; ↓ augmentation; ↓ PTP	Acq
Phospholipase-A2	*radish*	11E1 (X)	Phospholipid metabolism			ARM
Structural α-Integrin subunit	*Volando/scb*	51E10–11 (2R)	Cell adhesion protein	↑ Synaptic arbors; ↑ EJP amplitude; ↓ Ca^{2+} dependence	↓ Short-term facilitation; ↓ augmentation; ↓ PTP	STM
Fasciclin II	*fasII*	4B1–3 (X)	Cell adhesion molecule: regulates synaptic structure; role in cAMP-dependent plasticity	↑ Bouton number; no Δ in quantal content		STM, LTM, Acq

Bruchpilot	*bruchpilot*	45D3–4; 45F2–6 (2R)	Structural protein: associated with cytoskeletal matrix at the active zone	↓ Evoked transmission; loss of T-bars	Loss of depression with transient short-term facilitation; ↑ PTP	
Dystrophin	*dystrophin*	92A5–10 (3R)	Structural protein: link between cytoskeleton and extracellular matrix; ↓ dystrophin; ↑ probability of release	↑ Transmitter release; no Δ in synapse size, T-bar number, vesicle pool size, post morphology, or sensitivity	↓ Facilitation	
Transcription/DNA regulation cAMP response element-binding protein (CREB)	*DCREB*	71E1 (3L)	Transcription factor: phosphorylated by PKA, which then activates transcription of 'learning and memory' genes	Post ↓ CREB: ↓ in transmitter release and ↑ bouton number; pre or post ↑ CREB: also ↓ transmitter release, but no Δ in bouton number	Pre ↑ CREB: impairs short-term facilitation	LTM
Origin recognition complex subunit	*latheo*	49F7–8 (2R)	DNA regulation protein	↓ Ca^{2+} dependence; ↑ EJP amplitude		Acq
Staufen	*staufen/ pumillio*	55B5–7 (2R)	Location and translation of mRNA			LTM
Pumilio	*pumilio*	85C4–DI (3R)	mRNA translation repressor			LTM
EIF-5°C	*extrabases eIF-5°C*	83B4 (3R)	mRNA translation initiation factor			LTM
Oscar	*oscar*	85B7 (3R)	Involved in staufen-dependent mRNA translocation			LTM
Adh transcription factor 1	*Nalyot/ADF-1*	42C3 (2R)	Myb-related transcription factor	↑ Bouton number		LTM
AP1	*AP-1/Kayak/ Dfos*	99B10–C1 (3R)	Immediate-early transcription factor: with CREB and cAMP, ↑ EJC amplitude; without CREB, ↑ bouton number	↑ AP-1: ↑ EJC amplitude, ↑ bouton number; ↓AP-1: ↓ EJC amplitude, ↓ bouton number		
Synaptic vesicle proteins Cysteine string protein	*csp*	79D3 (3L)	Synaptic vesicle protein and chaperone: phosphorylated by PKA; plays a key role in transmitter release	↓ EJP amplitude; ↑ presynaptic resting Ca^{2+} and Ca^{2+} entry; transmission block at moderate temperature	↓ Short-term facilitation; ↓ augmentation; ↓ PTP	
Synapsin	*syn*	85F16–86A1 (3R)	Synaptic vesicle protein: target of PKA, which recruits synaptic vesicle from reserve pool through spectrin			Nonassociative memory deficit STM/MTM

Figure 6 Low-frequency depression and the modulating role of phosphorylation in the presynaptic terminal. (a) Simultaneous recordings of the presynaptic action potential (AP) and the excitatory postsynaptic potential (EPSP) taken before (1) and after (2) induction of low-frequency depression in the phasic excitatory axon of the crayfish leg extensor muscle. Stimuli were delivered at 0.2 Hz for 75 min; the action potential retained its initial amplitude, while the EPSP declined. (b) Time course of decline of transmitter release at the phasic axon's neuromuscular junctions during 0.2 Hz stimulation; measurements were of maximum rate of rise (slope) normalized to the first EPSP. Two phases of depression appeared, with time constants of 4 and 105 min, respectively. (c) Recovery from depression with application of the phosphatase inhibitor, okadaic acid (10 μM), after 30 min of stimulation at 0.2 Hz. From Silverman-Gavrila LB, Orth PMR, and Charlton MP (2005) Phosphorylation-dependent low-frequency depression at phasic synapses of a crayfish motoneuron. *Journal of Neuroscience* 25: 3168–3180.

initiating additional presynaptic modifications. Protein kinase A has been implicated as a mediator of postsynaptic alterations, while an unknown retrograde signal is thought to initiate presynaptic changes. Feedback regulation of structure and synaptic strength have been investigated in several studies of *Drosophila* neuromuscular junctions (the details are beyond the scope of this article). The studies on experience-dependent strengthening illustrate the great advantages of the genetic approaches available in *Drosophila* for investigations of synaptic modification at the neuromuscular junction.

Long-term depression A presynaptically mediated form of long-term depression (LTD) has recently been analyzed at the larval *Drosophila* neuromuscular junction. Induction of this form of LTD requires tetanic activation of the motor axons at 30 Hz for 20 s, and persists for at least an hour. Mutations in the *akt* gene (which encodes protein kinase B/Akt) disrupt LTD expression but do not affect other forms of activity-dependent modulation (STF and potentiation).

Long-term adaptation Chronic modulation of the normal activity of crustacean phasic neurons leads to striking physiological and structural alterations at the neuromuscular junction. These neurons are normally inactive and are recruited sporadically for fast muscle contractions, when they fire one or a few impulses in a brief burst, evoking large, rapidly depressing EJPs. Imposition of tonic activity at 5 Hz for 1 h on two to three successive days initiates a transformation of the neuromuscular junction to a more tonic phenotype: the EJP becomes smaller in amplitude but more resistant to depression when challenged with continuous stimulation. Strikingly, the physiological changes are accompanied by morphological alteration of the neuromuscular junction. Varicosities enlarge and their contained mitochondria increase in volume and metabolic activity (Figure 9). The changes require several days for completion, and once established persist for several weeks if neural activity reverts to the normal phasic pattern. Activity of the motor neuron's central processes is required for this transformation; this is thought to induce synthesis and transport of proteins or aggregates that mediate synaptic modification. These adaptive changes have been demonstrated in normal populations of crayfish and are more readily induced in small, immature individuals, demonstrating greater plasticity of neuromuscular junctions in younger animals.

Partial analysis of the underlying mechanisms has been undertaken. Fatigue resistance of synaptic transmission correlates with mitochondrial volume

Figure 7 Long-term facilitation at the crayfish neuromuscular junction. (a) Time course of long-term facilitation of excitatory neurotransmission, and of simultaneous changes in conduction speed of the motor axon's action potential monitored by latency of the presynaptic nerve terminal potential (crayfish opener muscle). Growth of the excitatory postsynaptic potential (EPSP) to almost 1000% during stimulation at 15 Hz is shown, together with decay in amplitude of a test response (to 64 stimuli at 10 Hz) following the inducing stimulus train. Changes in response latency reverse more rapidly than does synaptic transmission, which remains elevated for many hours. (b) Simultaneous intracellular recordings of the action potential from a presynaptic nerve terminal, and the excitatory postsynaptic potential from a postsynaptic muscle fiber in the crayfish leg 'opener' muscle. Records were taken during 5 Hz stimulation before (control) and 40 min after (test) tetanic stimulation at 20 Hz for 10 min. The EPSP was persistently enhanced by tetanic stimulation, but there was no corresponding change in the presynaptic acton potential. (c) Quantal events at a single presynaptic bouton (lower traces) associated with persistent enhancement of the EPSP (upper traces). Records were taken at 5 Hz before and 40 min after tetanic stimulation at 20 Hz for 10 min. Mean quantal content (m) at the selected bouton increased by 35%; this change was due to an increase in the number of responding units (n) rather than to increased mean probability of response (p), according to best-fitted binomial distributions for the data. (d) A model for long-term facilitation (LTF) shown in panel c, illustrating recruitment of previously ineffective synapses to the responding population following induction of LTF. (a) After Atwood HL, Swenarchuk LE, and Gruenwald CR (1975) Long-term synaptic facilitation during sodium accumulation in nerve terminals. *Brain Research* 100: 198–204. (b,d) Reproduced from Wojtowicz JM and Atwood HL (1986) Long-term facilitation alters transmitter releasing properties at the crayfish neuromuscular junction. *Journal of Neurophysiology* 55: 484–498, with permission from The American Physiological Society; (c) from Wojtowicz JM, Marin L, and Atwood HL (1994) Activity-induced changes in synaptic release sites at the crayfish neuromuscular junction. *Journal of Neuroscience* 14: 3688–3703.

and mitochondrial membrane potential. Reduced EJP amplitude is linked to smaller quantal emission rates per synapse; however, the basis for reduced exocytosis has not been fully analyzed. The large size of the motor neurons in crustaceans affords an opportunity for single-cell analysis of changes in protein synthesis during long-term adaptation. Similar adaptive manifestations have been reported at other neuromuscular junctions and may also occur at central synapses.

Figure 8 Diagram of the sites of activity-dependent modulation in crustacean presynaptic nerve terminals. Structures shown are mitochondria (m), synaptic vesicles (sv), endoplasmic reticulum (er), synapses (s), dense-cored vesicles (d), and subsynaptic reticulum (SSR). Sites of action are (1) synapse and active zone (modified in long-term facilitation), (2) surface membrane (site of Na^+/K^+–ATPase, Na^+/Ca^{2+} exchanger, and Ca^{2+}-ATPase, all of which participate in regulation of Na^+ and Ca^{2+}, affecting facilitation, augmentation, and posttetanic potentiation), (3) mitochondria (involved in posttetanic potentiation and high-frequency depression), (4) endoplasmic reticulum (a source of intracellular Ca^{2+}), and (5) synaptic vesicles (involved in short-term facilitation, augmentation, and posttetanic potentiation).

Figure 9 Long-term adaptation of synaptic transmission at a crayfish phasic neuromuscular junction. (a) Comparison of excitatory postsynaptic potentials (EPSPs) at neuromuscular junctions of phasic excitatory motor axons in normal (control) and conditioned (experimental) claws of the crayfish *Procambarus clarkii*. The axons were stimulated at 5 Hz for 30 min, and EPSPs were recorded throughout the period of stimulation. The time course of changes in EPSP amplitude is shown in the graph for representative muscle fibers of a conditioned claw (experimental; solid triangles) and the contralateral unconditioned claw (control; solid circles). Each point on the graph represents the mean value for 10 muscle fibers. Conditioning was achieved by activating the experimental phasic axon at 5 Hz for 2 h a day over a 14-day period. EPSPs in the experimental claw are initially smaller, but decline less with continued stimulation, compared to EPSPs in the control claw. Scale bar = 4 mV, 20 ms. (b) Morphological transformation of nerve terminals of the fast axon after 2 weeks of conditioning, as observed in serial electron micrographs. Varicosities are more pronounced and contain a greater volume of mitochondrial material after conditioning. Reproduced from Atwood HL and Lnenicka GA (1987) Role of activity in determining properties of the neuromuscular system in crustaceans. *American Zoologist* 27: 977–989, with permission from Oxford University Press.

Molecular Approaches

Genetic and molecular studies in the fruit fly *Drosophila melanogaster* and the nematode *Caenorhabditis elegans* have recently provided numerous candidates for molecules that affect synaptic transmission and synaptic plasticity; some of these are also linked to processes of learning and memory. A catalog of significant molecular candidates found in *Drosophila* is provided in Table 2, which illustrates that several different categories are involved in regulation of synaptic performance. Most physiological processes depend on interacting networks of molecules rather than on single players. Thus, establishing the relative importance of individual molecular species for synaptic performance typically requires many independent studies with various techniques.

Inhibitory Modulation

Presynaptic Inhibition

Peripheral inhibitory neurons of crustaceans and insects synapse extensively on muscle fibers of limb and abdominal muscles, producing inhibitory junction potentials (IJPs). This inhibitory action affects the postsynaptic muscle fiber membrane directly (postsynaptic inhibition). An additional indirect effect known as presynaptic inhibition is prominent in limb muscles of some groups of decapod crustaceans, including crayfish and crabs.

Presynaptic inhibition is mediated by axo-axonal synapses formed by inhibitory nerve terminals on

excitatory neuromuscular junctions. When an inhibitory nerve impulse activates axo-axonal synapses 1–4 ms before the arrival of an excitatory impulse, transmitter release at the excitatory synapses is reduced, often drastically (Figure 10). That this effect is presynaptic was first established by demonstrating reduction in number of emitted quantal units comprising the EJP without an effect on quantal size. Intracellular recordings from excitatory axons confirm the occurrence of evoked inhibitory potentials in response to stimulation of the inhibitory axon. These inhibitory potentials have the same reversal potential as that obtained for exogenously applied γ-aminobutyric acid (GABA), the transmitter substance of inhibitory neurons. The amplitude of the excitatory axon action potential is significantly reduced during inhibitory stimulation. It is clear that presynaptic inhibition at crustacean excitatory neuromuscular junctions results from activation of GABA receptors on the excitatory axon, which when opened increase the axonal membrane's conductance for Cl^- and reduce the amplitude of the excitatory action potential. The smaller action potential is less effective in opening calcium channels and triggering exocytosis at affected excitatory synapses. Modeling of the effects of the inhibitory conductance change on conducted action potentials has indicated that these effects are accentuated by the varicose structure of the excitatory neuromuscular junctions.

Figure 10 Presynaptic inhibition at a crab neuromuscular junction. (a) Inhibition of excitatory junction potentials at a neuromuscular junction in the leg 'stretcher' muscle of the crab *Hyas araneus*. Stimulation of the excitatory axon at 1 Hz produced large excitatory junction potentials, which were almost completely abolished by optimally timed stimulation (Stim) of the specific inhibitory (SI) axon. The common inhibitory (CI) axon was less effective for comparable stimulation. (b) Reduction of quantal emission at a single bouton shown by extracellular recording during stimulation of SI and CI axons. Upper traces, excitatory junction potentials; lower traces, extracellular recordings from a single bouton. In each record, several superimposed traces are shown, taken at 1 Hz stimulation. The control recording is without inhibition; the other records show the effects of optimally timed SI and CI pairing. Transmission at this bouton is reduced more drastically by the CI axon, although the SI axon is more effective in reducing the excitatory postsynaptic potential of the muscle fiber as a whole. From Wiens TJ and Atwood HL (1975) Dual inhibitory control in crab leg muscles. *Journal of Comparative Physiology* 99: 211–230.

Pharmacological experiments have implicated two types of GABA receptors in crustacean presynaptic inhibition. The predominant $GABA_A$ ionotropic receptors are coupled to Cl^- ionophores, while slower-acting metabotropic $GABA_B$ receptors activate G-proteins, which in turn probably act to open K channels in the membrane of the excitatory axon. The ultimate effect of both receptor types is to reduce excitatory transmission by lowering the peak of the presynaptic action potential. At neuromuscular junctions of crabs and crayfish, $GABA_A$ receptors account for 70–90% of presynaptic inhibition, and $GABA_B$ receptors account for 10–30%. The proportional contributions vary among different crustacean muscles that have been investigated.

The functional significance of presynaptic inhibition is debatable. It occurs in relatively few of the muscles that have been investigated. The requirement for precise timing of inhibitory impulses is not met during normal activity in many crustaceans, although one report suggests that timing is utilized in a crab species. There is no doubt that presynaptic inhibition adds efficiency to rapid suppression of muscle contractions during locomotion, and in some cases allows short-term facilitation of EJPs to be retained during the period of inhibition, thereby promoting faster contractions for the next cycle of movement.

Autoinhibition

At crayfish neuromuscular junctions, autoinhibition of quantal release by micromolar concentrations of L-glutamate has been described. The receptor responsible for this inhibition reportedly activates a glutamate transporter with an associated Cl^- ionophore. Increased Cl^-conductance mediates the autoinhibition. An additional glutamate autoreceptor that facilitates quantal release has also been reported for both crayfish and insect neuromuscular junctions, suggesting the occurrence of multiple autoreceptors on many arthropod neuromuscular junctions. The normal functional roles of these receptors have not been worked out.

Neuromodulators and Neurohormones

General Features

The activity resulting from synaptic communications can be altered by neuroactive substances from adjacent or distant neurons. Neuromodulators are released by neurons at synapses and access their targets by diffusion, modulating the activity of other local cells. Neurohormones enter the circulatory system to alter the cellular activity of cells distant from their release sites. Several types of modulatory substances exist, including amines, peptides, steroids, and lipids/phospholipids. Many neuroactive substances have multiple roles as neurotransmitters, neuromodulators, and neurohormones. Here we summarize the effects on invertebrate neuromuscular transmission of the two most-studied groups of neuroactive modulatory substances, amines and peptides.

The physiological activities regulated by amines and peptides are very diverse and include tissue growth, metabolic pathways, immune system activity, apoptosis, and behavior such as fight or flight responses. Early work in lobsters revealed that several of these neuroactive substances could induce fight- or flightlike behaviors. Amines and peptides affect behavior by acting both centrally, on the cell bodies of motor neurons and the circuitry controlling them, as well as peripherally, on muscles and the nerve endings which excite them. We focus here primarily on the modulation of exoskeletal neuromuscular transmission. The sites of modulation in the presynaptic nerve terminal are indicated in Figure 11.

Several aminergic and peptidergic modulators, including octopamine and pituitary adenylyl cyclase-activating peptide (PACAP)-like peptide, act both locally and distally to their release sites. Thus, the actions of these signaling molecules are determined not only by the receptors they bind to and the signal transduction pathways they activate, but also by the pattern of their release. In addition, activity-dependent modulation of the crayfish opener muscle by octopamine first revealed that the level of modulation depends on the target cell's activity state.

Figure 11 Diagram of the sites of external modulation in a crustacean presynaptic nerve terminal. Excitatory (EX) and inhibitory (IN) nerve terminals are shown, together with an inhibitory axo-axonal synapse mediating presynaptic inhibition. Transmitter substances are γ-aminobutyric acid (GABA) and glutamate (GLUT). Surface receptors on the excitatory terminal are for neurohormones and neuromodulators: octopamine (Oct), serotonin (5HT), and peptides (PEP). In addition, glutamatergic autoreceptors are indicated. Structural features: mitochondria (m), synaptic vesicles (sv), endoplasmic reticulum (er), synapses (s), dense-cored vesicles (d), and subsynaptic reticulum (SSR).

Amines

Amines are derived from amino acids and include indoles such as serotonin, and catecholamines such as dopamine and octopamine.

Octopamine The biogenic monoamine octopamine (OA) is related structurally and functionally to noradrenaline; both act as 'stress hormones' in fight or flight responses. Octopamine has no physiological role in vertebrates, making it the focus of much pesticide research, since antagonists for OA would likely not affect humans but would selectively target insects. The modulatory effects of OA in invertebrates are very broad and include effects on flight muscles, heart muscles, oviducts, endocrine glands, hemocytes, and fat bodies; on sensory receptors involved in taste, vision, olfaction, proprioception, and phermone responses; and on central nervous system activity related to learning and memory, motivation, and rhythmic motor behaviors.

Octopamine (OA) can be released directly into the circulatory system from the pericardial organ of crustaceans, or the copora cardiacum of insects, both of which are neurosecretory structures containing several other neurohormones. OA is found in the dorsal unpaired median (DUM) and ventral unpaired median (VUM) neurons of insects from which it is released into most neuropils of the brain, acting as both neurotransmitter and neuromodulator. DUM neurons are believed to provide the majority of OA

released into the hemolymph. *Drosophila* type II motorneuron terminals, which form small (1–2 μm) varicosities, contain OA and its cotransmitter glutamate. These terminals are formed by three VUM neurons, each covering either the dorsal, ventral, or lateral musculature. Thus, OA can be released either from neurosecretory structures into the circulation or onto neurons and muscles from nerve endings. Octopamine is typically released during bouts of high neural activity, as might be expected when an animal is startled or in an excited state.

Activity-dependent release of OA at the locust extensor tibiae neuromuscular junction increases both muscle tension and the rate of muscle relaxation, along with modest enhancement of EJPs. Thus, OA induces a physiological transition in the state of the muscle from one which favors maintenance of posture to one which favors rapid movements. The opposite occurs in a similar but primitive orthopteran insect, the 'weta' (*Hemideina femorata*) which does not use its legs for jumping but instead exhibits a defensive posture by extending the legs and rotating them toward the threat. Instead of promoting rapid changes in tension, as in locusts, OA induces a very long-lasting plateau of catchlike tension accompanied by large increase in EJP amplitude. The differences in muscle tension responses in orthopterans may be due to postysynaptic (muscle) properties. In the marine gastropod *Rapana thomasian*, OA enhances the radula protractor twitch contraction, while it reduces it in the antagonistic retractor by hyperpolarizing the muscle. This functionally significant coordination of opposite actions on antagonistic muscles is termed 'orchestration.'

A single type of modulator can have widely differing actions, depending upon its target cell. The G-protein-coupled OA receptors have been found in several invertebrate tissues, including locust leg and flight muscles. Three subtypes have been elucidated using the extensor tibiae muscle preparation: type 2A is found presynaptically, type 2B is found postsynaptically, and class 1 is restricted to the myogenic bundle, a small group of muscle fibers that is spontaneously active. A third type of receptor (class 3) is found in the CNS. All of these OA receptors are G-protein coupled. Binding of OA dissociates the $G\beta\gamma$ subunit from the $G\alpha$ subunit. Depending upon the type of receptor, the $G\alpha$ subunit can either stimulate or inhibit adenylyl cyclase activity, leading to either an increase or a decrease in cAMP levels. The second-messenger cAMP regulates protein kinase A (PKA) activity, which has modulatory actions on various ion channels (K^+), ion pumps (Na^+/K^+-ATPase), and transcription factors (cAMP response element-binding protein; CREB). In the locust extensor tibiae preparation, OA increases muscle Cl^- conductance, decreases K^+ conductance, and increases Na^+/K^+ pump activity; presynaptically, it enhances transmitter release. The mechanism for its presynaptic effects is not presently known.

Serotonin Serotonin (5-hydroxytryptamine; 5-HT) is a very important neuroactive substance which acts as a neurotransmitter, neuromodulator, and neurohormone for invertebrates, with widespread and profound effects on motor programs, behavioral repertoires, synaptic transmission, and muscular contraction. Serotonergic neurons of invertebrate central nervous systems typically have wide distributions of their processes within the CNS, and often project in peripheral nerves to neurosecretory organs or zones, where they release serotonin into the circulating hemolymph. Decapod crustaceans (lobsters and crayfish) have provided the most detailed information on serotonin's effects at neuromuscular junctions. In contrast, insects, including *Drosophila* larvae, have not shown the dramatic effects of serotonin at neuromuscular junctions characteristic of crustaceans.

Initial studies in crustaceans established that serotonin, at low concentrations, makes muscles produce more action potentials and greatly enhances synaptic transmission at both excitatory and inhibitory neuromuscular junctions. Enlargement of EJPs is primarily due to increased quantal content. The enhancement occurs rapidly and decays in two phases after removal of serotonin: a rapid phase, which is over in less than 30 min, and a long-lasting phase prolonged for 1–2 h. Significantly, the duration of serotonin enhancement is much less than for LTF, and different cellular mechanisms are evidently utilized.

The two phases of enhancement apparently represent activation of two presynaptic second-messenger cascades, though whether two different serotonin receptors are involved has not been determined. Activation of phospholipase C is implicated by the effects of pharmacological inhibitors directed against it: both phases of enhancement are completely eliminated. The initial phase is imitated by inositol 1,4,5-trisphosphate (IP_3) injections into the presynaptic axon, while the long-lasting enhancement likely involves activation of protein kinase C and adenylyl cyclase, leading to increased intracellular cAMP.

Given elevated cAMP, the logical next step would be increased activity of protein kinase A and phosphorylation of susceptible presynaptic proteins involved in aspects of excitation–secretion coupling. However, recent pharmacological manipulations at the crayfish excitatory neuromuscular junction

present a different scenario. Rather than protein kinase A, the prime targets for cAMP are (a) hyperpolarization and cyclic nucleotide-activated (HCN) ion channels and (b) exchange factor activated by cAMP (Epac). The first target is coupled to polymerization of actin; the second is coupled to presynaptic proteins associated with synaptic vesicles and the exocytotic machinery, including the G-protein Rab3 and its interacting partner, Rim. Collectively, the effects of these intermediate targets for cAMP are responsible for enhancement of transmission. Involvement of Epac in synaptic enhancement has now been reported for other synapses, including the *Drosophila* neuromuscular junction and the mammalian calyx of Held in the auditory pathway.

A striking feature of serotonin's effect is the reduction in requirement for Ca^{2+} in exocytosis. Transmission can take place in very low concentrations of external Ca^{2+} after serotonin treatment. This indicates increased Ca^{2+} sensitivity of exocytotic mechanisms. In addition, serotonin treatment does not lead to a detectable increase in presynaptic Ca^{2+} with action potentials, contradicting expectations that prime effectors might be synaptic Ca^{2+} channels or endoplasmic reticulum Ca^{2+} stores. Synaptic vesicle recycling is much enhanced, suggesting that a larger proportion of synaptic vesicles is in the readily releasable pool. Thus, the most likely targets for serotonin's effect are the synaptic vesicles, which appear to be more fully primed and mobilized for exocytosis, and one or more of the proteins that control exocytosis or endocytosis.

Peptides

FMRFamide-like peptides The tetrapeptide Phe-Met-Arg-Phe-NH_2 (FMRFamide) and homologous peptides containing the FMRFamide or FLRFamide sequence form the largest known group of invertebrate peptides. Several of theses peptides are found in the pericardial organ of crustaceans, where they regulate cardiac function. These peptides are also released into the hemolymph and modulate exoskeletal muscle. Their mechanisms of action include activation of G-protein-coupled receptors, modulation of second messengers (cAMP and IP_3), and direct effects on ion channels (Na^+ and Ca^{2+} channels). Peptides generally have stronger effects on muscle than they do at the neuromuscular junction, but in several cases there is evidence for neuromuscular modulation.

Several members of this peptide group, including DRNFLRFamide (DF_2), increase the amplitude of EJPs recorded in crustacean muscle. In crayfish extensor muscle, DF_2 does not alter muscle-fiber input resistance nor does it have any effect on postsynaptic glutamate receptors, but it does increase the amount of transmitter released from presynaptic terminals. Elevation of either PKA or PKG activity by direct activation, or by inhibition of phosphodiesterases (which break down cyclic nucleotides), increases EJP amplitude, paralleling the effect of DF_2. Inhibition of kinases (PKA, PKC, PKG, or CaMKII) disrupts DF_2 modulation of EJPs. Thus, cyclic nucleotides and their protein kinases are required components of the neuropeptide modulation of transmitter release. Whether the effects of these second-messenger pathways occur directly on presynaptic mechanisms or via a retrograde messenger has not been established.

In the crab (*Eriphia*) closer muscle, DF_2 targets the fast (phasic) closer excitor but not the slow (tonic) closer excitor. This specific action, which enhances neurotransmitter release, is mediated by N-like calcium channels which are found almost exclusively at phasic nerve terminals.

Proctolin The pentapeptide proctolin was first identified in the hindgut of the cockroach (*Periplaneta americana*) and may be unique to arthropods. It can cause contractions in exoskeletal, cardiac, and hindgut muscles in insects and crustaceans. Proctolin acts as neurotransmitter, neuromodulator, and neurohormone.

Proctolin is co-localized with glutamate in three of the five excitatory motorneurons in the tonic flexor postural muscle of the crayfish. Proctolin has no effect by itself, but when released together with glutamate, muscle tension is increased. A major site of proctolin modulation is the muscle fiber membrane, where voltage-dependent calcium channels are activated. Proctolin, in general, enhances excitation–contraction coupling but has no observed presynaptic effect. However, in the leg closer muscle of the crab *Eriphia*, proctolin targets both the phasic and tonic excitor axon terminals. This presynaptic action is mediated by P/Q-like calcium channels.

PACAP-like neuropeptide Recent work on pituitary adenylyl cyclase-activating polypeptide-like neuropeptide is perhaps the most detailed study of the molecular pathways of invertebrate peptidergic modulation. During high-frequency activity the type 1b boutons of *Drosophila* larval muscle release PACAP-like neuropeptide. This leads to a biphasic modulation of postsynaptic responses – an immediate depolarization of the muscle followed by a hyperpolarizing voltage-activated potassium current. Activation of the adenylyl cyclase/cAMP pathway through $Gs\alpha$, and the Ras/Raf pathway through $G\beta\gamma$, is required for potassium

channel activation. Other proteins, such as neurofibromin 1 (NF1) and the Shaker potassium channel subunit, have also been implicated in mediating the modulatory effects of PACAP-like neuropeptide.

Conclusion

Invertebrate neuromuscular junctions are structurally closer to central synapses than to many vertebrate neuromuscular junctions, and have often been used as a convenient model for central neurotransmission. Invertebrate neuromuscular junctions, especially in mollusks, also share some features with vertebrate autonomic innervation of smooth muscles – varicose structure of nerve terminals, and often co-release of neuromodulators – but in most cases differ profoundly in synaptic organization and speed of response, due to the very close apposition of pre- and postsynaptic membranes. Arthropod neuromuscular junctions have been investigated more than those of other invertebrate groups; these junctions have a wide range of modulatory adjustments at their disposal. At the single-neuron level, various forms of activity-dependent short-term plasticity provide adjustments in synaptic transmission to meet the requirements for action on a moment-to-moment basis. Should the demands for altered performance be on a longer time scale, amounting to a change in the neuron's lifestyle, several forms of long-term adjustment are available, exemplified by experience-dependent synaptic strengthening in *Drosophila* and long-term adaptation in crustaceans. Neurohormonal mechanisms produce a more global change in performance, with neuromuscular modulation being only a part. The actions of large families of peptides have barely been explored at the neuromuscular level. Future work on many of the known neuromodulators will be directed to molecular aspects of cellular mechanisms, and, for this, *Drosophila* offers an excellent experimental system.

Neuron Doctrine: Historical Background

G M Shepherd, Yale University School of Medicine, New Haven, CT, USA

Overview

As a new scientific discipline develops, concepts emerge that help to organize the diverse data into general principles. In experimental biology, a key organizing principle has been the cell, introduced for plants by Matthias Schlieden in 1838 and for animals by Theodor Schwann in 1839. The cell was established by an outpouring of microscopical studies in the 1840s as the basic principle of organization in most organs of the body, but acceptance of this role in the nervous system was delayed by the difficulty of visualizing under the light microscope the branches of cellular processes.

The impregnation method discovered by Camillo Golgi in 1873 finally enabled visualization of individual cells in the central nervous system. With this method, Golgi established a number of firsts. The branching dendrites end freely, an observation which disposed of previous theories of networks involving dendrites. Golgi recognized the different dendritic branching patterns as the basis for classifying different types of nerve cells. He extended Deiters' observation of a single axon arising from a motor neuron to show that this was also true of central neurons on the brain. He classified cells on the basis of their axons into cells of long axon (projecting out of a region to other regions) and cells of short axon (which came to be recognized as interneurons). The discovery of which he was most proud was the extensive collateral branches of the axon. In all these findings Golgi was the pioneer; all who followed him were building on his foundation, a fact probably not adequately recognized at the time and certainly not in our own time.

Beyond these fundamental findings, all confirmed by Santiago Ramón y Cajal and later histologists, Golgi made a further observation and fateful interpretation. In his stained preparations it appeared to him that the finest collaterals were continuous with each other. His interpretation was that these widely branching collaterals, and only these collaterals, form a reticulum which carries out the basic signaling functions of the nervous system.

The story of the discovery of the Golgi technique by an obscure histologist in Spain, Cajal, has been told many times, beginning with Cajal's own memoirs. In his first studies in the late 1880s, Cajal confirmed Golgi's findings that the dendrites end freely and that their different patterns are the basis of different types of nerve cells, and that the axon is usually single and that it characteristically gives off collaterals in different branching patterns. However, he also found persuasive evidence that the axon collaterals, too, end freely. This implied that the collaterals do not form a reticulum, but rather that communication between nerve cells is by contacts rather than by continuity.

Cajal's findings and interpretations were supported by most of the other classical histologists who took up the Golgi method. Cajal in particular worked furiously, producing an outpouring of papers on different cells throughout the nervous system during the 1890s. The consensus emerging from the early work was reviewed in 1891 by Waldeyer:

> [A]ll those authors who do not accept a network formation of the nerve fibers inside the central organ (Ramón y Cajal, Kolliker, His, Nansen, Lenhossek, Retzius) can easily unite points I and II above into one common brief fundamental law of wider range. It would sound thus: "The nervous system consists of numerous nerve units (neurons), anatomically and genetically independent." (Waldeyer, *Deutsche Medizinische Wochenschrift* 17, 1891)

This gave rise to the neuron theory, which soon became known as the neuron doctrine. As commonly understood, it states that each nerve cell is a separate individual, bounded, like all other cells in the body, by its plasma membrane. This conclusion was in line with the interpretation of the relations – by contact, not contiguity – between cells in other tissues and organs throughout the body. It is for this reason that the neuron doctrine was regarded as the extension of the cell theory to the nervous system. The points of contact between nerve cells were assumed to have special properties allowing for transfer of signals. Charles Sherrington, a physiologist, suggested the term 'synapse' for these contacts, and was the first to envisage special functional properties for them.

In addition to his insistence on the individuality of the entire nerve cell and its interactions through contact, Cajal made two other conceptual contributions that were essential for understanding the functional significance of the neuron. The first had to do with the flow of information through the nerve cell. Waldeyer had left this question uncertain. In further work in the early 1890s, Cajal, together with Alfred van Gehuchten of Belgium, inferred that there was a polarization of the flow of activity, from contacts on the dendrites and soma to the axon and out of the axon terminals. He termed this the 'law of dynamic

polarization.' This was a fundamental contribution which gave a functional meaning to the nerve cell as an integrative entity, taking in inputs from different sources and distributing them to different target cells.

The second conceptual contribution built on the first. By applying his tremendous powers of imagination to the functional interpretation of the relations between his stained cells, he deduced the flow of information not only within each cell but also between the cells. He devised diagrams showing how these relations formed the pathways within a region to accomplish multineuronal functions of integrating inputs from different regional sources and distributing them to different target regions. This enabled him to represent the flow of activity through the cells of the olfactory bulb, for example, and compare it with an equivalent flow of activity through the retina. This approach provided persuasive evidence that the nervous system is built of interconnected nerve cells that form the circuits and pathways that carry out the functional operations of the different regions and systems.

Many authors have attested to the importance of the original neuron doctrine and these functional concepts for the rise of modern neuroscience. For example, David Hubel observed that Cajal's textbook of histology of the nervous system, replete with the evidence of nerve cells as separate entities, "is considered to be the most important work ever published in neurobiology." On the physiological side, Sherrington made clear the central importance of the extension of the cell theory to the nervous system. In his great work *The Integrative Activity of the Nervous System*, published in 1906 just after Cajal's *Histologia* in Spanish, the first sentence reads: "Nowhere in physiology does the cell-theory reveal its presence more frequently in the very framework of the argument than at the present time in the study of nervous reactions."

In its simplified set of postulates the neuron doctrine thus provided the conceptual basis for the rise of modern neuroscience in understanding normal brain function, and the rise of the clinical neurological disciplines in understanding neurological diseases. In this respect it can be said to have provided the fundamental organizing principle for modern cellular neuroscience, performing a role similar to that of the Bohr atom for modern physics, the chemical bond for chemistry, the cell for cell biology, and the gene for genetics and molecular biology.

Modern Research First Confirmed, Then Challenged the Classical Neuron Doctrine

Cajal's last publication, in 1934 just before his death, was an exhaustive review of the evidence for the neuron theory against the reticular theory. By then the neuron doctrine had narrowed to one key point: "that the expansions of nerve cells end freely in the gray substance just as they do in the peripheral sense organs."

The advent of modern methods of cell biology in the 1950s, particularly the electron microscope for the fine structure of cells and the recording microeletrode for membrane and cell physiology, brought both support for and challenges to the classical doctrine. When the first electron microscopical investigations were carried out on nerve cell synapses, they focused on whether, at sites of synapses, the plasma membrane was continuous or not. The initial finding of the continuity of the plasma membrane at the chemical synapse appeared to validate the concept of synaptic transmission by contact and not continuity, and the neuron theory was widely assumed to have been validated. However, the discovery soon after of electrical synapses, and their subsequent identification with gap junctions, showed that in fact cells could also be interconnected by continuity as well. It is amusing, and perhaps a little sobering, to imagine that if electrical synapses had been discovered first in electrophysiological recordings or if gap junctions had been seen first under the electron microscope, it would have been taken as initial evidence to vindicate Golgi and the reticular theory over Cajal and the neuron theory.

Chemical versus Electrical Transmission

As the importance of gap junctions and electrical synaptic functions has been increasingly recognized, especially in the mammalian nervous system, it has seemed to some that it supports Golgi's concept of the reticular nature of nervous organization over Cajal's neuron theory. However, it should be clear from the remarks thus far that the situation is not that simple. Let us discuss the reasons.

First, Golgi restricted his continuous network to the finest branches of axon collaterals. Any electrical synapses or gap junctions between dendrites or between axons and dendrites would have been outside his theory. Therefore, the ubiquity of gap junctions and electrical synapses does not prove Golgi right; in fact, it proves him wrong, just as much as it does Cajal. Second, there has been evidence over many years for the action at a distance of different types of neuroactive substances, both classical neurotransmitters and neurohormones. This type of action by diffusion through the extracellular space to distant targets is inconsistent with both Golgi's network of continuous branches and Cajal's transmission by contact. Third, it has been claimed that the tiny branches of Golgi's reticulum would be a substrate for plastic

changes underlying learning, against the rigid connectivity of Cajal's contacts. However, Cajal always thought in terms of function, and assumed that learning would take place at contacts. This was explicit in Manouelian's suggestion of plasticity at contacts, a concept brought forward already in 1897.

Finally (though other points could also be made), the ubiquity of gap junctions is not a recent discovery. It has been recognized for over 30 years that gap junctions are present throughout the body, including the brain. In the body, this has not been taken as evidence against the cell theory; on the contrary, the cell theory has continued to be the basis for cell biology, and has incorporated the molecular biology of the gene as well. It may be that a radical new view of the cell as an anatomical, physiological, and developmental unit may emerge, and as it does, the concept of the nerve cell will undoubtedly evolve with it. In fact, it may even be leading the way, as we shall discuss next.

The Neuron: From Simple to Complex Functional Unit

Cajal's functional concepts of the neuron also come in for criticism. Given that Cajal made all of his interpretations on the basis of only the histology of the neurons, more than a half century before any experiments could be carried out on cells in the brain, it is not surprising that the physiological evidence would give new insights. Theodore Bullock (1959), in reviewing the early electrophysiological studies in the 1950s, argued that these results showed that rather than functioning as a single element, the nerve cell has different properties in its dendrites and axons, so that its function is characterized by 'complexity-within-unity.'

In our own studies we have focused on the mammalian olfactory bulb as a model for probing the properties first revealed in the spinal motor neuron. Using the new approach pioneered by Wilfrid Rall, we combined fine structure, electrophysiology, and computational models of the neurons and their dendrites. We found that the dendrites of mitral and granule cells interact directly with each other through dendrodendritic synapses, providing a pathway for feedback and lateral inhibition of the mitral cells. In this circuit, an action potential in the mitral cell dendrite causes synaptic excitation of granule cell dendritic spines; the excitatory postsynaptic potential (EPSP) in the spines then causes feedback synaptic inhibition of the mitral cell dendrite, and lateral inhibition of neighboring mitral cell dendrites through electrotonic spread. The combined study enabled the computational model to predict the interactions, the fine structure to confirm the synaptic circuit, and the physiological properties to be correlated with the fine structure.

These properties were inconsistent with the functional postulates of the neuron doctrine. Instead, several new principles were exemplified in this circuit. The direction of action potential propagation in the dendrites may be forward or backward. Dendrites can have specific synaptic outputs as well as inputs. The synapses may be activated by action potentials (mitral cells) or by local synaptic potentials (granule cells). The circuit can mediate feedback as well as lateral inhibition. A local part of a neuron (e.g., dendritic spine) can have input–output functions that are semi-independent of the rest of the cell. These local parts could be of differing extents, from a single synapse up to a dendritic branch. These properties have been repeatedly tested and extended and compared with equivalent properties in the retina, thalamus, and many other parts of the nervous system.

A New Theoretical Framework for Brain Organization: Multilevel Functional Units

Each of the parts of a neuron was thus seen to operate as a 'functional unit.' The key was that a functional unit at one level of organization (e.g., a synapse) provided the ensemble that gave rise to the functional unit at the next level (e.g., a synaptic pattern on a dendritic branch). This suggested that an enlarged hierarchical framework was needed for understanding the functional units in the nervous system and how they related to each other:

1. The nervous system is organized in terms of functional units. A functional unit is defined as the morphological substrate for a specific function.
2. Neurons (and functionally related cells) provide the morphological substrate for functional organization. Neurons have different combinations of morphological processes and physiological properties. For a given process of a given neuron, the synaptic position and physiological property depend on the integrative context within the functional units of which it is a part.
3. Functional units are formed at several levels of organization: synaptic terminals, dendritic trees, and multineuronal interconnections. The nervous system is built of overlapping assemblies and hierarchies of such units of increasing extent and complexity.

In the intervening years evidence has been obtained for functional units at different levels of organization in many regions. To review this work would take us deep into current research across a wide range of disciplines in neuroscience. It will suffice to note that a hierarchical framework is eventually necessary

for organizing this evidence, both for the organization of the individual neuron and for the organization of multineuronal circuits.

As an example of the complexity-within-unity of the single neuron, consider that the integrative functions of single dendritic branches form the functional units that are the basis for the integrative functions of multiple branches, which are the basis for the integrative functions of that part of a dendritic tree, which in turn are the basis for the integration in the entire tree. The properties at each of these levels need to be clearly related to their particular level, in order to be able to coordinate the functions in a bottom-up or top-down direction.

A similar problem arises in characterizing multineuronal assemblies. Here the problem is the apparent variety of circuits within any given region. An approach to reducing this complexity is to identify first a minimum pattern of connections and interactions that serves as the backbone, so to speak, of the circuits of a region, termed a 'basic circuit.' The concept is very close to the concept of the basic seven-transmembrane domain structure of G-protein receptors, a 'backbone' which is adapted by local diversification within the binding pocket for different neurotransmitter ligands and different G-protein effectors. It was further suggested that a 'microcircuit is a specific pattern of synaptic interaction within the basic circuit – in other words, at a more local organizational level. An example would be the specific interactions between olfactory mitral and granule cells, within the overall multilayer basic circuit of the olfactory bulb.

Recently, work on the cerebral cortex has focused on a 'canonical microcircuit' underlying cortical organization, the term being equivalent to the concept of a basic circuit. It conveys more strongly the idea of a stereotyped backbone that is adapted in different cortical regions by variations in local synaptic interactions. A key question currently under investigation is whether there is a canonical microcircuit (i.e., 'basic circuit') for all of cerebral cortex. Answering this question will require being specific about the level of organization. For example, one can hypothesize that there is a 'canonical' circuit for the entire cerebral cortex (equivalent to the seven-transmembrane structure of all G-protein-coupled receptors), that is adapted in different cortical areas by local variations in synaptic connections (binding pocket diversity in G-protein-coupled receptors).

These considerations indicate how important it will be to analyze experimental studies of circuits in different brain regions within a theory of multilevel organization. For the case of the cerebral cortex, it may be hypothesized that there will be specific stereotyped microcircuits identified at several levels of organization that, working in coordination, carry out the information processing functions of an overall canonical microcircuit.

Summary

In conclusion, familiarity with the history of the neuron doctrine is interesting not only for a perspective on the rise of modern neuroscience, but also for the challenges that lie ahead. Almost from the moment that the new methods appeared a half-century ago to support the original neuron doctrine, it began to be clear that it was inadequate to account for the extraordinary complexity of the individual neuron and of multineuronal circuits. A new theoretical framework is needed within which to organize the tremendous amounts of data that modern neuroscience is producing. The effort appears to be essential if the complexity of neuronal organization underlying behavior is to be understood. Whether having this new framework will play as important a role in supporting research in the future as the role that the neuron doctrine has played in the past is for the future to decide. This gives a new perspective on the magnitude of the achievement of Cajal and his contemporaries. Thus, in judging the classical neuron doctrine, the question is not whether it can stand up to our criticism today; the question is rather, can we produce a conceptual framework that will equal theirs in practical value, and serve as well in guiding experiments in the century ahead as theirs did for the century that is past?

Overview of Systemic Angiotensin Production

Our understanding of the renin–angiotensin system began in the late 1800s with the discovery of a pressor agent, called renin, derived from the kidney. Further work throughout the 1900s defined a humoral system in which the active agent, angiotensin (Ang II), was derived from a protein precursor, angiotensinogen (Aogen), via the sequential action of two enzymes, renin and angiotensin converting enzyme (ACE) (Figure 1). In this humoral system, Aogen is produced by the liver and secreted into the circulation. Renin, an aspartyl protease, is secreted into the plasma from cells of the juxtaglomerular apparatus in the kidney. Renin's only known substrate is Aogen, and the activity of this enzymatic reaction is considered to be the rate-limiting step in the pathway. Cleavage of Aogen yields a large glycoprotein of no known function and an inactive decapeptide, Ang I. Cleavage of Ang I by the zinc-dependent carboxypeptidase, ACE, produces the active octapeptide, Ang II. ACE is located on endothelial cells throughout the vascular system, with a particularly high concentration in the lung. Subsequent N-terminal cleavage of Ang II produces the heptapeptide Ang III, which is equipotent at Ang II receptors and may be an important ligand in some tissues.

Receptors for Ang II were cloned in the 1990s and shown to be G-protein-coupled receptors with seven transmembrane spanning domains. Two receptors, with approximately 30% homology, were cloned and termed AT_1 and AT_2 receptors. The AT_1 receptor, which mediates most of the classical actions of Ang II, was shown to occur in two isoforms in rodents, AT_{1A} and AT_{1B}. Although the number of intracellular signaling pathways employed by the AT_1 receptor continue to expand, many of the principal actions involve coupling to the $\alpha_{q/11}$ G-protein subunit. Activation results in cleavage of phosphatidyl-inositol (4,5) bisphosphate, by phospholipase C_β, to yield diacylglycerol and inositol trisphosphate with subsequent increases in intracellular calcium concentrations and activation of protein kinase C. The angiotensin AT_2 receptor signals via activation of the protein phosphatases PP2A, SH2 domain-containing phosphatase, and mitogen-activated protein kinase phosphatase 1, resulting in the dephosphorylation and inactivation of kinases including growth factor tyrosine kinase receptors and extracellular signal-regulated kinase 1 (ERK-1) and 2 (ERK-2). Antiproliferative and proapoptotic actions mediated by the AT_2 receptor appear to involve the inactivation of ERK-1 and -2 by dephosphorylation. The binding of Ang II to the AT_2 receptor has also been shown to activate nitric oxide and phospholipase A2 in certain tissues. Investigation into the signaling pathways associated with AT_2 receptor activation is further complicated by the complex physiological roles of the receptor, often in pathological states.

Studies have indicated the involvement of other enzymes and receptors in the activity of the renin–angiotensin system (Figure 1). Angiotensin converting enzyme 2 (ACE2) was cloned and found to exhibit 40% homology with ACE but with one catalytic domain. In contrast to ACE, ACE2 cleaves single amino acid residues from the C-terminus of peptides. ACE2 is thought to have a counterregulatory role in the renin–angiotensin system, being involved in the degradation of Ang II and the generation of Ang 1–7, an effector peptide that often shows opposing actions to Ang II. The receptor for Ang 1–7 was found to be the 'orphan' G-protein-coupled receptor that is encoded by the proto-oncogene *mas*. Mice with a deletion of the *mas* proto-oncogene are not responsive to Ang 1–7 and lose the binding site for Ang 1–7 in the kidney.

ACE2 is also the receptor for some coronaviruses, including the virus that causes severe acute respiratory syndrome (SARS-CoV) and another virus associated with respiratory tract infections, HCoV-NL63. ACE2 facilitates viral entry into and infection of target cells by binding specifically and with high affinity to the S protein of the viruses.

Angiotensin IV is generated from Ang III by the cleavage of the N-terminal arginine by aminopeptidase N. Angiotensin IV was initially thought to be biologically inactive because it exhibited very low affinity for the AT_1 and AT_2 receptors. However, injection of Ang IV into the cerebral ventricles enhances performance in memory tasks, and it was shown to bind to a specific, high-affinity site termed the angiotensin AT_4 receptor. Subsequent work identified the AT_4 receptor as an enzyme, insulin-regulated amino peptidase.

Tissue Renin–Angiotensin Systems

In the early 1970s, evidence of local formation of angiotensin peptides in specific tissues began to

Figure 1 Overview of the enzymes and receptors involved in the production and function of angiotensin peptides. The bold arrows indicate the pathway traditionally ascribed to this system. Proteins and peptides are indicated in bold type. Enzymes are shown in normal type, and receptors are shown in italics. ACE, angiotensin converting enzyme; AP, aminopeptidase; IRAP, insulin-regulated aminopeptidase; PEP, prolyl endopeptidase.

emerge. It has since been demonstrated that many tissues, including kidney, heart, blood vessels, adrenal gland, uterus, testes, and brain, have the potential to produce Ang independently of the circulating renin–angiotensin system. Although the exact mechanism of formation remains controversial for many of these tissues, the existence of independently regulated tissue renin–angiotensin systems is widely accepted. As discussed in the following sections, there is also considerable evidence for the local generation of Ang peptides in the brain which act on receptors within the blood–brain barrier to regulate a variety of functions.

Angiotensinogen in Brain

Angiotensinogen is expressed in relatively high levels by the brain, with mRNA levels reported to be approximately one-third those produced by the liver. Measurements of Aogen concentrations in cerebrospinal fluid by radioimmunoassay indicate that it represents 2% or 3% of the total protein content. This Aogen is identical in amino acid structure to that produced by liver but may be differentially glycosylated. Most Aogen mRNA expression in the brain occurs in ependymal and astroglial cells. Interestingly, there is regional heterogeneity of expression, with highest levels in hypothalamic, midbrain, and medullary regions that are associated with the known actions of Ang peptides. Transgenic mouse lines with reporter protein expression under the control of the Aogen promoter demonstrate neuronal expression of Aogen but only in a very small number of cell groups. Most evidence indicates that Aogen synthesized by glia is constitutively secreted into the extracellular space; however, studies have demonstrated that some Aogen might be directed to the nucleus. The relative proportion of intracellular versus secreted Aogen existing *in vivo* and the role of the intracellular protein have not been examined.

Transgenic rat and mouse models demonstrate the functional importance of brain-derived Aogen. Transgenic rats which produce an Aogen antisense under the regulation of a glial-specific promoter show multiple functional deficits, including decreased blood pressure and impaired fluid and electrolyte balance. Evidence for the converse is available in mice, in which global overexpression of renin and Aogen leads to increased blood pressure that can be reduced by glial-specific ablation of Aogen production. Together, these observations indicate that brain Aogen plays an important role in the regulation of blood pressure, but they do not shed light on how the Aogen is processed to yield Ang II and other active components of the system.

The presence of high concentrations of Aogen in astrocytes may also be suggestive of wider roles for the brain renin–angiotensin system. Investigation of functional alterations in the Aogen knockout mouse revealed impairment of blood–brain barrier function which can be restored by exogenous administration of Ang II or Ang IV. This blood–brain barrier dysfunction is thought to be due to the decreased expression of glial fibrillary acidic protein and laminin in the astrocytes of these animals.

Renin in the Brain

Efforts to demonstrate the existence and localization of renin in brain have proven extremely difficult.

Initial biochemical studies, which made every effort to remove contamination from systemic renin, demonstrated renin-like enzymatic activity in extracts of brain but did not establish the identity of renin. Several other enzymes, including cathepsin D and G, tonin, and kallikrein, have the capacity to form Ang peptides from renin substrate, and it remains a distinct possibility that enzymes other than renin might contribute to the generation of Ang peptides in brain. The use of renin antibodies in immunohistochemical and Western blot analysis to identify brain renin was also fraught with issues pertaining to antibody specificity. Initial attempts to demonstrate the existence of renin mRNA, using *in situ* hybridization or Northern blot analysis, also produced variable results, most likely due to the use of whole brain, which thus diluted any renin present in discrete brain regions to below the level of detectability. Using Northern blot hybridization methods, Dzau and colleagues found evidence for the existence of renin mRNA in brain with levels approximately 10% of those found in kidney.

In the kidney, renin is produced as preprorenin that is sequentially cleaved to form active renin. The renin gene has nine exons, the first of which encodes a signal peptide which targets the nascent protein to the endoplasmic reticulum for glycosylation and subsequent secretion from the cell. Exon 1 has three different transcriptional initiation points, which form different renin isoforms. Experiments have demonstrated two distinct renin isoforms formed by tissue-specific transcriptional initiation in brain. Initiation from exon 1a forms the classic 'renin a' found in the kidneys and systemic circulation, whereas the exon 1b transcription start point forms 'renin b.' This latter isoform lacks the coding for the signal peptide and is likely to be a constitutively active intracellular enzyme. These data raise the possibility of two distinct mechanisms of Ang peptide formation in brain – extracellular and intracellular.

However, these studies did not provide information on the distribution of renin or evidence of the cell type responsible for production. Other efforts have focused on the use of long lengths of renin promoter to drive expression of marker proteins in transgenic mice. Using a 4.1 kbp of the 5′ flanking sequence of the renin gene to drive expression of green fluorescent protein, Gross and colleagues demonstrated tissue-specific expression and regulation of the marker protein. Using this mouse model, Sigmund and colleagues localized renin expression in different regions of the mouse central nervous system. This expression occurs in many brain regions known to be involved in the regulation of fluid and electrolyte balance and autonomic control by Ang II and is predominantly localized to neurons.

Thus, current evidence supports the view that renin is expressed in the brain predominantly by neurons. The presence of renin isoforms indicates the potential for both intracellular and extracellular enzymatic activity.

Questions remain regarding the localization of renin in relation to the precursor, Aogen, and how these interact to produce Ang peptides in brain. The highest levels of renin expression occur in the cerebral and cerebellar cortices in regions where Aogen expression is low or absent. Observations in double transgenic mice, in which long sequences of the renin and Aogen promoters are used to drive expression of different reporter proteins, indicate that coexpression of renin and Aogen is rare; this is in line with observations that they are expressed in different cell types. However, adjacent cellular expression was observed in several nuclei, providing evidence to support the view that secreted Aogen might be cleaved locally in the extracellular space or taken into neighboring neurons for further processing to Ang I.

Angiotensin Converting Enzyme

Within the circulation, Ang I is rapidly converted to Ang II by the action of ACE, a zinc-dependent metallopeptidase that cleaves a dipeptide from the C-terminus of Ang I to form the effector peptide Ang II. Specific inhibitors of ACE are effective in inhibiting the formation of Ang II *in vivo* and attenuating the physiological effects of the peptide. Hence, these inhibitors have been developed very successfully into therapeutic drugs that are widely used to treat hypertension, heart failure, vascular disease, and renal disease. In addition to enzymatic cleavage of Ang I, ACE cleaves a range of other small peptide substrates, many of which are present in brain, including bradykinin, substance P, met-enkephalin, beta-endorphin, dynorphin 1–8, neurotensin, and luteinizing hormone releasing hormone.

Two isoforms of ACE exist in mammals and both are membrane bound, although a secreted form of ACE that is catalytically active is found in the circulation. The more abundant 140 kDa somatic enzyme occurs on the plasma membrane of endothelial and epithelial cells and has a large extracellular domain that contains two homologous regions, each with an active site. The testicular isoenzyme contains only one active site, which shares sequence homology with the C-terminal active site of the somatic enzyme and is the site that has been shown to selectively cleave Ang I.

In the many brain regions, ACE occurs in high concentrations. Many of these sites are also enriched with Ang II-containing cell bodies and fibers and Ang AT_1 receptors, including the circumventricular

organs, several hypothalamic nuclei, and the dorsal vagal complex in the medulla. It is proposed that at these sites, ACE participates in the local production of Ang II, either from circulating Ang I (as is the case for the circumventricular organs) or from brain-derived Ang I. However, ACE is much more abundantly distributed and high concentrations of the enzyme are detected in the basal ganglia, choroid plexus, hippocampus, cerebral cortex, and cerebellum, where its roles remain to be elucidated and may involve cleavage of other neuropeptide substrates. Although the predominant form of ACE in the brain appears to be membrane bound, a low level of the enzyme has been detected in cerebrospinal fluid, at a concentration 100-fold lower than that detected in serum.

Ang II/III Peptide Localization

Because they are cleavage products of a precursor that is secreted into the extracellular space, the cellular localization of Ang peptides in the brain has proven difficult. Immunohistochemistry has been problematic because of uncertain antibody specificity. Detailed maps of the distribution of Ang II-like immunoreactive cells and fibers have been produced but have mostly relied on results obtained with one antibody. Due to this scarcity of reliable antibodies, our knowledge of the neuronal circuitry that may utilize Ang II as a neurotransmitter is limited. However, in support of the veracity of the maps of Ang II distribution, there is a very high concordance in the distributions of Ang II-like immunoreactive nerve terminals and Ang II AT_1 receptors throughout the brain. There are some notable exceptions; for example, the magnocellular nuclei of the hypothalamus and central nucleus of the amygdala contain high levels of Ang II-like immunoreactive nerve terminals but low to undetectable concentrations of receptor.

Angiotensin AT_1 Receptors

As outlined previously, several controversies exist in relation to the production of Ang II in the brain. Some of the most convincing evidence for the existence of a brain renin–angiotensin system is derived from examination of the distribution of the Ang receptors and the physiological actions exerted through them. Unequivocal evidence points to the existence of Ang AT_1 and AT_2 receptor mRNA and binding sites (Figure 2) present in a characteristic distribution throughout the brain. These receptors show identical binding profiles to the peripheral receptor, including antagonism by the nonpeptide AT_1 and AT_2 receptor antagonists. In some cases, brain AT_1 and AT_2 receptors are located outside the blood–brain barrier, where they are accessible to systemic Ang peptides. However, the vast majority of sites are behind the blood–brain barrier, where they are presumably accessed by brain-derived Ang peptides. Administration of Ang peptides into these regions generally results in neuronal excitation and a characteristic range of site-dependent physiological responses. More important, in the context of establishing a role for brain-derived Ang peptides, pharmacological blockade of these receptors with specific and selective antagonists attenuates many physiological responses, such as drinking following dehydration or autonomic activation in response to mental stress. Together, these observations provide strong support for the existence of brain-derived Ang peptides that regulate physiological functions in the central nervous system.

There is an extensive distribution of Ang II AT_1 receptors in the brain. Moderate to high levels of AT_1 receptors occur in the sensory circumventricular organs (subfornical organ and vascular organ of the lamina terminalis and area postrema); piriform cortex; lateral septum; bed nucleus of the stria terminalis; median preoptic nucleus; periventricular, parvocellular paraventricular, and dorsomedial nuclei of the hypothalamus; locus coeruleus; lateral parabrachial nucleus; nucleus of the solitary tract; spinal nucleus of the trigeminal tract; and ventrolateral medulla. Most of these sites also possess high levels of Aogen-expressing astrocytes and ACE.

Actions via AT_1 Receptors

Electrophysiological studies have demonstrated that neurons in many of the sites listed previously are responsive to local application of Ang II. The predominant response is excitation via an AT_1 receptor-mediated inhibition of outward potassium channels. Microinjection studies with exogenous Ang II and/or AT_1 receptor antagonists have identified several actions of Ang II in the brain. In brief, these include the following:

- Alterations in autonomic activity to the cardiovascular system, leading to increases in blood pressure and heart rate, through direct stimulation of efferent pathways and regulation of sensory afferent (e.g., the baroreceptor reflex) information
- Increases in fluid and salt intake
- Stimulation of the secretion of several neuroendocrine hormones, including vasopressin, adrenocortictropic hormone, and luteinizing hormone releasing hormone
- Effects on learning and memory

Figure 2 Schematic diagram representing the distribution of angiotensin AT_1 and AT_2 receptors in the brain. The distribution of receptors, determined by either *in vitro* autoradiography or *in situ* hybridization histochemistry, is depicted on midsagittal sections of the rat brain. Am, amygdala; AP, area postrema; ARC, arcuate nucleus; BST, bed nucleus of the stria terminalis; DMV, dorsal motor nucleus of the vagus; IO, inferior olivary nucleus; LC, locus coeruleus; LOT, nucleus of the lateral olfactory tract; LPB, lateral parabrachial nucleus; LS, lateral septum; MD, mediodorsal nucleus of the thalamus; ME, median eminence; MnPO, median preoptic nucleus; MolCb, molecular layer of the cerebellum; NTS, nucleus of the solitary tract; OB, olfactory bulb; OVLT, organum vasculosum of the lamina terminalis; PeV, periventricular nucleus of the hypothalamus; PVN, paraventricular nucleus of the hypothalamus; RVLM, rostral ventrolateral medulla; SC, superior colliculus; SFO, subfornical organ; SON, supraoptic nucleus; SNC, substantia nigra pars compacta; STh, subthalamic nucleus; VLG, ventrolateral geniculate nucleus; VPM, ventral posteromedial nucleus of the thalamus.

Angiotensin AT_2 Receptors in Brain

Angiotensin AT_2 receptors occur in high levels with a wide distribution in the brain during development. In the adult, this distribution becomes restricted to a few sites, including some thalamic nuclei, the cerebellum, and the inferior olivary nucleus. This distribution indicates a role in sensory information processing. The phenotype of the AT_2 receptor knockout mouse also points to some effects of Ang II on these receptors in the brain. These mice show reduced spontaneous movement and exploratory behavior, and there is evidence for effects of Ang II on cognitive function and memory. However, these are often contradictory in regard to potentiation or inhibition of memory formation. It has been proposed that the detrimental effects of Ang II on memory consolidation and retrieval are mediated by the AT_2 receptor. Further support for the angiotensin AT_2 receptor altering cognitive function comes from the detection of mutations in the coding region of this receptor in patients with mental retardation.

Ang 1–7 and Its Binding Site, the *mas* Oncogene

Angiotensin 1–7 may play a role in the central regulation of blood pressure because microinjection of Ang 1–7 into various sites alters arterial pressure and stimulates release of vasopressin. Ang 1–7 has also been reported to enhance long-term potentiation in the lateral nucleus of the amygdala and in the CA1 region of the hippocampus, suggesting a role in memory formation.

Ang IV and Its Binding Site, IRAP

Intracerebroventricular injection of Ang IV in rats enhances performance in several different memory tasks. A binding site that recognizes Ang IV with high affinity, but not Ang I, Ang II, AT_1, or AT_2 antagonists, was named the AT_4 receptor based on its distinct pharmacology. A surprising finding was the discovery that this receptor is the previously known insulin-regulated aminopeptidase (IRAP), a transmembrane zinc metallopeptidase known to traffic with the GLUT-4 glucose transporter in response to insulin. Ang IV, LVV-hemorphin-7, and other AT_4 ligands were all found to be competitive inhibitors of IRAP but were not cleaved to any appreciable extent by the enzyme. The mechanism by which Ang IV and other AT_4 ligands mediate their memory effects is yet to be resolved.

Conclusion

During the past several decades, it has been established that Ang peptides are generated in the brain. However, despite considerable effort, many questions regarding the biochemical pathways involved in the generation of this peptide system remain incompletely resolved. This system appears to have unique properties with, for example, precursor and processing enzymes existing in different cellular compartments and the potential for neurotransmitter, paracrine, and even intracrine effects. Yet despite these deficiencies in our knowledge, it is clear that Ang peptides play important physiological and pathological roles in the central nervous system regulation of a wide variety of functions, including those that complement its peripheral actions (e.g., autonomic regulation and fluid and electrolyte balance) and other more disparate functions, such as modulation of memory and blood–brain barrier formation.

Neuronal Motility and Structure: Cdk5 Pathways

B A Samuels and L-H Tsai, Massachusetts Institute of Technology, Cambridge, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction to Cdk5

Cdk5 and the Cyclin-Dependent Kinase Family

Cdk5 is an atypical cyclin-dependent kinase Cyclin-dependent kinase 5 (Cdk5) was first isolated based on its homology to other Cdks, specifically human cell division control kinase 2 (Cdc2/Cdk1). The typical role of a Cdk is to phosphorylate substrates that drive progression through the cell cycle. Cdc2, for example, is the catalytic subunit of the maturation promoting factor (MPF) that is necessary for the G2/M phase transition. Cdk5, however, is an atypical Cdk. There is no strong evidence that Cdk5 is functionally involved in promoting the cell cycle. In fact, the principal associated kinase activity of Cdk5 is detected in the central nervous system, where the protein is enriched in postmitotic neurons. Although this signifies a functional distinction from other Cdks, Cdk5 does share a few very basic characteristics with members of the Cdk family that are important for understanding its various roles.

p35 and p39 are essential activators of Cdk5 Monomeric forms of Cdks do not display any kinase activity; instead, association with an activator is required. Most Cdks associate with and are activated by cyclins, a family of unstable proteins whose expression level during the cell cycle is phase dependent. For example, MPF is achieved through the association of Cdc2 with cyclin B, a protein whose expression rises through the cell cycle until M phase, when it is abruptly degraded. Such regulation of activator expression and turnover is a major mechanism underlying the regulation of Cdk activity. Cdk5 activity is achieved through association with one of two activators, p35 or p39. Although p35 and p39 are very similar to each other, they have little sequence similarity to cyclins. However, the tertiary structure of a portion of p35 bears some resemblance in that it adopts a cyclin-like fold. Another similarity to cyclins is that p35 is very unstable. Ubiquitination of p35 is readily detectable, and the protein is rapidly targeted for degradation by the proteasome, retaining only a 20–30 min half-life in primary cultured cortical neurons.

Posttranslational modifications of Cdk5 In addition to the turnover rate of the activators, Cdk5 activity, like that of other Cdks, can be regulated by posttranslational modifications such as phosphorylation. Phosphorylation of Cdk5 on tyrosine 15 enhances Cdk5 activity. Cdk5 associates with the c-Abelson tyrosine kinase (c-Abl) through a linker protein termed Cables, and this association stimulates phosphorylation of Cdk5 on Y15 in a c-Abl-dependent manner. Cdk5 may also be phosphorylated on serine 159 by casein kinase I. Structural studies suggest that this phosphorylation event would inhibit Cdk5 activity by preventing association with its activators.

Consensus site for phosphorylation by Cdk5 The only other similarity to the Cdk family is that Cdk5 shares the consensus phosphorylation site on its substrates. Cyclin-dependent kinases are proline-directed serine/threonine kinases, phosphorylating substrates at the minimal consensus motif S/TP. Cdc2, Cdk2, and Cdk5 also prefer a basic residue in the +3 position, making the consensus sequence for phosphorylation (S/T)PX(K/H/R).

Cdk5 and Its Activators

Cdk5 activity is defined by the distribution of p35 and p39 Whereas Cdk5 protein is enriched in postmitotic neurons, its expression is widespread in nonneuronal tissues. Importantly, Cdk5 activity is primarily restricted to the nervous system because p35 and p39 are detected at high levels exclusively in neurons. The intracellular distribution of the activators is likely also important for regulating Cdk5 activity and restricting the kinase to its physiological substrates. In this regard, p35 contains an N-terminal myristoylation site that helps target kinase activity to membrane fractions. Cdk5 and its activators are also distributed to detergent-insoluble cytoskeleton fractions and both pre- and postsynaptic compartments. The spatial distribution pattern of Cdk5 activity defines its chief physiological roles, which seem to be regulating cytoskeletal elements during developmental neuronal migration and synaptic function in the mature nervous system. A diverse group of identified Cdk5 substrates have corroborated these functions and also have implicated altered regulation of the kinase in the pathology of neurodegeneration.

Cdk5 Regulates Neuronal Migration

Mouse Models of Cdk5 Deficiency

Cerebral cortex The best-understood role of Cdk5 is in the regulation of the cytoarchitecture of the central nervous system. The characteristic phenotype of mice deficient in Cdk5 activity is an inverted laminar organization of pyramidal neurons in the cerebral cortex. Mice deficient in Cdk5 and double knockouts of p35 and p39 display indistinguishable phenotypes, suggesting that p35 and p39 are the only activators of Cdk5 during development. p35 knockout mice display a similar but less severe phenotype and survive into adulthood.

Other brain regions In addition to the inverted neocortex, mice lacking Cdk5 activity display widespread cytoarchitectural abnormalities in many brain regions. The pyramidal neurons of the cornus ammonus in the hippocampus form only diffuse laminae with cell-free rifts between clusters of cells. Furthermore, the dentate gyrus of the hippocampus is imperceptible in Cdk5-deficient mice. The cerebellum of Cdk5-deficient mice is also strikingly abnormal because it completely lacks foliation (the several folds or gyri normally seen on the cerebellar surface), is much smaller in size, and does not have a Purkinje cell layer. There are also major disruptions in the olfactory bulb, thalamus, and brain stem. Furthermore, motor neurons exhibit ballooned perikarya suggestive of chromatolysis, where the cell body swells, Nissl bodies disperse, and the nucleus becomes displaced peripherally in the cell. Chromatolysis, also known as the 'axonal reaction,' is commonly seen upon damage or lesion to an axon.

Brief Introduction to Neocortical Development

Different neurons in the neocortex come from distinct places Pyramidal neurons and interneurons are the principal types of neurons comprising the neocortex, but these different classes of neurons take distinct paths to their final destination. The pyramidal neurons are generated in the dorsal ventricular zone and migrate in a radial manner toward the pial surface before reaching their final cortical position. Interneurons, on the other hand, are produced in the ventral telencephalon and must migrate dorsally by taking a tangential route. Consequently, the distance traversed by the tangentially migrating interneurons is much longer than that of the radially migrating pyramidal neurons (Figure 1).

Formation of cortical laminae Classic studies of corticogenesis have shown that the earliest born cortical neurons align above the ventricular zone to form the preplate, which signifies the first distinct event in the histogenesis of the neocortex. The next group of neurons born in the ventricular zone migrates radially to split the preplate into the superficial marginal zone and the deeper subplate, forming the cortical plate in between. The assembly of the cortical plate proceeds in an 'inside-out' manner, in which each cohort of neurons migrates past its cortical plate predecessors to form a more superficial layer (closer to the eventual pial surface). Ultimately, the six cortical laminae can

Figure 1 Two distinct routes of neuronal migration. Pyramidal neurons are produced along the ventricular surface in the dorsal telencephalon (heavy green band) and migrate in a radial direction (green arrow) to the outermost layer of the developing cortex (heavy blue band). Interneurons are produced in the ventral telencephalon (light red band) and migrate along a much longer route in a tangential manner (red arrow).

be distinguished by the earliest born neurons residing in the deepest layers of the neocortex and the latest born neurons forming the most superficial layer (Figure 2).

Cdk5 Activity Is Essential for Proper Neocortical Lamination

Formation of cortical laminae in p35 knockout mice Neuronal birth dating and histological experiments demonstrated that in p35-deficient mice early born neurons are capable of splitting the preplate. However, unlike normal inside-out cortical plate assembly, each subsequent cohort of neurons in p35-deficient mice is unable to migrate past its predecessors. Therefore, without proper Cdk5 activity, corticogenesis proceeds in an erroneous 'outside-in' manner, resulting in an inverted laminar structure.

Reelin Signaling Also Regulates Neuronal Migration

The phenotype of the mutant mice has cemented the Cdk5 pathway as a major regulator of neuronal migration during development of the central nervous system. However, to fully grasp the importance of Cdk5 in brain development, it is necessary to also consider another classical neuronal migration pathway that involves Reelin signaling. Upon gross inspection, there are many similarities in the abnormal neuronal cytoarchitecture between Cdk5 and Reelin mutant mice.

Mouse Models of Reelin Deficiency

Multiple mutant mice deficient in Reelin signaling have been described, including naturally occurring mutants such as *reeler*, *scrambler*, and *yotari*, as well as genetically modified mice such as Dab1, VLDLR, and ApoER2. In *reeler* mice, first described approximately 50 years ago for their ataxic 'reeling' gait, the early born neurons intended to form the cortical plate fail to split the preplate. Subsequent waves of migrating neurons are unable to pass their predecessors and accumulate in gradually deeper positions. Therefore, similar to Cdk5 mutants, *reeler* mice have an inverted laminar organization of the neocortex. The defective migration in these mice is attributable to a deficiency in the protein Reelin, a very large secreted extracellular matrix protein. The other naturally occurring or genetically modified mice with identical phenotypes have defined a pathway in which Reelin binds to VLDLR and ApoER2 receptors on the surface of migrating cells, which triggers a signaling cascade mediated by tyrosine phosphorylation of Disabled-1 (Dab1), the gene that is mutated in *scrambler* and *yotari* mice.

Figure 2 Development of the mouse cerebral cortex via radial migration from E11 to E17. (Top) Corticogenesis proceeds in an 'inside-out' manner. Neuronal progenitors are present in the ventricular zone (VZ) along the surface of the lateral ventricle (LV). The earliest born neurons align above the VZ and form the preplate at the young pial surface (PS). The next wave of neurons (red) to be born splits the preplate into the marginal zone and subplate, forming the cortical plate in between. The following cohort of neurons (yellow) migrates past their cortical plate predecessors (red) to form a more superficial layer. Successive waves of neurons then continue to migrate past their predecessors into six distinct laminae, with the earliest born cortical plate neurons residing in the deepest layer. This is described as inside-out formation of the cerebral cortex. Also labeled are the preplate (PP), the superficial marginal zone (MZ), and the subplate (SP). (Bottom) Distinct cortical zones during development. The VZ exists along the surface of the LV. The first wave of neurons, the PP, aligns above the VZ. The next wave of neurons forms the cortical plate, splitting the PP into the superficial MZ (at the pial surface and composed mostly of Cajal–Retzius cells) and the SP. As the brain matures, neurons must migrate longer distances, including through a cell body-sparse intermediate zone (IZ) composed mostly of an increasing number of projecting axons.

Distinctions between Cdk5 and Reelin Mutant Mice

Formation of the Preplate

The similarities between mice deficient in Reelin and Cdk5 signaling have fueled much research aimed at

determining if there is any potential cross-talk between these two pathways. However, time has demonstrated that it is really the distinctions, not the similarities, between these mutant mice that are more useful in defining the relative importance of the pathways and understanding the developmental neuronal migration program. One major difference is that early born cortical plate neurons in Cdk5-deficient mice migrate fairly normally and split the preplate into the superficial marginal zone and the deeper subplate. However, in Reelin-deficient mice these early born neurons intended to form the cortical plate fail to split the preplate, instead accumulating in a deep position, beneath the preplate.

Migratory Mode

Further distinctions in Cdk5 and Reelin mice have come from analysis of the behavior of migrating neurons at the cellular level *in vivo*. Neurons that migrate radially to form the neocortex (i.e., the pyramidal neurons born in the dorsal ventricular zone) display one of two characteristic migratory modes.

Somal translocation Early born neurons migrate primarily by extending a leading process that attaches to the nearby pial surface. The cell body of the migrating neuron then moves in a rather continuous manner toward the pial surface, with the leading process shortening progressively as the cell traverses. This migratory mode is called somal translocation, and it is likely used by the early born neurons because they have the shortest distance to migrate and are capable of maintaining their leading process and its attachment to the pial surface throughout their journey. Importantly, somal translocation requires only a single step of continuous nuclear movement and consequent shortening of the leading process.

Locomotion Later born neurons that must traverse longer distances display a distinct and more complex migratory behavior described as locomotion. These neurons extend a leading process into the subventricular zone, which they move into and then pause to become multipolar. Some of these neurons then reverse direction and move back into the ventricular zone before reversing polarity, and all of these neurons ultimately use a pia-directed leading process to migrate along their mother radial glia cell scaffold toward their final cortical position. Neurons that are undergoing locomotion display a short leading process that is not attached to the pial surface and migrate in a saltatory manner characterized by short bursts of movement followed by long stationary phases. In the final stage of migration, when their leading process has reached the pial surface and there is only a short distance to traverse, neurons switch from locomotion to somal translocation. This complex migratory behavior of later born neurons, which consists of multiple switches in polarity and repeated bursts of movement, likely requires much more intricate cytoskeletal rearrangement than that of the early born neurons that move by one step of somal translocation.

Migratory modes in Cdk5 and Reelin mutant mice As might have been predicted, the cellular behavior in mice with decreased Cdk5 activity (p35−/− mice) displays mostly normal somal translocation of early born neurons that first form the cortical plate properly by splitting the preplate. However, when the migratory mode should switch to that involving locomotion, p35−/− neurons fail to remain attached to their mother radial glia guide and start to move by an abnormal branched migration mode in which there is repeated extension of a branched leading process and subsequent zigzag movement of the soma to different branch points. This phenotype is in sharp contrast with mice that have a deficiency in the Reelin signaling pathway (scrambler mice). First, early born scrambler neurons fail to attach the endfeet of their leading process within the preplate. More important, however, scrambler neurons seem unable to dissociate from their mother radial glia at the completion of the migratory journey. This rather major distinction between Cdk5- and Reelin-deficient migrating neurons suggests that the two pathways mediate different cellular functions.

Compound Mutant Mice

Further evidence that Cdk5 and Reelin are operating in parallel pathways to regulate neuronal migration comes from studies of compound mutant mice. Mice that are deficient in ApoER2 or Dab1 and p35 exhibit an exacerbated cytoarchitectural phenotype in the hippocampus and neocortex suggestive of synergistic contributions of each pathway to brain development. Taken together, all of these studies suggest that proper lamination of the neocortex requires distinct functions of Cdk5 and Reelin signaling.

Doublecortin and Dynein Pathways in Neuronal Migration

Doublecortin

In addition to those directly involved in Cdk5 and Reelin signaling, several proteins that are also important for proper corticogenesis have been discovered through analysis of mutant mice and human diseases. Most of these proteins are important for cytoskeletal functions or cell adhesion. Missense mutations in

Doublecortin (DCX) can result in an X-linked form of lissencephaly (smooth brain) in humans. Furthermore, silencing of DCX expression with RNAi in rats, or genetic knockout of DCX and DCLK (a related protein) in mice, results in neuronal migration defects. DCX is expressed only in postmitotic neurons and is a microtubule-associated protein containing two tandemly repeated 90-amino acid domains that are capable of binding purified tubulin. Analysis of disease-causing human mutations showed that several of the missense mutations cluster in the tandem repeats. It is believed that DCX normally functions to stabilize microtubules.

Dynein, Lis1, and Ndel1 (Nudel)

Another pathway involved in neuronal migration involves the function of the minus-end microtubule motor dynein and two dynein interacting proteins, Lis1 and Ndel1 (also referred to as Nudel). In addition to DCX, human lissencephaly-causing mutations have been linked with the LIS1 gene. Furthermore, mouse models of Lis1 deficiency show a dosage-dependent effect on neuronal positioning. Ndel1 was first cloned as a Lis1-binding protein, but it can also associate directly with dynein. Further evidence has suggested that both Lis1 and Ndel1 positively regulate dynein function and maintain microtubule networks essential for migration. RNAi-mediated knockdown in embryonic mouse brain of dynein heavy chain, Lis1, or Ndel1 results in severe neuronal positioning defects.

Cdk5 Pathways Controlling Neuronal Migration

Since the phenotype of Cdk5-deficient mice is identical to the double knockout of its activators, p35 and p39, it is Cdk5 kinase activity that is essential for neuronal migration. Therefore, elucidation of relevant Cdk5 substrates will provide the underlying molecular mechanisms by which this kinase regulates neuronal migration. Furthermore, since Cdk5-deficient neurons display irregular migratory behavior that likely requires massive cytoskeletal rearrangement, logic dictates that Cdk5 substrates would regulate cytoskeletal functions during migration.

Cdk5 Phosphorylation of Focal Adhesion Kinase

S732-phosphorylated Focal Adhesion Kinase regulates centrosome-associated microtubules The first Cdk5-dependent phosphorylation event demonstrated to be essential for neuronal migration was phosphorylation of focal adhesion kinase (FAK) at serine 732. FAK was identified as a tyrosine kinase that localizes to focal adhesions, which are structures linking the extracellular matrix to the actin cytoskeleton. Interestingly, Cdk5-dependent phosphorylation of FAK is actually more important for microtubule organization during neuronal migration. S732-phosphorylated FAK, which is abolished in Cdk5-deficient mice, is enriched along a centrosome-associated microtubule fork/cage-like structure that abuts the nucleus in wild-type neurons. In Cdk5-deficient neurons, and in neurons overexpressing the S732A nonphosphorylatable FAK mutant, there is no discernible organization to this microtubule fork/cage structure.

The role of the cytoskeleton in migrating neurons A general hypothesis to explain the role of the cytoskeleton during neuronal migration relies on a simplified model based mainly on *in vitro* experiments in which the movement of a neuron consists of a few steps. First, there is extension of a leading process from the cell soma in the direction of migration, an event that primarily relies on the actin cytoskeleton. At this point, the centrosome, which is the major microtubule-organizing center, is located ahead (in the direction of migration) of the cell soma in the leading process. Second, microtubules linking the centrosome and the nucleus, which occupies most of the cell soma, drive nuclear movement into the leading process. This second step is commonly referred to as nucleokinesis. A third step is retraction of the trailing process. Successive cycles of leading process outgrowth and nucleokinesis will result in a migrating neuron. Importantly, this model suggests that different components of the cytoskeleton have distinct cellular functions during migration (Figure 3).

S732-phosphorylated FAK and nucleokinesis It was hypothesized that the microtubule fork/cage structure decorated with Cdk5-phosphorylated FAK, linking the centrosome to the nucleus, and disorganized in the cases of FAK–S732A expression or Cdk5 deficiency, would be essential for proper nucleokinesis. Indeed, live imaging of neurons migrating *in vitro* showed impaired nuclear movement. When the portion of the nucleus distal to the leading process began to translocate in the direction of migration, the proximal pole of the nucleus failed to move in tandem, resulting in a more rounded nuclear morphology. Furthermore, overexpression of FAK–S732A in embryonic brain by *in utero* electroporation resulted in neuronal migration defects with a characteristic rounded nuclear morphology phenotype that was very similar to what was observed in Cdk5-deficient brains (Figure 4). Therefore, Cdk5 phosphorylation of FAK is important for the maintenance of an essential microtubule network that mediates nucleokinesis. Although the discovery

Figure 3 The role of the cytoskeleton in neuronal migration. Neurons first extend a leading process in the direction of migration (leading edge extension), an event primarily dependent on the actin cytoskeleton. Microtubules (red) emanating from the centrosome (green) and abutting the nucleus then drive nucleokinesis, the movement of the nucleus (dark gray) toward and into the leading process.

Figure 4 Cdk5 phosphorylation of FAK at S732 regulates nucleokinesis. (Left) Microtubules (red) emanating from the centrosome (green) and abutting the nucleus (dark gray) in a fork-like configuration are decorated with Cdk5-phosphorylated FAK (yellow). Nucleokinesis occurs as the nucleus moves into the leading process (compare nuclear position in the two cells). (Right) In cases of Cdk5 deficiency or expression of a nonphosphorylatable form of FAK, microtubules are severely disorganized. The pole of the nucleus proximal to the leading process fails to move, whereas the distal pole does move. This aberrant coupling of movement results in a more rounded nuclear morphology and a failure of nucleokinesis.

of FAK–S732 phosphorylation represented an important step in understanding the mechanisms that underlie Cdk5-mediated neuronal migration, recent work has suggested that a few other substrates are also important for implementing the complete downstream effects of Cdk5.

Cdk5 Phosphorylation of Doublecortin

An essential neuronal migration protein, DCX, is also a Cdk5 substrate. DCX has been shown to regulate the distance of nuclear-centrosome coupling in neurons, and it is localized to the microtubule fork/cage-like structure linking the centrosome and nucleus. Phosphorylation of DCX at serine 297 by Cdk5 regulates the interaction between DCX and microtubules, and mutation of S297 blocks the effects of DCX in a migration-dependent cellular reaggregation assay in a manner similar to pharmacological inhibition of Cdk5 activity, suggesting a role in nucleokinesis.

Cdk5 Phosphorylation of Ndel1

Cdk5 can also phosphorylate Ndel1, an essential member of the dynein/Lis1/Ndel1 complex. Indications that this complex is involved in nucleokinesis during neuronal migration first came from counterparts in *Aspergillus nidulans*, in which mutations in the orthologs of dynein (NudA, NudC, and NudG), Lis1 (NudF), and Ndel1 (NudE) all result in abnormal nuclear distribution ('Nud'). Furthermore, dynein, Lis1, and Ndel1 all are localized to the microtubule fork/cage that links the centrosome to the nucleus, and RNAi-mediated knockdown of these proteins caused a disruption of microtubule bundles. Live imaging of RNAi transfected cultured neurons demonstrated that

nuclear movement is also disrupted; rather than moving continuously toward the centrosome in the leading process, the movement of the nucleus oscillated back and forth. Cdk5-phosphorylated Ndel1 is capable of interacting with 14–3-3ε, a gene that is deleted along with Lis1 in severe cases of lissencephaly (e.g., Miller–Dieker syndrome). Interestingly, mice deficient in 14–3-3ε display a mislocalization of Ndel1 and Lis1 and a mild cortical distortion. Cdk5-dependent phosphorylation of Ndel1 also facilitates an interaction with the microtubule severing protein katanin/p60, and dominant negative mutants of p60 result in defective migration.

Cdk5 Phosphorylation of p27 (kip1)

Whereas the majority of Cdk5 research aimed at understanding migration has suggested a critical role for the kinase in regulating microtubules, the description of p27 (kip1) as a novel substrate opened up the possibility that Cdk5 can also regulate the actin cytoskeleton in migrating neurons. Cdk5 phosphorylates p27 on serine 10, an event that is important for stabilizing p27 levels. Once stabilized, higher p27 levels result in the activation of cofilin, an actin-severing protein. Although p27-deficient mice do not have any obvious neuronal migration phenotype, RNAi-mediated knockdown of p27 in embryonic brains results in impaired migration of cortical neurons and decreased amounts of F-actin in neuronal processes.

Other Substrates of Cdk5 Potentially Important for Neuronal Migration

One intriguing candidate to play a role in neuronal migration is Pak1, a small GTPase effector that regulates both the microtubule and the actin cytoskeleton. Cdk5 can phosphorylate Pak1 at threonine 212, and expression of a nonphosphorylatable form of Pak1 results in severe neuritic patterning defects. Pak1 phosphorylation at T212 by Cdc2 regulates microtubules in dividing cells, so it is possible that the altered patterning in cortical neurons is due to a microtubule defect. Another microtubule-associated protein involved in neuronal migration that can be phosphorylated by Cdk5 is MAP1B. Stimulation of cultured cortical neurons with reelin or netrin increased MAP1B phosphorylation in a GSK3- and Cdk5-dependent manner, but Cdk5 does not appear to phosphorylate MAP1B in nonstimulated brain slices. *In vitro* experiments have also demonstrated that Cdk5 activity can regulate N-cadherin/β-catenin-mediated complexes, indicating a direct role for Cdk5 in cell adhesion. Finally, Cdk5 is capable of phosphorylating Dab1, a critical mediator of Reelin signaling, at serine 491. Interestingly, although this phosphorylation event occurs *in vivo*, it seems to be completely independent of Reelin signaling. It will ultimately be important to determine if phosphorylation of Dab1 impacts on neuronal migration (Figure 5).

Cdk5 and Axon Guidance

Corpus Callosum Defects in p35-Deficient Mice

In addition to neuronal migration, there is strong evidence that Cdk5 plays an important role in guidance for the correct establishment of axon/target connections. The first indication of this role of Cdk5 came from studies of the corpus callosum in p35-deficient mice, in which callosal axons display an abnormal projection pattern. Tracer injection and axonal staining experiments performed in p35−/− mice demonstrated a general failure of projecting cortical axons to assimilate into the body of the corpus callosum, suggesting a defect in fasciculation between axons.

Cdk5 and Semaphorin 3A

Further experiments have placed Cdk5 into a pathway with semaphorins, a well-established, large family of

Figure 5 Cdk5 substrates involved in cytoskeletal regulation during neuronal migration. The majority of Cdk5 substrates understood to be involved in migration localize to the centrosome and microtubules, and they are known to regulate microtubule function and nucleokinesis. These include FAK, doublecortin (DCX), and Nudel. MAP1B phosphorylation, if important for migration, likely also regulates microtubule function. The first Cdk5 substrate shown to regulate the actin cytoskeleton during neuronal migration, and likely leading edge extension, was p27 (kip1). Phosphorylation of Pak1 may regulate actin or microtubule function.

secreted and membrane-bound proteins that can function as chemorepulsive/attractive cues. In cell culture, Sema3A normally induces collapse of growth cones through a large signaling pathway that includes functional roles for collapsin response-mediator proteins (CRMP), Rac, and LIM-kinase. Interestingly, dorsal root ganglia growth cones from Cdk5-deficient mice fail to collapse in response to Sema3A. Likewise, a dominant negative Cdk5 mutant attenuates Sema3A-induced collapse. *In vitro* kinase assays demonstrated that Cdk5 is capable of phosphorylating CRMP-2 at serine 522. Importantly, overexpression of a CRMP-2 alanine 522 mutant inhibited Sema3A-induced collapse. Mechanistically, it seems that Cdk5-dependent phosphorylation primes CRMP-2 for phosphorylation by GSK-3β, another event necessary for growth cone collapse. Therefore, the essential role of Cdk5 in Sema3A-induced growth cone collapse is likely mediated in part through phosphorylation of CRMP-2.

Cdk5 and GDNF/GFRα1

A second guidance pathway that seems to be associated with Cdk5 activity involves the function of GFRα1, a GPI-anchored receptor for glial cell line-derived neurotrophic factor (GDNF) that can be secreted or exist as a membrane-bound protein. Treatment of the motor cell line MN1 with GDNF in the presence of exogenous GFRα1 induced an increase in Cdk5 activity. Most interestingly, use of the Cdk inhibitor roscovitine or a dominant negative Cdk5 blocked GDNF/GFRα1-stimulated neurite outgrowth and guidance in explanted sympathetic ganglia.

Cdk5 Pathways Control Neuronal Motility and Structure

Taken together, all these findings suggest that Cdk5 is directly upstream of substrates that regulate the cytoskeleton during neuronal migration, and it specifically maintains the integrity of a microtubule network that links the centrosome with the nucleus and is essential for nucleokinesis. It is possible that Cdk5 activity is a signaling mediator during neuronal migration, relaying extracellular cues about the migration status to the cytoskeleton to permit the necessary remodeling. Multiple types of cues may converge on Cdk5 to translate their message into cytoskeletal rearrangement. Furthermore, Cdk5 is emerging as an important regulator of axon guidance, suggesting that the functions of Cdk5 in orchestrating brain development are manifold.

Neurons are highly polarized cell types that send and receive signals through two structurally and functionally distinct processes – axons and dendrites. The microtubule cytoskeleton serves as the structural core of the neuronal processes and its dynamic behavior is critical for neurite outgrowth, extension, and branching. Microtubule-associated proteins (MAPs) modulate microtubule dynamics by attaching to microtubules and stabilizing them. Phosphorylation plays a key role in regulating the microtubule-binding activity of MAPs. The microtubule affinity regulating kinase/partitioning defective-1 pathway has emerged as a major signaling pathway that regulates MAP–microtubule interaction. Deregulation of this pathway may underlie the pathogenesis of neurodegenerative diseases.

Introduction

Microtubules play an important function in regulating cell division, intracellular transport, and the maintenance of cell shape and polarity. To carry out these tasks, microtubules need to be dynamically unstable. This is best illustrated in neurons, the most polarized cells in the human body. Neurons send out axons and dendrites to communicate with their target cells by forming synapses. The 'outbound' transport of synaptic vesicles and organelles and the 'inbound' transport of neurotrophic factors and signaling complexes, among others, are essential for the proper functioning and survival of neurons. Microtubules provide the tracks for axonal and dendritic transport, whereas microtubule-based motor proteins such as kinesins and dyneins with built-in directionality provide the driving force. Both microtubule-stabilizing and -destabilizing drugs can inhibit the formation of axons and dendrites in neurons. This necessitates the precise control of microtubule dynamics in neurons.

Microtubules and Microtubule-Associated Proteins in Neuronal Motility and Structure

MAPs bind to microtubules along their entire length and modulate their dynamics. The best-studied MAP is the tau protein, which contains a conserved microtubule-binding domain with three or four imperfect repeats of 31-amino-acid motifs. Tau has been shown to be a microtubule stabilizer, a regulator of axonal trafficking, and a linker between the microtubule network and the plasma membrane. Tau promotes neurite outgrowth during neuronal differentiation. Even in nonneuronal cells, tau can promote the formation of cellular processes with characteristics of neurites. Despite these impressive cell culture studies, tau knockout mice are viable and do not show dramatic defects in neuronal differentiation. This is likely due to functional compensation by other MAPs *in vivo*. Consistent with this, tau and MAP1b double-mutant mice show severe defects in axonal elongation and neuronal migration.

The microtubule-binding activity of tau is regulated by phosphorylation. Most of the phosphorylation sites are SP or TP sites that have relatively small impact on the microtubule-binding activity of tau. These sites are likely acted on by some Pro-directed kinases, such as glycogen synthase kinase (GSK)-3β, cyclin-dependent kinase (Cdk)-5, or mitogen-activated protein kinase (MAPK). Other phosphorylation sites are non-Pro-directed. Of these, phosphorylation within the KXGS motifs in the microtubule-binding domains exerts a strong influence on tau–microtubule interaction. Drewes et al. pursued a biochemical purification of the kinase(s) responsible for phosphorylating the KXGS motifs in tau and this led to the identification of microtubule affinity regulating kinase (MARK).

A Conserved Role of MARK/PAR-1 Kinases in Establishing Cell Polarity

MARKs are mammalian homologs of the *Caenorhabditis elegans* Ser/Thr kinase PAR-1 (partitioning defective-1). PAR-1 kinase was initially identified in a genetic screen for genes that control the cell polarity and asymmetric division of *C. elegans* early embryos. PAR-1 is required for the polarized distribution of P granules to the germline lineage. The function of PAR-1 as a cell polarity regulator appears to be conserved. The *Drosophila* homolog of PAR-1 is required for microtubule organization and embryonic axis formation. In the fission yeast, the PAR-1/MARK ortholog Kin1 localizes to new cell ends after cell division and is important for bipolar growth. Mammalian MARK is asymmetrically localized in epithelial cells and may influence epithelial apical–basal polarity. Although it is a formal possibility that PAR-1 may regulate cell polarization through phosphorylation of MAPs in *C. elegans* and other organisms, this has not been proven biochemically or genetically. A total of six *par* genes (*par-1* through *par-6*) were isolated from the original genetic screen

in *C. elegans*. The products encoded by the six PAR genes perform evolutionarily conserved roles in establishing cellular polarization in different cell types, including neurons.

MARK Kinases Play an Important Role in Regulating Axonal Transport and Neurite Outgrowth

In addition to tau, other MAPs, such as MAP2 and MAP4, are also phosphorylated by MARK at the KXGS motifs in their microtubule-binding domains. Such phosphorylation events similarly led to the detachment of MAP2 and MAP4 from the microtubule and increased the dynamic instability of microtubules. These studies thus define a general role of MARK/PAR-1 kinases in regulating microtubule dynamics. Although the binding of MAPs to microtubules can have stabilizing effects, it also competes with microtubule-based molecular motors for microtubule binding. Thus, overexpression of tau can lead to reduced attachment of kinesin to the microtubule surface, inhibition of kinesin and dynein-directed axonal transport, and accumulation of mitochondria and amyloid precursor protein (APP)-containing vesicles at the cell interior, eventually resulting in the degeneration of the axons. Interestingly, moderate expression of MARK2 can rescue the toxic effects of tau on axonal transport, presumably by detaching tau from the microtubule surface. Because the velocity of motor-mediated active transport is not changed by MARK expression, it appears that simply by removing tau and creating a more open path, motor-driven axonal transport is facilitated. It should be noted that in this experimental condition, in which there is excess tau associated with the microtubule, modest coexpression of MARK removes excess tau without removing all tau from the microtubule and affecting the integrity of microtubules. It is possible that when higher levels of MARK kinase activity are induced, or in cell types containing less tau and other MAPs, disintegration of the microtubules and cellular toxicity could occur. Indeed, in cell types with a low endogenous level of MAPs, transient expression of MARK leads to rapid disintegration of microtubules and subsequent cell death. This biphasic effect of MARK/PAR-1 on microtubule function and cell survival depending on gene dosage may explain some divergent results from animal studies in which different levels of PAR-1 activity can have opposite effects on cell survival.

The importance of the MARK pathway in neurite outgrowth has been demonstrated in two different culture systems, although the effects may differ depending on the cell type. In neuroblastoma N2a cells, overexpression of MARK promoted neurite outgrowth, whereas inhibition of MARK2 using either a dominant negative mutant or kinase inhibitor blocked the formation of neurites. This suggests that MARK2-induced plasticity of microtubules is needed for neuronal polarity and the formation of neurites. In another study using cultured primary hippocampal neurons, it was demonstrated that knocking down the expression of MARK2 with small interfering RNAs (siRNAs) induced the formation of multiple axonlike neurites and promoted axon outgrowth, whereas ectopic expression of MARK2 led to loss of axons. It was further shown that the PAR-3/PAR-6/atypical protein kinase C (aPKC) complex negatively regulates the activity of MARK via aPKC-mediated phosphorylation of MARK, leading to less tau phosphorylation and stable microtubules. Thus, MARK2 appears to play a role in axon/dendrite fate specification and neurite outgrowth, but its effects may differ in different cell types. This may reflect a difference in the cytoskeletal composition or organization in different cell types. One caveat of these studies is the heavy reliance on transfection and neuronal culture. More rigorous tests using genetic mutants of MARK/PAR-1, especially in model organisms such as *Drosophila* and *C. elegans*, in which there is only one PAR-1 gene in each organism, will test the exact physiological roles of PAR-1 in axon–dendrite specification and neurite outgrowth. It will also be interesting to define the molecular and cellular mechanisms by which MARK/PAR-1 kinases may regulate the specification of axons. Local destabilization of actin has been proposed as a trigger for axonal specification and PAK5 has been described as an inhibitor of MARK/PAR-1 that can lead to stable microtubules and dynamic actin. It would be interesting to test whether PAK5–MARK interaction is involved in axonal specification by regulating actin dynamics.

Upstream and Downstream of MARK/PAR-1

Since the discovery of tau and MAPs as substrates of MARK, several other MARK/PAR-1 substrates have been identified, including Doublecortin (Dcx), Dishevelled, and several 14-3-3-binding proteins (PTPH1, Cdc25C, KSR1, and Plakophilin 2) whose interaction with 14-3-3 depends on prior phosphorylation by MARK/PAR-1. In the case of Dcx, phosphorylation by MARK regulates its affinity for microtubules in a manner similar to the regulation of tau and MAPs. The MARK phosphorylation site in Dcx is mutated in individuals affected by X-linked lissencephaly, a neurodevelopmental disorder associated with aberrant neuronal migration. This provides further *in vivo* evidence for the importance of the MARK/PAR-1

signaling pathway in regulating neuronal motility and structure. *Drosophila* PAR-1 was isolated in a biochemical purification for kinases that can phosphorylate Dishevelled, a key component of the Wingless/Wnt signaling pathway. Phosphorylation of Dishevelled by PAR-1 leads to activation of β-catenin and inhibition of Jun N-terminal kinase (JNK) signaling. A similar mechanism of Dishevelled regulation by MARK appears to be operating in mammalian systems. Interestingly, Dishevelled was found to be associated with axonal microtubules and to regulate microtubule stability through inhibition of the Ser/Thr kinase GSK-3β. As discussed later, the GSK-3β pathway has also been implicated in the control of neuronal motility and structure. It thus appears that the MARK/PAR-1 pathway may act through Dishevelled to impinge on the GSK-3β pathway in these processes.

The upstream signaling events that regulate MARK/PAR-1 kinase activity are just beginning to be understood. MARK kinases purified from bovine brain have been phosphorylated at multiple sites, including the T208 and S212 sites located in the kinase domain, suggesting that MARK/PAR-1 activity is regulated by phosphorylation *in vivo*. The T208 site is located at a strategic position in the kinase domain consistent with an activating role for T208 site phosphorylation on MARK/PAR-1 activity since a phosphate group at that position would stabilize the kinase domain via electrostatic interactions with other charged residues. Mutagenesis studies have largely confirmed this finding. In contrast, conflicting data have been reported on the role of S212 site phosphorylation. Two kinases, the tumor suppressor LKB1 and MARK kinase (MARKK), have been implicated as the upstream activating kinases that act on the T208 site (Figure 1). LKB1 binds *in vivo* with two ancillary proteins (STRAD and MO25) to form an active kinase complex. LKB1 has been shown to respond to stress signals and MARKK is a member of the Ste20 family of kinases that are also implicated in stress response. It is thus possible that the LKB1 and MARKK pathway may incorporate upstream stress signals to regulate MARK/PAR-1 activation. Supporting this notion, in mammalian cell culture, MARK is activated by osmotic stress. There is also evidence that MARKK may act through MARK to regulate the binding of tau and MAPs to microtubules and influence microtubule stability. Whether LKB1 may exert similar effects on MARK/PAR-1 remains to be determined. GSK-3β was reported to be a kinase that acts on the S212 site of the MARK kinase domain to positively regulate the activity of MARK toward tau (Figure 1). If confirmed, this finding suggests yet another level of interaction between the MARK and GSK-3β pathways.

Both mammalian MARK and *Drosophila* PAR-1 are phosphorylated by aPKC at the C-terminal 'spacer' domain. Although this domain is the least conserved region among the MARK/PAR-1 kinases, the aPKC phosphorylation site is highly conserved. Phosphorylation by aPKC disrupts the peripheral membrane localization of MARK and negatively regulates its activity (Figure 1). A study of mammalian hippocampal neurons confirmed the functional significance of this phosphorylation event in regulating neurite outgrowth. Overexpression of MARK2 or a mutant form of MARK2(T595A) in which the aPKC phosphorylation site is mutated causes failure of axonal specification. Whereas the coexpression of PAR-3/PAR-6/aPKC could rescue the defects caused by wild-type MARK2,

Figure 1 Diagram summarizing the current knowledge of the PAR-1 and GSK-3β signaling pathways that regulate microtubule dynamics, axonal/dendritic identity, neurite outgrowth, and synaptic plasticity. Dashed arrows indicate potential sites of cross-talk between the two pathways.

it had no effect on MARK2(T595A)-induced polarity defects. The involvement of aPKC–MARK interaction in neuronal polarization was further demonstrated by the finding that overexpression of a mutant form of MARK with a deleted kinase domain but an intact aPKC-binding domain abolished neuronal polarization. Moreover, suppression of MARK2 by siRNA rescued the polarity defects induced by a dominant negative aPKC mutant. These results thus establish aPKC as an upstream negative regulator of MARK/PAR-1 in axonal specification (Figure 1). In addition to PAR-3 and PAR-6, the insulin/PI3K/Akt pathway can also regulate aPKC activity, suggesting that diverse physiological signals may impinge on aPKC to regulate the MARK pathway.

GSK-3β in Neuronal Motility and Structure and Its Relationship with MARK/PAR-1

As mentioned previously, the GSK-3β pathway can be connected to the MARK pathway through various mechanisms. Although the exact relationship between the two pathways in determining neuronal motility and structure remains to be determined, given the known important roles of GSK-3β in regulating microtubule dynamics and neuronal polarity, it is necessary to review what is known about the regulation and function of the GSK-3β pathway in these processes, which will shed light on its interaction with the MARK pathway. GSK-3β is a multifunctional kinase highly conserved in eukaryotes. GSK-3β has been implicated in a range of biological processes, including the canonical Wnt signaling pathway, microtubule dynamics and cell migration, and axonal specification. Unlike MARK, which requires activation by upstream activating kinases, GSK-3β generally has a high basal kinase activity and various signaling pathways act by inhibiting GSK-3β activity. Phosphorylation of Ser at position 9 is a major mechanism by which the activity of GSK-3β is inhibited. In cultured hippocampal neurons, there is no significant difference in the distribution of activated GSK-3β in the neurites of nonpolarized neurons. However, after the transition from nonpolarized to polarized neurons, GSK-3β activity is higher in dendrites than in axons. This asymmetry in GSK-3β activity is important for determining axon–dendrite polarity. Akt and Pten act upstream of GSK-3β to determine neuronal polarity, and they play opposite roles in the process, with Akt inhibiting GSK-3β and Pten activating it.

There are multiple downstream targets through which GSK-3β may regulate neuronal polarity (Figure 1). Collapsin response mediator protein-2 (CRMP-2) is a microtubule-binding protein that plays a critical role in specifying axon/dendrite fate, possibly by promoting neurite elongation via microtubule assembly. CRMP-2 is phosphorylated by GSK-3β at Thr514 and this phosphorylation event inactivates CRMP-2's activity in axonal specification. Expression of a nonphosphorylatable form of CRMP-2 induced the formation of multiple axonlike neurites in hippocampal neurons and suppressed the loss of neuronal polarization phenotypes caused by a constitutively active form of GSK-3β. Furthermore, treatment of hippocampal neurons with neurotrophin-3 (NT-3) led to inactivation of GSK-3β, dephosphorylation of CRMP-2, and axonal outgrowth. Knockdown of CRMP-2 inhibited the effects of NT-3. These results thus convincingly demonstrate that GSK-3β regulates neuronal polarity by phosphorylating CRMP-2.

GSK-3β can also phosphorylate other microtubule-binding proteins, such as MAP1B, tau, and adenomatous polyposis coli gene product (APC). Phosphorylation by GSK-3β inhibits the ability of tau and MAP1B to bind microtubules. Hippocampal neurons isolated from mice lacking both tau and MAP1B could form dendrites but not axons, suggesting that tau and MAP1B may also mediate the effect of GSK-3β in regulating axonal specification. Inactivation of GSK-3β in axonal tips would allow tau and MAP1B to promote microtubule assembly and axonal elongation. Phosphorylation of APC and inhibition of its microtubule-binding activity by GSK-3β may also play a role in establishing neuronal polarity. APC and kinesin superfamily (KIF)3A have been shown to interact with mPAR-3. In polarized hippocampal neurons, APC selectively accumulates and co-localizes with mPAR-3 at nascent axon tips. Inhibition of GSK-3β activity at axon tips is required for mPAR-3 targeting and neuronal polarization. Given the role of the PAR-3/PAR-6/aPKC pathway in regulating MARK/PAR-1 activity, as discussed previously, this effect of GSK-3β on PAR-3 localization via APC may indirectly impact the MARK pathway. However, it should be kept in mind that the relationship between the MARK pathway and the GSK-3β pathway may be more complicated and there may not be a simple linear relationship between them. For example, as described previously, MARK/PAR-1 can directly phosphorylate and regulate Dishevelled in both *Drosophila* and mammals. Dishevelled can stabilize microtubules by inhibiting GSK-3β through a transcription- and β-catenin-independent pathway, resulting in a decrease in GSK-3β-mediated phosphorylation of MAP1B. Thus, through Dishevelled, MARK/PAR-1 could also impinge on the GSK-3β pathway.

In addition to a connection between MARK and GSK-3β via cross-talk between the two signaling

pathways, MARK and GSK-3β may cooperate at another level by acting on the same substrate proteins. GSK-3β phosphorylation of its substrates usually requires prior (priming) phosphorylation by other kinases. In *Drosophila*, there is evidence that prior phosphorylation of tau by PAR-1 in the microtubule-binding domain is required for the subsequent phosphorylation of tau by downstream kinases including GSK-3β. Similarly, phosphorylation of tau at a different site by Cdk5 may also serve a priming role for GSK-3β-mediated phosphorylation at a nearby site. It will be interesting to test whether the phosphorylation of other substrates by GSK-3β may also require prior phosphorylation by MARK/PAR-1. In this regard, it would be interesting to test whether GSK-3β and MARK/PAR-1 cooperate in phosphorylating some of the known GSK-3β substrates such as kinesin motors, whose potential phosphorylation by MARK/PAR-1 has not been tested.

MARK and GSK-3β Pathways in Neurodegenerative Diseases

The regulation of tau phosphorylation by kinases and phosphatases has received considerable attention because abnormal phosphorylation of tau is associated with a number of neurodegenerative diseases, such as Alzheimer's disease, frontotemporal dementia, Pick's disease, and supranuclear palsy. In diseased neurons, tau becomes hyperphosphorylated, highly insoluble, and forms aggregates called neurofibrillary tangles. Although a few of these phosphorylation events may be disease specific, the majority of these events, including those at MARK/PAR-1 and GSK-3β target sites, also occur in normal brains, albeit at a reduced frequency compared to diseased brains. This suggests that dysregulation of these tau kinases or the corresponding phosphatases may be integral to disease pathogenesis. Transgenic animal studies are beginning to decipher the functional roles of the different tau kinases in mediating tau toxicity and neurodegeneration. In *Drosophila*, for example, overexpression of PAR-1 can lead to neurodegeneration in photoreceptor neurons in a tau-dependent manner. Overexpression of PAR-1 also promotes the phosphorylation and neurotoxicity of human tau in *Drosophila* photoreceptor neurons. Genetic analysis has demonstrated that PAR-1 kinase activity is required for the phosphorylation of tau in the microtubule-binding domain and for conferring tau toxicity. Importantly, PAR-1 appears to play an initiator role in triggering a sequential phosphorylation event that involves downstream kinases such as GSK-3β and Cdk5. PAR-1 may act as a priming kinase, as discussed previously. Alternatively, phosphorylation of tau in the microtubule-binding domain by PAR-1 may efficiently release tau from the microtubule network, facilitating its subsequent phosphorylation by other kinases such as GSK-3β. Overexpression of GSK-3β can also enhance tau toxicity in *Drosophila*. Interestingly, although tau transgenic flies do not normally exhibit obvious neurofibrillary tangle formation, in GSK-3β and tau coexpression animals, prominent tau aggregates resembling neurofibrillary tangles are induced. Since there is no direct correlation between the extent of neurofibrillary tangle formation and neurotoxicity, the neurofibrillary tangle formation process is generally considered a late step in the disease process or may even be a protective response by the neurons attempting to sequester the smaller neurotoxic tau species. Several transgenic mouse models of GSK-3β have also been established. Whereas some of these models can enhance tau-induced neurodegeneration, others show rescue of tau-induced neurotoxicity. These divergent results may be due to the different promoters and different levels of GSK-3β transgene expression.

The cellular mechanism by which tau abnormality leads to neurodegeneration in disease state is not understood. Although it is possible that hyperphosphorylated tau may acquire some novel toxic function, it is also possible that abnormal phosphorylation of tau and other MAPs may interfere with their normal function in axonal transport and neuronal polarity. Because of their highly polarized morphology, neurons rely heavily on intracellular movement and transport such that even slight perturbation of the transport system will have dire consequences on neuronal physiology and result in neuronal death. There is increasing evidence that neurodegeneration in a number of diseases, such as Alzheimer's disease and Huntington's disease, is accompanied by defects in axonal and dendritic transport. For example, the APP, mutations in which cause familial Alzheimer's disease, may play a role in neurons as a vesicular receptor protein for kinesin I motor proteins. Studies have shown that APP is required *in vivo* for the transport of a particular class of vesicles that may contain the proteolytic processing machinery for APP. These is also evidence that overexpression of tau can inhibit axonal transport, including the transport of APP-containing vesicles. Disruption of axonal transport may therefore lead to increased intracellular cleavage of APP and generation of the neurotoxic Aβ peptides. Loss of axonal–dendritic polarity has long been considered a hallmark of neurodegeneration. It is possible that in Alzheimer's disease and other tauopathies, disease-initiating events may lead to dysregulation of tau kinases such as MARK and GSK-3β,

leading to defects in axon/dendrite fate specification or neurite polarization.

If MARK and/or GSK-3β are indeed aberrantly activated and are the culprits in causing neurodegeneration, then pharmacological inhibition of these kinases may offer therapeutic benefits against a range of neurodegenerative diseases with tau pathology. Although the unwanted side effects of long-term inhibition of these essential kinases, such as potential activation of the oncogenic Wnt pathway by GSK-3β, should not be overlooked, preliminary animal studies have shown that inhibition of GSK-3β can attenuate the toxic effects of tau. It is possible that by adjusting the dosage of kinase inhibitors to partially inhibit the disease-causing elevation of kinase activity but maintain the normal function of these kinases, a desired therapeutic effect may be achieved without the unwanted side effects. The approval of a small molecule inhibitor of a cancer-associated tyrosine kinase raises the hope that MARK- or GSK-3β-targeted drugs for the treatment of neurodegenerative diseases may soon be developed.

Summary

Neurons use axons and dendrites to send and receive signals. Axon/dendrite polarity is important for information processing and for ensuring unidirectional information flow in the nervous system. Furthermore, for neurons to function properly and to survive, axonal and dendritic transport of organelles, vesicles, and trophic factors needs to be precisely regulated. Microtubules and MAPs play essential roles in neuronal transport and axon/dendrite polarity formation. Protein kinases such as MARK and GSK-3β phosphorylate MAPs, regulate the binding affinity of MAPs toward microtubules, and in turn impact neuronal transport and axon/dendrite specification. These kinases respond to physiological and stress signals through various signal transduction pathways, and there is evidence that these signaling pathways may cross-talk. The physiological importance of the MARK and GSK-3β kinase pathways is highlighted by the association of their aberrant activation with neurodegenerative diseases. Understanding the molecular regulation and function of these pathways in regulating neuronal transport and structure may therefore offer novel and rational therapeutic strategies for the treatment of neurodegenerative diseases.

Neuronal Pacemaking

B P Bean, Harvard Medical School, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Neuronal pacemaking refers to the ability of some neurons to generate spontaneous electrical activity by firing action potentials without being stimulated by synaptic input or by input from sensory receptors (Figure 1). When spontaneous firing of single neurons is rhythmic and regular, it is often called 'pacemaking,' by analogy to the regular pacemaking of action potentials in the sinoatrial node of the heart. However, firing of a pacemaking neuron need not necessarily trigger firing of downstream cells in a manner analogous to the pacemaker region of the heart. In fact, many neurons with pacemaking electrical activity are inhibitory neurons that release GABA.

Types of Pacemaking Neurons

Many different types of neurons in the mammalian brain have intrinsic pacemaking activity. One broad class of pacemaking neurons comprises neurons that release a variety of modulatory neurotransmitters, including acetylcholine, norepinephrine, dopamine, serotonin, and histamine. Spontaneous activity of such neurons is not surprising, since it appears that many such transmitters are often continuously released so as to produce tonic effects at low levels in a manner that is not cell-specific. Neurons releasing modulatory transmitters are often found to be spontaneously active at typical frequencies of 0.5–10 Hz (action potentials per second) if all synaptic input is removed. In a few cases, such as serotonergic neurons in the dorsal raphe nucleus, the neurons are silent in the absence of all synaptic input but fire rhythmically in a pacemaker-like fashion when there is steady excitation by norepinephrine acting on α-adrenergic receptors.

Many neurons involved in controlling sleep and wakefulness are spontaneously active. Neurons in the suprachiasmatic nucleus of the hypothalamus fire spontaneously at frequencies that show circadian rhythmicity, with faster firing daytime than during nighttime. Hypothalamic neurons that release the neuropeptide orexin, which promotes both wakefulness and feeding behavior, also show pacemaking activity, as do neurons in the tuberomammillary nucleus of the hypothalamus, which release histamine, associated with general stimulatory or activating effects throughout the brain.

A subset of interneurons in the cortex and hippocampus show pacemaking activity. Firing of groups of interneurons is often synchronized, with synchrony mediated both by electrical synapses (gap junctions) and by phase-lock of firing by means of chemical γ-aminobutyric acid (GABA)ergic synapses. It is believed that synchronous firing of networks of interneurons is centrally involved in controlling overall oscillatory activity of the cortex, especially at higher frequencies.

Several neuronal types in the thalamus are spontaneously active. Thalamic relay neurons, which receive sensory input and make glutamatergic projections to the cortex, are spontaneously active during sleep, when their spontaneous activity and synaptic input to the cortex (along with thalamocortical loops of synaptically connected neurons) may serve to underlie slow wave oscillations.

Many neurons throughout the motor system show pacemaking activity. Examples include neurons of the inferior olive; cerebellar Purkinje neurons; neurons in the deep cerebellar nuclei; and a number of neuronal types in the basal ganglia, including GABAergic neurons in the globus pallidus and substantia nigra pars reticulata, glutamatergic neurons in the subthalamic nucleus, giant cholinergic interneurons in the striatum, and dopaminergic neurons in the substantia nigra pars compacta.

Mechanisms of Pacemaking

Changes in the voltage across the membrane of excitable cells are produced by ionic currents flowing through ion channels, transmembrane proteins that form pores through the membrane. Neurons contain dozens of different types of ion channels with differing selectivity to various ions. In most cases, ion channels are normally closed but can be opened ('activated') by changes in membrane voltage. Activation is usually transient, either because the membrane voltage returns to a level that causes closing ('deactivation') of the channels or because of a property called 'inactivation,' whereby channels close even though a change in voltage is maintained. Pacemaking depends on opening of ion channels that pass electrical current flowing from outside to inside the cell. Such current produces depolarization of the cell membrane. In most cases, this current is carried by sodium ions, calcium ions, or both. A variety of different ion channels are involved in different types of pacemaking neurons.

Hyperpolarization-Activated Current

The best-known mechanism of pacemaking involves activation of a voltage-dependent current known as

hyperpolarization-activated current (I_h). This current is carried by a family of ion channels called hyperpolarization-activated cyclic nucleotide-sensitive (HCN) channels. I_h is a voltage-gated current with an unusual voltage dependence: it is closed at normal resting potentials and is activated by hyperpolarization, the opposite of the voltage dependence of almost all other voltage-dependent channels, which are opened by depolarization. The HCN channels carrying I_h are permeable to both potassium and sodium, with P_K:$P_{Na} \sim 3$:1. This gives a reversal potential near −30 mV. The channels begin to be activated by hyperpolarization below −60 to −70 mV, and at these potentials the inward current is carried by sodium ions. The flow of sodium ions into the cells produces depolarization toward threshold for action potential formation.

I_h is present in many neurons. However, many of its properties and a role in spontaneous firing of action potentials were first described in cardiac muscle cells in the sinoatrial node of the heart, where the electrical pacemaking of the heart originates. Because of this association, the channels underlying I_h have sometimes been called 'pacemaker' channels. (It is interesting, however, that although I_h is clearly involved in pacemaking in the heart, blocking the channels generally only slows but does not stop the heartbeat, showing that other channels are also involved.) In mammalian central neurons, I_h appears to play a major role in pacemaking in a subset of pacemaking neurons. These include thalamic relay neurons, large cholinergic interneurons in the striatum, globus pallidus neurons, some interneurons, and a subset of dopaminergic neurons in the midbrain. The role of I_h is often assayed by applying a reasonably selective channel blocker called ZD 7288 (Figure 2).

Figure 1 Electrical pacemaking in a suprachiasmatic nucleus neuron. Spontaneous firing of action potentials was recorded first in cell-attached patch mode and then in whole-cell current-clamp mode from an acutely isolated neuron from the suprachiasmatic nucleus of a rat hypothalamus. (a) Action currents from spontaneous firing recorded in cell-attached mode. In this recording configuration, the interior of the cell is undisturbed. (b) Spontaneous firing recorded in whole-cell mode 7 min after breaking through into whole-cell mode. The pipette solution consisted of 123 mmol^{-1} K-methanesulfonate, 9 mmol^{-1} NaCl, 1.8 mmol^{-1} $MgCl_2$, 0.9 mmol^{-1} EGTA, 9 mmol^{-1} HEPES, 14 mmol^{-1} creatine phosphate, 4 mmol^{-1} Mg–adenosine triphosphate, and 0.3 mmol^{-1} guanosine triphosphate, pH 7.3. The external solution included 1.2 mmol^{-1} $CaCl_2$, 3.5 mmol^{-1} KCl, 150 mmol^{-1} NaCl, 1 mmol^{-1} $MgCl_2$, 10 mmol^{-1} glucose, and 10 mmol^{-1} HEPES, pH 7.4. Reproduced from Jackson AC, Yao GL, and Bean BP (2004) Mechanism of spontaneous firing in dorsomedial suprachiasmatic nucleus neurons. *Journal of Neuroscience* 24: 7985–7998.

Figure 2 Effect of the hyperpolarization-activated current (I_h) blocker ZD 7288 on pacemaking in two dissociated substantia nigra pars compacta dopaminergic neurons. (a) Left, pacemaking in an acutely dissociated dopaminergic neuron from the substantia nigra par compacta (mouse). To identify dopaminergic neurons, a transgenic mouse line was used in which catecholaminergic neurons in the central nervous system express human placental alkaline phosphatase (PLAP) on the outer surface of the cell membrane. The line was obtained by introducing into the mouse genome PLAP complementary DNA linked to a promoter sequence of the gene for tyrosine hydroxylase. Living dopaminergic neurons were identified before recording by labeling of their membrane with a monoclonal antibody to PLAP directly conjugated to the fluorochrome Cy3 (E6-Cy3). Right, spontaneous firing in the same cell after application of 30 mmol^{-1} ZD 7288 to block I_h. (b) Lack of effect on pacemaking of ZD 7288 applied in a different acutely dissociated neuron (also identified as dopaminergic neuron by antibody to PLAP). Although I_h contributes to pacemaking in the cell in (a), it is not absolutely necessary, and it plays little or no role in the cell in (b). Reproduced from Puopolo M, Raviola E, and Bean BP (2007) Roles of subthreshold calcium current and sodium current in spontaneous firing of mouse midbrain dopamine neurons. *Journal of Neuroscience* 27: 645–656.

Persistent Sodium Current

In many pacemaking neurons, blocking I_h with ZD 7288 has little or no effect on spontaneous electrical activity. In most of these, the spontaneous depolarization activity appears to be due to current through voltage-activated sodium channels that produce steady state, noninactivating sodium current at subthreshold voltages (Figure 3). In such neurons, application of tetrodotoxin (TTX), an alkaloid toxin from puffer fish that selectively blocks voltage-dependent sodium channels, silences the firing and produces a stable resting potential (Figure 3(b)). Current through voltage-dependent sodium channels can be characterized most clearly in voltage-clamp experiments, in which the voltage of the membrane is controlled (using electronic circuitry) and ionic currents are measured. Current through voltage-dependent sodium channels is usually most obvious as a large transient current that activates rapidly (<1 ms) and inactivates (during several milliseconds) when the membrane is suddenly depolarized from rest. However, voltage-dependent sodium channels can also carry smaller, steady, noninactivating currents. This steady-state current is often called 'persistent' sodium current. It activates with a steep voltage dependence, with activation first evident near −70 or −65 mV and with maximal activation near −40 mV. Figures 3(c) and 3(d) show an example, in which TTX inhibited a steady inward current at −60 mV, as well as a bigger noninactivating current that was activated when the voltage was stepped from −60 to −52.5 mV. Figure 3(e) shows current as a function of voltage in the absence and presence of TTX, illustrating a TTX-sensitive inward current (shown subtracted in Figure 3(f)) that increases steeply from −65 to −50 mV. This steep voltage dependence produces regenerative depolarization, so if the membrane voltage is depolarized to −65 mV, inward sodium current flows, which produces further depolarization, which activates more channels, which pass larger inward currents, depolarizing the cell further.

Figure 3 Role of subthreshold sodium current in driving pacemaking in a cholinergic interneuron in the striatum. (a) Spontaneous firing in a striatal cholinergic interneuron. (b) Application of tetrodotoxin (TTX) (1 μmol^{-1}) prevented action potential generation and established a stable subthreshold membrane potential (approximately −60 mV). (c) In voltage clamp, stepping the membrane from a holding potential of −60 to −52.5 mV elicited a slowly developing inward current that persisted throughout the pulse. The dashed line indicates the zero current level. (d) After TTX (1 μmol^{-1}) treatment, the inward current produced by the depolarizing voltage step was absent, and a small outward current was observed. In addition, the zero current level was shifted to −60 mV. (e) The current–voltage plot for a range of voltage steps (V_{cmd}) shows that, under control conditions, there is a region of negative slope conductance at potentials positive to −60 mV and no zero current point in the subthreshold voltage range. The inward current generated by depolarizing steps was blocked by TTX. (f) Voltage dependence of the TTX-sensitive current that was obtained by subtraction for nine neurons and pooled (mean ± standard deviation). V_{cmd}, voltage command. Reproduced from Bennett BD, Callaway JC, and Wilson CJ (2000) Intrinsic membrane properties underlying spontaneous tonic firing in neostriatal cholinergic interneurons. *Journal of Neuroscience* 20: 8493–8503.

This regenerative process continues until the threshold for action potential formation (typically in the range near −55 to −40 mV) is reached.

Evidence suggests that persistent sodium current active at subthreshold voltages is carried by the same population of channels that underlie the transient, inactivating sodium current that underlies action potentials. Models of gating of conventional inactivating sodium channels suggest that with strong depolarization, inactivation of transient sodium channels is ~99.5% complete and that the incomplete nature of inactivation results in steady-state sodium current that activates steeply at voltages between −65 and −40 mV. Virtually all neurons have large transient sodium currents, reaching typical magnitudes of 5–20 nA. Thus, steady-state current at the level of 0.5% would be in the range of 25–100 pA, typical of steady-state persistent sodium currents that are measured. Some neurons, such as pyramidal neurons in the entorhinal cortex, also have specialized sodium channels with more incomplete inactivation that can produce particularly large persistent sodium currents.

The ability of a single population of sodium channels to make both persistent sodium current at subthreshold voltages and transient sodium current at more-depolarized voltage constitutes an intrinsic system of rhythmic pacemaking generated by a single type of ion channel. The presence of a large density of voltage-dependent sodium channels in virtually all neurons implies that virtually all neurons have an intrinsic drive to spontaneous firing. Clearly, many neurons do not fire spontaneously, and pacemaking by this mechanism can be prevented if there is a resting potassium conductance large enough to produce a resting potential negative to −70 mV or so, at which persistent current is first activated. However, the association of persistent sodium current with transient sodium current suggests that pacemaking behavior is an intrinsic propensity of all neurons that use sodium channels for spike formation, requiring the presence of resting potassium channels to prevent or modulate this inherent tendency.

Neurons in which pacemaking appears to be mainly due to persistent sodium current at subthreshold voltages include neurons of the suprachiasmatic nucleus, pedunculopontine nucleus neurons, subthalamic neurons, Purkinje neurons, tuberomammillary nucleus neurons, and neurons of the deep cerebellar nuclei. Even in neurons in which blocking I_h stops pacemaking, it is possible that persistent sodium current plays the major role in generating spontaneous depolarization in the range from −70 mV to threshold, with I_h serving to ensure that the membrane voltage does not fall below −70 mV for very long.

Resurgent Sodium Current

Some pacemaking neurons have an unusual component of TTX-sensitive voltage-dependent sodium current called 'resurgent' sodium current, which activates when the membrane is repolarized to resting potentials following strong depolarizing pulses that have produced maximal inactivation of the sodium channels. Resurgent sodium current appears to arise from an unusual mechanism of inactivation in which channels are plugged by a positively charged intracellular blocking particle after they open. On repolarization, the block is relieved, and the channels carry an inward sodium current transiently before deactivating. This is unlike recovery from the most common mechanism of inactivation in sodium channels, which occurs without any current passing through the channels. Resurgent sodium current gives rise to a component of TTX-sensitive sodium current immediately after a spike. This produces a depolarizing influence and promotes a more rapid approach to threshold than would otherwise occur. Recovery from the mechanism of inactivation associated with resurgent current is faster than recovery from normal inactivation, so as sodium channels pass resurgent sodium current after a spike, they are also recovering from inactivation and able to give transient sodium current on depolarization. This effect also promotes faster firing of a second spike. Resurgent current has been found in several types of neurons that have pacemaking activity at rapid frequencies, notably cerebellar Purkinje neurons (which often fire spontaneously at ~40 Hz), subthalamic nucleus neurons (which often fire at ~20 Hz), and motor neurons of the trigeminal mesencephalic nucleus.

Voltage-Activated Calcium Current

In a few types of neurons, voltage-dependent calcium currents seem to be important for pacemaking. For example, in dopamine neurons in the pars compacta of the substantia nigra, blocking entry of calcium though calcium channels by replacing calcium with cobalt (which is impermeant in most calcium channels) stops spontaneous firing (Figure 4), and cessation of firing is accompanied by hyperpolarization, as if a depolarizing inward current carried by calcium has been blocked. This effect of blocking calcium entry is relatively unusual: in many other pacemaking neurons, such as cerebellar Purkinje neurons, subthalamic nucleus neurons, and suprachiasmatic nucleus neurons, blocking calcium entry has little effect on firing frequency (or may speed it) and often produces depolarization rather than hyperpolarization. These effects likely occur because calcium entry is often strongly coupled to activation of calcium-dependent

Figure 4 Role of calcium current in pacemaking of dopaminergic neurons from the substantia nigra pars compacta. (a) Effect of tetrodotoxin (TTX) on spontaneous activity in an acutely dissociated dopaminergic neuron from the substantia nigra pars compacta. Spontaneous activity continued, with smaller and broader spikes from a more depolarized potential. (b) Effect of blocking calcium entry (cobalt substitution for extracellular calcium) on spontaneous activity in another dissociated dopaminergic neuron. Immediate hyperpolarization and cessation of pacemaking suggest a role for calcium current. (c) Effect of the L-type calcium channel blocker nimodipine on spontaneous firing in an acutely dissociated dopaminergic neuron from the substantia nigra pars compacta. From Puopolo M, Raviola E, and Bean BP (2007) Roles of subthreshold calcium current and sodium current in spontaneous firing of mouse midbrain dopamine neurons. *Journal of Neuroscience* 27: 645–656.

potassium channels, and the net effect of blocking calcium entry is to inhibit an outward current.

Pacemaking dopaminergic neurons in the pars compacta of the substantia nigra will continue firing action potentials in the presence of TTX (Figure 4). This firing appears to be caused by calcium action potentials since it can be inhibited by removal of Ca or by cobalt, which blocks voltage-dependent calcium channels. The calcium current involved in pacemaking of midbrain dopaminergic neurons appears to be at least partly 'L-type' calcium current, since pacemaking is slowed or stopped by L-type channel blockers such as nifedipine and nimodipine (Figure 4). Although the dominant type of L-type calcium channels in most neurons (Cav1.2 channels) requires suprathreshold depolarizations for activation (positive to ∼−40 mV), L-type current carried by Cav1.3 channels can activate at much more negative voltages, as negative as −70 mV. Evidence suggests that current through Cav1.3 channels may play a major role in pacemaking of dopaminergic neurons in the substantia nigra. It is interesting that Cav1.3 channels are also strongly expressed in the sinoatrial node of the heart and probably contribute significantly to cardiac pacemaking.

Another class of calcium channels that can open at subthreshold voltages and likely contribute to pacemaking in some neurons includes low-threshold, T-type calcium channels (also called low-voltage-activated channels) formed by channels in the Cav3 family. These channels can activate at voltages as negative as −75 mV, but they also inactivate strongly, so that at steady voltages near −60 mV, they are almost completely inactivated. They are likely to contribute to pacemaking primarily when the action potential is followed by a deep afterhyperpolarization lasting long enough to remove inactivation. A significant role for current through T-type channels has been proposed for pacemaking in thalamic relay neurons. However, as there are no blockers that are highly selective for T-type channels, this theory has been difficult to test directly in these or other neurons.

Importance of Resting Potential

A key element regulating the occurrence and frequency of spontaneous firing is the resting potential of a cell. The mixture of conductances that are not voltage-dependent and that determine resting potential of neurons is not well understood. Obviously, a neuron that is continually active does not have a true resting potential. For spontaneously active neurons, the resting potential must be determined when firing is stopped, for example by application of TTX. TTX application usually, but not always, results in a stable resting potential (dopaminergic substantia nigra neurons being one of the exceptions). In general, neurons have resting potentials is the range between −75 and −55 mV, considerably depolarized to the potassium equilibrium potential (near −90 mV for mammalian solutions). Pacemaking neurons frequently have somewhat more depolarized resting potentials than neurons in general, from −60 to −45 mV. The resting potassium conductance of neurons (and all cells) appears to result primarily from expression of 'two-pore domain' family (KCNK) potassium channels, which are not voltage-dependent channels. These channels are highly potassium-selective. In cells with resting potentials considerably positive to E_K, it is unclear whether there is relatively moderate expression of KCNK channels or whether there is additional

conductance with permeability to other ions. Some cells with depolarized resting potentials have very high input resistances (i.e., very low resting conductance), and in these, there may simply be relatively little expression of KCNK channels. In lower-resistance cells, there may be substantial expression of KCNK channels but additional expression of background sodium conductances. Evidence for the latter is that in some neurons, replacement of external sodium by the larger cation *N*-methyl-D-glucamine causes hyperpolarization of the resting potential. In some neurons there may also be background calcium conductances that are not voltage-dependent, but these have not been characterized in any detail.

A very simple mechanism of pacemaking is provided by a cell in which there is expression of a reasonably high density of voltage-dependent sodium channels (which provide both persistent steady-state sodium current positive to −65 mV and also transient sodium current to form spikes) along with background conductances that by themselves would produce a stable resting potential positive to −65 mV. Such a cell is likely to fire spontaneously in a pacemaker-like manner as long as the action potential activates potassium conductances that can repolarize the membrane during the falling phase of the action potential sufficiently to provide recovery from inactivation of the transient sodium channels.

Voltage-Dependent and Calcium-Dependent Potassium Conductances as Regulators of Firing Rate

Most neurons have at least a half-dozen to a dozen distinct types of voltage-dependent or calcium-activated potassium channels, and the frequency of pacemaking can be strongly influenced by these conductances. A particular potassium current strongly implicated in control of pacemaking frequency is a current known as 'A-type' current (I_A), generally carried by channels in the Kv4 family, which both activates and inactivates at subthreshold voltages. I_A enables repetitive firing at low frequencies. During the period of relative hyperpolarization after a spike, some inactivation of I_A is removed. Then, as the membrane depolarizes at potentials in the range of −70 to −55 mV (still below threshold for an action potential), I_A increasingly activates and thereby slows the approach to threshold. In the steady state, I_A inactivates nearly completely at voltages positive to about −65 mV, so it eventually inactivates, allowing depolarization to threshold. Expression of a large density of I_A appears common in pacemaking neurons that fire rhythmically at relatively slow frequencies (0.5–5 Hz), such as midbrain dopaminergic neurons. There are other potassium currents that can be activated at subthreshold voltages, notably a current called 'I_D,' which is activated by subthreshold depolarizations, inactivates slowly (more slowly than I_A), and can similarly prolong approach to threshold. However, subthreshold I_D has been characterized mainly in nonpacemaking neurons such as cortical and hippocampal pyramidal neurons, and it is unclear whether there is prominent expression of I_D in pacemaking neurons.

Most voltage-dependent potassium channels require suprathreshold depolarizations to be activated significantly and are not activated in the lead-up to the action potential but rather during the spike itself. Potassium currents through these channels can still influence the frequency of pacemaking if they deactivate slowly enough after the spike repolarizes, pushing the membrane voltage toward E_K as long as they are activated. Of purely voltage-activated potassium channels, channels in the Kv1 family generally have the slowest deactivation kinetics and might influence pacemaking frequency by producing a period of relative hyperpolarization following the action potential.

Calcium-activated potassium currents may also play a major role in regulating firing frequency. During the action potential, there is generally activation of voltage-dependent calcium channels, especially during the falling phase of the action potential, producing a large increase in intracellular calcium, which activates calcium-activated potassium currents. There are two major types of calcium-activated potassium channels: KCa1 channels (also known as 'BK' channels), which are activated both by intracellular calcium and by depolarization, and KCa2 channels (also known as 'SK' channels), which are activated purely by increases in intracellular calcium. Both KCa1 and KCa2 channels are strongly expressed in most neurons. KCa1 channels respond to relatively large increases in intracellular calcium, and they are activated very quickly during the falling phase of the action potential. KCa2 calcium-activated channels respond to lower levels of calcium than do KCa1 channels but have intrinsically slower activation kinetics. Current through KCa2 channels contributes little to the fast repolarization phase of the action potential but helps shape the afterhyperpolarization that follows the action potential. After a spike, KCa2-mediated conductance can last for many hundreds of milliseconds before decaying, probably reflecting the relatively slow decay of intracellular free calcium. In contrast, KCa1 channels generally deactivate far more quickly. The longer-lasting conductance from KCa2 channels gives them a larger role in controlling pacemaking frequency. In several types of pacemaking neurons, block of KCa2 channels (or block of the

Figure 5 SK(KCa2) calcium-activated potassium channels are critical for the rhythmicity of pacemaking activity in rat subthalamic nucleus neurons. (a) Pacemaking was extremely regular in control conditions. Right, interspike interval histogram generated from 100 interspike intervals. Coefficient of variation (CV) = 0.05; frequency = 21.8 Hz. (b) Partial inhibition of SK channels by 0.5 $nmol^{-1}$ apamin. Firing was less regular (CV = 0.1), and frequency was somewhat faster (28.1 Hz). (c) Complete inhibition of SK channels by 100 $nmol^{-1}$ apamin. Firing was much less regular (CV = 0.18), frequency (27.5 Hz) not much changed from 0.5 $nmol^{-1}$ apamin. Calibration in (c) also applies to (a) and (b). From Hallworth NE, Wilson CJ, and Bevan M (2003) Apamin-sensitive small conductance calcium-activated potassium channels, through their selective coupling to voltage-gated calcium channels, are critical determinants of the precision, pace, and pattern of action potential generation in rat subthalamic nucleus neurons *in vitro*. *Journal of Neuroscience* 23: 7525–7542.

calcium current that activates them) has the striking effect of producing substantially less-regular firing (Figure 5). The reasons for this are not clear.

Plasticity of Pacemaking

A number of cases are known in which the frequency of firing of pacemaking neurons can be altered in a relatively long-lasting manner (many minutes to hours). For example, in spontaneously firing neurons in the medial vestibular nucleus, silencing the neurons for relatively brief periods (~5 min) by sustained inhibitory synaptic input can result in increases in the frequency of pacemaking that can last more than 2 h. These neurons serve to transform information about head movement into eye movements and are central to the vestibulo-ocular reflex that keeps appropriate eye position when the head moves. The plasticity of the pacemaking frequency (which is accompanied by an increase in the excitability of the neurons when responding to excitatory stimulation) is believed to constitute a form of motor learning that can recalibrate the gain of the vestibulo-ocular reflex. The mechanism of plasticity of vestibular neurons is thought to involve, during the period of inhibition, a decrease in intracellular calcium that leads to a decrease in basal Cam-kinase II enzymatic activity and a reduction in BK calcium-activated potassium current.

A remarkable example of plasticity is seen in principal neurons in the entorhinal cortex of the parahippocampal region, a key brain area for acquisition and consolidation of working memory. When the conductances in these neurons are modulated by steady activation of muscarinic acetylcholine receptors (known to be important in memory), the neurons acquire the ability to fire in a pacemaker-like fashion at frequencies that can be stepped up or down in a remarkably stable manner (Figure 6). Specifically, stimulation with a short (4 s) injection of current (which transiently produces high-frequency firing)

Figure 6 Plasticity of firing frequency in entorhinal cortical neuron exposed to an agonist of muscarinic acetylcholine receptors ($10\,\mu mol^{-1}$ carbamylcholine). Stimulation with a 4 s depolarizing step first induces persistent spontaneous firing (cell was initially quiescent at a stable resting potential of −64 mV). Five more episodes of stimulation each give rise to a further increase in firing frequency, in each case stably expressed until the next stimulation. Top trace shows membrane voltage, middle trace shows injected current, and bottom trace shows frequency of firing. Reproduced from Egorov AV, Hamam BN, Fransen E, Hasselmo ME, and Alonso AA (2002) Graded persistent activity in entorhinal cortex neurons. *Nature* 420: 173–178.

can produce a sustained increase in pacemaking frequency that can last for many minutes. Moreover, this process can be repeated with multiple stimuli, with pacemaking frequency increasing step-wise over a wide range. The increase in frequency can be reversed in a step-wise manner by application of 6 s hyperpolarizing steps that temporarily silence the cell. (Note that the increase in firing frequency following periods of stimulation and the decreases following inhibition are opposite to the plasticity in medial vestibular neurons.) This plasticity constitutes a mechanism of short-term analog memory at a single-cell level. The mechanism is not completely understood but appears to involve increased calcium entry during the period of stimulation that may activate calcium-activated nonselective cation conductances.

Another prominent instance of plasticity of pacemaking behavior occurs in the neurons controlling electric organ discharge of the weakly electric fish *Apteronotus leptorhynchus*. These fish generate an oscillating electric field around their bodies, used for detecting objects and other organisms in muddy water. The oscillatory discharge of electric organ is controlled by pacemaker neurons that fire action potentials at up to 1 kHz, the highest frequency of electrical pacemaking that is known. Because the cells in the pacemaker nucleus are electronically coupled, they have been difficult to study under voltage clamp, and so the ionic conductances underlying pacemaking are not well-characterized. Most likely, pacemaking is generated by TTX-sensitive sodium currents with unusually rapid kinetics, together with rapidly activating and rapidly deactivating potassium channels that keep the spikes short. Pacemaking is extremely regular. However, when two fish using similar frequencies of electric organ discharge share the same area, the one using the higher frequency shifts its frequency higher to avoid jamming of the two signals. This change in pacemaker frequency is normally temporary, lasting only as long as the other signal is present. However, if the exogenous signal is maintained for >30 min, the increase in pacemaking frequency can last for many hours after the other signal is terminated. The mechanism of this plasticity is not understood.

Neurons in the suprachiasmatic nucleus of mammals are the 'master pacemaker' neurons for circadian rhythms in behavior. They fire spontaneously (although sometimes with less regularity than seen in other types of electrical pacemakers), and if the firing of individual neurons is followed, the frequency of spontaneous firing shows a circadian rhythm, higher in the daytime and slower at nighttime (even in nocturnal animals like rats and mice that are less active in the day than in the night). Intensive work over the last decade has identified a molecular clock based on feedback loops of transcription factors and enzymes, involving regulation of translation, dimerization, nuclear translocation, and degradation of multiple elements. However, how the molecular clock is linked to the circadian regulation of electrical pacemaking frequency has been very difficult to determine. Day–night differences in a number of different conductances have been described, including voltage-dependent L-type calcium channels, Kv3-family voltage-dependent potassium channels, BK calcium-activated potassium

channels, and background potassium channels, but it has been difficult to definitively ascribe differences in firing frequency to any of the changes in conductance that have been described.

Significance of Pacemaking

The central nervous system is characterized by overall oscillatory electrical activity, as is evident from the oscillatory signals at many different frequencies present in the electroencephalogram. Oscillatory electrical activity occurs at many different levels, including the pacemaking activity of single neurons, oscillations in local networks, and oscillations involving larger-scale connections between brain regions. Oscillatory activity does not require sensory input but rather appears to occur spontaneously (although it can certainly be modified and influenced by sensory input). Presumably neuronal pacemaking at the single-cell level is central in generating the overall spontaneous activity of the brain, amplified and modified by circuits and networks.

Pathophysiology of Pacemaking

It is striking that so many neurons in the motor system are characterized by rhythmic spontaneous firing. Pacemaking activity seems counterintuitive for a system which must often be inactive and in which very rapid events and processing must occur in almost an all-or-none manner. It seems likely that the underlying pacemaking activity of elements of the motor system plays a major role in the generation of oscillatory tremors that characterize diseases such as Parkinson's disease and Huntington's disease. It is not yet clear whether the pathophysiology of tremors involves changes in the pacemaking activity of single neurons, changes in control and circuit connections, or both. It is interesting that a current treatment for Parkinson's disease involves deep brain stimulation of neurons in the subthalamic nucleus, which show prominent pacemaking activity, but the exact mechanism by which deep brain stimulation works is not yet known.

Altered pacemaking mechanisms may also be involved in some other diseases of the nervous system involving hyperexcitability of neurons, including neuropathic pain (some forms of which might involve spontaneous firing of primary pain-sensing neurons, which normally would require input from sensory receptors to be active) and epilepsy.

Summary

In some neurons, electrical pacemaking activity produces spontaneous activity in the absence of any synaptic or sensory input. Such pacemaking activity at the cellular level probably underlies spontaneous oscillatory activity at the level of networks and brain regions, which appears to be a crucial characteristic of the operation of the mammalian brain. There are several different ionic mechanisms of pacemaking in different types of pacemaking neurons, most commonly depending on activation of ion channels that allow entry of either sodium ions or calcium ions into the cell, thus carrying an electrical current that depolarizes the cell membrane to the threshold for firing an action potential.

Measuring Brain Plasticity

Although brain plasticity is presumed to reflect changes in the synaptic organization of the brain, it can be inferred from the measurement of change at many levels of analysis. Perhaps the most obvious level is behavior. If an organism's behavior is altered, such as when a new habit or bit of information is learned, we can infer that there must be some persistent change in the nervous system that represents the habit or information. The identification of this plastic change may be seen by utilizing a range of techniques that run from global to molecular analyses of brain organization. One of the most global measures is the analysis of brain maps that can be demonstrated either by recording electrical activity of the cortex in response to external stimulation (e.g., sound, touch, visual patterns), by stimulating the cortex to elicit movements or perceptions, or less invasively by using *in vivo* imaging techniques such as functional magnetic resonance imaging (fMRI). For example, it has been known for over 50 years that stimulation of the cerebral cortex of humans or lab animals with a mild electric current will elicit movements of different body parts such that a map (in humans known as an homonculus) can be identified. Stimulation of specific points will elicit movements of the digits, leg, face, etc. As animals learn new motor skills, the details of the maps change, thus representing the newly learned skill. Thus, if a person learns to play a musical instrument, we can expect that the representation of the digits will expand to reflect the newly learned ability to make fine and rapid digit movements.

Changes in the maps must reflect changes in the synaptic organization of the underlying cerebral tissue. Such synaptic changes can be shown by using specific stains to identify the structure of the neurons in the region of interest. One procedure, known as a Golgi stain, allows the dendritic fields of the neurons to be visualized and measured. Because most synapses are found on the dendrites and because space on dendrites is inevitably filled with synapses, we can measure the amount of dendritic space and infer synapse number. This is much like estimating the number of leaves on a tree by measuring branch length and the typical distance between the leaves. Simple arithmetic would allow an estimate of the total number of leaves. A similar logic allows synapse number to be estimated on the dendrites visualized in Golgi stains. As animals learn new tasks, there are changes in dendritic organization that reflect the experience-dependent behavioral changes. But this method only allows an inference about synaptic change. In order to confirm that synapses really have changed, one must use electron microscopic (EM) techniques. EM analyses make it possible to visualize individual synapses, to identify synaptic type (excitatory vs. inhibitory), and to count the number of each type of synapse. Such analyses are laborious and time consuming, however, and not practical for most behavioral studies.

If new synapses are formed in response to some experience, there must be some molecular mechanism that underlies the change. Thus, if new synapses are formed, proteins must be manufactured by cells, and the instructions for this manufacture will ultimately be controlled by genes. It is possible to measure both protein and gene expression in brain by using molecular probes, which provide yet another measure of brain plasticity. Finally, although thought to be relatively uncommon, brain plasticity can also result from the production of new neurons (known as neurogenesis) that become integrated into the host brain. Specific markers can be used to identify the birth of such new cells. The best studied region for these new cells is the hippocampus, although they may occur in small numbers elsewhere in the human brain.

In sum, brain plasticity can be measured at many levels. Although the ultimate measures of plasticity are molecular, it is not realistic to begin there. The place to begin is with detailed analysis of behavior followed by global measures such as topographic maps, where relevant, and measures of synaptic change by using stains for pre- or postsynaptic processes.

Behavioral Change after Brain Injury

We can identify at least three outcomes that could occur after brain injury. First, there may be compensation resulting from an adaptation to the lost function. Compensation could reflect a change in strategy or it may represent a substitution of a new behavior for the lost one. For example, a person who has a deficit in moving the eyes can be expected to have difficulty in reading. This difficulty can be solved, however, by moving the head, which allows restitution of function (reading) by substitution of one behavior for another. There are unlikely to be many plastic changes in the cortex to produce this behavioral change because the needed circuits are presumably already present. Similarly, if, following a stroke, a person can walk only with the aid of a cane, the

ability to walk has returned but the original walking ability has not returned, just an adaptation to the behavioral difficulty.

A second outcome might be partial restitution of the original behavior. This could reflect recovery from some sort of nonspecific effect of the injury, such as swelling, or it may reflect plastic changes that allow the brain to partly restore the disturbed behavior. Such plastic changes are most clearly seen in people with motor disturbances. Individuals may be unable to make movements of the digits or to organize their movements into purposeful sequences, but over time the capacity partially returns. Mapping studies using *in vivo* imaging have shown that the partial return of function is related to an expansion of the remaining motor cortical regions, as well as the recruitment of more distal regions (especially in the intact hemisphere) to control the movements. Animal studies have shown correlated changes in dendritic organization that presumably underlie the changes in map topography.

Third, there is the possibility that there could be a complete restitution of the original behavior. Although it is at least theoretically possible for lost functions to completely return in a plastic brain, careful behavioral analysis shows that this is rarely, if ever, the case in either adult laboratory animals or human patients. In principle, however, it ought to be possible to reorganize the brain to allow at least some functions to completely recover. This process is most likely in the developing brain, and it has been documented for over 100 years that children with damage to language areas can show almost complete recovery of lost language functions.

Neuronal Adaptations to Brain Injury

When the brain is damaged, there is a loss of neurons in the injured area, but, in addition, many neurons that are not directly injured lose their normal synaptic inputs. The immediate effect of this synaptic loss is (1) neuronal death, (2) atrophy of the dendritic and/or axonal fields that have lost their connections, and/or (3) subsequent reorganization of the connections. In principle, there are three ways that the brain could make changes that might support recovery. First, there could be changes in the organization of the remaining intact circuits in the brain. The general idea is that the brain could reorganize in some way to do 'more with less.' It is unlikely that a complexly integrated structure like the cerebral cortex could undergo a wholesale reorganization of cortical connectivity, but rather, recovery from cortical injury would be most likely to result from a change in the intrinsic organization of local cortical circuits in regions directly or indirectly disrupted by the cortical injury. Although it might be possible to produce significant reorganization of cortical connections in the young brain, the overwhelming evidence in experimental animals is that this is rare and it is just as likely to be associated with abnormal functioning as with recovery.

Second, there could be a generation of new circuitry. Cerebral reorganization can be stimulated either by some sort of behavioral therapy or the application of some sort of pharmacological treatment. In either event, the stimulus could influence reparative processes in the remaining brain or could enhance the production of new circuitry. Once again, it seems most likely that the induced neuronal changes would be in the intrinsic organization of the cortex. One might predict that induced neuronal changes might be more extensive than in the case of endogenous change, in part because the treatment can act upon the whole brain rather than just on affected regions.

Third, there could be a generation of new neurons and glia to replace at least some lost cells. Stem cells that give rise to the neurons and glia of the brain remain active in the brain throughout life. It is thus possible that neurogenesis could be stimulated after injury, especially during development, and that these new neurons could replace those lost to injury or disease. All three of these possibilities for cerebral plasticity do occur, but the likelihood of each type of change varies with age at injury.

Plasticity after Adult Brain Injury

The hippocampal formation of adult rats provided one of the first models to study synaptic replacement. When input to the hippocampus is reduced by damage to the major input pathway via the entorhinal cortex, there is a massive denervation of the hippocampal formation, which leads to atrophy of the dendritic fields of the hippocampal cells in the week after injury. Beginning at about 7–10 days after the injury, there is a slow regrowth of the dendritic fields, although the pattern of regrowth is different than the original pattern. This regrowth reflects a reorganization of the circuitry and it is correlated with a partial recovery of cognitive functions. The restructuring of the synaptic organization of the hippocampus occurs primarily because the remaining inputs to the hippocampus expand to occupy the regions of lost inputs.

An analogous process appears to occur after restricted neocortical injury in adulthood. Frontal lesions in rats lead to atrophy of neurons in adjacent cortical regions, but by 30 days postinjury the atrophy begins to reverse, and by 3 months the affected neurons actually have more synaptic space than

normal. Again, the dendritic change is correlated with partial recovery of cognitive tasks associated with the frontal injury. More recently, there has been much research on the effect of unilateral motor cortex injury on adjacent motor regions, contralateral motor regions, and the striatum. The general finding is that there is an initial atrophy of affected regions on the ipsilateral hemisphere, followed by a compensatory reorganization of neural networks that can be seen in dendritic organization in both the cortex and striatum. Some studies have shown increased dendritic fields in the motor regions of the intact hemisphere as well, which might be predicted from the *in vivo* imaging studies in humans. One unexpected finding of the studies is that lesion etiology appears to interact with the synaptic plasticity. It appears that the way the cortical tissue is killed may somehow affect the molecular cascade that subsequently leads to the synaptic reorganization.

Little is known about the changes in gene or protein expression that give rise to the synaptic changes after cortical injury but there are large changes in the expression of various growth factors, such as fibroblast growth factor-2 (FGF-2), that likely play some role in stimulating the synaptic remodeling.

Plasticity after Infant Brain Injury

Much more is known about plasticity following injury to the developing brain. Damage to various cortical areas in the second week of life in rats has been shown to lead to good functional recovery in adulthood, and this recovery is correlated with expansion of dendritic fields across the cortical mantle. This dendritic expansion takes several weeks to develop, however, and as the dendritic fields reorganize, there is an associated improvement in a variety of behavioral measures. In contrast, damage to cortical regions in the first week of life in rats produces atrophy of cortical neurons and this atrophy does not recover, nor does the lost behavior.

Infant animals show changes not only in local cortical circuits but also in more distant cortical connectivity. Perhaps the most extensive studies of changes in cortical connectivity are those showing that after unilateral motor cortex lesions in infant rats or cats there is a major expansion of the ipsilateral corticospinal pathway from the undamaged hemisphere, which is correlated with partial recovery of skilled forelimb use. These expanded connections typically do not reflect the growth of new pathways, however; rather, they reflect the failure of superfluous pathways to die off during development. That is, normally in development, there is a period during which many pathways are eliminated, but after some types of brain injury these pathways are maintained. The presence of these abnormal pathways may support some types of functional recovery, but it may also interfere with the normal functioning of remaining cortical functions. This possibility has been termed 'crowding' to reflect the idea that the normal functions of a cortical region can be crowded out by the development of abnormal connections. Thus, there may be recovery of some types of behaviors, such as motor functions, at the expense of other functions. This appears to be especially likely if the injury occurs during the period of neuronal migration and unlikely if it occurs during the period of maximal synaptogenesis.

As noted earlier, synaptic change may also occur after injury because the brain generates new neurons. Although this is likely to be rare in the adult, it does occur during development, but the generation of these neurons varies with precise embryonic age and location of injury. If the brain is damaged prenatally during the time of neuronal generation, the brain can compensate by generating rather large numbers of new cells that appear to support at least partial restitution of function. If the developing brain is damaged postnatally, there can also be extensive neurogenesis, although it appears largely limited to injury during the second week of life and is most extensive when the injury is to the certain regions of the midline telecephalon, namely, the olfactory bulb or midline cortex. The newly generated tissue is functional and animals regain at least partial function.

As in adult injury, little is known about the changes in gene or protein expression that give rise to the synaptic changes after cortical injury in infancy. There are increases in FGF-2 that correlate with functional outcome, but the exact role of the growth factors in synaptic reorganization and neurogenesis is poorly understood.

Factors Influencing Recovery and Plasticity after Cortical Injury in Adulthood

Given that a wide range of factors can stimulate synaptic plasticity in the normal brain, it is not surprising that brain plasticity and behavior after cortical injury can be modified by many factors. The most powerful influence appears to be complex housing. Studies have shown consistently that placing experimental animals in complex environments in which there are conspecifics to interact with, novel objects to explore and interact with, and an opportunity for motor activity in complex terrain produces widespread changes in dendritic organization, endogenous growth factor production, and gene expression. Animals with cerebral injuries clearly benefit behaviorally from such experience, and there is a

correlated reorganization of neuronal networks. A key feature of complex housing is that such experience produces extensive changes in the brain of laboratory animals; but what is the equivalent treatment in humans? The best guess is some type of multidisciplinary rehabilitation program that is relatively intense and thus lasts several hours a day. Such treatments may not be practical for many patients who may tire easily or have other ailments that make the intensity difficult. Other treatments thus may provide more viable options. The most common option is rehabilitation training, which is probably the most common treatment in human patients. Experimental studies in lab animals have shown functional improvement correlated with shifts in the organization of cortical motor maps with rehabilitation training, but rehabilitation training is generally only effective with fairly restricted brain injuries.

One type of treatment that has been tried is the use of psychomotor stimulants such as amphetamine and nicotine. These stimulants produce large changes in synaptic organization in the normal frontal cortex, the effects being more widespread with nicotine. The administration of stimulants after brain injury is presumed to stimulate synaptic plasticity that can be co-opted by the damaged brain to facilitate recovery. Because stimulants also increase the endogenous production of neurotrophic factors such as FGF-2, it might be expected that neurotrophic factors might also facilitate reactive synaptic plasticity after brain injury and that is the case. Both FGF-2 and nerve growth factor (NGF) stimulate synaptic plasticity and functional recovery after cortical injury.

There are a few studies looking at other types of factors including (1) inosine, which is a compound that enhances the production of connections from the injured hemisphere across to the damaged one, and (2) antibodies to a protein known as NoGo, which untreated acts to prevent synaptic plasticity. Both treatments are correlated with increased synapse formation in the remaining brain.

Factors Influencing Recovery and Plasticity after Cortical Injury in Infancy

It is generally assumed that the developing brain will show more plasticity after injury than the adult brain and, similarly, that plasticity in the injured developing brain should be influenced more by factors than the adult brain. This is generally true, although the precise age at the time that the treatments are initiated does interact with the extent of observed plasticity. As a general rule of thumb, the sooner the treatments are initiated, the larger the plastic changes (and correlated recovery) will be.

As in adults, complex housing has a very large effect on both synaptic organization and behavior. Another treatment that is nearly as effective is tactile stimulation with a soft brush, typically lasting about 15 min several times a day. As little as 2 weeks of such stimulation after perinatal injury facilitates recovery measured in adulthood and produces large increases in synapse numbers relative to control animals. One reason for this large effect appears to be related to the stimulation of FGF-2 in the skin. This FGF-2 travels through the bloodstream to the brain and acts to enhance plasticity. Direct administration of FGF-2 can act in a similar fashion and under some circumstances can stimulate neurogenesis and the partial regeneration of injured cortical tissue.

But not all treatments are beneficial after early injury. Prenatal stress or prenatal selective serotonin reuptake inhibitors (SSRIs) can interfere with reactive plasticity after perinatal injury and animals show severe behavioral impairments in adulthood. The fact that prenatal experiences can alter later brain plasticity suggests that the experiences alter gene expression, which later interacts with the brain's capacity to generate plastic changes to facilitate functional recovery.

Summary

In summary, the brain is capable of significant synaptic reorganization in response to a wide range of experiences, including injury. Plasticity can be measured at many levels ranging from behavior to genes. As methods of analysis are refined, we can anticipate that the mechanisms underlying brain plasticity and recovery of function after injury will become better understood and will allow the development of better treatments for brain injury throughout the life span.

Introduction

The tripeptide glutathione (GSH; γ-L-glutamyl-L-cysteinylglycine) is present in all cells in millimolar concentrations. GSH has essential cellular functions as an important antioxidant. In addition, it serves as cofactor for some enzymes, is a storage and transport form of the amino acid cysteine, and keeps the cellular thiol reduction potential in a strongly reduced form, thus protecting essential thiol groups in enzymes against oxidation. More recently, GSH has been demonstrated to be involved in cellular regulation, since the activity of proteins can be modulated by glutathionylation. Thus, the availability of a sufficiently high concentration of GSH is essential for a variety of cell functions.

The antioxidative function may be the most important activity of GSH, since reactive oxygen species (ROS), such as radicals and peroxides, are continuously generated in cells. ROS generation is counterbalanced by an appropriate antioxidative defense to prevent cell damage. The consequence of a disturbance of this balance of oxidative and antioxidative processes by insufficient antioxidative defense and/or an increased rate of ROS generation is oxidative stress. The human brain utilizes about 20% of the oxygen consumed by the body, indicating that this organ has the potential to generate ROS in high quantities. Thus, a disturbance in the homeostasis and the metabolism of the antioxidant GSH in brain increases the risk for oxidative stress and therefore has been connected with oxidative damage in neurodegenerative diseases such as Parkinson's disease (PD) and Alzheimer's disease.

In the brain, especially the neurons appear to be handicapped regarding GSH metabolism, since the availability of extracellular cysteine as GSH precursor limits the synthesis of the tripeptide. Since neurons cannot use extracellular cystine as GSH precursor, these cells rely on the supply of cysteine from neighboring cells. Astrocytes are well known for their broad range of metabolic pathways and for their function in supplying various essential metabolites, including GSH precursors, to neighboring neurons. In the following sections, the current knowledge on the mechanisms involved in the supply of GSH precursors from astrocytes to neurons is summarized, and consequences of a disturbance of this metabolic cooperation are considered in relationship to the pathology of PD.

Metabolism of GSH in Brain Cells

Synthesis of GSH

GSH synthesis in brain cells follows the pathway known to function in other tissues. GSH is synthesized by consecutive reactions of two enzymes, γ-glutamylcysteine (γGluCys) synthetase and GSH synthetase (Figure 1). γGluCys synthetase generates γGluCys from glutamate and cysteine. Catalyzed by GSH synthetase, this dipeptide reacts with glycine to GSH. ATP is cosubstrate for both enzymes. GSH synthesis is strongly regulated by a feedback inhibition of γGluCys synthetase by the end product GSH.

Cellular GSH synthesis depends on the intracellular availability of the substrates glutamate, cysteine, and glycine (Figure 1). Since glutamate and glycine are neurotransmitters and cysteine in high concentrations is toxic to neurons, the extracellular availability of these amino acids in the brain is limited. Thus, GSH synthesis in brain cells depends on their ability to take up suitable extracellular GSH precursors and/or to synthesize sufficient amounts of the substrates for GSH synthesis (Figure 1). Uptake and metabolism of GSH precursors differ among brain cell types. In contrast to neurons, astrocytes can use a wide range of amino acids and peptides that are taken up by the respective transporters and subsequently converted to the substrate amino acids of the two enzymes of GSH synthesis. In neurons the availability of cysteine limits GSH synthesis. These cells do not use extracellular cystine as source for the GSH substrate cysteine and prefer glutamine as the best extracellular precursor for the glutamate moiety of GSH. In contrast, astrocytes prefer glutamate and cystine as extracellular GSH precursors. This differential preference for extracellular GSH precursors prevents competition between neurons and astrocytes. However, since neurons require cysteine for GSH synthesis, these brain cells depend for their GSH synthesis on the supply of cysteine or a cysteine precursor from neighboring astrocytes.

Metabolism of GSH

During detoxification of peroxides GSH is oxidized to glutathione disulfide (GSSG; Figure 2). This reaction is catalyzed by glutathione peroxidase (GPx). Several GPx isoenzymes have been reported that differ in their tissue expression and in substrate specificity.

Figure 1 Cellular synthesis of glutathione (GSH). GSH is synthesized in the consecutive reactions of γGluCys synthetase (1) and GSH synthetase (2). Glutamate, cysteine, and glycine are the intracellular substrates for GSH synthesis and may be derived from the extracellular precursors A, B, and C, respectively.

Figure 2 Metabolism of glutathione (GSH). In cells, GSH is oxidized during peroxide disposal by glutathione peroxidase (1) to GSSG (two molecules of disulfide-bonded GSH) and is regenerated from GSSG by glutathione reductase (2). In addition, GSH can react (3) in glutathione-*S*-transferase-catalyzed reactions with xenobiotics and endogenous compounds (X). Members of the transporter family of multidrug-resistance proteins mediate (4) the export of GSH, GSSG, and glutathione-*S* conjugates from the cells.

In addition, GSH is oxidized by chemical reactions with radicals. The product of GSH oxidation is glutathione disulfide. Within cells, GSH is regenerated from GSSG by glutathione reductase (GR) (Figure 2). This enzyme uses NADPH as electron donor. Thus, efficient regeneration of GSH from GSSG requires sufficient supply of the reduced coenzyme NADPH. By the intracellular GSH redox cycling of GPx-mediated GSH oxidation and GR-catalyzed regeneration of GSH from GSSG (Figure 2), the total amount of cellular GSH is not substantially altered. Reduction of GSSG by GR is highly efficient due to the low K_m values of GR for GSSG and NADPH. Therefore, under unstressed conditions GSSG is hardly detectable in cells. In contrast, under oxidative stress GR can become rate limiting for GSH redox cycling, as indicated by accumulation of GSSG and a corresponding shift in the thiol reduction potential of the stressed cells.

In contrast to the GSH redox cycling, cells lose GSH by the formation of glutathione-*S* conjugates (GS-X), a reaction catalyzed by glutathione-*S*-transferases (GSTs), and by export of GSH or GSSG (Figure 2). Such processes participate in the consumption of GSH in brain cells. Members of the family of multidrug-resistance proteins (MRPs) mediate the cellular export of GSH and its conjugates. MRPs are ATP-driven export pumps of organic anions and belong to the family of ATP-binding cassette transporters. In addition to MRPs, other transporters, such as organic anion transporters (OATPs) or the cystic fibrosis transductance regulator (CFTR), have also been connected with GSH transport processes.

Delivery of GSH Precursors from Astrocytes to Neurons

The mechanisms involved in the transport of sulfur-containing amino acids in the brain are still a matter of debate. Nevertheless, within the brain the availability of cysteine is crucial for GSH synthesis in neurons. Since the presence of co-cultured astrocytes maintains and even increases GSH content in neurons, the amino acid cysteine that limits neuronal GSH synthesis is supplied by neighboring astrocytes. The mechanism involved in this cysteine supply involves efficient export of GSH from astrocytes, the cleavage of extracellular GSH by the ectoenzymes γ-glutamyltranspeptidase (γ-GT) and aminopeptidase N, and the uptake of cysteine into neurons (Figure 3).

Export of GSH

Release of GSH from brain cells has been reported so far only for astrocytes. These cells release, under unstressed conditions, substantial amounts of GSH and even protect the GSH exported against oxidation by a superoxide dismutase-like factor that is released into the medium. Cultured astrocytes export, within 1 h, about 10% of their intracellular GSH. A variety of transporters have been connected with cellular GSH transport. Several MRP family members are known to be expressed on the mRNA level in cultured astrocytes from mouse or rat brain. For MRP1, the presence of the protein has also been demonstrated for astrocytes *in vitro* and *in vivo*. This transporter mediates about 60% of GSH export from astrocytes. The transporter responsible for the residual 40% of MRP1-independent GSH export has not been identified so far. However, the use of astrocytes from MRP-deficient mice and inhibitor studies suggest that the MRPs 4 and 5, the OATPs 1 and 2, and CFTR do not contribute to the residual 40% GSH export from MRP1-deficient astrocytes.

Figure 3 Metabolic interaction between astrocytes and neurons in glutathione (GSH) metabolism. In astrocytes and neurons, GSH is synthesized from glutamate (Glu), cysteine (Cys), and glycine (Gly) in the consecutive reactions of γGluCys synthetase (1) and GSH synthetase (2). The GSH exported from astrocytes (3) by multidrug-resistance protein 1 or other transporters is substrate for the astrocyte ectoenzyme γ-glutamyltranspeptidase (4). This enzyme transfers the γ-glutamyl (γGlu) moiety from GSH onto an acceptor Y. The dipeptide CysGly generated by the γ-glutamyltranspeptidase reaction is hydrolyzed by aminopeptidase N (5), and the generated amino acids cysteine and glycine are taken up into neurons by the excitatory amino acid carrier 1 (6) and sodium-dependent glycine transporters (7), respectively. In addition, glutamine (Gln) is provided by astrocytes and serves as extracellular precursor for the glutamate required for neuronal GSH synthesis. In astrocytes, glutamate is amidated by glutamine synthetase (8) to glutamine, which is released from astrocytes by glutamine transporters (9). Extracellular glutamine is taken up into neurons (10) and subsequently hydrolyzed by phosphate-activated glutaminase (11). Consequently, all three amino acids that are required for GSH synthesis in neurons are provided as extracellular precursors by neighboring astrocytes.

Extracellular Processing of GSH

Extracellular processing of the GSH exported from astrocytes is a key requirement for the metabolic interaction between astrocytes and neurons in GSH metabolism of the brain. The enzymes involved in this process are the astrocytic γ-GT and a neuronal ectopeptidase (Figure 3).

γ-GT catalyzes the transfer of the γ-glutamyl moiety of GSH onto an acceptor amino acid, as well as the hydrolysis of GSH to glutamate and the dipeptide CysGly. Thus, the astrocytic ectoenzyme γ-GT produces the dipeptide CysGly and consumes the substrate GSH in equimolar concentrations (Figure 3). Inhibition of γ-GT by acivicin totally prevents the astrocyte-induced increase of the GSH content of co-cultured neurons, demonstrating that this enzyme plays a key role in the supply of cysteine for neuronal GSH synthesis.

Both γ-GT activity and γ-GT immunoreactivity have been reported for astrocytes *in vitro* and *in vivo*. The activity of γ-GT in cultured astrocytes is increased after treatment of the cells with lipopolysaccharide, nitric oxide (NO) donors, or thyroid hormone. In addition, a dramatic increase in the specific γ-GT activity of astrocytes is observed after application of tumor necrosis factor-α (TNF-α). This cytokine increases by stimulation of the γ-GT expression the specific activity of γ-GT by a factor of 3–4, and thereby improves the ability of the cells to process extracellular GSH.

The γ-GT-product CysGly is efficiently utilized, in micromolar concentrations, as a precursor for neuronal GSH. Inhibition of the neuronal aminopeptidase N (ApN) prevents the use of extracellular CysGly for GSH synthesis, demonstrating that intact CysGly is not taken up into neurons by a peptide transporter, but is hydrolyzed extracellularly to amino acids (Figure 3). This contrasts with the situation for astrocytes, which take up CysGly via the peptide transporter PepT2 and hydrolyze the dipeptide intracellularly.

Cysteine availability for neuronal GSH synthesis depends on astroglial GSH export and extracellular processing of GSH by γ-GT and ApN (Figure 3). With the release of the glutamate precursor glutamine by astrocytes and the extracellular generation of CysGly, all three constituent amino acids of GSH are provided to neurons by astrocytes (Figure 3). This interaction of astrocytes and neurons in GSH metabolism of the brain has been deduced from data obtained on cultures and co-cultures of brain cells. However, γ-GT-dependent generation of cysteine from GSH by brain cells has been confirmed for brain slices and for the brain, strongly suggesting that astrocytes *in vivo* also supply neurons with cysteine for GSH synthesis.

Uptake of Amino Acids into Neurons

A variety of amino acid transporters have been reported to be expressed in neurons. Most important for GSH metabolism is the uptake of the glutamate precursor glutamine, as well as uptake of cysteine and glycine into neurons (Figure 3). Glutamine is the best extracellular precursor for the glutamate used in neurons for GSH synthesis. In neurons, glutamine is deamidated by phosphate-activated glutaminase, yielding glutamate. Glycine and cysteine are substrates of sodium-dependent transporters. Since cysteine availability limits neuronal GSH synthesis, cysteine uptake into neurons is crucial for GSH metabolism of these cells. Recently it was demonstrated that deficiency of the sodium-dependent excitatory amino acid carrier 1 (EAAC1) leads to neuronal GSH deficiency, oxidative stress, and age-dependent neurodegeneration, suggesting that the cysteine for GSH synthesis in neurons is predominately taken up by EAAC1.

Implications for a Disturbed GSH Metabolism in Parkinson's Disease

Oxidative stress has been connected with physiological processes such as aging and with pathological processes in neurological disorders. A reduction in GSH content of given brain areas has been reported for PD as well as for other neurological disorders, such as schizophrenia, Alzheimer's disease, and epilepsy. Currently it is not known whether the decline in the GSH concentration in pathological brains is due to insufficient synthesis of GSH or to an uncompensated elevated consumption of GSH. Nevertheless, disturbance of the supply of cysteine from astrocytes to neurons could contribute to the lowered GSH levels of diseased brain. The best evidence for a connection between a disturbed GSH metabolism and a neurodegenerative disease has been presented for PD.

PD is characterized by a progressive degeneration of dopaminergic neurons in the substantia nigra pars compacta. The GSH content in this brain region is only 40–50% of that seen in normal controls. This and other biochemical analyses of postmortem tissues provide evidence for oxidative stress in the substantia nigra. On the cellular level, a significant loss of GSH in the surviving nigral neurons has been reported. The decline of GSH levels is an early marker for PD, since a lowered GSH level in the substantia nigra is found in incidental Lewy body disease, a presymptomatic form of PD. Nevertheless, a loss of GSH alone is not sufficient to induce nigrostriatal damage in PD, since chronic infusion of an inhibitor of γGluCys synthetase lowers GSH levels substantially but causes no decline in the number of dopaminergic neurons. Thus, GSH depletion may instead enhance the susceptibility of brain cells to harmful events such as an impairment of mitochondrial respiration. Since astrocytes in the substantia nigra also contain substantial amounts of GSH, a loss in GSH content in this brain area in PD is likely to involve astrocytes, suggesting a compromised antioxidative defense of astrocytes as well as an impairment in their supply of cysteine for neuronal GSH synthesis.

Both dopamine (DA) and TNF-α have been connected with pathological alterations observed during the progression of PD. Since both compounds also modulate GSH metabolism of astrocytes, their presence could strongly affect the cooperation between astrocytes and neurons in GSH metabolism.

Dopamine and GSH

The DA metabolism has been closely linked to an alteration in the GSH metabolism of the brain, since injection of DA in the striatum causes a decline in the GSH content in this brain region. This loss of GSH is most likely the consequence of a chemical reaction of the catecholamine DA with GSH, to form 5-glutathionyl dopamine. This reaction of GSH with DA takes also place in cultured astrocytes. Here, DA has two independent effects on the GSH metabolism, depending on the DA concentration applied. At low micromolar concentrations DA reacts with the GSH released from astrocytes in a superoxide-dependent reaction, whereas at high micromolar concentrations H_2O_2 is generated by DA autoxidation, which is followed by intracellular GPx-catalyzed oxidation of GSH and subsequent GSSG export via MRP1. Both effects of DA on the GSH metabolism of astrocytes could contribute to the observed loss of GSH in the striatum after injection of DA into this brain region. However, since the superoxide-dependent reaction of DA with GSH occurs with DA concentrations as low as 1 μM, this reaction appears to be especially important for pathological situations. The high levels of the DA conjugate of GSH found after injection of DA into the brain demonstrates that DA indeed reacts *in vivo* with GSH. Such processes also occur in pathological conditions, as demonstrated by the elevated amounts of DA conjugates in the substantia nigra of PD patients.

Extracellular GSH conjugates are converted to the corresponding cysteinyl conjugates by γ-GT and aminopeptidases. Cysteinyl conjugates of DA and its derivatives are neurotoxic. Some of these compounds inhibit the activity of complex I of the mitochondrial respiratory chain and also α-ketoacid dehydrogenase complexes. These observations are important for PD, since in the substantia nigra of PD patients a lowered activity of complex I and a reduced immunostaining for the α-ketoglutarate dehydrogenase complex are observed. Consequently, besides the impairment of the supply of the extracellular GSH precursor cysteine to neurons, the reaction of GSH with DA could generate neurotoxic compounds from DA thioethers that interfere with the energy metabolism of neurons. Both effects may contribute to the loss of nigral GSH, to the selective vulnerability of the nigrostriatal system, and to the neuronal degeneration in the substantia nigra of PD patients.

TNF-α and γ-GT

The cytokine TNF-α has been considered to participate in the pathogenesis of PD, since elevated levels of TNF-α in the substantia nigra and an increased TNF-α immunoreactivity in glial cells have been reported for this disease. Source of this TNF-α in the PD brain could be infiltrated peripheral cells as well as microglial cells and astrocytes that release, upon activation, cytokines, including TNF-α. TNF-α strongly induces

γ-GT activity in astrocytes. Thus, the elevated levels of this cytokine in PD may cause the increase in γ-GT activity that is observed for the substantia nigra in PD. Since TNF-α treatment of astrocyte cultures improves the extracellular consumption of the GSH exported by the cells, the elevation of γ-GT activity in the substantia nigra of PD brain may be beneficial for neurons by improving the availability of the extracellular GSH precursor cysteine. Nevertheless, the improved consumption of extracellular GSH could also contribute to the lowered total GSH content that is seen in the substantia nigra in postmortem brain tissue of PD patients.

γ-GT is also involved in the extracellular processing of glutathione-*S* conjugates. Thus, a TNF-α-induced elevated γ-GT activity could contribute to a quicker extracellular breakdown of compounds such as 5-glutathionyl dopamine, which is formed by the reaction of DA with GSH. Indeed, compared with controls, the substantia nigra of PD patients contains significantly higher concentrations of 5-cysteinyl dopamine. Since this compound and its derivatives have been reported to act as neurotoxins, the TNF-α-induced increase in astroglial γ-GT activity could improve the formation of toxic compounds and subsequently foster neuronal cell death.

Conclusions

GSH has essential functions in the intracellular defense of brain cells against oxidative stress. Neurons rely on the supply of GSH precursors, especially of cysteine, from neighboring astrocytes. Thus, astrocytes are highly important for the GSH metabolism and GSH homeostasis in the brain. Export of GSH from astrocytes is the first step in the supply of the GSH precursor cysteine to neurons. The extracellular GSH is processed by γ-GT and ApN to generate extracellular cysteine, which limits the synthesis of GSH in neurons. Alterations of the release rate of GSH from astrocytes, reduced activities of the ectoenzymes, and extracellular reactions of GSH, CysGly, or cysteine with catecholamines such as DA substantially disturb the availability of the GSH precursor cysteine for neurons. Such processes may contribute to a lowered antioxidative defense in neurons, to an increased susceptibility to oxidative stress, and to neuronal death in neurodegenerative diseases such as PD. On the other hand, improvement of the ability of astrocytes to synthesize, export, and/or process extracellular GSH would enhance the supply of GSH precursors to neurons and could be beneficial for the antioxidative defense of neurons in brain.

Neuron-Glia pH Regulation

J W Deitmer, Technische Universität Kaiserslautern, Kaiserslautern, Germany

Introduction

In nerve and glial cells, and in the extracellular spaces of nervous systems, pH changes can be evoked by neuronal activity, neurotransmitters and neuromodulators, active cellular pH regulation, metabolic processes, and secondary transporters carrying acid–base equivalents. In particular, neurotransmission mediated by glutamate, γ-aminobutyric acid (GABA), or glycine as the transmitters is associated with intra- and extracellular pH changes which can be large and rapid, with kinetics not unlike intracellular calcium transients. However, unlike intracellular calcium changes that rise and then recover, pH shifts can occur in two directions, namely in acid and alkaline directions. Indeed, since acid–base fluxes with different time courses may be elicited by a stimulus (e.g., a brief train of action potentials), the pH changes, particularly in the extracellular spaces, may be multiphasic. These multiphasic changes in extracellular pH (pH_e) may in turn affect the electrical and synaptic activity of neurons by modulating voltage- and ligand-gated ion channels and also the transport of metabolic substrates between glial cells and neurons.

The interpretation of acid–base fluxes in tissues is restricted by the methods employed to measure intra- and extracellular pH. The two standard techniques to measure pH in cells and tissues involve pH-sensitive, neutral carrier microelectrodes, which are impaled into larger cells and into extracellular spaces of a tissue and provide an 'online' recording of pH, and fluorescent probes (e.g., 2′,7′-bis (carboxyethyl)-5,6-carboxyfluorescein or seminaphtorhodafluor), which can be loaded into cultured cells or distributed in tissues and measured by fluorescence microscopy. New pH-sensitive fluorescent dyes, such as phosphoethanolamine fluorescein, DHPE, can be used to measure surface pH (i.e., on the extracellular face of the cell membrane). The pH-sensitive microelectrodes are very reliable but relatively slow, and they may cause some damage to the tissue, whereas pH-sensitive dyes are basically noninvasive and fast but more difficult to calibrate, and they bleach, which can produce radicals harmful to cells and tissues.

Rapid pH transients may be signals rather than simply resulting from inadequate homeostatic acid–base regulation. Analogous to the signaling pattern of other ions, such as calcium and potassium, transient shifts of protons and bicarbonate, together with the gas carbon dioxide and carbonic anhydrase activity, may influence or initiate functional processes in the nervous system. These include pH-induced changes in neuronal excitability, synaptic activity, gating of acid-sensing ion channels, the modulation of gap junctions (connexins) forming electrical synapses and the glial syncytium, transport processes in which acid and/or base are involved, and regulation of enzyme activities. Proton signaling in cells and local extracellular domains, particularly the microenvironment of synapses, may contribute to information processing in nervous systems.

Intracellular pH and Buffering

The free H^+ concentration in cells is in the nanomolar range, and the high buffer capacity of cells provides a reservoir of acid equivalents in the millimolar range. In other words, there is a pool of protons in rapid exchange between buffer sites and free solution, with approximately 10^5 protons being buffered for each proton in solution. The buffer capacity β is measured in millimoles of acid or base needed to shift the pH by one unit. The value β in cells is dependent on pH and on the type of buffer present. In experiments on isolated tissues or cells, β is usually measured either in the nominal absence of CO_2/HCO_3^- (the intrinsic buffer capacity, β_i, made up of mostly H^+ binding sites of cellular proteins) or in the presence of CO_2/HCO_3^-, providing the total buffer capacity, β_t. The difference between β_t and β_i gives the Co_2/bicarbonate-dependent buffer capacity β_{CO_2}.

For neurons and glial cells, β_i has been measured to be 10–40 mM, and β_{CO_2}, approximated to be 2.3 times the HCO_3^- concentration, is between 14 mM (corresponding to 6 mM HCO_3^- at a pH_i of 6.8) and 40 mM (corresponding to 17 mM HCO_3 at a pH_i of 7.2) in the presence of 5% CO_2. Hence, β_t is usually between 24 and 80 mM in nerve and glial cells, with the CO_2/HCO_3^- system contributing a large part of the pH buffering in cells and tissues. Its effectiveness, and particularly its kinetics, is dependent on the activity of carbonic anhydrase (CA), which catalyzes the reaction $CO_2 + H_2O \leftrightarrow HCO_3^- + H^+$ and hence speeds up equilibration between CO_2 and H^+/HCO_3^-. In the absence of this enzyme, the reaction is slow, and CA can accelerate the reversible conversion of CO_2 by several 100-fold, depending on the isoform and concentration of the enzyme. Within the vertebrate nervous system, CA is present in all cells, with prominent expression in oligodendrocytes and

astrocytes. Due to the rapid conversion of CO_2 to H^+ and HCO_3^- by CA, glial cells may act as sinks for CO_2, resulting in an increase in H^+ and HCO_3^- and subsequent activation of H^+ and HCO_3^- coupled transporters.

Little is known about the buffer capacity of the extracellular fluid. Nonbicarbonate buffering is believed to occur as a result of the collective contributions of inorganic phosphate and various proteins and amino acids. There is no quantitative measurement for the extracellular intrinsic buffer capacity in mammalian brain; however, in the leech central nervous system, extracellular intrinsic buffer capacity has been estimated to be approximately 5 mM. Given the small volume fraction of the extracellular compartment, the interstitial buffer reservoir per unit volume is low compared to that of the intracellular space. These two factors render the extracellular spaces a volume, in which a given amount of acid/base equivalents results in much larger pH changes than in the cytosol of the cells.

Extracellular pH and Buffering

Baseline Interstitial pH of the Brain

The pH of the brain extracellular fluid (pH_e) is determined primarily by the partial pressure of CO_2 (PCO_2) and the bicarbonate concentration. The contribution of phosphate and titratable groups on proteins to the baseline pH_e is negligible. pH_e over the long term is thus governed by the Henderson–Hasselbach equation:

$$pH = pK_a + \log[HCO_3^-]/s\ PCO_2 \qquad [1]$$

where K_a refers to the apparent dissociation constant of carbonic acid, s is the solubility coefficient of CO_2 expressed in mM/torr, and the PCO_2 is expressed in torr.

The interstitial fluid of the brain is typically more acidic than the blood and cerebral spinal fluid. A variety of mammalian studies have reported a brain pH_e ranging between 7.2 and 7.3. Given a brain PCO_2 of 46 torr, the $[HCO_3^-]_e$ is approximately 22 mM at a pH_e of 7.30. The origin of the low pH_e of the brain may be the metabolic production of CO_2, as well as the process of transporter-mediated acid extrusion from cells.

It is not widely appreciated that the extracellular fluid of a brain slice preparation is typically more acidic than both the bath solution and the corresponding interstitial fluid *in vivo*. pH_e in brain slices is often as low as 7.10–7.20. The extracellular acidosis measured in rat hippocampal slices has been attributed to an elevation of the PCO_2 and lack of non-CO_2/HCO_3^- buffers in the interstitial space. Given a typical bath PCO_2 of 40 torr (i.e., 5% CO_2), the elevation above this level in the interstitial space can be 10–20 torr for slices in an interface chamber and greater than 20 torr in a submersion-style chamber. CO_2 is an end product of aerobic respiration. Its retention in a brain slice can be explained by the absence of blood flow. Egress of the gas from the slice is therefore limited by diffusion, which must occur across both the thickness of the tissue and the unstirred fluid layer at its surface.

Buffering Properties of the Brain Interstitial Fluid

The 'buffering power' or 'buffer capacity' of an aqueous solution (β) is classically expressed as the ratio of the concentration of added strong base (ΔB), or strong acid (ΔA), to the consequent ΔpH. Thus, β is given in units of concentration. For a solution in which only HCO_3^- and CO_2 serve as buffer, and in which PCO_2 is essentially constant (via equilibration with a large, fixed CO_2 source), and the system is at equilibrium, the buffer capacity can be approximated by $\beta = 2.3 \times [HCO_3^-]$. Thus, assuming that PCO_2 is clamped over the long term by the systemic circulation and pulmonary ventilation, the extracellular buffer capacity of the brain (β_e) would be anticipated to be 50–60 mM against an acid or base load. In the face of a CO_2 challenge, however, the interstitial buffering system would have little ability to mitigate the resulting pH change, given the low concentration of phosphate and titratable groups on proteins. A doubling of the PCO_2 would be expected to cause a decrease in pH_e of approximately 0.30, with little change in $[HCO_3^-]_e$. This accounts for the significant extracellular acidosis in a brain slice, and it stands in marked contrast to the buffering properties of intracellular fluid. Within cells, a doubling of PCO_2 would cause a much smaller change in cytosolic pH and a measurable increase in the cytoplasmic $[HCO_3^-]$ due to the sizable intrinsic buffer capacity that is provided by intracellular proteins and phosphate.

Buffer capacity is typically considered for a system at equilibrium, with fixed PCO_2. These assumptions may not be valid over small segments of time, when the brain interstitial fluid may be subject to rapid acid or base loads. In the short term, a disequilibrium can arise due to the slow kinetics of the reversible reactions,

$$CO_2 + H_2O \underset{k-1}{\overset{k_1}{\leftrightarrow}} H_2CO_3 \leftrightarrow HCO_3^- + H^+ \qquad [2]$$

In the face of a rapid base load, as occurs during neural activity, the time for this buffer system to obtain equilibrium is on the order of 10–20 s (varying with temperature). The slow settling is due entirely to the low rate constants for the hydration of CO_2 (k_1) and the dehydration of H_2CO_3 (k_{-1}).

The enzyme CA can speed this process by the reversible, direct formation of HCO_3^- from CO_2 and water. Three extracellular isoforms of CA have been associated with the brain interstitial space: CA IV, CA XIV, and CA XV. Several studies indicate that buffering of this compartment is accelerated by these enzymes, with most of this catalysis attributable to CA IV and CA XIV. The localization of these CA isoforms may be both cell and region dependent. In the hippocampus and cortex, CA IV appears to be the principal isoform on astrocytes, whereas CA XIV is confined to neuronal surfaces. In contrast, CA XIV appears to be the glial isoform in the retina and is absent from the surface membrane of retinal neurons.

Although it is clear that CA speeds extracellular buffering in brain slices and *in vivo*, the total interstitial CA activity is apparently insufficient to maintain equilibrium when faced with a rapid alkaline load. Moreover, studies with CO_2 microelectrodes suggest that the PCO_2 does not remain fixed during sustained synchronous neural activity. Consequently, in some circumstances, interstitial buffering can be expected to be considerably less than the theoretical equilibrium value, despite the presence of extracellular CA.

Disequilibrium during a rapid acid or base challenge implies that the effective buffer capacity of the interstitial fluid will exhibit a time dependence. Depending on the acceleration coefficient (a) of the hydration–dehydration reactions, the time required to attain equilibrium can range from milliseconds to seconds. In hippocampal slices, a CA inhibitor had a limited effect on the rate of onset and recovery from interstitial alkalization. These experiments suggested that endogenous extracellular CA activity accelerated the buffering reactions less than threefold within the general interstitial space. With such limited acceleration, the full equilibrium buffer capacity of the interstitial fluid would not be realized for several seconds. Accordingly, within the time frame of synaptic events, the effective buffer capacity would be extremely low.

Buffer disequilibrium may have functional consequences in that a small acid or base source could have a relatively large effect on pH_e, provided it occurred with sufficient speed. Limited buffering of this sort may be relevant to a number of studies in the retina. Evidence suggests that suppression of presynaptic calcium currents within a few milliseconds of transmitter release is due to a decrease in subsynaptic pH_e, mediated by the release of the acidic contents of synaptic vesicles. Compared with Ca^{2+}channels, *N*-methyl-D-aspartate (NMDA) receptors are more sensitive to pH_e changes in the physiological range.

It may be speculated that the low effective buffer capacity of the extracellular fluid, coupled with the rapid transmembrane acid–base fluxes during neural activity, generated the need for pH_e regulatory mechanisms activated by neural activity. Thus, the evolution of glial transport systems that can respond to changes in membrane potential and quickly 'muffle' transient extracellular alkaline shifts may have been fueled by the time-dependent constraints on extracellular buffering.

pH Regulation in Neurons

Pioneering investigations of intracellular pH (pH_i) regulation in eukaryotic cells were performed on large invertebrate neurons. Studies of the squid giant axon and the nerve cell bodies of the snail established many of the principles, protocols, and norms of analysis subsequently utilized to study pH_i regulation in vertebrate cells. It has been established that for most cells, the membrane potential is considerably more negative than the equilibrium potential for H^+, which is typically in the range of 0 to −20 mV. Thus, given a transmembrane pathway, H^+ will enter a cell and acidify the cytosol. Combining the Nernst and Henderson–Hasselbach equations, it is readily shown that other charged acid or base species (e.g., OH^-, HCO_3^-, and NH_4^+) have the same equilibrium potential as H^+ and, given a flux pathway, will similarly acidify the cytosol. Metabolic processes, such as the aerobic generation of CO_2, may also contribute to acidification. Given a typical membrane potential of −50 to −70 mV, electrochemical equilibrium for a charged acid–base species would occur at a pH_i of approximately 6.4. Thus, to maintain a typical pH_i near 7.0–7.2 requires the continuous, energy-dependent, extrusion of acid.

In most invertebrate and vertebrate nerve cells, the net extrusion of acid is accomplished via secondary active transport, wherein the efflux of H^+ or the influx of HCO_3^- is coupled to an Na^+ influx, utilizing energy stored in the transmembrane Na^+ gradient. In many invertebrate and vertebrate neurons, acid extrusion is accomplished via an Na^+–H^+ exchanger and a Na^+-dependent HCO_3^- cotransporter. In the squid giant axon, snail giant neurons, and leech Retzius neurons, HCO_3^--dependent acid extrusion is mediated by an electroneutral, Na^+-driven, Cl^-–HCO_3^- exchanger (Figure 1).

Cloning and characterization of the Na^+-H^+ exchangers, as well as various Na^+-linked HCO_3^- transporters has been carried out for the mammalian forms of these carriers. The mammalian Na^+–H^+ exchangers comprise the SLC9A gene family, consisting of at least eight functional genes. These include five plasma membrane transporters, SLC9A1–SLC9A5 in human (or SLC9a1–SLC9a5 in mouse), also designated by their respective protein names NHE1–NHE5.

Figure 1 Major membrane acid–base carriers involved in cytosolic pH regulation in neurons (left) and in glial cells (right).

The most extensively characterized is NHE1. This ubiquitous transporter typically exhibits sensitivity to amiloride and its derivatives, and it is considered to serve a housekeeping role in maintaining pH_i. Although NHE1–NHE5 share a 1 Na^+:1 H^+ electroneutral stoichiometry, they exhibit differences in pharmacological sensitivities and in kinetics. All five of these Na^+–H^+ exchangers are expressed in the brain.

The Na^+-coupled HCO_3^- transporters are part of the human SLC4A gene family (SLC4a in mouse). Most abundantly expressed in brain are SLC4A4, SLC4A7, SLC4A8, and SLC4A10. The respective proteins are commonly designated as NBCe1 (from SLC4A4), an electrogenic Na^+–HCO_3^- cotransporter with typical Na^+:HCO_3^- stoichiometry of 1:2 when acting as an acid extruder; NBCn1 (from SLC4A7), an electroneutral Na^+–HCO_3^- cotransporter; NDCBE (from SLC4A8), an Na^+-driven, Cl^-–HCO_3^- exchanger; and NCBE (from SLCA10), an electroneutral Na^+–HCO_3^- cotransporter, with a possible dependence on Cl^-.

Acid transport has been physiologically characterized in a variety of vertebrate neurons. Typically described is a Na^+–H^+ exchanger and one or more Na^+-coupled HCO_3^- transporters. Apart from a few studies, the molecular identification of Na^+–H^+ exchangers and Na^+-coupled HCO_3^- transporters has not been correlated with the various physiological descriptions of acid extrusion in particular neurons. In this respect, the cells of the hippocampus are the best characterized mammalian neurons. Early physiological studies indicated that hippocampal neurons utilize an Na^+–H^+ exchanger that is insensitive to amiloride and its derivatives, as well as a Na^+-driven, Cl^-–HCO_3^- exchanger. Staining with polyclonal antibodies indicated that these cells also express the electrogenic Na^+–HCO_3^- cotransporter NBCe1. These observations suggest that mammalian neurons can make use of a complement of Na^+-linked HCO_3^- transporters. Diversity in the utilization of Na^+–H^+ exchangers in particular neurons may also be expected. For example, the CO_2-responsive or 'chemosensitive' neurons in the medulla appear to recover from acid loads mainly via an Na^+–H^+ exchanger that appears to be the NHE3 isoform.

In addition to mechanisms that extrude acid, neurons and other cells express transporters that import acid and lower pH_i. An 'acid loader' may be used to recover from an increase in pH_i, or it may function concomitantly with acid extrusion to effect tighter control over steady-state pH_i. Acid loading is commonly attributed to passive Cl^-–HCO_3^- exchangers. Anion exchangers of this class belong to the SLC4A gene family comprising the genes SLC4A1, SLC4A2, and SLC4A3, corresponding to anion exchange (AE) proteins AE1, AE2, and AE3, respectively. Both AE2 and AE3 are found in brain, and expression appears to increase with maturation. The AE proteins are transporters that link pH with Cl^- regulation in neurons, which may be significant for synaptic inhibition mediated by $GABA_A$ receptors. Prominent intracellular alkalinization may activate Cl^- influx via Cl^-–HCO_3^- exchange and thus shift the Cl^- equilibrium potential, and the inhibitory reversal potential, to more positive values; this may lead to a membrane depolarization, and hence excitation, following activation of $GABA_A$ receptors.

pH Regulation in Glial Cells

Glial cells have been ascribed a special role for acid–base regulation in the brain, particularly the extracellular spaces. The major pH regulating systems in glial cells are the sodium–bicarbonate cotransporter (NBC) and the sodium–hydrogen exchanger (NHE). The NHE extrudes H^+ out of the cell at the expense of Na^+ influx, and it is electroneutral and operates in the same way as described for neurons and many other cell types. In some glial cells, such as the leech giant glial cell, NHE has a much smaller impact on intracellular pH regulation due to the dominant presence of NBC in these cells. In vertebrate glial cells, however, NHE and NBC both contribute significantly to cellular pH regulation (Figure 1).

NBC has been described in nearly all types of macroglial cells, including astrocytes, oligodendrocytes, Schwann cells, and retinal Müller glial cells. NBC of most glial cells is electrogenic and cotransports one Na^+ with two HCO_3^-. The reversal potential of the NBC lies near the membrane resting

potential and can be adjusted to the actual membrane potential by driving NBC in the inward or outward direction. Activation of NBC in the inward direction results in an intracellular alkalinization and an increase in Na_i^+ and also a membrane outward current leading to hyperpolarization of the membrane, whereas activation of NBC in the outward direction acidifies the cytosol, drives Na^+ against a steep gradient out of the cell, and depolarizes the cell membrane. In addition, with the bicarbonate carried out of the cells, buffering capacity is added to the extracellular spaces. In the Müller cells of the retina, NBC is localized in the end foot processes and has a stoichiometry of 3 HCO_3^-:1 Na^+, specializations that suggest a role in the transport of CO_2/HCO_3^- from the retina to the vitreous humor.

The direction in which NBC operates across the plasma membrane depends on the pH_i and pH_o (and the $[HCO_3^-]_{i/o}$), the $[Na^+]_i$, and the membrane potential. This is also reflected by the pH_i changes induced by slow voltage steps in voltage-clamped leech giant neuropil glial cells. De- and hyperpolarizing voltage steps resulted in an intraglial alkalinization and acidification, respectively, providing an extrapolated change of 1 pH unit/110 mV membrane potential change, supporting a stoichiometry of 2 HCO_3^-:1 Na^+. Expressed in *Xenopus* oocytes, NBC imposed a membrane current, which was voltage and pH dependent (Figure 2(a)). The cotransporter appears to have a remarkably high affinity for HCO_3^- since it was found to be active even in the nominal absence of CO_2/HCO_3^-, when the extracellular bicarbonate concentration is usually less than 0.3 mM corresponding to air–CO_2. Expressed in frog oocytes, NBC significantly contributes to the apparent cytosolic buffer capacity, which becomes voltage dependent, and may enhance the efficacy of other acid–base transport systems. NBC thus contributed 0.7 mM mV^{-1} apparent buffer capacity to the cytosol (Figure 2(b)). Binding of CA to NBC renders the transport activity of NBC significantly more efficient by forming a 'transport metabolon' with CA, as shown when expressed in *Xenopus* oocytes. *In situ* hybridization revealed NBC mRNA expression throughout the rat central nervous system, with particularly high levels in the olfactory bulb, the hippocampus dentate gyrus, and the cerebellum.

Figure 2 Functional characteristics of the electrogenic sodium–bicarbonate cotransporter (NBC) which contribute to cytosolic pH regulation mainly in glial cells. (a) Current–voltage relationship of the NBCe1 when expressed in *Xenopus* oocytes at different pH in the external solution. (b) Voltage dependence of the buffer capacity of native oocytes (open circles) and oocytes expressing NBCe1 (solid circles), revealing that the buffering increases by 0.7 mM/mV depolarization due to the activity of NBCe1. (b) Adapted from Becker HM and Deitmer JW (2004) Voltage dependence of H^+ buffering mediated by sodium–bicarbonate cotransport expressed in *Xenopus* oocytes. *Journal of Biological Chemistry* 279: 28057–28062.

Changes in pH Evoked by Neuronal Activity

Electrical activity can give rise to rapid, localized changes in the pH of the brain intracellular and extracellular fluid. These pH shifts are not uniform but, rather, can occur with different magnitude, direction, and time course in the neuronal, glial, and interstitial compartments. These distinct compartmental pH responses are considered in turn.

Activity-Dependent Shifts in Neuronal Intracellular pH

Depolarizing stimuli have been observed to cause a decrease in pH_i in several kinds of neurons. The earliest studies of neuronal pH_i responses were performed on invertebrate cells. Repetitive firing was associated with cytosolic acidification in molluscan and leech neurons, and depolarizing receptor potentials were found to acidify barnacle muscle. In snail neurons, depolarization elicited an acidification that

was Ca^{2+} dependent, and injection of Ca^{2+} into the cytosol was found to decrease pH_i as well, an effect partially explained by mitochondrial Ca^{2+}–H^+ exchange. Later experiments on snail neurons indicated that a large component of the cytosolic acidification was due to the Ca^{2+}–H^+ exchange property of the plasmalemmal Ca^{2+}-ATPase.

Similar Ca^{2+}-dependent acidification of neuronal cytosol has been observed in a wide variety of vertebrate neurons in which a voltage- or ligand-gated Ca^{2+} conductance was activated. Although most of these changes have been relatively slow, fast dendritic acidifications have been described in cerebellar Purkinje cells. Activation of a plasmalemmal Ca^{2+}-ATPase has been suggested as a basis for many of these observations, but other mechanisms may be involved as well. A metabolic source of acid is an additional possibility that has been suggested by some studies.

Activity-Dependent Shifts in Glial Intracellular pH

A rapid alkalosis has been observed in glial cells following adjacent neural activity. This response was observed *in vivo* in astrocytes of rat cortex and was also noted in the giant glial cells of the leech. Its presence in these unrelated species indicates that the underlying mechanism has been well conserved across evolution. Numerous studies suggest that the basis for this response is activation of an electrogenic Na^+–HCO_3^- cotransporter caused by depolarization of the glial cell membrane, as was first described in giant glial cells of the leech. This glial mechanism and its role in the regulation of extracellular pH are discussed in more detail later.

Some neurotransmitters, such as glutamate, can induce an intracellular acidosis via the glutamate uptake carrier, which is not only driven by the inward gradient of Na^+ but also takes up one H^+ per cycle. Intraglial pH decreases of several tens of pH units have been reported during exposure to glutamate or D-aspartate. As glutamate is converted to glutamine in glial cells, a reaction catalyzed by the pH-sensitive glutamine synthetase, this may in turn stimulate glutamine export from glial cells using neutral amino acid transporters which are coupled to H^+, such as SNAT3 and SNAT5 (human genes SLC38A3 and SLC38A5, respectively). Hence, glutamine uptake and glutamine export by glial cells, as described by the glutamate–glutamine shuttle hypothesis, can cause intraglial acidosis.

Activity-Dependent Shifts of Interstitial pH

Changes in interstitial pH that arise from neural activity vary greatly among the regions of the central nervous system. The most widely observed pH_e change consists of an interstitial alkaline shift at the onset of neural activity, followed by a more prolonged acidosis. This alkaline–acid response occurs in the hippocampus, cortex, cerebellum, and lateral geniculate nucleus (**Figure 3(a)**). In the spinal cord, activity elicited by stimulation of the dorsal root was found to produce a similar early alkalosis in neonatal preparations. At approximately 1 week of age, however, only an early acidification was present in the spinal cord (**Figure 3(b)**). A developmental shift from initial alkaline to initial acid transient has also been described in the dentate gyrus of rat hippocampal slices.

The early activity-dependent extracellular alkaline shifts studied in hippocampal slices arise from two distinct mechanisms. One component of the alkalosis has been attributed to the efflux of HCO_3^- across $GABA_A$ anion channels, a feature originally described for these receptors in crayfish muscle. This alkalosis requires extracellular carbonic anhydrase and, accordingly, is blocked by inhibitors of this enzyme. The second form of alkalosis is independent of HCO_3^-, mitigated by extracellular carbonic anhydrase, and becomes markedly amplified when this enzyme is blocked. On the basis of this observed amplification, the underlying mechanism has been referred to as a 'proton sink,' in distinction from the aforementioned 'bicarbonate source' that was attributed to $GABA_A$ receptors. This proton sink was found to be largely dependent on the presence of external Ca^{2+}. It was therefore suggested to arise from the Ca^{2+}–H^+ exchange property of the plasmalemmal Ca^{2+}-ATPase. Thus, entry of Ca^{2+}, by activating this transporter, would generate an extracellular alkalosis accompanied by a cytoplasmic acidification. However, apart from its

Figure 3 Variation in activity-dependent interstitial pH shifts. (a) Typical alkaline–acid response in rat hippocampal area CA1, elicited by repetitive electrical simulation of the Schaffer collateral fibers. (b) Typical rapid acid response in the dorsal or ventral horn of adult rat spinal cord during repetitive electrical stimulation of the dorsal root. Note that acid responses are upward.

dependence on extracellular Ca^{2+}, there is no additional compelling evidence to support this hypothesis.

Upon synaptic activation of hippocampal pyramidal neurons, inhibition of extracellular CA with benzolamide caused an amplification of the bicarbonate-independent alkaline transient and a simultaneous prolongation of the NMDA receptor-mediated component of the postsynaptic current. This suggested that the amplified pH_e changes had sufficient amplitude and speed to relieve the extracellular proton block of these receptors during the synaptic response. Similarly, benzolamide also increased epileptiform activity. It has been confirmed that these alkaline transients arise within tens of milliseconds, and evidence indicates that they can augment NMDA receptor activity even without amplification by benzolamide.

Other kinds of extracellular alkaline shifts have been described in retinal preparations in response to light. In frog retina, a light-evoked alkalosis was amplified by CA inhibitors and was suggested to arise from a downturn of ongoing metabolic acidosis, consistent with the light-evoked decrease of photoreceptor glycolysis. In the bee retina, light stimulation of the photoreceptors caused an increase in interstitial pH that was accompanied by an acidification in the photoreceptors and the glial cells. This insect response was likely due to enhanced uptake of ammonium into the cells by a chloride-dependent transporter.

The interstitial acid shifts that arise in response to neural activity are categorized as either rapid, short latency responses or slow, persistent acidifications. In rats, stimulation of the dorsal roots elicited a rapid acid shift in spinal cord. The absence of this acidification in x-irradiated pups was correlated with diminished astrocyte proliferation. In addition, the acid response was inhibited by stilbene derivatives such as 4,4-diisothiocyanostilbene-2,2′-disulfonic acid (DIDS) and 4-acetoamido-4′-isothiocyanostilbene-2,2′-disulfonic acid (SITS). These observations are consistent with an extracellular acidosis arising from glial electrogenic Na^+–HCO_3^- cotransport.

Late, slow acid shifts have been associated with metabolic activity. In cerebellum, activity-dependent acidosis was attenuated by fluoride, a glycolytic inhibitor. In rat hippocampal slices, the late acid shift was entirely attributed to elevation of tissue PCO_2, consistent with a transient increase in aerobic respiration.

Functional Aspects of H^+ Homeostasis and H^+ Signaling

The intracellular, cytosolic, pH (pH_i) of neurons and glial cells is actively maintained usually between 7.0 and 7.4, which is similar to the extracellular pH value (pH_o) in nervous tissue (7.1–7.3). Thus, 'resting' intra- and extracellular pH ranges between 40 and 100 nM free H^+ concentration. This means that there is often only a small chemical gradient of H^+ concentration, if any, across the cell membranes of resting neurons and glial cells. The main driving force of H^+ from the outside to the inside of a cell is the negative membrane potential. Any conductance of the cell membrane for H^+ and/or HCO_3^- at cell membrane potentials negative to −30 mV would result in a gain of acid or loss of base and would hence lead to an intracellular acidification.

In isolated cells and tissues, pH_i depends on whether the preparation is bathed in a solution buffered with a standard buffer, such as 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), or with CO_2 and HCO_3^-. In general, the steady-state pH_i is lower in CO_2–HCO_3^- buffered saline by 0.1–0.4 pH units. Neurons are the main consumers of ATP and, therefore, the main producers of CO_2. The link between CO_2 production and pH is the CO_2–HCO_3 buffer system, which plays a major role in the maintenance of pH both intra- and extracellularly. In order to understand the mechanisms of the acid and alkaline transients, it is often necessary to monitor pH in all three compartments of the tissue: neurons, glial cells, and the extracellular spaces. If there is a predominant flux of acid or base in one direction, then extracellular pH shifts will be approximate mirror images of intracellular pH changes. Net acid flux across glial and neuronal membranes may occur in opposite directions in different cells, however. Thus, during neural activity, cytosolic alkalization of glial cells, cytosolic acidification of neurons, and interstitial alkalization may occur simultaneously.

The proton equilibrium potential thus ranges between 0 and −30 mV in most animal cells. At a negative cell membrane potential of brain cells between −40 and −90 mV, the total H^+ gradient is 10–90 mV. Acid must be actively extruded by the cells against this electrochemical gradient, which requires energy. In most cells, this energy is provided by the Na^+ gradient, which drives NHE and other acid–base transport systems. The different isoforms of the NHE are the most prominent and ubiquitous transport proteins for acid extrusion in animal cells, and their malfunction is associated with a variety of diseases. NHE helps the cytoplasm to maintain a more alkaline pH than the acid–base electrochemical equilibrium across the plasma membrane, which is 6.4–6.8 in most animal cells. When cells become alkaline beyond their steady-state pH_i, base equivalents are extruded mainly by the Cl^-–HCO_3^- exchanger.

Active maintenance of the cytosolic pH is required to allow many enzymatic processes in cells to operate

at a normal rate. Most of these processes and reactions there are optimum at a pH of approximately 7.0 or higher. Changes in pH_i can therefore critically modulate molecular processes and cellular activity. Although the proton gradient across animal plasma membranes is not very large, and amounts to only approximately half the size of the Na^+ gradient, it is a significant source of energy that can be used to fuel secondary transport. Thus, membrane acid–base transporters can be fueled by the H^+ gradient, and they may also be modulated on the protein level by intra- and/or extracellular pH changes. In addition, there are a variety of voltage- and ligand-gated ion channels which are pH sensitive. Protons can either block these channels, as is the case for NMDA-sensitive, ionotropic glutamate receptors, or they may modulate gating, inactivation and/or deactivation, as found for some voltage-dependent channels. Changes in intra and extracellular pH can therefore modulate the excitability of neurons and can do so with the temporal dynamics of these pH changes. Thus, H^+ may acquire the function of signaling molecules both in the cytosol and in the extracellular spaces.

There are a number of pathological processes related to the impairment or the failure of acid–base regulation in the brain; in particular, hypoxia, anoxia, glucose deprivation, and conditions associated with ischemia can severely interfere with the normal acid–base homeostasis in the brain as in other tissues. Alkalosis in nervous tissue can contribute to hyperexcitability of neurons and hence ignite epileptiform activity in the brain. Oxidative stress decreases the activity of NHE and hence the intracellular pH as shown in rat solitary complex neurons. Hyperosmotic changes in the brain, which lead to shrinkage of cells, can lead to intracellular alkalinization due to activation of NHE. Changes in cellular and tissue pH are associated with hyperammonemia, which results from liver failure or urea cycle enzyme deficiencies, leading to brain edema and hepatic encephalopathy. The main pathways for acid-linked Ca^{2+} influx are reversed Na^+–Ca^{2+} exchange following increased intracellular Na^+ levels and Ca^{2+}-permeable acid-sensing ion channels (ASICs). Indeed, blocking ASICs or deleting the ASIC1a gene protect the brain from ischemic injury, suggesting that ASICs are responsible for glutamate-independent, acidosis-mediated brain injury during ischemia. Thus, acidosis can injure the brain via membrane receptor-mediated mechanisms with subsequent Ca^{2+} overload. This appears to be a major, glutamate-independent, pathological process underlying ischemic brain damage, directly mediated by extracellular acid shifts.

However, extracellular acidosis has also been associated with neuroprotective mechanisms (i.e., contributing to the survival of neurons during ischemia) by tuning down excitatory voltage- and ligand-gated membrane channels, such as Na^+ and Ca^{2+} channels, NMDA-sensitive glutamate channels, and other ionotropic receptor channels. The protective and harmful effects of long-lasting acidosis or alkalosis in nervous tissue also depend on the origin and context of these pH changes.

Summary

pH regulation by neurons and glial cells involves a variety of membrane acid–base carriers, including sodium–hydrogen exchange, sodium–bicarbonate cotransport, and sodium-dependent and sodium-independent chloride–bicarbonate exchange. Transport of acid–base equivalents across the plasma membranes of neurons and glial cells also results in pH changes in the extracellular spaces. Cytosolic and extracellular buffer capacity and the activity of carbonic anhydrase contribute to pH changes. pH changes can be elicited by neuronal activity, neurotransmitters and neuromodulators, metabolic processes, active cellular pH regulation, and secondary transporters carrying acid–base equivalents. Rapid pH transients may be signals rather than simply resulting from inadequate homeostatic acid–base regulation. Proton signaling in cells and local extracellular domains, particularly in the microenvironment of synapses, may contribute to information processing in nervous systems and to pathological, as well as neuroprotective mechanisms in nervous tissue.

Neuropathic Pain

J Borzan and R A Meyer, The Johns Hopkins University, Baltimore, MD, USA

© 2009 Elsevier Ltd. All rights reserved.

Neuropathic pain is a chronic pain condition that is caused by pathology in the nervous system. The pathology can be due to diseases that involve the nervous system (e.g., AIDS and diabetes), to dysfunction of the nervous system (e.g., following stroke), or to a traumatic injury of the nervous system. The pathology can involve the peripheral nervous system, the central nervous system, or both. Clinical characteristics of neuropathic pain depend on the type and the progression of disease but include burning pain, dysesthesias, pain to light stroking of the skin, sensory deficits, and widespread pain.

Etiology of Neuropathic Pain

Nerve Trauma

Nerve trauma can occur in the peripheral or the central nervous system. Peripheral lesions can be caused by nerve compression, limb amputation, or traumatic injuries and commonly result in dysesthesias, paresthesias, or chronic neuropathic pain. After limb amputation, painful sensations may be perceived as originating in the missing part of the body. Unfortunately, this phantom pain is experienced by more than half of amputees.

Pain of central origin may occur following spinal cord or brain trauma due to injury, compression (by tumors or cysts), or hemorrhagic or ischemic stroke. Not all central nervous system traumas result in central pain, but a necessary condition is damage to the spinothalamic tract. Moreover, it appears that spinal cord injury induces pain only if the gray matter is damaged.

A number of animal models of nerve trauma have been developed. The majority of the peripheral nerve injury models involve a lesion of all or part of the sciatic nerve system (Figure 1(a)). A complete sciatic nerve axotomy at the midthigh level leads to the degeneration of the nerve distal to the cut. The animals display autotomy (biting of the injured paw) which some interpret as a sign of pain but others argue is merely an attempt to remove the paw as a 'foreign object' because of the loss of sensation in that paw. In models of partial axotomy, the animals do not display self-injurious behavior but, rather, exhibit guarding behavior and signs of mechanical, heat, and cold hyperalgesia similar to the frequently observed clinical symptoms. Each partial nerve injury model has inherent advantages and disadvantages. For example, some models are easier to produce than others, some models lead to more reproducible injuries than others, and some models allow the relative roles of injured and uninjured afferents to be easily investigated. Animal models of central nervous system neuropathies involve contusion, compression, or partial transection of the spinal cord; electrical or chemical lesions of the spinal cord or various brain regions; and cerebral or spinal cord ischemia by occluding a major blood vessel.

A variety of behavioral assays are used to investigate the pain and hyperalgesia in these models. Behavioral tests measuring the threshold, latency, or duration of a reflexive response to mechanical, heat, or cold stimuli are used most frequently (Figures 1(b) and 1(c)). Several escape/avoidance conditioning paradigms have also been developed to elucidate changes in supraspinal processing due to nerve injury. A more challenging task is measuring spontaneous pain behavior in animals. No ideal model exists, but researchers typically record the number or duration of foot lifts, guarding behavior, and degrees of autotomy.

Disease Induced

Various disease states can lead to the development of neuropathic pain. Diabetes can often lead to a painful peripheral neuropathy. Diabetic neuropathy is a length-dependent neuropathy because it most commonly affects the extremities and progresses from more distal to proximal levels. High intracellular glucose levels can lead to pathological changes, such as vasoconstriction endothelial hyperplasia, and increased oxidative stress. These changes in turn promote neuronal dysfunction through decreased nerve blood flow and consequent neural hypoxia. Chronic alcohol abuse may also result in a peripheral neuropathy in the lower extremities due to direct degenerative effects on both myelinated and unmyelinated nerve fibers, disruption of axonal transport, and enhancement of glutamate neurotoxicity in neurons. Animal models of diabetes include genetic mutations such as in obese, leptin-deficient ob/ob mice or drug-induced diabetes produced by injection of streptozotocin.

Painful neuropathies can also develop as a result of viral infections. For example, after an acute infection of chicken pox, the neurotropic human herpes virus, varicella-zoster, remains dormant in the dorsal sensory or cranial nerve ganglia. A localized reoccurrence of the varicella-zoster virus (herpes zoster or shingles) can occur particularly when the immune

Figure 1 Animal models of neuropathic pain. (a) Peripheral nerve injury models include ligation of one or more spinal nerves (SNL), partial ligation of the sciatic nerve (PSL), loose ligation of the sciatic nerve using chromic gut sutures referred to as the chronic constriction injury (CCI), and ligation of common peroneal and tibial nerves to spare the sural nerve (SNI). (b, c) For each of these nerve injuries, the animals exhibit behavioral signs of hyperalgesia. (b) Animals develop a decreased paw withdrawal threshold to mechanical stimulation of the foot with von Frey monofilaments (mechanical hyperalgesia). (c) The latency to withdraw the paw from a heat stimulus is significantly shorter on the injured paw compared to the contralateral paw after nerve injury (heat hyperalgesia). Reproduced from Campbell JN and Meyer RA (2006) Mechanisms of neuropathic pain. *Neuron* 52(1): 72–92, with permission from Elsevier.

system is suppressed, as is common in older adults or individuals with other immunosuppressive conditions (e.g., Hodgkin's disease or HIV). This is most likely to occur in the dermatomes that had been most severely affected by the primary disease. The acute rash and pain are restricted to the area of one or several dermatomes and most commonly occur in the chest and trunk. After the acute viral infection subsides, approximately one-third of patients develop a chronic pain condition known as postherpetic neuralgia (PHN). The pain is described as burning, tingling, deep aching, itching, or stabbing. The pain in a subset of PHN patients is thought to be due to 'irritable nociceptors.' These patients report severe mechanical hyperalgesia but have minimal sensory loss in the painful area and their responses to thermal stimulation remain normal. Lidocaine gel or patches can be effective in providing at least temporary pain relief. Frequent topical application of capsaicin cream is moderately effective in reducing pain if the patients can tolerate the initial burning sensation capsaicin causes. Varicella-zoster virus is specific to humans, so animal models of PHN had to be developed using a different virus from the same family, namely herpes simplex virus type I. Animals develop lesions in the injected skin and show signs of hyperalgesia within 5 days after inoculation.

HIV infection commonly leads to the development of neuropathy either by immune system and macrophage-mediated axonal degeneration or by toxic effects of antiviral treatment medications on mitochondria. Similar to diabetic neuropathy and amyloidosis, HIV-induced neuropathy characteristically progresses by first affecting the most distal portions of axons. Activation of proinflammatory mediators such as tumor necrosis factor-α (TNF-α), interleukin (IL)-6, and nitric oxide in the dorsal root ganglia (DRG) is thought to contribute to the axonal damage and to the development of a painful neuropathy frequently characterized by bilateral painful paresthesias, dysesthesias, or numbness. Because the most common cause of sensory neuropathy in HIV patients stems from antiretroviral drugs, animal models of HIV-related sensory neuropathy utilize these drugs (e.g., didanosine, 2′,3′-dideoxycytidine) to study the mechanisms underlying the observed hyperalgesia and neuronal degeneration.

Autoimmune diseases such as Guillaine–Barré syndrome and multiple sclerosis (MS) cause demyelination and sensory deficits including pain. Approximately

80% of Guillaine–Barré and 50% of MS patients report pain. The etiology of MS is not well-known, although it is believed that the onset of the disease involves pathology of the immune system, particularly disruption of myelin proteins. Guillaine–Barré syndrome has several subtypes based on the suggested etiology of the disease, namely acute inflammatory demyelinating polyradiculoneuropathy, acute motor axonal neuropathy, and acute motor and sensory axonal neuropathy. T cell disruption of myelin proteins is indicative of the first subtype, whereas antibodies to gangliosides are thought to promote demyelination and injury in the other two subtypes. Bacteria (e.g., *Campylobacter jejuni*) and viruses have also been implicated as disease triggers for Guillaine–Barré syndrome. Animal models of these autoimmune disorders include induction of experimental autoimmune encephalomyelitis or demyelination of primary afferents by lysolecithin.

Chemotherapy Induced

Chemotherapeutic drugs such as vincristine or paclitaxel promote microtubule stabilization, thus inhibiting tumor cell proliferation. However, the effectiveness of chemotherapy agents is often limited by severe neurotoxic side effects. Many patients undergoing paclitaxel chemotherapy develop peripheral neuropathies. Chemotherapeutic agents such as paclitaxel, cisplatin, or vincristine also cause sensory neuropathies in animals and are used to elucidate mechanisms of this type of painful neuropathy. The most common animal model of cancer pain involves injections of sarcoma cells into the medullary cavity of the humerus, calcaneous, or femur bone. Sarcoma cells cause gradual degradation of bone that is accompanied by behavioral signs of hyperalgesia.

Mechanisms of Neuropathic Pain

Neuropathic pain is associated with pathological changes at many sites along the neural axis. For the spinal nerve ligation model of neuropathic pain, numerous abnormalities that may account for neuropathic pain have been identified in both the peripheral and the central nervous system (Figure 2). At the site of nerve injury (Figure 2, no. 1), spontaneous neural activity and sensitivity to mechanical stimuli develops. At the DRG of the injured fibers (Figure 2, no. 2), there is an up-(or down)regulation of numerous molecules in small and large neurons reflecting, at least in part, the loss of trophic support from the periphery. Spontaneous neural activity also develops. Wallerian degeneration of the nerve fibers distal to the injury exposes the neighboring intact fibers to a milieu of cytokines and trophic factors (Figure 2, no. 3). Partial denervation in the target tissues can lead to a sensitization at the primary afferent terminals due to an excess of trophic factors (Figure 2, no. 4). At the DRG of the uninjured fibers (Figure 2, no. 5), there is an up-(or down)regulation of numerous molecules in small neurons reflecting, at least in part, the enhanced trophic support from the periphery. In the central nervous system, sensitization develops in dorsal horn neurons (Figure 2, no. 6) characterized

by an enhanced responsiveness to cutaneous stimuli that may account for the hyperalgesia/allodynia observed in the animals. This sensitization may be driven by spontaneous activity in nociceptors but also may be due, at least in part, to activation of glial cells (Figure 2, no. 7) and alterations in descending modulation (Figure 2, no. 8).

Role of the Peripheral Nervous System

The importance of the peripheral nervous system in neuropathic pain is supported by the observation that peripherally acting drugs alter neuropathic pain behavior. For example, the cannabinoid receptor 2 (CB2) is selectively expressed in the peripheral nervous system, and selective CB2 agonists were effective in reversing mechanical and heat hyperalgesia in an animal model of neuropathic pain. In addition, peripherally acting opiates have been shown to ameliorate neuropathic pain behavior.

Ectopic activity A hallmark of neuropathic pain is ectopic activity in primary afferents. In the case of nerve axotomy, ectopic activity develops at the site of injury as well as in the nearby spared afferents. Ectopic activity consists of ongoing neural activity as well as sensitivity to mechanical stimuli. The spontaneous neural activity provides a novel impulse barrage to the spinal cord that contributes to spontaneous pain and to the development of sensitization in second-order neurons. The mechanosensitivity may account for the pain to mechanical stimulation of the nerve injury site.

For distal nerve injuries, ectopic activity is seen in injured myelinated and unmyelinated fibers. In contrast, for proximal injuries (e.g., a spinal nerve ligation) the ectopic activity in injured afferents appears to be restricted to myelinated fibers (Figure 3). These spontaneously active A fibers appear to be low-threshold mechanosensitive afferents that normally transmit information about nonnoxious stimuli. As described later, ongoing activity of nociceptive C (but not A) fibers is considered critical in the development of central sensitization and neuropathic pain. In fact, electrical stimulation of primary afferents at A fiber strength does not result in sensitization of dorsal horn neurons. One possible explanation is that large DRG neurons undergo a phenotypic switch after nerve injury such that they express substance P and brain-derived neurotropic factor (BDNF); release of these transmitters in the dorsal horn could lead to central sensitization. A small proportion of large-diameter, myelinated, Aβ afferent neurons are nociceptors. It is possible that if these afferents develop ectopic activity

Figure 3 Large-diameter primary afferents develop ectopic activity following a spinal nerve injury. (a) Action potential (AP) recordings were made in the L5 dorsal root after an L5 spinal nerve lesion. (b) The spontaneous activity observed in large myelinated fibers was bursting (large AP shape), at uniform frequency (medium size AP), or irregular (small AP). (c) Nine days after the lesion, spontaneous activity was not eliminated by resecting the neuroma (but an injury discharge was apparent at arrows). (d) The spontaneous activity was eliminated by cutting the dorsal root, indicating that it originated from the dorsal root ganglia. Adapted from Liu CN, Wall PD, Ben-Dor E, Michaelis M, Amir R, and Devor M (2000) Tactile allodynia in the absence of C-fiber activation: Altered firing properties of DRG neurons following spinal nerve injury. *Pain* 85(3): 503–521, with permission.

after nerve injury, they could potentially play a role in neuronal sensitization.

Neuropathic pain is not solely dependent on the changes that occur in the injured nerve. The fact that neuropathic pain still occurs after a ganglionectomy (in which the injured afferent soma are removed) or ventral rhizotomy provides evidence that alterations in uninjured afferent fibers are sufficient to produce hyperalgesia. Both myelinated and unmyelinated uninjured afferents develop ectopic activity. In this case, unmyelinated C fibers in uninjured axons show rates of spontaneous activity sufficient to contribute to sensitization, hyperalgesia, and neuropathic pain.

Alterations of sodium channel expression and activation properties are considered major contributors to the development of ectopic activity. Nerve lesions lead to a reduction of tetrodotoxin (TTX)-resistant currents and their channel transcripts and an increase in rapidly repriming TTX-sensitive current and Nav1.3 channel transcripts. These changes alter cell membrane potential properties and make the cells more excitable. Whereas the TTX-resistant, sensory neuron-specific channels, Nav1.8 and Nav1.9, are reportedly downregulated in injured afferents, Nav1.8 is upregulated in the uninjured neighboring fibers. The Nav1.7 TTX-sensitive sodium channel is also thought to play an important role in nociception and certain forms of neuropathic pain. Nav1.7 is expressed predominantly in the small-diameter primary afferents and is believed to participate in the action potential initiation at the peripheral nerve terminals. Certain mutations of the SCN9A gene encoding the α subunit of the Nav1.7 channel have been found to account for the neuropathic pain associated with erythermalgia and paroxysmal extreme pain disorder. Other mutations of the same gene result in loss of function of Nav1.7 and are the underlying cause of channelopathy-associated insensitivity to pain.

Peripheral sensitization Following many types of tissue injury, including nerve injury, primary afferents develop lower activation threshold, become more responsive to natural stimuli, and develop larger receptive fields. In other words, they become sensitized. A change occurs in the transduction mechanisms that convert external stimuli (heat, touch, etc.) to electrical signals of neurons. After injury, proteins and ion channels in the primary afferents can undergo structural changes (e.g., phosphorylation) or primary afferents can develop altered gene expression that signals the production of new molecules. Consequently, previously nonnoxious stimuli may now be sufficient to activate a given channel or receptor, they may remain active for a longer period of time, or new channels may become activated by different factors within the injury site. These changes are responsible for peripheral sensitization.

It is well known that cyclo-oxygenase enzymes play a role in inflammatory pain conditions by converting arachidonic acid into proinflammatory factors such as prostaglandin E2 (PGE2). Prostaglandins have also been shown to contribute to peripheral sensitization in neuropathic pain by shifting the activation threshold of tetrodotoxin-resistant sodium channels (TTX-R Na^+) Nav1.8 and Nav1.9. PGE2 binds to G-protein-coupled receptors and increases cyclic AMP, which can sensitize TTX-R Na^+ channels by activating protein kinases A and C.

Following peripheral nerve lesion, peripheral sensitization occurs in the uninjured fibers innervating the same territory. Sensitization of uninjured fibers occurs partly because Wallerian degeneration of the injured nerve (**Figure 2**, no. 3; **Figure 4**) results in a release of a number of proinflammatory factors, including cytokines and growth factors, that can alter the activation threshold of the surviving neurons (**Figure 2**, no. 4; **Figure 4**). Several studies have demonstrated increased sensitivity of uninjured afferents to chemical (TNF-α), mechanical, and heat stimuli following peripheral nerve injury. Upregulation of TRPV1 and TRPA1 expression in the dorsal root ganglia of intact nerves that neighbor damaged nerves may contribute to the perception of heat and cold hyperalgesia observed after injury (**Figure 2**, no. 5). Animal models of nerve injury have also demonstrated upregulation of calcitonin gene-related peptide (CGRP), BDNF, $P2X_3$, and substance P mRNA in the uninjured DRG or nerve (**Figure 2**, nos. 3 and 5). Release of the neuromodulator CGRP causes activation of dorsal horn neurons and facilitates sensitization by other stimuli (**Figure 2**, no. 6). Upregulation of primary afferent release of BDNF can result in greater phosphorylation of NMDA receptors on second-order neurons in the dorsal horn and their subsequent sensitization. Adenosine 5′-triphosphate activation of $P2X_3$ receptors on sensory nerve terminals can also contribute to spinal cord sensitization. Increased levels of nerve growth factor (NGF) can sensitize uninjured afferents and contribute to peripheral sensitization and ectopic activity.

Hyperexcitability of peripheral sodium channels is a contributing underlying mechanism in a number of painful peripheral neuropathies, such as PHN. Patients with 'irritable nociceptor'-type PHN obtain pain relief with sodium channel blockers (e.g., anticonvulsant medications). The fact that application of local anesthetics (e.g., 1% lidocaine) or partial denervation by topical application of capsaicin also provides pain relief in these patients is evidence that ectopic peripheral input maintains the hyperalgesic state in these patients.

Figure 4 The properties of uninjured afferents may be altered by the neighboring injured fibers. An L5 spinal nerve lesion leads to Wallerian degeneration of the axons distal to the cut. This leads to invasion of the nerve by macrophages and the release of cytokines and chemokines. The adjacent, uninjured fibers from the L4 and L6 spinal nerves are exposed to a pool of reaction products associated with degeneration that could lead to an alteration of their properties including the development of ectopic activity. Spinal nerve injury also leads to a partial denervation in the peripheral target tissue. This could lead to the upregulation of factors in the tissue that could result in a sensitization of the primary afferent nociceptors. Adapted from Ringkamp M and Meyer RA (2005) Injured versus uninjured afferents: Who is to blame for neuropathic pain? *Anesthesiology* 103: 221–223, with permission.

Role of the Central Nervous System

Peripherally directed treatments do not always help in alleviating neuropathic pain, indicating that changes also occur in the central nervous system. Nerve injury can lead to sensitization of central pain-signaling neurons as well as changes in the properties of the inhibitory interneurons and descending inhibition. Enhanced ongoing input from the periphery onto spinal dorsal horn neurons causes central sensitization – an altered response of the central neurons.

Wind-up is a single synapse phenomenon of enhanced responsiveness of a central neuron following continuous low-frequency nociceptor activation from the periphery (Figure 2, no. 6). Central sensitization can result from spatial and temporal summation of wind-up. Wind-up is a short-lasting phenomenon (tens of seconds) largely mediated by glutamatergic activation of NMDA receptors. Hence, blocking NMDA receptors abolishes wind-up to various stimuli in healthy individuals and reduces neuropathic pain in select conditions, such as painful phantom limb and PHN. However, secondary hyperalgesia (pain in the area surrounding the injury and attributed to central sensitization) is generally not altered by inhibiting NMDA receptors. Enhanced responsiveness of dorsal horn neurons after central sensitization lasts for prolonged periods of time, suggesting additional or alternative mechanisms to the wind-up phenomenon. Specifically, the release of substance P from primary afferent neurons can facilitate depolarization of dorsal horn neurons by directly activating NK-1 receptors and by subsequent modulation of NMDA receptor activation.

Low-threshold mechanoreceptors normally provide a central inhibitory influence on the peripheral nociceptive input. Injury results in a sensitization of nociceptive dorsal horn neurons such that light touch or brushing now evokes activity in these neurons (Figure 2, no. 6). Allodynia, or pain evoked by normally nonnoxious stimuli such as brush, is signaled by low-threshold mechanoreceptors.

Some of the spinal cord interneurons rich in GABA, glycine, or opioid peptides have an inhibitory influence on synaptic transmission. Peripheral nerve injury can lead to impaired tonic inhibitory function of these interneurons by reducing the synthesis or release of inhibitory neurotransmitters or to apoptosis of these interneurons due to glutamate neurotoxicity. Decreased expression of potassium chloride exporter (KCC2) in lamina I dorsal horn neurons after injury alters the transmembrane chloride ion gradient. The net result is depolarization of the cell membrane and a phenotypic switch of GABA and glycine neurotransmission from an inhibitory to an excitatory role in the spinal cord. Additionally, disinhibition in the

dorsal horn occurs in part due to direct loss of spinal GABAergic neurons which is sufficient (although not necessary) to produce neuropathic pain following nerve injury. Mice lacking the μ opioid receptors show enhanced nerve injury-induced behavioral hyperalgesia and wind-up compared to wild-type animals. Intrathecal administration of delta opioid agonist reversed mechanical and cold hyperalgesia following spinal nerve ligation. These and similar studies indicate that endogenous opioids serve an antinociceptive role following nerve injury.

Similarly, nerve trauma in the central nervous system along the spinothalamic pathway can result in central pain in part due to the spinal or cortical changes in GABA or glutamate function. Spinal cord hemisection in animals leads to mechanical hyperalgesia reversed by intrathecal administration of antagonists to ionotropic glutamate receptors. Upregulation of metabotropic glutamate receptor group I (mGluR1) but not mGluR5 and downregulation of mGluR2/3 expression in the spinal cord mirrors the development of behavioral hyperalgesia following spinal contusion injury. Group I mGluR antagonist or group II and group III mGluR agonists effectively reversed mechanical but not heat hyperalgesia in this model. As mentioned previously, glutamate receptors are important contributors to the overall excitability of the spinal cord neurons and hence influence the development or maintenance of central sensitization. Serotonin-rich descending neurons from the brain stem or ascending projection neurons in the spinal cord neurons contain serotonin receptors 5-HT1, 5-HT2, and 5-HT3 that can serve an inhibitory or a facilitatory role in modulation of nociceptive input. However, downregulation of serotonin following spinal cord injury parallels development of hyperalgesia, an effect reversible by intrathecal administration of serotonin.

Central pain patients have been shown to have increased activity in the thalamic neurons. In an animal model of central pain, the hyperactivity of thalamic neurons was exaggerated by local application of glutamate and inhibited by application of MK-801 (NMDA antagonist) or GABA agonist. These results support clinical use of GABA agonists or NMDA antagonists in the treatment of central pain. In fact, ketamine, lamotrigine (NMDA antagonist or glutamate inhibitor), baclofen, propofol, and benzodiazapines (GABA agonists) are sometimes successful in providing pain relief in central pain patients. Cortical activation of μ opioid receptors (e.g., in prefrontal ventrolateral orbital cortex or anterior cingulate cortex) attenuates sensory or aversive components of neuropathic pain in animal models of nerve injury.

Nociceptive input from the periphery is also regulated by supraspinal descending neuronal pathways (Figure 2, no. 8). The major brain structures demonstrated to provide inhibitory control in nociception are periaqueductal gray (PAG) and rostral ventromedial medulla (RVM). Neuronal activation in PAG or RVM by electrical stimulation or opioid agonist (morphine) administration leads to analgesia, whereas transaction of their descending axons in dorsolateral funiculus results in hyperalgesia. Additionally, descending serotonergic input from the brain stem can either inhibit excitation of spinal cord neurons by activating 5-HT_1 and 5-HT_2 receptors or facilitate maintenance of neuropathic pain by activating spinal serotonergic 5-HT_3 neurons. Locus coeruleus and locus subcoeruleus participate in descending inhibition of the dorsal horn neurons by noradrenergic release (particularly the α_2 receptor subtype). Certain antidepressant medications are efficacious in neuropathic pain because they act on serotonergic or noradrenergic receptors.

Role of the Sympathetic Nervous System

In some patients, blockade of the sympathetic nervous system leads to pain relief. This sympathetically maintained pain (SMP) is thought to depend on the peripheral release of norepinephrine from sympathetic efferent fibers that activates and sensitizes primary afferents. Animal studies have shown that peripheral nerve injury can result in *de novo* expression of α_1 adrenergic receptors in adjacent uninjured afferents and sensitization to adrenergic agonists, indicating that the coupling site between the sympathetic and pain systems may be in the primary afferent fibers. In human studies, intradermal norepinephrine injections caused pain in patients with SMP but not in healthy controls. Some patients with complex regional pain syndrome have SMP and gain pain relief following sympathetic ganglion block or after intravenous administration of phentolamine, an α-adrenergic antagonist.

The sympathetic nervous system has been implicated in central pain mechanisms as well. Neuropathic pain patients with stroke-induced central pain frequently complain of exacerbated pain under stress and have areas of abnormal blood flow and sweating.

Influence of the Immune System

In addition to the obvious role of the immune system in inflammatory pain, there is accumulating evidence that immune factors are of importance in neuropathic pain. Following nerve injury, the immune system response includes macrophage infiltration, T-cell activation, and increased expression and release of proinflammatory factors such as IL-1β and IL-6, prostanoids such as PGE2, and TNF-α (Figure 2, no. 3;

Figure 5(b)). Damaged or denervated Schwann cells secrete leukemia inhibitory factor (LIF) and monocyte chemoattractant protein-1 (MCP-1). Upregulation of LIF following injury results in increased release of substance P and other molecules that contribute to nociceptor sensitization. MCP-1 is a chemokine cytokine that binds to chemokine receptor CCR2 and has been shown to activate monocytes and depolarize nociceptors following nerve injury either directly or by promoting the release of proinflammatory factors from surrounding nonneuronal cells. Cytokine IL-1β promotes expression and release of NGF that can lead to sensitization of primary afferents. Deletion of IL-1β or overexpression of IL-1β antagonist largely diminished the development of neuropathic pain following spinal nerve ligation or axotomy. These results complement previous evidence that injection of IL-1β or TNF-α in the sciatic nerve causes mechanical and heat hyperalgesia. However, it appears that inhibition of cytokine TNF-α effectively reduces neuropathic pain only when administered preemptively. It is suggested that pretreatment with TNF-α inhibitors prevents phosphorylation of MAP kinase p38 in DRG, which parallels attenuation of behavioral hyperalgesia following spinal nerve ligation.

Immunological factors participate in the pathology of neuropathic pain in the central nervous system as well. Microglia, the immune cells of the central nervous system, become activated following peripheral nerve injury (Figure 5(a)), particularly if the lesion site is distal to the DRG. Painful peripheral neuropathy due to HIV infection may also be caused in part by spinal cord microglia activation. Various approaches to inhibit microglial activation provide direct support that immune cell activation in the central nervous system contributes to neuropathic pain, especially in its development. Immune cells may influence neuronal activation and sensitization through upregulation of purinergic receptors and chemokines, activation of various kinases, and release of various

Figure 5 Immune cells present or recruited in the central (a) and peripheral (b) nervous system following nerve injury influence the excitability of primary afferents and second-order neurons. cytokines. Microglia express a number of purinergic receptors. Two have been demonstrated as important in neuropathic pain: P2X4 and P2X7. Inhibition of P2X4 after nerve injury alleviates mechanical allodynia and prevents upregulation of P2X4 in the dorsal horn. Genetic deletion of the P2X7 receptor resulted in decreased neuropathic pain, but it is not clear whether this effect is mediated specifically by microglia or includes involvement of other central or peripheral cell types. Neuronal release of chemokine fractalkine activates spinal microglia via CX3CR1 receptor and causes activation of the MAPK p38 pathway. Nerve injury also leads to activation of Src kinase in microglia but not neurons or astrocytes. Spinal inhibition of Src kinase attenuates mechanical allodynia by inhibiting extracellular signal-regulated protein kinase. Increased levels of proinflammatory cytokines have been observed in the spinal cord tissue following peripheral nerve injury. Additionally, intrathecal delivery of cytokine inhibitors can lead to the reduction of neuropathic pain.

Evidence indicates that the immune system plays an important role in neuropathic pain conditions, both peripherally and centrally. Interestingly, it appears that immune cell responses are more critical in initiating rather than maintaining neuropathic pain.

Neuropathy: Chemically-Induced

M Jokanović, Experta Consulting, Belgrade, Serbia

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In the nervous system there are four targets for the action of chemicals: the neuron, the axon, the myelinating cell, and the neurotransmission system. As a result, it is possible to identify neurotoxic chemicals which cause neuronopathies, axonopathies, myelinopathies, and neurotransmission-associated toxicity. This is a common classification system and is utilized here to discuss chemically induced neuropathies and mechanisms of action of selected neurotoxic compounds.

Neuronopathies

Certain chemicals selectively act on neurons, causing their injury or, when relatively high doses are taken, their death. The loss of a neuron is irreversible, since it includes degeneration of all neuronal components, such as dendrites and axons, and the myelin. Some typical characteristics of the neuron are a high metabolic rate, a cellular process supported by the cell body, and an excitable membrane that can be rapidly polarized and depolarized.

Neurotoxic compounds share certain common characteristics. Most of these compounds selectively interact with the neuron. The initial injury to the neuron is followed by apoptosis or necrosis, leading to permanent loss of the neuron. Some neurotoxic compounds may act specifically on certain neuronal subpopulations and, as a result, injury and interruption of particular functions may occur.

Methylmercury

The neurotoxicity of mercury compounds has received worldwide attention for centuries. However, it was not until the outbreak of methylmercury poisoning in Minamata, Japan, in the 1950s, that the extreme toxicological consequences of human exposure were fully recognized. During this outbreak of poisoning, thousands of inhabitants were exposed to methylmercury. The source of exposure was found to be industrial effluent that contained large amounts of mercury. The mercury made its way into Minamata Bay, where it was converted to methylmercury by marine biota. This accumulated in fish and shellfish, which were eventually consumed by the local residents. This consumption of contaminated seafood continued for several years and resulted in hundreds of reported cases of methylmercury poisoning. Since that time, methylmercury poisoning has been referred to as 'Minamata disease.'

A second major outbreak of methylmercury poisoning occurred in Iraq during 1971–72. In this case, the source of exposure was the ingestion of seed grain treated with a methylmercury fungicide; the grain had been ground into flour to make bread. Approximately 6500 people were hospitalized due to poisoning, and at least 400 died.

Methylmercury poisoning has several important features: (1) a long latent period, usually lasting several months; (2) damage almost exclusively limited to the central nervous system; (3) areas of damage to the brain are highly localized (focal; e.g., in the visual cortex and the granular layer of the cerebellum, especially in the infolded regions, or sulci); (4) effects in severe cases are irreversible due to destruction of neuronal cells; (5) the earliest effects are nonspecific subjective complaints, such as paresthesia, blurred vision, and malaise, progressing to concentric constriction of the visual field, deafness, dysarthria, ataxia, and, in the worst cases, coma and death.

Observations of methylmercury exposure in both humans and animals indicate that the developing central nervous system is more sensitive to damage from methylmercury than is the adult nervous system. The first indications arose from the Minamata outbreak of methylmercury poisoning when it was found that mothers who were slightly poisoned gave birth to infants with severe cerebral palsy. Subsequent studies on experimental animals confirmed the increased sensitivity of the fetus.

The clinical picture is dose dependent. In those infants who have been exposed to high maternal blood levels of methylmercury, microcephaly, hyperreflexia, and gross motor and mental impairment, sometimes associated with blindness or deafness, are the main pattern. After exposure to lower doses, patients show mainly psychomotor impairment and persistence of pathological reflexes.

Inhibition of protein synthesis in target nerve cells at the initial stage of synthesis, associated with transfer RNA, is well documented and appears before the first clinical signs of intoxication. The mechanisms involved include interaction with sulfhydryl groups of active ribosomes, effects on membrane structure, integrity of microtubules, glucose transport across the blood–brain barrier, axonal transport and inhibition of acetylcholine transmission at the neuromuscular junction, and inhibition of neuronal cell division by causing metaphase arrest, presumably by disruption of the mitotic spindle.

Methanol

Like most hydrocarbon solvents, methanol (methyl alcohol) can produce reversible sensory irritation and narcosis at airborne concentrations below those producing organ system pathology. Serious methanol toxicity is most commonly associated with ingestion. When untreated or treated too late, acute methanol poisoning in humans is characterized by an asymptomatic latent period of 12–24 h followed by formic acidemia, ocular toxicity, coma, fatal cerebral edema with seizures as a preterminal event, and, in extreme cases, death. Visual disturbances generally develop between 18 and 48 h after ingestion and range from mild photophobia and misty or blurred vision to markedly reduced visual acuity and complete blindness. Although there is a considerable variability among individuals in susceptibility to methanol toxicity, a frequently cited lethal oral dose is $1\,\mathrm{ml\,kg^{-1}}$. Blindness and death have been reported with dosages as low as $0.1\,\mathrm{ml\,kg^{-1}}$.

The target of methanol within the eye is the retina, specifically the optic disk and optic nerve. Optic disk edema and hyperemia are seen, along with morphological alterations in the optic nerve head and the intraorbital portion of the optic nerve. Both axons and glial cells exhibit altered morphologies. Evidence is accumulating that Müller cells, neuroglia that function in the maintenance of retinal structure and in intra- and intercellular transport, are early targets of methanol. Rods and cones, the photoreceptors of the retina, are also altered functionally and structurally due to mitochondrial disruption, including ATP reduction in Müller and photoreceptor cells.

Methanol exerts its primary toxicity after undergoing biotransformation by alcohol dehydrogenase to formaldehyde and then to formic acid by the action of aldehyde dehydrogenase. The formic acid is thought to be responsible for both the ocular (blindness) and the acid–base toxicity of methanol.

While there is still much to be learned about mechanisms of methanol toxicity, what is known allows for effective therapies, if they are applied in a timely manner. Sodium bicarbonate is usually given to correct severe acidosis. Metabolic blockade is usually achieved with ethanol or 4-methylpyrazole, both acting as effective competitive inhibitors of alcohol dehydrogenase by virtue of their greater affinity than methanol for the enzyme.

Axonopathies

The neurotoxic disorders termed axonopathies are those in which the primary site of toxicity is the axon itself. The axon degenerates with the myelin surrounding it; however, the neuron cell body remains intact. It is now understood that neurotoxic chemicals cut off the axon at some point along its length, and the axon distal to the transection, biologically separated from the cell, degenerates. Longer axons are more affected in toxic axonopathies. The involvement of long axons of the central nervous system, such as ascending sensory axons in the posterior columns or descending motor axons, along with long sensory and motor axons of the peripheral nervous system, suggested the frequent use of the term 'central peripheral distal axonopathies' for this type of neurotoxic event.

A basic difference exists in the significance of axonal degeneration in the central nervous system compared with that in the peripheral nervous system: peripheral axons can regenerate whereas central axons cannot. In the peripheral nervous system, glial cells and macrophages support axonal regeneration, and Schwann cells maintain this ability. In the central nervous system, release of inhibitory factors from the damaged myelin and astrocyte scarring interfere with regeneration. When this glial interference is removed through transplantation of neurons from the central nervous system to the peripheral nervous system, the neurons are capable of extending neurites. The inability of the central nervous system to regenerate appears to be due to both limiting environmental glial factors and properties of the mature neuron.

Axonopathies can be considered to result from a chemical transection of the axon. The number of neurotoxic chemicals acting on the axon is large, but all of them share the common pathologic loss of distal axons with the survival of the cell body. Axonal transport appears to be the target in many of the toxic axonopathies. When the axons degenerate the result is frequently the clinical condition of peripheral neuropathy, in which sensory and motor pathways are first damaged in the most distal parts, such as the feet and hands. With time and continued injury the damage progresses toward more proximal areas of the body and the long axons in the spinal cord. The potential for regeneration is significant when the damage is limited to peripheral nerves, and complete in axonopathies in which early events are recognized and removed.

Organophosphate-Induced Delayed Polyneuropathy

Organophosphorus compounds (OPCs) are widely used in industry, agriculture, and maintenance of community hygiene. Organophosphate-induced delayed polyneuropathy (OPIDP) is unique in that it is caused by a single exposure to certain OPCs, with effects

appearing after 7–21 days. In addition, the most important reasons historically for interest in OPIDP were the thousands of cases of poisoning with triorthocresyl phosphate that occurred mainly due to beverage and food contamination in the United States in 1930 and in Morocco in 1959. By the end of twentieth century, there were many human cases of OPIDP due to different OPC-based insecticides.

OPIDP is a relatively rare neurodegenerative disorder in humans characterized by loss of function and ataxia of distal parts of sensory and motor axons in peripheral nerves and ascending and descending tracts of the spinal cord. The early neurological symptoms usually are sharp, cramplike pains in the calves, tingling in the feet and hands, followed by distal numbness and paresthesia. Symptoms of pain and weakness in muscles develop rapidly and patients become unsteady and unable to keep their balance. Progressive leg weakness occurs, together with depression of tendon reflexes. Symptoms may also appear in the arms and forearms. Sensory loss may be mild. Muscle tonus of the limbs gradually increases and spasticity appears in the lower limbs. Physical examination reveals distal symmetrical, mainly motor, polyneuropathy, with wasting and flaccid weakness of distal limb muscles, especially in the lower limbs. In severe OPIDP, quadriplegia, with footdrop and wristdrop, is observed, as well as mild pyramidal signs. There may be some functional recovery, but pyramidal and other signs of central neurological involvement may become more evident with time. The recovery affects only sensory nerves, while motor neurons may permanently lose function. The prognosis for functional recovery depends on the degree of pyramidal involvement, with ataxia and paralysis representing a permanent outcome of severe OPIDP. In children up to 12 years old, OPIDP rarely develops, appearing in mild form, and recovery is usually complete within 6 months.

Electrophysiological evaluation has revealed partial denervation of affected muscles with abnormal spontaneous activity (fibrillation potentials, positive sharp waves), increased insertional activity, reduced interference pattern, and large polyphasic motor unit potentials. The muscle action potentials are reduced in amplitude, terminal motor latencies are delayed, and with motor conduction velocity slightly reduced or normal.

Histopathological studies have described Wallerian degeneration affecting myelin sheaths of peripheral nerves and involvement of the central nervous system, with changes in fasciculus gracilis at the cervical level and on the corticospinal tracts at lumbar levels. The extent of involvement of the nervous system is dependent on the chemical structure of the OPCs, the dose administered, the clinical signs of exposure, and the time elapsed until the appearance of signs of OPIDP, and assessment of these features depends on the site and method of tissue sampling. Aggregation, accumulation, and partial condensation of neurofilaments in peripheral nerves prior to onset of OPIDP have been described. After the appearance of OPIDP, mitochondrial accumulation was observed. In the central nervous system there was degeneration of myelin sheets and axons in the cerebrospinal system involving 'swelling of axons.' After the onset of paralysis, the disappearance of muscular tissue and its replacement with connective and lipid tissue was described.

In numerous experimental studies a correlation was established between the clinical signs of OPIDP and activity of a protein, initially named 'neurotoxic esterase' and later 'neuropathy target esterase (NTE).' NTE is an integral membrane protein in vertebrate neurons and its activity depends on lipid content. It is present in all neurons, but is absent from glia. The active site of NTE contains Ser966 and two aspartates, Asp960 and Asp1086, that appear essential for enzymatic activity. It was recently shown that NTE is anchored in the endoplasmic reticulum, interacting with the cytoplasmic face of the endoplasmic reticulum, and that overexpression of NTE causes aggregation of endoplasmic reticulum.

Physiological functions of NTE are presently unknown. It was recently shown that human NTE catalyzes hydrolysis of several naturally occurring membrane-associated lipids, indicating that it may be involved in intracellular membrane trafficking. A possibility that NTE may have an important function during brain development through involvement in a cell-signaling pathway between neurons and glial cells is under investigation. Elucidation of the molecular mechanisms of OPIDP may provide valuable clues to the functioning of the normal adult nervous system and during neurodegenerative disorders.

n-Hexane

n-Hexane is used as a solvent in the extraction of vegetable oils, production of glue and in rubber, and in the shoe industry. *n*-Hexane is metabolized oxidatively to a number of compounds, including 2,5-hexanedione, which is thought to be the ultimate neurotoxic agent. 2,5-Hexanedione is also a toxic metabolite of *n*-butyl ketone and several other γ-diketones. γ-Diketones react with amino groups in all tissues to form pyrroles, and this step is important in pathogenesis of this axonopathy. The cellular changes are

characterized by development of neurofilament aggregates and swelling in the distal parts of the axon.

Peripheral neuropathy has been reported in humans exposed occupationally to *n*-hexane or through solvent abuse of glues or solvents containing *n*-hexane. The first signs of *n*-hexane neuropathy are symmetrical paresthesia and weakness. The lower extremities are affected first. A number of other symptoms, such as headache, anorexia, and dizziness, may precede or coincide with the neuropathy. A 'stocking and glove' sensory impairment to touch, pain, vibration, and temperature develops, with weakness and atrophy affecting proximal muscles of the extremities. On clinical examination, most patients show reduced body weight and diminished or absent reflexes. There is a marked reduction in conduction velocity in sensory and motor nerves. Electromyography shows a neuropathic pattern including fibrillation potentials, positive sharp waves, polyphasic potentials, and reduced interference patterns. Axonal lesions of the large myelinated fibers, with axonal swelling followed by myelin retraction at the node of Ranvier, are found on nerve biopsy. There is only a slight to moderate reduction in the number of fibers, mainly of large myelinated fibers. With continued intoxication, swellings are seen more proximally and there is degeneration of the distal axon along with its myelin. Muscle biopsies show signs of myofibrillar atrophy. Recovery is always gradual and slow and signs of residual neuropathy may persist in severe cases for 3–4 years. Signs of pyramidal tract defects, such as residual hyperreflexia and spasticity, and autonomic defects have been reported. Electrophysiological evidence of central nervous system dysfunction (abnormal evoked potentials) has occasionally been reported in individual cases of peripheral neuropathy.

Carbon Disulfide

Carbon disulfide (CS_2) is a volatile solvent used for a variety of industrial purposes. Many cases of human CS_2 poisoning, characterized by various neurological and behavioral effects, occurred during and after World War II. The psychological effects consisted of personality changes, irritability, memory deficits, insomnia, bad dreams, decreased libido, and constant fatigue. Paresthesia and dysesthesia from CS_2 exposure tend to occur in a 'stocking and glove' distribution characteristic of peripheral nerve injury due to a slowing of motor conduction in peripheral nerves. In addition to this chronic axonopathy, CS_2 can also lead to aberrations in mood and signs of diffuse encephalopathy. Some of these are transient at the beginning and later become long-lasting, a feature that is common in vascular insufficiency in the nervous system. Various sensory alterations have been reported following CS_2 exposure, particularly in vision, such as central field loss, disturbances in color vision, enlargement of the blind spot, and reduction in peripheral vision. Alterations in auditory, vestibular, and olfactory senses have also been observed.

Experimental CS_2 neuropathy consists of weakness or loss of power in the limbs, depressed reflexes, and general behavioral suppression. CS_2 produces filamentous inclusions in axons in both the central and peripheral nervous systems that are similar to those caused by *n*-hexane. However, there is a an important difference between CS_2 and *n*-hexane toxicity: *n*-hexane has to be metabolized to its active metabolite, 2,5-hexanedione, to be toxic, while CS_2 is the ultimate toxicant; it interacts with protein amino groups to form the dithiocarbamate adducts involved, through a series of reactions, in the pathogenesis of CS_2 axonopathy.

Acrylamide

Acrylamide is a vinyl monomer used in the manufacture of paper products, water treatment, crude oil production, and mineral ore and concrete processing. Smaller quantities are used as cosmetic additives and in food processing, and have application in molecular biology for acrylamide gel electrophoresis. Acrylamide is a potent neurotoxin affecting both the central and peripheral nervous systems. Only the acrylamide monomer is toxic.

Most cases of human acrylamide toxicity have occurred in the context of chronic occupational exposure, with predominant routes believed to be combined inhalational and dermal. Excessive sweating of the extremities is an early and universal symptom of chronic acrylamide toxicity. Other initial symptoms include inflammation of the skin of the hands and feet with blistering and desquamation. The acrylamide neuropathy is a toxic distal axonopathy, beginning with degeneration of the nerve terminal. Within nerve terminals early events include decreased numbers of synaptic vesicles and mitochondria and accumulation of neurofilaments with terminal sprouting. Multifocal accumulations of membranous bodies, mitochondria, and neurofilaments are observed in the distal axon, suggesting impaired retrograde axonal transport. The clinical course is characterized by the development of symptoms and signs of a motor and sensory peripheral neuropathy that slowly progress in severity if exposure continues. Symptoms initially involve the hands and feet and may progress to involve the entire upper and lower extremities. Symptoms include paresthesias and numbness, coldness, and difficulty with fine

movements such as writing. Signs include impaired touch or vibration sense in a 'stocking and glove' distribution, impaired joint position sense, absent tendon reflexes, and atrophy of the small muscles of the hand. Features suggesting involvement of the central nervous system include tremor, slurred speech, and hallucinations. Muscle pain and weakness are less common. Complete recovery usually occurs over a period of weeks to months following removal of the person from the toxic environment, preventing further exposure.

Myelinopathies

Myelin provides electrical insulation of neuronal processes and its absence leads to a slowing of conduction and aberrant conduction of impulses between adjacent processes. The diverse, structurally unrelated chemicals that cause toxic myelinopathies have been investigated and can be categorized into two groups. Some demyelinating chemicals seem to leave intact the myelinating cells (oligodendrocytes in the central nervous system and Schwann cells in the peripheral nervous system), while others damage the myelinating cells as well as the myelin. The significance between the two is that with the myelinating cells still intact, repair of the myelin sheath can occur. However, if the myelinating cells are destroyed, repair and reversal of the neuropathy may not occur. Histologically, these chemicals produce an edema of the white matter of the brain. By electron microscopy, vacuoles can be seen in the myelin surrounding axons; these are characterized as fluid-filled separations of myelin lamellae. Vacuoles can further degenerate to full demyelination, affecting conduction through those axons. Regeneration of the myelin layers can occur. Some of these chemicals, however, can increase cerebrospinal fluid pressure in the brain, optic nerve, and spinal cord, and/or intraneuronal pressure in the perineurium surrounding the axons in the peripheral nervous system. This increased pressure has been correlated with decreased conduction capacity through the axon, ischemia to the neuronal tissue from decreased blood flow, and, subsequently, permanent axonal damage.

Hexachlorophene

Hexachlorophene (2,2′-methylenebis-3,4,6-trichlorophenol) induces, in both humans and animals, vacuolation of central and peripheral myelin by the separation (splitting) of myelin lamellae at the intraperiod lines of the oligodendroglial and Schwann cells. Experimental studies with erythrocyte membranes show that hexachlorophene binds to cell membranes, resulting in the loss of ion gradients across the membrane. It is possible that hexachlorophene causes the loss of the ability to exclude ions from between layers of myelin, and that, with ion entry, water also separates the myelin layers, forming edema. Another related effect is uncoupling of mitochondrial oxidative phosphorylation by hexachlorophene, because this process is dependent on a proton gradient. Intramyelinic edema is reversible in the early stages, but with increasing exposure, hexachlorophene causes demyelination. Swelling of the brain causes increased intracranial pressure which may be fatal. The optic nerve fibers are especially vulnerable, and may not recover. Humans exposed acutely to hexachlorophene may have generalized weakness, confusion, and seizures, progressing to coma and death.

Lead

Peripheral neuropathy is a classical manifestation of lead toxicity, particularly the footdrop and the wristdrop that characterized the workers in past centuries who were occupationally exposed to lead for decades. Segmental demyelination and possibly axonal degeneration follow lead-induced Schwann cell degeneration. Wallerian degeneration of the posterior roots of sciatic and tibial nerves is possible, but motor nerves are apparently more sensitive to lead than are sensory nerves.

Toxic effects of lead are different in adults and children. For adults, the major concerns are peripheral neuropathy with injury of long neurons, chronic nephropathy, and hypertension. Other symptoms include abdominal pain, anemia, headache, ataxia, and memory loss. In children the symptoms are lead encephalopathy, lethargy, vomiting, irritability, loss of appetite, dizziness progressing to ataxia, reduced level of consciousness, coma, and death. It appears that lead exposure has an adverse effect on the intellectual abilities of children.

The pathologic findings at autopsy are severe edema of the brain due to extravasation of fluid from capillaries in the brain, accompanied by the loss of neuronal cells and an increase in glial cells. Vacuoles are seen as the result of splitting of both the major dense line and the intraperiod lines of the myelin. It has been shown that there is vascular injury as the initial neuropathological event, followed by endothelial, microglial, and astrocytic proliferation and widespread edema. The changes in the permeability of the blood–brain barrier for lead, possibly as the result of activation of protein kinase C in microvessels, have been suggested as one of the initial pathological events in lead neuropathy. Lead has been shown to accumulate in the endoneurium at potentially toxic levels, resulting in segmental demyelination before development of edema. Movement of lead into the endoneurial compartment is associated with ultrastructural abnormalities of Schwann cells,

which show degenerative cytoplasmic changes, as well as intranuclear inclusions typical of lead poisoning.

A highly significant morphologic effect in the nervous system is the result of lead impairment of timed programming of cell–cell connections, resulting in modification of neuronal circuitry. Lead impairs normal calcium homeostasis and uptake by calcium membrane channels and substitutes for calcium in calcium–sodium ATP pumps. Lead also blocks entry of calcium into nerve terminals; it inhibits calcium uptake in brain mitochondria, with a decrease in energy production to perform brain functions. Lead interferes with calcium receptors that are coupled with second-messenger functions.

Neurotransmission-Associated Neurotoxicity

There are many chemicals that interact with the process of neurotransmission. Among them are natural toxins and synthetic drugs. These chemicals may interrupt the transmission of impulses, block or support transsynaptic communication, block reuptake of neurotransmitters, and interfere with second-messenger systems. In general, the acute toxic effects of these compounds are directly related to the immediate concentration of the chemical at the active site, which is comparable to the level of the chemical in the blood. Toxic effects of these substances are usually short-term interactions that are reversible after removal of the substance from the blood. Their effects may be counteracted by the use of appropriate antagonists. The effects of certain substances may be irreversible. Both reversible single-dose toxicity and the effects of repeated exposure are common characteristics of substances interacting with neurotransmission.

Nicotine

Nicotine is a widely available natural alkaloid having a considerable medical significance because of its toxicity, its presence in tobacco, and its propensity for conferring a dependence on its users. Nicotine exerts its effects by binding to nicotinic receptors located in ganglia, at the neuromuscular junction and within the central nervous system. Tobacco smoking and low doses of nicotine accelerate heart rate, elevate blood pressure, constrict blood vessels in the skin, and facilitate neurotransmission. When larger doses of nicotine are applied, the initial stimulation is quickly followed by a blockade of transmission. Nicotine also possesses a biphasic action on the adrenal medulla; small doses evoke the discharge of catecholamines and larger doses prevent their release in response to splanchnic nerve stimulation.

Poisoning from nicotine may occur from accidental ingestion of insecticide sprays in which nicotine is present as the toxic agent, or, in children, from ingestion of tobacco products. In each of these settings, the rapid rise in circulating levels of nicotine leads to excessive stimulation of nicotine receptors followed by ganglionic paralysis. The onset of symptoms of acute severe nicotine poisoning is rapid – symptoms include nausea, salivation, abdominal pain, vomiting, diarrhea, cold sweat, headache, dizziness, disturbed hearing and vision, mental confusion, and weakness. Faintness and prostration ensue; the blood pressure falls, breathing is difficult, the pulse is weak, rapid and irregular, and collapse may be followed by terminal convulsions. Somnolence, confusion, and coma may occur; if death results it is often the result of paralysis of respiratory muscles.

Exposure to lower doses of nicotine for longer duration is very common, and the health effects are a significant epidemiological problem. In smokers the effects of nicotine are accompanied by the effects of other components of cigarette smoke. The complications include cardiovascular disease, cancers, chronic pulmonary disease, and attention-deficit disorders in children of women who smoke during pregnancy. High levels of nicotine in smokers may be a factor in increased propensity for platelets to aggregate and in myocardial ischemia. In addition, nicotine inhibits apoptosis and may have a direct role in tumor promotion and tobacco-related cancers.

Conclusion

A large number of chemicals act on the nervous system and can influence its functions. Among them are the substances used in medicine as drugs (anesthetics, analgesics, sedatives), those consumed as life-style factors (ethanol, nicotine, caffeine). In addition, humans are exposed to many potent chemicals (pesticides, heavy metals, organic solvents, additives) present in their environment, food, and water. The nervous system is very sensitive and vulnerable to these agents. In the nervous system there are four targets for the action of chemicals: the neuron, the axon, the myelinating cell, and the neurotransmission system; each target has clinical, histopathological, and toxicological features and mechanisms due to the neurotoxic effects of chemicals.

Diabetic Neuropathies: Overview

The public health importance of diabetic neuropathy, the most common neuropathy in Europe and North America, will increase substantially as the result of the looming global epidemic of type 2 diabetes. The prevalence of diabetic neuropathy depends on criteria selected, ranging from 10% to 15% of diabetics who are clinically symptomatic to 48–90% of diabetics with electrophysiologically detectable dysfunction. A variety of clinical presentations include sensory loss symmetrically involving the distal extremities (stocking–glove pattern), occasionally complicated by disabling neuropathic pain; autonomic insufficiency involving many modalities; and, asymmetrical presentation of pain and weakness. Patients may develop neuropathy as adults or children, in both type 1 and type 2 diabetes and following years of diabetes or at its initial presentation. Risk factors for diabetic neuropathy include duration of diabetes, age, hypertension and smoking (in type 1 diabetics), patient height, alcohol consumption, and worsening degree of glycemic control. Neuropathy is commonly associated with other diabetic complications including retinopathy and nephropathy. Multiple presentations suggest that diabetic neuropathies may have different causative (pathogenetic) mechanisms and require different therapies.

Diabetic neuropathy is not a single neuropathy with a single pathogenetic mechanism, rather it is a complex spectrum of neuropathies (Table 1). Subclassification of diabetic neuropathies is clinically significant since different types of diabetic neuropathy may require individualized therapy. Some newly recognized forms of diabetic neuropathy (e.g., diabetic lumbosacral radioplexus neuropathy (LRPN)) may reflect a possible immune pathogenesis and the therapeutic possibility of treatment by immune suppression. Furthermore, not all diabetic patients with peripheral nerve dysfunction have diabetic neuropathy; specifically, neuropathy in an individual patient may represent a second superimposed process (e.g., vasculitis (blood vessel inflammation or destruction) or chronic inflammatory demyelinating neuropathy (CIDP)) rather than diabetes itself. Thus, the initial workup (including a detailed history, electrophysiologic testing, determination of the presence of a paraprotein (an abnormal plasma protein) or autoantibodies (antibodies directed against normal tissue constituents) of diabetic patients must address the possibility of additional factors contributing to the neuropathy. An atypical presentation dominated by motor symptoms, severe sensory loss (particularly joint and vibration sense out of proportion to the severity of diabetes), asymmetry of involvement, or an acute, rapidly worsening course represent grounds for nerve biopsy. New studies of cutaneous nerves using multiple skin biopsies will allow the ability to monitor the effect of therapy on autonomic and sensory axons in diabetic patients.

Neuropathy with Impaired Glucose Tolerance

Recently, in patients without a history of frank diabetes, an idiopathic, typically painful neuropathy has been described in the absence of elevated HbA1c or fasting hyperglycemia but in the presence of an impaired glucose tolerance test (GTT). Considering the frequency of abnormal GTT in the adult patient population and the frequency of neuropathy without established cause, some of these cases may represent a collision of both processes. Nonetheless, it has been reported that small axons, including those comprising the innervation of the epidermis, are prominently affected and may be the earliest detectable sign of neuropathy in the presence of glucose dysmetabolism. A syndrome of paresthesias (abnormal skin sensations with no apparent physical cause) and pain in newly diagnosed diabetes, that is, hyperglycemic neuropathy, or increased resistance to experimentally induced ischemia (decreased blood supply) may respond quickly to normalization of blood glucose valueso.

Symmetric Sensorimotor Polyneuropathy

The most common form of diabetic neuropathy is symmetric sensorimotor polyneuropathy which ranges in severity from subclinical electrophysiologic alterations to distal 'stocking–glove' anesthesia. The presence of neuropathy contributes to the increased risk of amputation in diabetes.

The pathologic hallmark of symmetrical sensory polyneuropathy is the variable loss of myelinated and unmyelinated axons (Figure 1), which is particularly severe in the distal aspects of the lower limbs. This form of diabetic neuropathy is characterized by axonal degeneration with the formation of numerous bands of Büngner (collections of Schwann cell processes forming a substrate for axonal regeneration)

and clusters of regenerating axons which may vary with severe or sustained neuropathy. Some patients, particularly those with chronic involvement or mild symptoms, show primary or secondary forms of demyelination, remyelination, and occasional onion bulbs (i.e., imbricated concentric proliferation of collagen and Schwann cell processes around a central axon), although this may reflect coexistence of diabetes and CIDP. Active axonal degeneration, numerous bands of Büngner, and regenerative clusters of small, thinly myelinated axons suggest axonal degeneration and regeneration. The examination of individual axons (osmium-stained to highlight myelin sheaths) by teased fiber analysis may be needed to discriminate axons with myelin sheaths that are too thin for axon caliber (produced as the end stage of axonal regeneration) from true demyelination. Axonal atrophy is not a consistent finding in human diabetic neuropathy. A common finding, thickened basement membranes, involve the endoneurial microvasculature, Schwann cells, and particularly perineurial cells, and may result from failure to degrade glycated basal laminae (i.e., containing nonenzymatic bound glucose or related saccharides). The microvasculature within the nerve fascicles is thickened (Figure 2) by multiple concentric layers of basal laminae and collagen, a pattern which, although commonly seen in diabetic nerve, is not specific for diabetes. Recent studies of diabetic neuropathy early in its clinical course, which may possibly elucidate the initial insult, have reported normal myelinated axon density, axonal area, and *g*-ratio (the ratio of axon diameter to diameter of axon + myelin sheath, one measure of myelinopathy) in the presence of paranodal abnormalities, segmental demyelination (myelin loss with preservation of axonal integrity), and remyelination in the absence of degeneration of myelinated axons.

Although neuropathy develops in both types 1 and 2 diabetes, differences in the pathology of diabetic somatic nerves have been proposed. Type 1 diabetic patients are reported to develop a lesser degree of axonal degeneration and more evidence of myelinopathy than type 2 diabetics, in whom axonal degeneration is more prominent. Anders Sima and colleagues have described axoglial dysjunction, an unusual and contentious ultrastructural and molecular alteration of the perinodal junctional apparatus resulting in paranodal demyelination and conduction, particularly in type 1 diabetes in rats and man. Diabetic BB/Wor rats (a model of type 1 diabetes) develop severe nerve conduction defects, node of Ranvier-based pathology with molecular alterations of nodal proteins, axonal atrophy, defects in axonal regeneration, and, eventually, significant loss of myelinated axons. In comparison, neuropathy in the type 2 diabetic BBZDR/Wor rat model exhibits a lesser degree of atrophy of myelinated

Table 1 Classification of the diabetic neuropathies

Impaired glucose tolerance and hyperglycemic neuropathy
Generalized (symmetrical) neuropathies
Acute painful (including treatment induced)
Sensorimotor
Autonomic
Acute motor
Focal and multifocal neuropathies
Lumbosacral radioplexus (Bruns–Garland syndrome)
Cranial
Thoracolumbar
Superimposed chronic inflammatory demyelinating neuropathy (CIDP)
Hypoglycemic neuropathy

Figure 1 Endoneurial vessels in diabetic symmetrical sensory neuropathy are markedly thickened (arrows), a morphologic feature commonly seen in, but not confined to, diabetic neuropathy (1-μm-thick plastic embedded section, toluidine blue stain).

Figure 2 Endoneurial vessels in diabetic symmetrical sensory neuropathy are thickened by reduplication of basement membranes (arrows) (electron micrograph).

axons, minimal nodal pathology with no molecular changes, segmental demyelination, and active axonal degeneration with relative preservation of axon number, suggesting increased axonal regeneration.

Although axon loss in diabetic sensory neuropathy is typically diffuse and symmetrical distally, foci of axon loss suggested that it arises as the result of summation of ischemic foci. However, patchy intrafascicular or fascicle to fascicle variability of axon loss may be seen in CIDP and in inherited nonvasculopathic neuropathies, in which ischemia has no recognized role. Nonetheless, endoneurial microvasculopathy correlates with electrophysiologic dysfunction and may anticipate the development of significant neuropathy. However, the expected deficiency of nerve blood flow in diabetic patients with early polyneuropathy has not consistently been shown, even in the presence of decreased sensory nerve action potential amplitudes and numbers of axons. Therefore, argument continues whether microvasculopathy results in an ischemic pathogenesis in diabetic neuropathy or is unrelated to nerve dysfunction.

Recently, a number of investigators have begun to examine the terminal epidermal cutaneous innervation of the skin in patients with a variety of neuropathies using antibodies to PGP9.5 (which labels axons of all modalities) or selected neurotransmitters. A decrease in and disorganization of epidermal axons have been demonstrated in diabetic patients (Figure 3) and, in some cases, are accompanied by the formation of terminal axonal swellings at the distalmost portions of the cutaneous innervation. The ability to use skin biopsies to detect the early development of neuropathy and to follow the effect of therapeutic regimens holds much promise.

A number of diabetics develop debilitating painful neuropathy characterized by spontaneous pain or exaggerated response to normal stimuli (dysesthesias). Although it was initially suspected to reflect preferential damage to small caliber axons, painful diabetic neuropathy has not been consistently correlated with active fiber degeneration or regeneration in sural nerve biopsies. However, recent studies using skin biopsies suggest a correlation with intraepidermal sensory nerve fiber density in some, but not all, patients. Ectopic discharges related to pain perception have been demonstrated to arise from dorsal root ganglia (DRG) neurons and accompany changes in sensory neuron sodium channels. The presence of dystrophic axonal swellings, often immediately adjacent to normal-appearing cell bodies, containing neurofilaments and calcitonin-gene-related peptides (CGRP), trkA-, and substance P-immunoreactivity are thought to involve are thought to involve potentially dysfunctional intraganglionic sprouts of nociceptive small neurons, although there is no proven association with painful neuropathy.

Figure 3 Immunohistochemical studies of skin biopsy of a type 1 diabetic patient with symmetrical sensory neuropathy shows decreased numbers and disorganization of epidermal nerve fibers (ENF, (a)) in comparison with an age-matched nondiabetic control (b). (Immunohistochemical detection of PGP 9.5, which stains all types of cutaneous nerves.) Images courtesy of Dr. William R. Kennedy.

Asymmetric Diabetic Neuropathies

Occasional diabetic patients, typically middle-aged or elderly men with early type 2 diabetes, may develop an unusual asymmetric neuropathy, often following institution of insulin therapy or associated with significant weight loss. Such patients experience sudden or subacute onset of motor dysfunction with muscle wasting, typically involving large nerves to the lower limb or cranial nerves. This unusual category of diabetic neuropathy includes diabetic LRPN (diabetic amyotrophy, truncal radiculopathy, Bruns–Garland syndrome, femoral neuropathy of diabetes, and proximal diabetic neuropathy), upper limb mononeuropathy, and cranial nerve palsies (usually cranial nerves 3, 4, and 6). Rarely, upper limb involvement occurs.

These cases have an unusual pathology which may reflect an autoimmune pathogenesis. An inflammatory (mostly T cell) nonnecrotizing epineurial microvasculitis

Figure 4 Diabetic LRPN is characterized by microvasculitis (arrows: (a) and (b); hematoxylin and eosin stain and 1 μm plastic section, respectively) and perineuritis (arrowheads: (b) and (c)).

(Figures 4(a) and 4(b)) may be prominent, often accompanied by significant axon loss, which varies from fascicle to fascicle, perineuritis (inflammation of the covering of individual fascicles) (Figure 4(c)), and endoneurial and perineurial hemosiderin deposition indicative of prior hemorrhage, in some cases forming neuromas. The pathologic findings in diabetic LRPN are identical to those in nondiabetic patients with LRPN, although it has been suggested that some nondiabetic patients with LRPN may also have abnormal glucose tolerance. The typical course results in spontaneous recovery over several months.

Diabetic Autonomic Neuropathy

Diabetic patients may develop a constellation of autonomic complaints involving any or several modalities. Although early on parasympathetic dysfunction was thought to be predominantly affected, sympathetic dysfunction occurs in diabetes and may be accompanied and exaggerated by superimposed enteric or visceral sensory dysfunction. Cardiovascular dysfunction may be manifest as abnormal R–R interval, often involved early on; later, cardiac reflexes may be lost and, in a minority of patients, orthostatic hypotension (i.e., significant loss of blood pressure, typically with change in position from recumbent to standing) develops. Genitourinary dysfunction includes erectile defects (in 35–50% of diabetic men) as well as loss of bladder tone (with subsequent distension and infection). Visceral sensory neuropathy may result in bladder distension without a strong voiding stimulus. Dysfunction may involve any level of the alimentary tract resulting in esophageal dysmotility, gastroparesis (slowed gastric emptying), loss of gall bladder contractility, or chronic diarrhea or constipation which may alternate. Patients may have difficulty sweating or sweat excessively in response to various stimuli (e.g., 'gustatory sweating' in anticipation of food). The presence of symptomatic diabetic autonomic neuropathy significantly worsens morbidity and mortality, due to cardiac arrhythmias, kidney failure, stroke, or increased perioperative mortality. Visceral dysfunction in diabetes also involves

subpopulations of cells of the enteric nervous system, the nonadrenergic noncholinergic pathway in the pylorus and the interstitial cells of Cajal. Although symptomatic autonomic neuropathy is considered infrequent, the involvement of autonomic functions in the extremities commonly parallels somatic neuropathy and may have different pathogenetic mechanisms than visceral autonomic neuropathy.

Systematic autopsy studies of the sympathetic autonomic nervous system in diabetic patients and rats have demonstrated the preservation of neurons in prevertebral (located adjacent to main vascular trunks serving viscera) and paravertebral (bilateral chains of ganglia adjacent to vertebral bodies serving somatic and selected visceral functions) sympathetic ganglia. Instead, the pathologic hallmark in the diabetic prevertebral sympathetic ganglia is the development of markedly swollen neurofilament- and membrane-laden axons and synapses, designated neuroaxonal or neuritic dystrophy (Figure 5(a)), accompanied by the loss of normal terminals (which may be the most functionally relevant finding). Marked differences in involvement of subpopulations of terminal axons suggests selective vulnerability (Figures 5(b) and 5(c)) and may account for the targeting of sympathetic prevertebral and lumbosacral chain ganglia while largely sparing superior cervical chain ganglia. The often-quoted classic study of the sympathetic ganglia of diabetic patients with symptomatic alimentary tract autonomic neuropathy demonstrated dystrophic changes accompanied by lymphocytic infiltrates, the latter finding interpreted as evidence for a possible autoimmune pathogenesis. However, inflammatory cells were neither more frequent nor of greater intensity in diabetic sympathetic ganglia in a large series of autopsied patients compared to those of nondiabetic subjects. Loss of myelinated axons in the preganglionic greater splanchnic nerves (i.e., preganglionic axons to prevertebral sympathetic ganglia) and abdominal vagus nerves in diabetic gastroparesis has also been described. Diabetic mouse parasympathetic ganglia experience the

Figure 5 The prevertebral superior mesenteric sympathetic ganglion in a patient with diabetic autonomic neuropathy shows perisomal argyrophilic dystrophic axons (arrows, (a); Bielschowsky axon stain) which are markedly immunoreactive for neuropeptide Y (arrows, (b)) but do not stain with antibody against substance P (arrows indicate normal terminals, (c)).

selective loss of nitrergic (using nitric oxide (NO) as a neurotransmitter) innervation of the stomach and penis; in other studies, subpopulations of autonomic fibers within the gut, bladder, penis, and other end organs may show preferential damage.

Pathogenetic Mechanisms of Diabetic Neuropathy

The pathogenesis of diabetic neuropathy is largely unknown; however, many pathogenetic mechanisms have been advanced with no current consensus. Considering the range of pathologies described in patients with diabetic neuropathy, multiple mechanisms may interact and vary between forms. It is believed that tight glucose control does delay the development of somatic and autonomic neuropathy; however, it does not appear to completely prevent it. Intensive insulin treatment of type 2 diabetics produced minimal improvement in established neuropathy. A variety of mechanisms have been proposed to play a role in its pathogenesis.

Advanced Glycosylation End Products Formation

Glycosylation of various intracellular and extracellular proteins in response to hyperglycemia may be followed by chemical rearrangement into advanced glycosylation end products (AGEs), some of which may result in cross-linking of a variety of proteins and subcellular organelles. Additionally, the binding of AGEs to their receptors (RAGEs), members of an immunoglobulin superfamily, is thought to increase oxidative stress. Aminoguanidine, an inhibitor of AGE formation, has shown a positive effect on a variety of disturbed functions in diabetic somatic nerves.

Apoptosis

A role for apoptosis (a complex, highly regulated pattern of cell death) in a large variety of developmental and pathologic processes has been proposed, including diabetic sensory and autonomic neuropathy. Largely based on *in vitro* studies, a prime role for glucose-induced apoptosis was proposed. However, this hypothesis conflicts with the maintenance of neuron number in dorsal root and sympathetic ganglia and only a minor degree of axon loss in the somatic nerves of the streptozotocin-induced (STZ)-diabetic rat. Experiments with rats diabetic for extended periods have shown caspase-3 activation in DRG neurons in the absence of neuronal degeneration, confirmed by nonbiased counting methods, although others have claimed a small decrease in subpopulations of DRG neurons. In contrast, loss of sensory neurons and axon numbers in diabetic mice suggests that even rodent models may differ.

Autoimmune Processes

A role for an autoimmune cell- or antibody-mediated pathogenesis has been proposed, particularly for diabetic autonomic neuropathy. Antibodies directed against adrenal gland, sympathetic ganglia, and vagus nerve may be associated with an increased incidence of autonomic neuropathy in diabetic patients, although its role in autonomic neuropathy is still contentious.

Axonal Transport

Diminished axonal transport of a variety of materials, initially thought to represent a primary pathogenetic mechanism, may primarily reflect decreased neuronal synthesis or altered production of trophic substances by target tissues, rather than a defect in the transport apparatus itself.

Ischemia

The relevance of ischemia to the pathogenesis of diabetic sensory neuropathy has been controversial in man and animal models. Nonetheless, evidence exists for a role of tissue hypoxia in nerve and ganglia in experimental animal models and humans, perhaps as the result of endothelial damage, red cell deformability, or defects in local oxygen release. The simultaneous presence of tissue hypoxia, alterations of NO metabolism with the formation of peroxynitrite, alterations of other vasoactive substances such as endothelin, and defective reactive hyperemia of nerve microvessels may combine to place diabetic nerves at risk. Although nerve ischemia is associated with dysfunction of diabetic nerves, it may not be a primary or major cause; rather, it may simply accelerate the pathologic process.

Mitogen-Activated Protein Kinases

Neurotrophic substances exert their effect by initiating a signaling cascade, only now being unraveled, which represents a possible pathogenetic mechanism and target for therapeutic intervention. Mitogen-activated protein kinases (MAPKs) are activated by excessive glucose and oxidative stress and may have an important role in the development of diabetic neuropathy possibly by inducing excessive neurofilament phosphorylation.

Neurotrophic Substances

Deficiencies in the amount, regulation, or function of a variety of neurotrophic substances (e.g., nerve growth factor (NGF), neurotrophin-3 (NT-3), insulin-like

growth factors (IGFs), even insulin itself) are thought to contribute to the development of sensory and autonomic neuropathies. Decreased endogenous target-derived and transported NGF may explain the decrease in sensory nerve expression of NGF-sensitive sensory neuropeptides CGRP and substance P in diabetic animal models. Unfortunately, clinical trials of exogenous recombinant NGF treatment have not produced a significant beneficial effect. Nerve brain-derived neurotrophic factor (BDNF) content is upregulated in diabetes and may exert a reparative or protective function. Similarly, NT-3 deficiency in diabetic animal models suggests that multiple neurotrophic elements may participate. IGF-I, decreased in diabetic serum and nerve, has antioxidant, survival-promoting effects. Exogenously administered IGF-I corrects hyperalgesia and deficits in axonal regeneration of diabetic rats *in vivo* and reverses established experimental autonomic neuropathy in diabetic rats. Direct application of insulin to diabetic somatic nerves (at doses that do not affect circulating glucose levels) unilaterally corrects nerve conduction velocity defects. C-peptide, cleaved from the proinsulin molecule during the secretion of insulin, has also been identified as a neurotrophic factor with a possible pathogenetic and therapeutic role in type 1 diabetes. Other trophic substances, including vascular endothelial growth factor (VEGF) and erythropoietin, may represent therapeutic avenues.

Oxidative Stress

Reduction in antioxidant defenses in the face of increased production of oxidant stressor molecules in diabetes may increase production of lipid peroxides, DNA damage, and mitochondrial injury with resultant damage to intracellular and extracellular proteins. Brownlee et al. have proposed a unifying hypothesis by which diabetes-induced increased glucose metabolism exaggerates the mitochondrial proton gradient and results in increased superoxide production and general oxidative stress. Others, however, have reported an insulin- and NT-3-sensitive decrease in mitochondrial membrane potential in adult cultured DRG neurons. Antioxidants have produced a salutary effect on biochemical and physiologic defects of diabetic nerves and have been approved for clinical usage in some countries.

Polyol Pathway

The polyol pathway in diabetic nerve and ganglia (normally a minor pathway of glucose metabolism) converts glucose to sorbitol and then to fructose using aldose reductase and sorbitol dehydrogenase, respectively. Increased flux through the polyol pathway is thought to increase oxidative stress, presumably by diminishing nerve glutathione content. Inhibition of aldose reductase, the first synthetic enzyme of the polyol pathway, has resulted in marked improvement of various neuropathic parameters in experimental animals, although clinical trials have been disappointing.

Protein Kinase C

Increased protein kinase C β II (PKCβ II) isoform activity has been reported to result in alterations of microvascular structure and function and induces transforming growth factor-β (TGF-β) effects on the extracellular matrix. Inhibition of PKC activity is reported to have salutary effects on experimental diabetic neuropathy.

Regeneration and Synaptic Dysplasia

Recently, an interest has developed in the consideration of the distal axon/nerve terminal as an important part of somatic and autonomic neuropathy in diabetes. Skin biopsies have demonstrated the loss of intraepidermal sensory axons in the absence of comparable findings in their more proximal portions in the sural nerve. Marked swelling of axon terminals (neuroaxonal dystrophy) in the sympathetic ganglia and of diabetic rodents and man has been proposed to reflect a diabetes-induced defect in cycles of synaptic turnover or remodeling, which may underlie synaptic plasticity. Synapse-targeted processes (particularly those related to synaptic vesicle function, membrane retrieval, and turnover of subcellular organelles) or failure to degrade transported materials at the nerve terminal are poised to contribute to the pathogenesis of terminal swellings. Impairment of axonal regeneration following sciatic nerve crush injury has also been reported in diabetic rodent models. Delayed and attenuated upregulation of IGF-I, NGF, p75 mRNA, or asynchronous changes in IGF-I receptor mRNA at injury sites in the distal sciatic nerve may significantly worsen plasticity in type 1 diabetic rats and contrasts with significantly milder changes in type 2 models.

Uremia

Chronic renal failure induces a distal sensorimotor neuropathy which is characterized by both axonal degeneration (more prominent in larger than in smaller myelinated axons) and secondary demyelination. In secondary demyelination, analysis shows concentration of demyelinated segments on atrophic axons with complete sparing of other adjacent normal axons, different from the random distribution of demyelinated segments on all myelinated axons. Its precise pathogenesis remains unknown, although a

number of pathogenetic mechanisms (presence of toxic circulating molecules including urea, ischemia, etc.) have been considered.

Vitamin Deficiencies

Beriberi (Thiamine)

Patients suffer from a distal symmetrical sensorimotor neuropathy in which pain, dysesthesias (unpleasant sensations induced by ordinary stimuli), and cutaneous hyperesthesia (an abnormal increase in sensitivity to sensory stimuli) may be prominent, as may dysphonia (e.g., abnormal speech such as hoarseness) from involvement of the recurrent laryngeal nerve. Both 'dry' (neuropathic) and 'wet' (cardiac form with edema) forms of beriberi are the result of nutritional deficiency, although it is not clear that it represents a pure thiamine deficiency disorder. In somatic nerves in the extremities, vagus and phrenic nerves, axonal degeneration is most prominent in distal portions of the nerves and (secondary) demyelination is manifest more proximally. Relative preservation of small myelinated and unmyelinated axons has been described in the presence of intrafascicular edema. Axonal degeneration is also demonstrated in the gracile columns in the spinal cord, in which distribution it represents a central–peripheral distal axonopathy. A distinctive accumulation of flattened membranous sacs accompanied by decreased numbers of cytoskeletal constituent neurofilaments and microtubules have been described in the distal branches of peripheral axons and central sensory projections.

Thiamine deficiency produces decreased nerve thiamine pyrophosphate (TPP), a cofactor in the decarboxylation of α-ketoacids, particularly the reaction of pyruvate and acetyl coenzyme A catalyzed by pyruvate dehydrogenase, and the formation and degradation of α-ketols.

Pellagra (Niacin)

In pellagra, there is a constellation of cutaneous lesions, gastrointestinal disturbances, behavioral manifestations and dementia, spinal cord involvement, and peripheral neuropathy. The peripheral neuropathy in pellagra is characterized by mild axonal degeneration. An epidemic of optic neuropathy, painful sensory neuropathy, hearing loss, and myelopathy developed in Cuba. This pattern of injury resembled Strachan's syndrome (amblyopia, orogenital dermatitis, and painful neuropathy). The precise relationship of multinutritional defects to discrete syndromes is complicated by the complex metabolic milieu existing in some patients.

Cobalamin (Vitamin B_{12})

Patients deficient in vitamin B_{12} develop a symmetrical sensory polyneuropathy characterized by axonal degeneration, not demyelination, which may or may not coexist with subacute combined degeneration of the spinal cord. Experimental studies suggest that the biochemical deficit involves methyl group addition reactions as the result of inadequate methionine and S-adenosyl methionine synthesis, a methyl folate trap, and formate starvation.

Vitamin E

Vitamin E deficiency develops most typically in conditions in which fat malabsorption develops (e.g., abetalipoproteinemia, cystic fibrosis, and congenital biliary atresia). Vitamin E deficiency in man, rat, and monkey results in spinocerebellar degeneration and a sensory neuropathy in which there is loss of large myelinated axons as part of a central–peripheral distal axonopathy and development of numerous dystrophic axons in the gracile nuclei. Vitamin E, a natural antioxidant, in deficient amounts may result in increased oxidative stress.

Hypothyroid Neuropathy

Nerve damage in hypothyroidism frequently results from focal compression and produces, most typically, a carpal tunnel syndrome. In addition, a more generalized sensory-symptom dominant polyneuropathy may also develop which responds to thyroid replacement therapy. Controversy exists whether segmental demyelination or axonal degeneration is the dominant pathology, but there is agreement that nerves show a decrease in large-diameter myelinated axons. Excessive amounts of glycogen accumulate in Schwann cells, axons, capillaries, and perineurial cells and increased numbers of subperineurial Renaut bodies (rounded collections of collagen, other cytoskeletal elements, and fibroblasts/perineurial cells) also are noted.

Acromegaly

Similar to the situation in hypothyroid neuropathy, the most common neuropathy in patients with acromegaly is compression injury resulting in carpal tunnel syndrome. In acromegalic patients, the cause of the neuropathy may be multifaceted since these patients have a metabolic syndrome that may also include diabetes, which complicates the interpretation of neuropathic symptoms and pathology. Nerve biopsies show decreased numbers of myelinated and unmyelinated axons, axonal degeneration, segmental demyelination, and increased fascicular area with

increased subperineurial and endoneurial connective tissue, thought to reflect a growth hormone-driven increase in circulating IGF-I and the presence of IGF-I receptors on Schwann cells and fibroblasts.

Liver Disease

Nerve biopsies in patients with chronic liver disease are reported to show evidence of segmental demyelination and remyelination. As in other metabolic syndromes, the interpretation is complicated by a variety of underlying, often associated, neuropathic diseases (e.g., alcoholism and diabetes). Primary biliary cirrhosis, a sensory neuropathy in which distinctive xanthomatous (lipid-rich collections within perineurial cells) are found in the perineurium, may have an immunological basis.

Alcoholism

Some alcoholics develop a chronic insidious progressive distal symmetrical sensorimotor neuropathy which may occasionally be painful or hyperesthetic and in which weakness of feet, hand, and thigh muscles may be prominent. Although classical studies in alcoholic patients reported segmental demyelination, more recent studies of animal models of alcoholism show that distal axonal degeneration is the predominant pathology. As in other metabolic neuropathies, the complex, deficient nutritional status of patients with severe alcoholism may involve a final pathway reflecting superimposed nutritional deficiency.

Summary

Metabolic neuropathies are common and complicate the clinical management of a variety of diseases, which is particularly true for diabetes, the most common of this group. The specter of an epidemic of diabetes and its complications has accelerated the pace of research which, at times, appears complex and contradictory. Nonetheless, investigators have begun to find common themes (e.g., oxidative stress) which may underlie a number of possible mechanisms (e.g., the polyol pathway, mitochondriopathy, IGF-I deficiency, and formation of AGEs). The many forms of diabetic neuropathy may involve a single mechanism or, more likely, involve several mechanisms which may require a cocktail of therapeutic agents in addition to an ongoing effort to better control blood glucose levels.

Introduction

In its broadest sense, peripheral neuropathy means disease of the peripheral nervous system (PNS). However, PNS disorders are usually divided into disorders of individual peripheral nerves (mononeuropathies) and those that affect the PNS in more widespread fashion (polyneuropathies). In common use, the terms polyneuropathy and peripheral neuropathy are often used interchangeably. The distinction between mononeuropathy and polyneuropathy is made because of important etiological differences and functional implications. Mononeuropathies are most often a result of mechanical injury or compression of the nerve somewhere along its course, and the functional disability is limited to the nerve's motor or sensory distribution. Polyneuropathies, by contrast, have a long list of potential causes, ranging from neurotoxins to systemic metabolic disorders to genetic lesions, often making determination of their etiology difficult. From a functional viewpoint, polyneuropathies can range from trivial to life threatening. The main focus of this article is the polyneuropathies.

The PNS

The PNS comprises cranial nerves 3–12, the spinal roots, sensory and autonomic ganglia, and the somatic nerves. At a cellular level, the PNS is that part of the nervous system which is myelinated by Schwann cells, as opposed to the central nervous system (CNS), which is myelinated by oligodendroglial cells. In humans the transition between the CNS and PNS is quite abrupt, occurring a few millimeters distal to the points of exit of the cranial and spinal roots from the brain stem and spinal cord.

The PNS has three basic functions: (1) conveying motor commands to all voluntary striated muscles in the body; (2) carrying sensory information about the external world and the body to the brain and spinal cord (except visual information: the optic nerves, which convey information from the retina to the brain, are in fact outgrowths from the brain); and (3) regulating autonomic functions such as blood pressure or sweating. Most polyneuropathies impair all three types of PNS function, although disorders selectively affecting motor, sensory, or autonomic functions occur.

In most of the PNS, motor, sensory, and autonomic nerve fibers are intermingled to form mixed nerves, and as might be anticipated, most PNS disorders result in a mixture of motor, sensory, and autonomic dysfunction. However, at the proximal and distal extents of the PNS, functions are anatomically segregated: the ventral spinal roots contain efferent motor and autonomic fibers only, and the dorsal roots comprise only afferent sensory fibers. Likewise, neuronal cell bodies in the dorsal root ganglia, which lie in the intervertebral foramina just proximal to the confluence of the dorsal and ventral spinal roots, are exclusively sensory, and autonomic ganglia contain autonomic neurons only. At the distal extent of their distribution, the motor and sensory axons of mixed nerves are sorted into purely motor or sensory terminal branches. An appreciation of these anatomical arrangements is important in diagnosis as localizing the likely site of the disorder helps narrow the possibilities that must be considered. For example, a disorder affecting sensation and sparing motor and autonomic function can be localized to dorsal roots, dorsal root ganglia, or sensory terminal branches and is unlikely to be arising in mixed somatic or cranial nerves, ventral roots, or autonomic ganglia. The process of localization as the first step in diagnosis, which is axiomatic in brain and spinal cord disorders, is equally important in the PNS, yet it is often neglected.

Throughout the PNS, the same basic histological plan is found. Myelinated and unmyelinated axons, Schwann cells, and interspersed capillary-like blood vessels (collectively referred to as endoneurium) are bundled into fascicles by perineurium, composed of five to ten lamellae of cytoplasm of perineurial cells, a type of modified fibroblast. Most nerves consist of several such fascicles, bound together by a loose connective tissue, the epineurium. Within the epineurium, between the fascicles, are found arterioles and venules of various sizes, structurally similar to those found in other tissues. The epineurial vessels are the major blood supply of the nerve, with the capillary-like endoneurial vessels constituting a parallel system. This dual blood supply ensures that peripheral nerve is relatively well protected from ischemic insult. Cells in both the perineurium and the endoneurial microvessels are interconnected by tight junctions, producing a blood–nerve barrier (or blood–nerve interface). This structural specialization ensures that peripheral nerve axons and Schwann cells occupy an environment whose chemical and cellular constituents are carefully regulated, analogous to the situation for neurons and glial cells in the CNS. Certain parts of the PNS lack this regulated

blood–nerve interface: the sensory and autonomic ganglia, the portion of spinal roots and cranial nerves traversing the subarachnoid space, and the distal terminations of motor axons at neuromuscular junctions.

The relative simple histology and function of the PNS limits its range of expressions of pathology. In fact, PNS disorders can be conveniently divided into two main types: diseases primarily affecting axons and diseases in which derangement of myelin is the primary problem, a distinction that is useful for diagnosis as well as for a rational approach to therapy. Nerve conduction studies and needle electromyography, which are easily performed in patients and which are widely available, are used to help characterize a process as demyelinating or axonal.

Given myelin's physiological role in greatly enhancing the speed of action potential propagation along axons, demyelinating polyneuropathies can be identified by marked slowing of nerve conduction. In genetic disorders of PNS myelination, the nerve conduction slowing affects all peripheral nerves uniformly, whereas acquired causes of PNS demyelination typically affect myelin in a patchy, nonuniform way. A consequence of the latter point is that there may be marked variability in conduction slowing between adjacent nerves, dispersion of compound nerve action potentials, or focal conduction block. In axonal neuropathies, by contrast, nerve conduction velocities are preserved or only minimally slowed, and the loss of functioning motor or sensory axons is reflected in decreased amplitudes of motor or sensory compound nerve action potentials. This dichotomous view of polyneuropathies as either demyelinating or axonal is useful, but it is an oversimplification. Myelin and axon integrity are interdependent, so all types of polyneuropathies ultimately have an impact on both axon and myelin.

The clinical manifestations of a polyneuropathy are determined by the classes of nerve fibers involved. Motor findings are those of the lower motor neuron type, that is, weakness accompanied by decreased muscle tone and decreased or absent reflexes. Axonal loss is also marked by muscle atrophy and, sometimes, fasciculation. The main symptoms of sensory fiber involvement are sensory loss and paraesthesia (abnormal sensations such as prickling or 'pins and needles'), and the latter are often painful. Examination may show relatively selective loss of only some sensory modalities in diseases that affect only certain classes of sensory fibers (e.g., in most acquired demyelinating neuropathies, the main sensory finding is of vibration and joint position sensation, reflecting a disease process mainly involving large-diameter myelinated axons). Most often the motor and sensory impairments are first manifest and remain most pronounced in the distal parts of the legs and arms, a pattern referred to as a glove-and-stocking distribution. Autonomic dysfunction is prominent in some types of polyneuropathy, and usually vasomotor symptoms such as orthostatic hypotension are the most troublesome. However, a host of other symptoms reflecting autonomic failure may be seen, including absent or excessive sweating, impaired lacrimation and salivation, bladder dysfunction, abnormal intestinal motility, and erectile impotence and other impairments of sexual function.

Determining that a patient has a polyneuropathy usually presents little difficulty, but discovering the cause of the neuropathy can be challenging. The list of potential causes is long (at least 100 are known), and the clinical manifestations of many of these are indistinguishable. The usual clinical approach is to sift through the symptoms, neurological examination findings, and nerve conduction data to see whether the patient may have a syndrome with a short list of possible causes. For example, sensory symptoms and impairment of all sensory modalities without motor or autonomic impairment might lead one to diagnose a dorsal root polyganglionopathy, of which there are only a few causes. In a patient with motor and sensory abnormalities in the distal legs and arms, finding slowed nerve conduction velocities greatly limits the potential diagnoses.

Often, however, a distinctive syndrome is not present, and a broad range of possibilities must be considered. One approach to classifying the possibilities is to separate inherited from acquired diseases and to subdivide the acquired causes into four large categories: metabolic (e.g., diabetes mellitus), infectious (e.g., leprosy), toxic/deficiency states (e.g., vinca alkaloids and other antineoplastic drugs), and immune-inflammatory (e.g., vasculitic neuropathy). Worldwide, the three most common types of polyneuropathy are probably leprotic, diabetic, and inherited. The population from which patients are drawn influences the likelihood of certain diagnoses. For example, leprosy is common in developing countries but rare in North America and Europe. In a hospital-based practice, chemotherapeutic drugs are a common cause of neuropathy.

Establishing a clear etiology for a patient's polyneuropathy may lead to specific therapy, but equally important, establishing the cause allows the physician to advise the patient about the long-term prognosis (some types of polyneuropathy can lead to major loss of function, but more often the disability is mild or less and does not worsen substantially over the years). Some therapies can be useful in almost all types of

polyneuropathy, regardless of cause. Pain is common in many types of polyneuropathy, and drugs for neuropathic pain are a mainstay of therapy in many patients. Medications used include amitriptyline (a tricyclic antidepressant) and gabapentin (an anticonvulsant that reduces synaptic release of neurotransmitters by inhibiting voltage-gated calcium channels). In patients with distal leg weakness, the ankle–foot orthosis (an L-shaped plastic brace that fits into a shoe and is strapped to the leg) holds the foot in neutral position and stabilizes the ankle, improving walking and stability, irrespective of the cause.

Pathobiological Mechanisms in Peripheral Neuropathy

The wide range of causes of peripheral neuropathy implies that nerve injury may be produced by a considerable variety of mechanisms at the cellular level. Although little is known about the pathophysiology of many types of peripheral neuropathy, in some there is considerably detailed understanding of the cellular events involved. An exhaustive account of pathophysiological mechanisms in peripheral neuropathy is beyond the scope of this article. However, a sense of current knowledge can be gained by considering four important but disparate varieties of neuropathy: Charcot–Marie–Tooth disease, diabetic neuropathy, Guillain–Barré syndrome, and neuropathy due to exogenous toxins.

Charcot–Marie–Tooth Disease

Charcot–Marie–Tooth disease (CMT) was first described in the nineteenth century as a familial disorder of slowly progressive distal weakness, muscle atrophy, and sensory loss. The term 'hereditary motor and sensory neuropathy' is used interchangeably with CMT. At present, 24 distinct genes have been identified which can produce the basic CMT phenotype. Nerve conduction studies show that CMT can be divided into two major groups, those with slow nerve conduction (type 1) and those in which nerve conduction velocity is normal (type 2). Autosomal dominant inheritance is most frequent, although recessive and X-linked forms also occur.

The identification of causative genes has been most rapid in type 1 CMT, and eight distinct loci producing the CMT type 1 phenotype are now known. The most common is characterized by a 1.4 Mb duplication in the long arm of chromosome 17 containing the gene encoding a 22 kDa peripheral myelin protein, PMP22. Establishing that the human PMP22 gene duplication was indeed the cause of the CMT type 1 phenotype was aided by the demonstration of a homologous gene duplication in the trembler mouse, which was long known to have slowed nerve conduction and nerve pathology closely resembling the human CMT type 1. Transgenic mouse and rat models of CMT type 1 are now available; they exhibit the 1.5-fold increase in PMP22 expression and histological abnormalities characteristic of CMT type 1. Studies in these models and in Schwann cell cultures suggest that PMP22 overexpression leads to endoplasmic reticulum overload, a blockade of normal intracellular protein degradation, and eventually cell death. The resulting impaired nerve myelination is reflected in the slowed nerve conduction. However, functional disability is not correlated with conduction slowing but with the progressive axonal loss which also occurs in all types of CMT. Presumably Schwann cell–axon interactions are necessary for axonal survival, but a detailed understanding of these interactions is lacking. Another puzzle in CMT type 1 is the striking variability in the phenotype severity, both between and within kinships, despite a uniform causative genetic lesion. The nature of environmental or other genetic factors that influence phenotype severity is currently unknown, as are the cellular consequences of other genetic loci for CMT type 1, although disruption in intracellular myelin protein trafficking seems likely.

Progress in the genetics of CMT type 2 (the 'axonal' variety, with preserved nerve conduction velocity) has been slower, although a few genes and chromosomal linkages have been identified. One CMT type 2 gene, mitofusin 2, is a coregulator of mitochondrial fusion and fission. X-linked CMT has a phenotype similar to CMT type 1 and 2 but has nerve conduction slowing intermediate between type 1 and type 2. In most kinships, point mutations in a gene encoding a gap junction protein, connexin 22, have been found. It seems logical that the generation and maintenance of compact myelin around each axon may require the participation of intra- and intercellular gap junctions, but further studies to elucidate mechanisms are awaited.

Diabetic Polyneuropathy

Peripheral neuropathy is a common complication of diabetes mellitus. Estimates of the prevalence of neuropathy in diabetics are in the range of 10–50%, depending on factors such as how neuropathy is defined, methods of detection, and the population studied. The symptoms and signs of diabetic polyneuropathy mainly involve the distal parts of the limbs and are approximately symmetrical. Sensory loss and paresthesia (often painful) are predominant, while muscle weakness is mild in most patients. In addition to disability related to pain and the sensory

and motor deficits, polyneuropathy is an important independent predictor of foot ulceration in diabetics, and it is associated with a twofold to 25-fold increase in the risk of amputation.

The pathogenesis of diabetic polyneuropathy has been the subject of much study and discussion, and there is not universal agreement about its cause. Electrophysiological and nerve biopsy data suggest that the major pathological process is axonal degeneration, though there is evidence of secondary demyelination as well. Potential mechanisms of pathogenesis include an ischemic process secondary to microangiopathy, analogous to diabetic retinopathy and nephropathy, glycosylation of structural proteins consequent to chronic hyperglycemia, or oxidative stress injury stemming from altered glucose metabolism. These mechanisms are not mutually exclusive and may coexist and interact in many or most patients with diabetic polyneuropathy.

In animal models of diabetic neuropathy, such as diabetes produced in rats by the pancreatic islet cell toxin streptozocin, reduced endoneurial blood flow and endoneurial hypoxia can be demonstrated. These are assumed to be consequent to basal lamina thickening and other structural alterations in endoneurial and epineurial vessels that are evident in histological studies of diabetic nerve. Chronic hyperglycemia is hypothesized to have both extracellular and intracellular effects on peripheral nerve. Extracellular effects include various types of glycation reactions, including direct glycosylation of structural proteins, as well as chemical rearrangements resulting in the production of advanced glycosylation end products. Intracellular effects result from increased flux of glucose through the polyol pathway, resulting in various potentially deleterious consequences: (1) a decrease in cellular nicotinamide adenine dinucleotide phosphate levels, resulting in decreased concentrations of glutathione (a free radical scavenger) and nitric oxide (a vasodilator); (2) increased cellular sorbitol levels, leading to decreased levels of myoinositol (necessary for Na-K adenosine triphosphatase function); and (3) increased fructose levels, which enhance formation of advanced glycosylation end products (fructose is tenfold more active than glucose in glycosylation reactions).

Attempts to prevent or reverse human diabetic neuropathy using treatments based on the wealth of experimental data have been disappointing to date. There is some evidence that strict glucose control (best achieved by pancreatic transplantation) is beneficial. Suppressing glucose metabolism via the polyol pathway by inhibiting the pathway's rate-limiting step appears promising in animal models, but in human trials the aldose reductase inhibitors have failed to show a clear benefit. Likewise, free radical scavengers like α-lipoic acid have shown promise experimentally, but clinical trials have been negative. Part of the inability to translate experimental success into therapies for human diabetic neuropathy may be related to issues of trial design such as reliable endpoints and duration of trials.

Guillain–Barré Syndrome

Since the widespread use of poliomyelitis vaccine, the most common cause of acute flaccid paralysis in the West is Guillain–Barré syndrome (GBS), or acute inflammatory demyelinating polyradiculoneuropathy, with an incidence of about 1.5 per 100 000 people per year. Prior to the development of modern intensive care units and mechanical ventilation, about one-third of patients with GBS would die of respiratory failure. Death is now uncommon in this condition, but GBS continues to produce substantial immediate and long-term neurological disability.

The course of GBS is characterized by rapid onset and worsening, with maximum weakness usually attained within 2 weeks of onset. About 25% of patients will require artificial ventilation, and a greater fraction will be bed-bound because of limb weakness. After a period of stability lasting several weeks or more, there is slow recovery of function over several months or more, due to nerve remyelination and regeneration. The recovery in most patients is fairly complete, although about 20% are left with permanent major disability.

The onset of GBS often closely follows minor upper respiratory or gastrointestinal infections. As there is no evidence of direct infection of the PNS in GBS, the concept of GBS as a parainfectious syndrome arose, that is, consequent to immune system activation triggered by an infectious agent. It was subsequently appreciated that infections with certain agents were particularly likely to precede the onset of GBS, in particular the gram-negative enteric bacterium *Campylobacter jejuni* and the Epstein–Barr and cytomegaloviruses. These observations lead to the idea that GBS might be an example of molecular mimicry, in which the immune system recognizes and targets epitopes common to the triggering microorganism and peripheral nerve. This concept is now widely accepted, although the specific epitopes responsible in most patients remain unknown and understanding of the immune effector mechanisms at work is incomplete.

The fundamental pathological process in classical GBS is an attack on myelin by macrophages. Biopsy

material from GBS patients and animal models of the disease shows macrophages engaged in active phagocytosis of myelin, with processes insinuated between myelin lamellae and lysis of myelin fragments in phagocytic vesicles. Macrophage activation appears to depend on both antigen presentation by T cells and the elaboration of cytokines and B cell production of antibodies directed against myelin epitopes. In recent years a variant of classical GBS has been described, acute motor axonal neuropathy, in which the macrophage attack targets the axolemma at nodes of Ranvier rather than the myelin sheath. This axonal form of GBS is particularly common in China, Japan, and Latin America; in northern China, axonal GBS occurs in summertime epidemics and is closely associated with antecedent *C. jejuni* infection.

The main animal model of GBS, experimental allergic neuritis, is produced by immunizing rats with peripheral myelin. Although specific moieties of several myelin proteins are able to induce experimental allergic neuritis, none of these have been convincingly shown to be target antigens in human GBS. Another unresolved issue is the role that antibodies against myelin gangliosides may play in the pathogenesis of GBS. There are many reports of different ganglioside antibodies in patients with classical GBS and its variants, but there is little agreement at present about the pathogenic role of these antibodies. The most convincing association has been found in a cranial nerve variant of GBS, Miller Fisher syndrome, in which 90% of patients have serum antibodies against the ganglioside GQ1b, which is particularly abundant in the myelin of ocular motor nerves affected in this syndrome. GQ1b antibody titers follow the clinical course of Miller Fisher syndrome, and they are not found in other types of inflammatory neuropathy. The case for the role of molecular mimicry in GBS has also been most closely worked out in Miller Fisher syndrome, as the GQ1b antibodies also exhibit a high affinity for certain moieties contained in the lipopolysaccharide capsule of the *C. jejuni* serotypes frequently associated with Miller Fisher syndrome. Similar antigenic homology between myelin components and other triggering microorganisms in other forms of GBS is assumed to exist but remains unproven.

Other than respiratory and other supportive care, treatments in GBS aim to abrogate the immunological cascade that leads to peripheral nerve injury. Current therapies that have been demonstrated to improve the rate of recovery in GBS are plasma exchange and intravenous immunoglobulin infusions, both of which exert widespread but rather nonspecific modulatory effects on the immune system. Corticosteroids have been shown to offer no benefit in human GBS. It is hoped that better understanding of the antigenic target(s) and contributions of the several immune effectors in GBS may allow development of specific, targeted immune therapy to improve outcomes in this disease.

Toxic Polyneuropathy

Peripheral nerve is susceptible to many chemical toxins. Some of these have been identified by careful study of clusters of polyneuropathy in communities or factory workers. Notorious examples include arsenical neuropathy from contaminated beer in nineteenth-century England, tri-orthocresyl phosphate neuropathy ('jake leg paralysis') from contaminated Jamaica ginger extract during Prohibition in the United States, and neuropathy in factory workers handling acrylamide monomer. Once such environmental neurotoxins are identified, further outbreaks of neuropathy can usually be prevented.

A more difficult problem is encountered with drugs whose adverse effects include peripheral neuropathy. This has become particularly important in oncology and in the treatment of HIV infection, in which many effective drugs predictably produce neuropathy, usually in a roughly dose-related fashion. Drug-induced neutropenia, formerly the dose-limiting factor for most antineoplastics, can now be treated with granulocyte colony stimulating factor. Consequently, neuropathy is now the dose-limiting side effect for many of these drugs. Efforts to understand how these drugs injure peripheral nerve have an intrinsic biological interest and are of great practical clinical importance as well. Although toxic neuropathy appears to offer a relatively uncomplicated system for study of the cellular mechanisms of nerve injury, there has been surprising difficulty developing good animal models for many of these neurotoxins.

An important strategy in antineoplastic drug design has been to develop drugs that interfere with microtubule function, which will inhibit cell division by disrupting mitotic spindles. Examples include the vinca alkaloids (vincristine, vinblastine, vinorelbine, and vindesine) and the taxanes (paclitaxel, docitaxel). Most neurons in the PNS must maintain long axons (some one meter or more) and are critically dependent on microtubule-based axonal transport systems to do so. As a consequence, it was anticipated that drugs impairing microtubule function would affect the PNS.

The vinca alkaloids bind with high affinity to tubulin, thereby disrupting microtubule assembly. In animal models, disorganized axonal transport microtubules and accumulation of neurofilaments in neuronal soma can be demonstrated, implying that the

vinca alkaloids do indeed impair anterograde axonal transport. Subsequent axonal degeneration appears to be calcium dependent and mediated by calpain. The taxanes bind to the beta subunit of tubulin and result in abnormally stable microtubules, in which disassembly is inhibited. This is assumed to impair axonal transport, resulting in neuropathy. With both vinca alkaloids and taxanes, preventive treatments that block interactions with tubulin might prevent neuropathy but would also likely limit their antineoplastic properties. Therefore, strategies to minimize the neurotoxicity of these drugs have aimed at enhancing neuronal survival or axonal regeneration, using agents like acetyl-L-carnitine, glutamate, or growth factors such as insulin-like growth factor. Although promising in animal models, these approaches have had limited success in humans.

Five Neuropeptide Genes and New Receptor Mechanisms

Discovery of a New Neuropeptide Gene Family

It took a surprisingly long time after the discovery of neuropeptide FF (NPFF) and neuropeptide AF (NPAF) by Hsiu-Ying Yang and co-workers in 1985 to clone the corresponding gene. This was apparently due to the low abundance of the messenger RNA (mRNA) in the brain and the amino-acid composition (many codons) of the common C-terminus of these peptides. The NPFF gene is located in chromosome 12 in humans (Table 1). The well-conserved human, rat, mouse, and bovine genes encode for both NPFF and NPAF (or the corresponding peptide). The gene comprises two short introns and three exons. The second gene, named prolactin-releasing peptide (PrRP), was identified and cloned as an endogenous ligand for a previously known orphan G-protein-coupled receptor (GPCR), GPR10, in 1998. This gene gives rise to one active peptide which can vary in length. In different species, highly similar peptides referred to as $PrRP_{20}$ and $PrRP_{31}$ are produced.

The presence of additional genes was recognized after cloning of the NPFF gene because there was a distinct hypothalamic group of neurons that expressed no NPFF mRNA despite strong NPFF immunoreactivity, suggesting the existence of a closely related immunoreactive peptide. This Arg-Phe-amide-related peptide (RFRP) gene was identified from databases and cloned. It encodes for three distinct active peptides, two of which are Arg-Phe-amide (RFamide) peptides.

The Kiss-1, or metastin, gene was initially identified as a protein that suppresses tumor metastasis in mice. Several groups then showed that the peptide originating from the Kiss-1 precursor activates a G-protein-coupled receptor which is present in many tissues in the periphery and brain.

The P518/26RFa/QRFP peptide gene was identified as an open reading frame for a 124-ti 136-residue protein from gene databases after testing the affinity of predicted peptides to a previously known orphan receptor or by searching for new RFamide peptide genes. The human precursor encodes for two potential RFamide peptides, whereas in other mammals, one of the predicted peptides is an RLamide (Figure 1). The nomenclature of the predicted peptides derived from the two potential precursor regions is unclear at the moment as no thorough analysis has been done for all predicted peptides, and the activity of these peptides has not been studied in detail. They have been referred to as P51, P52, QRFP, or 26RFa. Currently, the nomenclature of the mammalian RFamide peptides is complicated, and no logical, understandable, and generally accepted one exists. The names and chromosomal localization of the genes, peptide names, and most important receptors are shown in Table 1. The peptide sequences of typical active peptides are shown in Figure 1.

Neuropeptide FF, the Prototype Mammalian RFamide Peptide

After the discovery of the clam cardioexcitatory peptide in 1977, it was possible to explore the possible existence of related mammalian peptides using antisera against the molluscan tetrapeptide. Reports on the presence of FMRFamide immunoreactivity in mammalian brain and pituitary were followed by the identification of the first mammalian (bovine) neuropeptides FLFQPGRFamide and AGEGLSSPFWSLAAPQRFamide by Hsiu-Ying Yang and co-workers in 1986. The new peptide was called FLFQPQRFamide by those who discovered it. Other names, such as morphine-modulating peptide, were also used. Investigators were reluctant to name it because the most important functions of the peptide were not obvious, and the name could have become a misnomer. The NPFF gene was difficult to clone, which may have nourished the idea that even the immunoreactivity was due to cross-reactivity to a more abundant neuropeptide Y (NPY). This was indeed supported by the fact that many FMRFamide antisera cross-reacted with NPY, which is much more abundant in the central nervous system (CNS) than NPFF. Despite the lack of evidence of the gene and mRNA, many studies were performed with synthetic peptides and antisera as reagents. The distribution of NPFF immunoreactivity in the spinal cord, medulla, hypothalamus, and posterior pituitary suggested that NPFF may have different functions in the CNS. Many studies have since shown distinct effects on the pain system, including acute, inflammatory, and neuropathic pain. NPFF was reported to induce a vigorous morphine abstinence syndrome in rats, and the NPFF antiserum given intracerebroventricularly (icv) attenuated naloxone-induced abstinence symptoms. Acute but not chronic morphine also upregulates NPFF mRNA expression in the brain stem, but not in the spinal cord. NPFF alone does not affect catecholamine turnover, but it enhances rather than

Figure 1 C-terminal peptide structures of the typical mammalian RFamide peptides shown in comparison with neuropeptide Y (NPY). Note that the human Kiss-1 peptide has the characteristic RFamide structure whereas the mouse peptide shares the RYamide C-terminus with NPY.

attenuates changes induced by acute morphine on brain monoamines. Inactivation of NPFF by immunoglobulin G from the antiserum affects spatial memory in mice.

Recently, the first dipeptide analog of RFamide was reported as a selective and potent antagonist of NPFF at NPFF receptors. The mammalian RFamide peptides are difficult to study functionally because they share functions and receptor mechanisms. Apparently at least some of them have evolved as results of gene duplication, and some peptides may have lost their functions during evolution in some species. Studies with antisera directed toward the related C-termini of these peptides may also be difficult to interpret because several endogenous peptides derived from different genes may be detected. Application of one peptide at a particular brain site may also mimic the action of another endogenous peptide. Studies with gene-modified animals may also be hampered by activation of compensatory mechanisms. So far, data is available from some receptor knockout animals, and these studies suggest important interactions between the different RFamide peptides. As research on these peptides is still limited, new functions for them are likely to emerge.

Prolactin-Releasing Peptide

Although PrRP was first reported to release prolactin from a pituitary cell line and isolated pituitary cells, several subsequent studies failed to demonstrate a direct prolactin-releasing activity in intact animals. Interstingely, both NPFF and RFRP release prolactin both *in vivo* and *in vitro*, which demonstrates that RFamide peptides do possess this activity. The PrRP gene is expressed in a neuronal population of hypothalamic cells in the dorsomedial nucleus and in two different sites of medulla: the commissural nucleus tractus solitarius (NTS) and the group A1/A2 noradrenergic neurons. The first location would fit with regulation of endocrine functions. Indeed, the PrRPs are implicated in corticotropin-releasing hormone-mediated adrenocorticotropic hormone-release and subsequent regulation of plasma corticosterone levels. Current evidence suggests that PrRP may be involved in stress-mediated regulation of oxytocin release from supraoptic neurons. Several different types of experiments have also supported the involvement of PrRP in regulation of energy metabolism: icv administration of PrRP reduces food intake and increases uncoupling protein-1 (UCP-1) mRNA expression in brown adipose tissue. GPR10 knockout mice are obese and display elevated leptin and insulin levels, and their glucose tolerance is decreased.

Arg-Phe-Amide-Related Peptide

The RFRP gene gives rise to three different active peptides, two of which are RFamides. Their C-terminal structure resembles closely that of NPFF precursor derived peptides, and the RFRP-3 peptide shares the C-terminal tetrapeptide sequence QPRFamide with NPFF. The RFRP gene expression in the brain is limited to a central hypothalamic area, an area that covers parts of the dorsomedial nucleus and the area between the ventromedial and dorsomedial nucleus, and the periventricular nucleus. RFRP peptides have clear endocrinological and sensory effects, whereas their other functions have not been studied in detail.

P518/26RFa/QRFP

The brain distribution of this newly identified peptide gene in the ventromedial nucleus and lateral hypothalamic area suggest roles in regulation of metabolism. In human CNS, the gene is also expressed in the ventromedial nucleus and in the paraventricular nucleus. It has also been reported in human spinal cord, suggesting possible involvement in sensory functions. In mice deprived of food, the peptide increases short-term feeding. Other CNS functions of this peptide are yet to be studied. Activity studies have been done mainly using the C-terminally located active peptide 26RFa/QRFP/P518, whereas the receptors and functions of the second active peptide (which is RFamide only in humans) are less well known. The gene is also expressed in several other tissues, including the prostate, testes, urinary bladder, gut, thyroid, and parathyroid glands, suggesting that the peptides may have several different functions.

Kiss-1

In the mouse brain, Kiss-1, or metastin, mRNA is expressed in the periventricular nucleus, the arcuate and anterodorsal part of the preoptic nucleus, and the medial amygdala and nucleus of the stria terminalis. The neuroendocrine role of Kiss-1 through GPR54 is now well known, but other central functions remain largely unexplored.

GPCR Mechanisms

All mammalian RFamide peptides activate one or several GPCRs (Table 1). The first identified ligand/peptide system was the PrRP/GPR10 system. GPR10 was known as an orphan receptor. The GPR10 receptor couples to at least G_q protein in cell assays. Binding sites for NPFF had been mapped throughout the CNS long before the NPFF receptor identities were revealed. High levels of binding were seen in, for example, dorsal horn of the spinal cord and dorsal medullary regions, suggesting important functions in sensory and autonomic regulation. The first NPFF receptor gene identified was the GPCR referred to as HLWAR77. This receptor was also identified as NPFF2 receptor, together with another GPCR nominated NPFF1 receptor, or OT7T7022, by independent research groups. The NPFF receptors are coupled to at least the $G_{i/o}$ pathway, although coupling to other G-proteins is also possible. The Kiss-1 peptide was identified as a natural ligand for the orphan receptor GPR54, also called OT7T175 or AXOR12. Activation or this receptor activates phospholipase C through G_q protein. The P518/25RFa/QRFP was soon shown to be the natural ligand for the orphan receptor GPR103, also called AQ27 or SP9155. P518/25RFa/QRFP induces a rapid elevation of intracellular Ca^{2+} and inhibits cyclic adenosine monophosphate formation, suggesting coupling to $G_{i/o}$ and G_q proteins in cells that express the receptor.

Thus, all known RFamide peptides are now known to act as natural ligands for at least one GPCR. Although it has not been shown that any of the mammalian RFamide peptides displace opioid ligands from opioid receptors, evidence from cells that express delta-opioid receptors but no NPFF receptors suggests that NPFF can allosterically modify the δ-opioid receptor responses as measured using different signaling assays. This remains a possible mechanism that may contribute

to the modulatory effect of NPFF on opioid-induced analgesia. In addition, a subfamily of GPCRs referred to as maslike receptors present in, for instance, sensory ganglia MrgA1 and MrgC11 have affinity for RFamide peptides. No clearly specific ion channel receptors for mammalian RFamide peptides have been identified so far. NPFF potentiates the H^+-induced currents through acid-sensing ion channels in sensory ganglion neurons at high concentrations.

Multiple Functions of Mammalian RFamide Peptides

Sensory and Autonomic Functions

NPFF was first identified as a peptide that modulates morphine analgesia. Injection of NPFF into the brain ventricles attenuates the analgesic response to morphine in rats. Recent studies suggest that the RFRP peptide is even more potent in antagonizing the opioid effects. A distinctly different effect can be obtained after intrathecal injections of NPFF to the spinal space. A prolonged and enhanced response to morphine has been reported in rats when NPFF has been administered simultaneously. In models of inflammatory pain, like carrageenan-induced paw inflammation, the number of NPFF-producing cells in the superficial dorsal horn of the rat increases significantly, and a concomitant increase in NPFF2R also appears. When applied topically to exposed cells, exogenous NPFF enhances the descending inhibitory effect to spinal wide dynamic range neurons through a direct spinal action, suggesting that the increased expression of NPFF in inflammatory conditions may have functional significance. Intrathecally administered stable NPFF analog (1DMe)NPYF is effective against both thermal hyperalgesia and mechanical allodynia.

Contrary to the inflammatory changes, neuropathy induced by ligation of spinal nerves does not induce significant increase in spinal NPFF expression. However, intrathecal NPFF reduces cold allodynia. Few cells in dorsal root ganglia have also been reported to express NPFF mRNA, especially after nerve ligation.

NPFF-containing nerve fibers are abundant in many brain stem nuclei involved in pain regulation and autonomic functions (Figure 2). Functionally, NPFF attenuates tactile allodynia induced by nerve ligation by a mechanism that is in part sensitive to naloxone. In both normal and neuropathic rats, NPFF reverses the antinociception induced by morphine in the periaqueductal grey. The effect of NPFF in this brain area is thus paradoxical: it both reverses the effect of morphine and displays a clear antiallodynic effect.

In a model of visceral pain (rat acute colonic inflammation), the NPFF and NPFF2R mRNA are not affected in the spinal cord, but the brain stem expression of receptor mRNA is increased, suggesting involvement of this system in visceral pain.

Figure 2 Immunocytochemistry of neuropeptide FF (NPFF) in the mouse brain. (a) A dense network of nerve fibers and small immunoreactive neurons in the nucleus tractus solitarius (NTS) are seen in the vicinity of the nonreactive hypoglossal nucleus (XII) and area postrema (AP). (b) Dense fibers immunoreactive for NPFF but no immunoreactive neurons in the lateral parabrachial nucleus (PB). The antiserum used here shows no staining in NPFF knockout mouse, so that the immunoreactivity shown here is due to NPFF gene products rather than the closely related peptides derived from the other RFamide peptide genes. Cc, central canal; Scp, superior cerebeller peduncle.

Considering the closely related structures of mammalian RFamide peptides, it is not surprising that several of these peptides show significant effects in various models of pain. Although $PrRP_{20}$ and its C-terminal octapeptide fail to produce antinociception on the spinal level, $PrRP_{20}$ injected into the brain stem produces strong mechanical antinociception which is not reversed by naloxone. RFRP-1 is effective particularly in tactile allodynia and also in thermal nociception when administered intrathecally, whereas mechanical hyperalgesia is not affected to the same degree. In NTS, FRRP-1 suppresses mechanical hyperalgesia, like $PrRP_{20}$. Whether these peptides act

through the same or different receptors is not currently known. Recently, it has been shown that the anti-opioid effects of NPFF are absent in mice lacking the PrRP receptor, which suggests that at least some of the central effects may be mediated through the PrRP/GPR10 system, although no significant affinity of NPFF and GPR10 has been demonstrated.

NPFF and NPAF injected into the systemic circulation elevate blood pressure significantly. This effect may be in part mediated by catecholamines as prazocin and guanethidine partially inhibit the elevation in conscious rats. NPFF injected directly into the NTS induces an increase in arterial blood pressure, bradycardia, and inhibition of the cardiac component of the baroreceptor reflex. PrRP20 at this site has been reported to be inactive, but it facilitates heat-evoked blood pressure elevation in the caudal ventrolateral medulla. On this level PrRP thus controls not only somatic but also autonomic responses to pain.

Central Endocrine Regulation

NPFF has been shown to release prolactin in rats, both *in vivo* and from isolated pituitary cells. After icv administration, RFRP-1 also releases prolactin and is more potent that NPFF. Under these circumstances, PrRP did not release prolactin. Thus, the NPFF and RFRP precursor-derived peptides seem to be more potent releasers of prolactin than is PrRP. The effects of PrRP seem to be more pronounced on other hypothalamic and pituitary hormones than is prolactin. PrRP regulates growth hormone release, probably through somatostatin, and luteinizing hormone (LH) surge through gonadotropin-releasing hormone (GnRH). Kiss-1 appears to be a crucial regulator of the hypothalamic GnRH neurons, as intracerebroventricular administration of either full-length 54 aa Kiss-1 or the C-terminal fragment increases both LH and follicle-stimulating hormone secretion. Furthermore, inactivation of GPR54 in mice leads to hypogonadotropic hypogonadism, and mutations in human GPR54 are responsible for the disorder in humans. These findings suggest Kiss-1 and GPR54 as the ligand and receptor in key position in GnRH regulation.

Energy Balance, Feeding, and Water Balance

The presence of very high levels of NPFF in the rat posterior pituitary renders it possible that NPFF regulates vasopressin and/or oxytocin or is co-regulated with these. Indeed, NPFF peptide is practically absent from the pituitary of homozygous Brattleboro rats, which produce no functional vasopressin, although NPFF peptide levels in other parts of the brain are normal. Similarly, salt loading depletes both vasopressin and NPFF storage sites in the pituitary. However, the vasopressin gene expression increases whereas NPFF gene expression decreases after salt loading in rats. Icv NPFF acutely stimulates water intake in rats. NPFF appears to inhibit vasopressin release on the hypothalamic and medullary levels. Since NPFF in at least some species is made in supraoptic and paraventricular neurons and is transported to the posterior pituitary, pituitary nerve terminals are one of the candidate cells that may release NPFF into the blood. NPFF immunoreactivity is detected in human blood in a manner that suggests pulsatile secretion independent of vasopressin. Electroconvulsive therapy also increases blood levels of both vasopressin and NPFF, but the physiological stimulus responsible for the regulation is not known.

NPFF injected into the lateral ventricle of rats suppresses feeding in rats. PrRP injected icv also reduces food intake without affecting drinking, and PrRP mRNA expression in the hypothalamus and brain stem decreases during fasting. PrRP injections also induce UCP-1 mRNA in brown adipose tissue, cause hyperthermia, and increase oxygen consumption. GPR10 knockout mice become hyperphagic and obese with associated endocrine changes in leptin and insulin levels. Peptide 26RFa also increases food intake in mice, suggesting that most mammalian RFamide peptides are involved in regulation of food intake and metabolism, although it is currently unclear to what extent the mechanisms are the same.

NPFF1R and NPFF2R are also found in fat tissue, and the peptides regulate a number of genes in adipocytes, including the β-adrenergic receptor, suggesting that one or several circulating peptides may regulate metabolism. NPFF is secreted in human blood, but the exact identity of the circulating peptide, its origin, and the regulation of its secretion are not known.

Neuropeptide Inactivation or Metabolism

B P Roques, Université Paris Descartes, Paris, France

Introduction

More than 100 peptides have already been characterized in mammalian brains, but their physiological roles remain to be clarified. For some of them, this has been achieved by modulating *in vivo* the extraneuronal levels of the secreted neuropeptides because the interruption of the neuropeptidergic transmission occurs mainly by inactivating the ectopeptidases anchored in the membranes of neuron and/or glial cells. Selective inhibition of these enzymes, which belong essentially to the zinc metallopeptidase group, gives us access to the functions of the peptides. The induced effects can be compared to those obtained by using selective agonists or antagonists or invalidation of the genes encoding the components of a neuropeptidergic pathway (neuropeptide precursor, receptor, inactivating peptidases). These approaches are briefly presented here for some important neuropeptides (e.g., enkephalins, angiotensin, substance P, and cholecystokinin) for which all these methods have been used. Finally, the putative clinical interest of this physiological approach is discussed.

Information Transfer by Neuropeptides versus Neurotransmitters

It is now well known that neuropeptides act as messengers in the central nervous system (CNS); they meet most of the criteria characterizing neurotransmitters (e.g., acetylcholine, glutamic acid, dopamine, and serotonin). For example, (1) neuropeptides are localized in neuronal cells but not exclusively at the nerve terminal level; (2) neuropeptides are synthesized from large precursors that are generated by gene expression and then undergo subsequent maturation by well-defined proteases cleaving the precursor at the level of dibasic (Arg, Lys) sequences; (3) neuropeptides are stored in large dense-core (or granular) vesicles, from which they are released following neuron stimulation at high frequency; (4) neuropeptides interact with specific receptors (usually of the G-protein-coupled family) not necessarily located at short distances from the site of release (evidenced by the mismatch between the distribution of many neuropeptides and their targets in brain structures); (5) the neuropeptide–receptor interaction is expected to produce changes in ionic permeability of the targeted neuron and modifications of cellular biological events and gene expression; and (6) the neuropeptidergic transmission is interrupted by well-adapted biological mechanisms, such as peptidases able to cleave the active peptides into inactive metabolites.

Despite this, there are several differences between neuropeptides and neurotransmitters. Neurotransmitters are almost exclusively located at the nerve terminal, where they are synthesized through an enzymatic reaction cascade. They are stored in small vesicles and released by low-impulse-frequency action potentials. Receptors for neurotransmitters are usually located in synapses and therefore at a very short distance from the site of effector release. The interruption of the neurotransmitter action is ensured mainly, although not exclusively, by the secreted neurons through an efficient reuptake process. Thus, the concentration level of neurotransmitters rapidly becomes too low to bind the postsynaptic receptors, and this clearing mechanism could eventually be assisted by presynaptic receptors modulating negatively the release of the neurotransmitter, as is clearly shown in the case of dopamine. Consistent with these features, the cell-to-cell transmission is very rapid. In contrast, neuropeptide receptors are located far from the site of neuropeptide release, the diffusion of these large effectors is slow, and the inactivating peptidases have a rather low efficiency compared to the neurotransmitters reuptake processes; thus, the neuropeptidergic transmission is generally slow (Figure 1).

Due to this (often called volume transmission), we expect that neuropeptides play the role of neuromodulator rather than neurotransmitter, accounting for their critical role in behavioral control. This is reinforced by the frequent coexistence in the same neurons of one (or more) neurotransmitter(s) and neuropeptide(s). Thus, numerous neuropeptides are co-localized in dopaminergic, cholinergic, or GABAergic neurons, most frequently in interneurons able to modulate the firing of long neuronal pathways. Examples are:

- cholecystokinin (CCK): Asp-Tyr(SO_3H)-Met-Gly-Trp-Met-Asp-Phe-NH_2;
- enkephalin (ENK): Tyr-Gly-Gly-Phe-Met(Leu);
- substance P (SP): Arg-Pro-Lys-Pro-Gln-Phe-Phe-Gly-Leu-Met-NH_2; and
- neurotensin (NT): pGlu-Leu-Tyr-Glu-Asn-Lys-Pro-Arg-Arg-Pro-Tyr-Ile-Leu.

The single or co-release of two different effectors provides a large variety of responses at the level of the recruited neurons, located either in the immediate surrounding area or at longer distance from the secreted compounds. This increases the amount and diversity of information required for brain functioning.

Figure 1 Schematic representation of a neuropeptidergic pathway.

Table 1 Nomenclature of the main peptidases involved in brain metabolism of neuropeptides[a]

Name	*Enzyme commission (EC) number*	*[Abbreviation] and other names*	*Type*[b]
Endopeptidase-24.11	3.4.24.11	[E-24.11] Neutral endopeptidase, neprilysin, enkephalinase, CALLA, CD10	II
Endothelin-converting enzyme	3.4.24.71	$[ECE]^{-1}$	II
Endopeptidase 24–16	3.4.24.16	Neurolysin	Cyt
Angiotensin-converting enzyme	3.4.15.1	[ACE] Peptidyl dipeptidase A	I
Dipeptidyl-peptidase IV	3.4.14.5	[DPP-IV] X-pro-dipeptidyl-aminopeptidase, CD26	II
Thyrotropin-releasing hormone-degrading enzyme	3.4.19.6	[TRH-degrading enzyme] Pyroglutamyl aminopeptidase II	II
Tripeptidyl-peptidase	3.4.14.10	TPP-II, subtilisin-like serine peptidase	Cyt
Aminopeptidase N	3.4.11.2	[APN] Aminopeptidase M, CD13	II
Aminopeptidase A	3.4.11.7	[APA] Gutamyl aminopeptidase, aspartate aminopeptidase, angiotensinase A	II

[a]Except for DPP-IV and TPP-II, which are serine peptidases, all these enzymes belong to the superfamily of zinc metallopeptidases.
[b]I, N-terminus of the protein outside the cell; II, C-terminus of the protein outside the cell; Cyt, enzyme found mainly in the cytosol with a small fraction bound to the internal or external part of the membrane.

Peptidase-Induced Inactivation of Neuropeptides

A large number of peptidases that are able to cleave neuropeptides are present in mammalian brains, but only some of them have been clearly characterized as inactivating enzymes that generate inactive metabolites from an active neuropeptide (Table 1). Most of these enzymes belong to the zinc metallopeptidase group, which can be divided into two subgroups: (1) the exopeptidases, which remove one (aminopeptidase N (APN) and aminopeptidase A (APA)) to three (tripeptidyl-peptidase (TPP)) amino acids from the N- or C-terminus of neuropeptides and (2) the endopeptidases (neutral endopeptidase (NEP), angiotensin-converting enzyme (ACE), and endothelin-converting hormone (ECE)), which can hydrolyze peptide bonds inside the peptide sequence. Another subclassification is by localization inside or outside the neurons. The most important group of inactivating peptidases possess a short intracytosolic domain, followed by a transmembrane sequence anchoring the enzyme in the external membrane of the neuron with the enzyme active site located in the extracellular domain (Figure 1); these peptidases are designated ectoenzymes.

In a limited number of cases, neuropeptides are released in an inactive form and must be activated by the removal of a part of the secreted precursor.

This is the case with big-endothelin, which is processed in the external medium by the ectopeptidase ECE to provide the active endothelin. Angiotensin II and CCK undergo similar processes in brain, with the peptidase-evoked formation of shorter peptides endowed with different pharmacological activities than their peptide precursors (Figure 1).

Similarities and Differences in Zinc Metallopeptidases Involved in Neuropeptides Catabolism

The early studies of brain peptide degradation were essentially devoted to neurohormones and releasing factors. An increasing interest in inactivating peptidases in the brain emerged after the discovery of the two opioid peptides enkephalins. Tyr-Gly-Gly-Phe-Met (Leu) binds opioid receptors with higher *in vitro* affinities than morphine, but induces a very weak and transient analgesia even after intracerebral administration in rodents. This was shown to result from the cleavage of the Tyr-Gly bond by APN and of the Gly-Phe bond by NEP. The metabolites formed by the action of these two membrane-bound zinc metallopeptidases are completely inactive. NEP was shown to be efficiently inhibited by phosphoramidon, a well-known blocker of the bacterial endopeptidase thermolysin (TLN), which contains 315 amino acids.

The structure of TLN has been resolved by X-ray crystallography with and without various types of inhibitors, including phosphoramidon, and a mechanism of zinc-assisted hydrolysis of the peptide bond was proposed as a result of all these studies (Figure 2). The hypothesized similarity in the organization of the catalytic sites of TLN and NEP was supported by the cloning and sequencing of NEP. Indeed, two consensus sequences of the type HEXXH and EXXXD were found in both enzymes. Each of the amino acids present in these short fragments have been shown to participate in the catalytic hydrolysis of the peptide bond in TLN. The same mechanism for NEP was established by several site-directed mutagenesis experiments.

All the critical amino acids present in the active site of TLN were also found in NEP. Unlike TLN, however, NEP possesses an Arg-102 residue located at the edge of the active site, which is probably responsible for the dipeptidyl carboxypeptidase activity of NEP that is observed in the release of Phe-Leu from Leu-enkephalin (Tyr-Gly-Gly-Phe-Leu).

All the zinc metallopeptidases have almost the same mechanism of action. Schematically, hydrolysis occurs through the formation of a penta-coordinated complex of the metal, which includes the three zinc-coordinating amino acids of the peptidase, the oxygen of the scissile bond, and the water molecule that is initially bound to the zinc atom (Figure 2).

The specificity of the zinc metallopeptidases is essentially ensured by van der Waals and ionic interactions between the S_2, S_1, S_1', and S_2' subsites and the lateral chains of the corresponding P_2, P_1, P_1', and P_2' moieties of the substrate (Figure 3). NEP has a broad selectivity and can cleave various short linear or cyclic peptides. The enzyme behaves like an efficient nonspecific endopeptidase, cleaving *in vitro* a large number of linear neuropeptides such as NT, SP, and CCK-8.

The consensus sequences of amino acids present in the catalytic sites of TLN and NEP were used for cloning ACE, ECE, and other zinc metallopeptidases. In the case of aminopeptidases, the second consensus EXXXD is not preserved; but for APN and APA, site-directed mutagenesis studies showed that the third zinc ligand is also a glutamate, as it is in endopeptidases (Figure 2). Moreover, the pure exopeptidase action of these enzymes was shown to be due to the interaction of the free N-terminal amino group of the

Figure 2 Zinc metallopeptidases: sequence homologies and mechanisms of peptide bond hydrolysis (left) and superposition of active sites of three different enzymes (right).

Figure 3 Inhibitors of neuropeptide-inactivating peptidases. ACE, angiotensin-converting enzyme; APA, aminopeptidase A; APN, aminopeptidase N; IC_{50}, median inhibitory concentration; NEP, neutral endopeptidase; TPP, tripeptidyl peptidase.

neuropeptidase substrate with a glutamate, hindering the displacement of the peptides beyond the S_1 subsite.

Another important group of zinc metallopeptidases, designated matrixins, has a slightly different organization of the consensus sequence, which is larger and contains three histidine as zinc ligands – HEXXHXXGXXH – but the mechanisms of peptide-bond hydrolysis is very close to that of TLN

and related enzymes. Several matrixins have been crystallized and co-crystallized, and the structure of their active site was shown to be superimposable on that of TLN and NEP, with the presence of four α-helices and three β-sheets forming both the catalytic site and the S_1' pocket (Figure 2). In 2000, NEP was crystallized, and the structure of the functional part of the protein was found to correspond to a previously proposed model obtained by computer-assisted modeling.

In spite of the large differences in the number of residues in TLN, NEP, neurolysin, and ACE and the very weak sequence homologies among all these enzymes, their crystal structures showed a close arrangement of active sites and an almost identical mechanism of catalysis and inhibitor recognition. The latter parameter is essentially governed by the importance of restriction in access to the active site. The molecular modeling of ECE-1 structure is perfectly consistent with these results.

The use of selective peptidase inhibitors showed that despite the relatively broad specificity of the limited number of brain peptidases, a certain *in vivo* specificity is achieved, at least for some peptides (ENKs, CCK, NT, and angiotensin) governed by the distribution of a given peptidase, its potential neuropeptide substrate, and their specific receptors.

Natural and Synthetic Inhibitors of Neuropeptide Metabolizing Enzymes

The synthesis of selective or dual inhibitors, the latter being able to block different peptidases (e.g., an endopeptidase such as NEP and an exopeptidase such as APN), has been facilitated by their membership of the zinc metallopeptidase group. The development of these inhibitors is based on the introduction into the structure that recognizes the active subsites ($S_1 \rightarrow S_n$ and $S_1' \rightarrow S_n'$) surrounding the catalytic site of groups capable of strongly binding the zinc atom (e.g., —SH, —COOH, —HONH-CO, —P(O)OH; Table 1). Thus, compounds with nanomolar inhibitory potencies and very high selectivity were obtained for ACE/NEP, ECE-1, APN, APA and for the serine protease TPP (Figure 3).

Natural inhibitors generally issued from cultures of bacteria such as bestatin, amastatin, and phosphoramidon are also often used. However, these substances are less potent and selective than inhibitors designed to fit the enzyme active site optimally.

The disadvantage of peptidase inhibitors compared with exogenous agonists or antagonists is their lower pharmacological potencies. However, this disadvantage is compensated by their more specific effects, which correlate with the phasic release of their peptide substrate in brain structures recruited by a particular stimulus (e.g., pain, stress, or emotion) and the absence or low change in either the secretion of the peptide or expression of its targets (e.g., metabolizing enzymes or receptors).

Thus, as expected, the maximal antinociceptive effects of NEP/APN dual inhibitors are in the 40–70% range of those produced by morphine; this is consistent with a local enhancement of endogenous ENKs that is too low to saturate brain opioid receptors. This eliminates or reduces strongly the major side effects of exogenous opiates (respiratory depression, constipation, tolerance, and dependence).

Biochemical Criteria Used to Characterize Neuropeptide-Activating or -Inactivating Peptidases

Anatomical Criteria

Several criteria must be fulfilled for an enzyme to be considered a neuropeptide-metabolizing peptidase. The most frequently claimed is the existence of a co-localization of the three components of the neuropeptidergic pathway (neuropeptide, specific receptors, and metabolizing peptidase). This criterion is often difficult to establish, due to the previously discussed extended distribution of the three proteins in a brain structure. Nevertheless, quantitative autoradiography using highly selective and potent tritiated or radioiodinated inhibitors of NEP and ACE has clearly demonstrated the discrete distribution of these metallopeptidases in brain structures where their physiological role is expected (in the case of ENKs, the spinal cord, the periaqueductal gray matter (PAG), the thalamus for the control of pain, and the mesolimbic and mesocortical pathways and the amygdala for the control of mood). This was completed recently through the discrete autoradiographic visualization of APN, the other ENK-inactivating peptidase showing its presence in brain tissue, although this enzyme was earlier thought to be present only in cerebral microvessels (Figure 4).

Lesion studies of neurons with kainic acid infused in a particular structure and subsequent labeling with radioactive probes showed the preferential localization of peptidases (e.g., NEP) on neurons which was consistent with the visualization of their mRNAs by *in situ* hybridization. In addition, lesions of the caudate-putamen, in the case of NEP, demonstrated a distant and large reduction in NEP and the opioid receptors in the pallidum, indicating a presynaptic co-localization of the enzyme and the receptors on axon terminals. In the spinal cord, unilateral rhizotomy demonstrated that approximately 60% of opioid

Figure 4 Co-localizations of: (a) NEP; (b) μ-opioid receptors; (c) δ-opioid receptors; (d) APN. APN, aminopeptidase N; NEP, neutral endopeptidase. Statistical analysis $^{*}p < 0.05$ and $^{**}p < 0.01$.

receptors are presynaptically located on afferent fibers and 40% are postsynaptically located. Interestingly, no change was observed regarding the level of NEP, suggesting that the peptidase and opioid peptides are co-localized in interneurons regulating the secretion of efferent neurons.

Most of these results were confirmed by immunohistochemical methods, showing in many cases the ultrastructural localization of the components of a neuropeptidergic pathways. Thus, it has been demonstrated that NEP is not concentrated at synaptic interfaces but, rather, uniformly distributed on the surface of the neuronal perikaryon and dendrites. The vicinal localizations of NEP visualized by the immunogold method and of SP in the substantia nigra, where the density of SP is much higher than that of ENK, suggest that NEP could play a role in the inactivation of SP in this structure.

Analytical Criteria: Microdialysis Experiments

The second method used to categorize an inactivating peptidase as a brain enzyme is the characterization of the metabolites of the peptidase-cleaved neuropeptide by microdialysis. This technique is now currently used in various animals, including mice; it allows the extracellular fluid secreted from a group of neurons in a given structure to be collected. Highly sophisticated methods using capillary electrophoresis coupled with fluorescence detection or online mass spectrometers (matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF)/time-of-flight mass spectrometry (TOF MS)) have now been developed that replace the immunodetection of the peptides. These methods, which can be used in freely moving animals, are preferred to the *in vitro* techniques in which homogenates or even slices of brain structures are employed. In these cases, the diffusion of the studied peptides, generally radiolabeled, across the tissue cannot escape the collision with peptidases not concerned with the physiological inactivation process. For these reasons, conflicting and uninterpretable results have been obtained for several important neuropeptides (e.g., ENK, SP, NT, and CCK). Another advantage of the *in vivo* microdialysis is the possibility of using the method in animals with different pathological conditions (e.g., pain, stress, and anxiety).

Nevertheless, to be entirely conclusive, the microdialysis experiments should be associated with the local or systematic administration of selective inhibitors of the incriminated metabolizing enzymes. This seems to have been achieved systematically only in the case of the ENKs, demonstrating clearly that in the superfused spinal cord of anesthetized rats dual NEP/APN inhibitors, such as kelatorphan, inhibit completely *in vivo* endogenous ENK catabolism. The use of selective NEP or APN inhibitors showed that each peptidase participates about equally in ENK inactivation. Interestingly, the level of extracellularly secreted ENKs is strongly increased by painful stimuli. Likewise, the systemic administration of dual inhibitors in freely moving rats produces a long-lasting four- and twofold increase in ENK levels measured by immunocytochemistry in the nucleus accumbens and the PAG, respectively.

Strikingly, although various metallo-ectoenzymes, in particular NEP, ACE, ECE, and APN, alone or in association, have been suspected of being involved in the *in vivo* inactivation of almost all the neuropeptides, often with conflicting results, the selective inhibitors of these peptidases have not been systemically added to the vehicle of the microdialysis experiments. In these cases, the role of inactivating peptidase cannot be attributed to these enzymes.

Nevertheless, measurements of ENK levels in presence or in absence of inhibitors showed that, for example, in primates an intravenous (i.v.) administration of SCH 32615, a NEP blocker that enters the brain, enhanced the level of ENKs in cerebrospinal fluid ninefold compared to controls (administered the vehicle alone). In addition, several microdialysis studies *in vivo* in rats using the dual NEP/APN inhibitor kelatorphan demonstrated that NEP probably cleaves SP in the substantia nigra but not in the spinal cord, where another specific enzyme appears to be implicated.

Pharmacological Experiments Required to Attribute the Role of Activating or Inactivating Peptidase to a Neuropeptide-Cleaving Enzyme

A rarely reported characteristic of the neuropeptidergic transmission is the frequent lack of direct relationship between the presence of specific receptors for a neuropeptide and its tonic or phasic release in a given structure. This has been studied in detail with the ENKs using selective or dual inhibitors of NEP and APN.

The effects of the inhibitors depend on (1) the magnitude and duration of the ENK release evoked by a particular stimulus, which varies in the different enkephalinergic pathways (this accounts for the higher analgesic responses observed using dual inhibitors such as RB 101 to nociceptive thermal stimuli than to mechanical stimuli) and (2) the efficiency of the inhibition of both peptidases, depending on their levels and localization with regard to the receptors and the rate of clearance of the inhibitor(s) from the site of peptidase(s) action. These considerations could explain why in many pharmacological assays the administration of the rather μ-selective antagonist naloxone does not produce a measurable effect on the response induced by the circulating ENKs. Thus, naloxone fails to affect pain thresholds in normal volunteers, but lowers the thresholds of patients with naturally high pain sensitivity.

The large differences in tonic or phasic release of ENKs in various tissues are nicely illustrated in structures such as the PAG, the locus coeruleus (LC), and the nucleus tractus solitarius (NTS). As shown in Figure 5(b), the systemic administration of RB 3007 induces a long-lasting increase in extracellular levels of Met-enkephalin measured by microdialysis in PAG, a structure critically involved in the control of pain. Accordingly, a significant antinociceptive activity was measured in rodents with the same time-course after the administration of RB 3007 (Figure 5(a)).

The LC contains a densely packed group of noradrenaline-containing neurons which develop a hypersensitivity following chronic morphine treatment, and this is considered to be one of the main causes of withdrawal syndrome and the development of dependence. Interestingly, kelatorphan was able to potentiate strongly the firing of LC neurons but had no significant intrinsic effect, indicating that there is little or no tonic endogenous opioid action in this brain region. This is probably the main reason why chronic treatment with peptidase inhibitors is unable to induce physical and psychic dependence compared to morphine.

The major side effect of opiates is a central respiratory depression, mainly due to the inhibition of the bulbar respiratory neurons. Unlike morphine, dual inhibitors applied locally in this brain structure or administered by systemic routes are unable to produce a reduction of respiratory frequency, suggesting again a weak tonic release of endogenous ENKs in the neural network that generates the motor respiratory activity.

The lack of psychological dependence observed after chronic treatment with dual inhibitors of ENKs used at high doses could be related to a rather low stimulation of the opioid receptors located in the ventral tegmental area (VTA), which are able to activate the dopamine receptors, leading to an increased release of dopamine in the nucleus accumbens. The chronic activation by opiates of this mesolimbic pathway seems to be involved in addiction. The failure of dual inhibitors to establish a conditioned place preference probably results from a lower recruitment of opioid receptors than opiates in the VTA. This hypothesis is supported by the minimal changes in dopamine release in the nucleus accumbens after local administration of kelatorphan into the VTA compared to morphine.

Investigation of the Physiological Roles of a Given Neuropeptide through Selective Inhibitor-Induced Modulation of Its Extracellular Levels

As previously discussed, peptidases capable of inactivating a given neuropeptide, such as NEP or ACE, are distributed in a very large number of structures, both in the CNS and in peripheral organs, as shown by autoradiography. This could indicate that they contribute to the activation or inactivation of a large number of peptides. However, only some physiological substrates (ENKs and SP in the CNS; atrial natriuretic peptides, bradykinin, and endothelin-1 for NEP in peripheral organs; and angiotensin I and bradykinin for ACE) have been clearly identified for both peptidases. Other peptides may be characterized in the future, but it appears that in numerous structures these peptidases have been recruited only during a phase of development or that the tonic or phasic release of putative unknown substrates by these peptidases is too low to give significant pharmacological responses following enzyme inhibition. The main interest in using selective inhibitors is to allow the investigation of the physiological actions of a (neuro)peptide by modulating its extracellular levels. Nevertheless, this requires to verify that the responses given by the selective inhibitors are really due specifically to the protection of the studied peptide from the targeted peptidase. This is illustrated in the case of ENKs, for which the invalidation of the preproenkephalin gene leads to a decrease in the pain threshold and an enhancement in anxiety and agressivity. These responses are the opposite of those observed by the systemic administration of dual NEP/APN inhibitors. Moreover, we recently showed that a dual inhibitor such as RB 101 loses its antinociceptive property almost completely in preproenkephalin knockout mice, supporting the specific role of ENKs as selective substrates for NEP and APN in brain. Likewise, knockout mice for the gene encoding NEP show a limited increase in the pain threshold, indicating that APN cannot completely compensate for the absence of NEP. Further, the increase in tissues of ENK levels by a feedback mechanism occurs only in certain regions, suggesting, as previously discussed, that the physiological role of NEP is restricted to structures with a sufficient phasic release of these neuropeptides. And, unlike naloxone, selective antagonists of the various neuropeptides (NT, SP, somatostatin, and CCK) that were shown generally *in vitro* to behave as substrates of NEP were unable to modify the responses given by ENKs protected by dual inhibitors.

The inhibition of inactivating peptidases to explore the physiology of a brain peptide has several advantages over the use of a selective receptor antagonist or gene invalidation of its receptors or of its neuropeptide precursor. During the blockade of a peptide receptor by an antagonist, the circulating levels of the peptide messenger remain unchanged or can even increase by a feedback mechanism. This also occurs following the invalidation of neuropeptide receptors. In such cases, depending on the volume of the neuropeptidergic transmission and the broad specificity of the inactivating enzymes, an even more important drawback could result – the possible inhibition of another peptidase by the generated orphan peptide could result in enhanced levels of the natural neuropeptide substrate of the mistakenly targeted peptidase, possibly modifying its physiological actions.

Thus, emotional stressors produce an increase of SP in the medial amygdala and anxiety-related behavior blocked by a specific SP antagonist. The anxiolytic effects of RB 101 suggest that, at least in this structure, SP is probably not inactivated by NEP. Contradictory results (analgesia and hyperalgesia) were observed following the local administration of SP in the spinal cord or the PAG. This was interpreted by a modulation of the endogenous opioid release, a part of which could be evoked by the binding of SP or one of its metabolites SP(1–7) to NEP.

Physiological Interactions between Two Neuropeptidergic Systems Studied by Inhibition of Metabolyzing Enzymes

Among the neuropeptides, CCK-8 (Asp^1-Tyr(SO_3H)-Met-Gly-Trp-Met-Asp-Phe^8NH_2) was shown to be cleaved *in vivo* by APA, leading to CCK-7, and to be cleaved by the ubiquitously distributed tripeptidyl peptidase II (TPP-II, EC 3.4.14.10), mainly enriched in the cytosol but also present as an internal and/or external component of the cell membrane. Butabindide is a highly potent and selective inhibitor of TPP-II (Figure 3). In contrast to various neuropeptides, including ENKs, the degradation of CCK-8 by rat brain membranes is much slower, suggesting that peptidases could be associated with other clearing mechanisms. Thus, an uptake system has been identified for CCK-8 that could function to accumulate CCK-8 and/or CCK-7 for subsequent degradation by TPP-II inside the cell, although we cannot exclude a role also for the dipeptidyl-aminopeptidase (DAP; EC 3.4.13.11).

Interestingly, in many cases, the metabolism of CCK-8 leads either to fragments interacting with

about the same affinity with CCK-1 and CCK-2 receptors, such as CCK-7, or to shorter metabolites such as CCK-5 or CCK-4. These small fragments, shown to be present in brain, interact selectively with high affinities with the CCK-2 receptor and could play a major role in the control of emotion, vigilance, and memory processes. Therefore, the metabolic cascade involved in CCK-8 metabolism warrants further study, especially because the administration in humans of CCK-4 or the CCK-5-related peptide pentagastrin triggers panic attacks.

An antagonism between opiates and CCK has been reported, and the association of a dual NEP/APN inhibitor with a CCK-2 antagonist allowed the mechanism of this process to be investigated. Thus, the analgesic effect of RB 101 in rodents is potentiated (200–800%) by the co-administration of CCK-2 antagonist, suggesting that endogenous CCK counteracts the action of endogenous opioids in all animal models of pain in which RB 101 was found active. Similarly, the antidepressant effects of RB 101, shown to be dependent on δ-opioid receptor stimulation, are enhanced by the CCK-2 antagonist L-365,260. They appear to result from an increase in dopamine in the nucleus accumbens and are almost completely suppressed by D1 and D2 antagonists. The opioid system is able, in turn, to regulate the release of CCK peptides. Thus, the stimulation of the δ-opioid receptor by endogenous ENKs (RB 101) or by a selective δ agonist enhances the release of endogenous CCK-8. These responses are antagonized by the δ-selective antagonist naltrindole (NTI) supporting a critical role of the δ-opioid receptor in the modulation of the CCK-2 system.

Increasing the levels of endogenous ENKs by RB101 was shown to induce antidepressant-like effects in relevant paradigms, such as forced swimming or the conditioned suppression of motility in rats. Behavioral studies showed that blockade of CCK-1 and CCK-2 receptors produces opposite effects. Thus, the antidepressant-like effects of RB 101 were suppressed by the CCK-1 receptor antagonist and enhanced by the CCK-2 receptor antagonist PD-134,308. The effects of RB 101 were potentiated by microinjection of PD-134,308 in the anterior nucleus accumbens and the central amygdala but not in the caudate nucleus, suggesting that the mesolimbic system plays an important role in the interaction between the CCK and opioid systems in the control of these behavioral responses.

Several Zinc Metallopeptidases Produce Two Active Neuropeptides, Angiotensin III and IV, from the Brain Angiotensin II

The physiological role of the brain renin–angiotensin systems was recently clarified, thanks to the use of highly potent and selective inhibitors of APA and APN, two zinc metallopeptidases involved in the degradation of angiotensin II (AII) (Figure 6). This peptide is formed under the action of ACE, both at the periphery and in the CNS. In the circulation, this peptide is responsible of blood pressure (BP) increase, and several studies suggest that AIII could be the peptide involved in the control of BP at the brain level. Selective inhibition of the formation of AIII by APA and blockade of its degradation by APN have confirmed unambiguously the hypothesis about the central role of AIII in the regulation of BP. Thus, EC 33 increased the half-life of [^{3}H]/AII injected intracerebrovascularly (ICV) into conscious mice and completely blocked the formation of [^{3}H]/AIII, whereas the APN inhibitor PC18 (Figure 3) enhanced the half-life of AIII by a factor of four. The central bioavailability of EC 33 was strongly enhanced by the

Figure 6 Angiotensinogen-derived regulatory peptides. ACE, angiotensin-converting enzyme; APA, aminopeptidase A; APN, aminopeptidase N; IRAP, insulin-regulated zinc aminopeptidase.

Figure 7 EC 33 disulfide (RB 150): (a) structure; (b) entering the brain after i.v. administration (1 mg kg^{-1}) and inducing blood pressure reduction. ΔMABP, change in mean arterial blood pressure; DOCA, desoxycorticosterone acetate. Statistical analysis $^{**}p < 0.01$.

formation of a disulfide bond in RB 150 ([H_2N-CH ($CH_2CH_2SO_3H$)-CH_2S]$_2$) (Figure 7(a)).

In the brain, RB 150 gives the active form EC 33 and produces a long-lasting (24 h) hypotensive effect in rats following i.v. administration. A possible peripheral effect can be rejected because the i.v. injection of EC 33, which is unable to cross the blood–brain barrier, has no effect on BP.

The action of APN on AIII generates AIV, which was shown to facilitate memory retention and retrieval in rats using various experimental models. This could be related to the long-term potentiation elicited by AIV in the hippocampus. Recent studies showed that the target of AIV, designated AT4 receptor, corresponds to insulin-regulated zinc aminopeptidase (IRAP). The mechanism by which IRAP improves memory function remains unclear, but the use of selective inhibitors is expected to clarify this fascinating problem. Two other neuropeptides, NT and TRH, seem to be almost exclusively inactivated in the CNS by the cleavage of their sequences by EC 24.16 and pyroglutamyl aminopeptidase II, respectively. The problem is more complicated with dipeptidyl-peptidase (DPP-)IV, which has several substrates in the brain and peripheral organs, although the most abundant brain peptide, neuropeptide Y (NPY), appears to be essentially inactivated by this peptidase. In all cases, microdialysis experiments, both with and without selective inhibitors, are required to confirm these hypotheses.

Conclusion

The modification of the extracellular levels of neuropeptides is a well-adapted means of investigating the physiology of a neuropeptidergic pathway. This requires the use of several *in vivo* methods able to delineate the role of the inactivating peptidases in various structures. This has been achieved for some neuropeptides (ENKs, angiotensins, and CCK), leading to promising pharmacological results in analgesia, depression, and BP control that have yet to be evaluated in clinical trials. Approximately 2% of the human genome could correspond to the zinc metallopeptidases, which represent putative pharmaceutically interesting targets. An anticipated, fascinating step in the study of the newly discovered activating/inactivating peptidases will be to achieve their de-orphanization, leading to the characterization of both the peptide substrates and subsequently their receptors.

Neuropeptide Ligands

Neuropeptides are 5- to 50-amino-acid-long linear polypeptide gene products, synthesized on ribosomes in the form of preprohormones, which are larger precursors that have to be cleaved and often posttranslationally modified. The first neuropeptide discovered was substance P, with potent pressor effects noted by Euler and Gaddum in 1931. Its sequence was determined more than 40 years later by Leeman and colleagues. The pace of discovery of neuropeptides picked up when Mutt and colleagues started to isolate C-terminally amidated peptides, with the rationale that such peptides are unlikely to be proteolytic degradation products. They discovered glucagon, secretin, vasoactive intestinal polypeptide (VIP), galanin (Gal), neuropeptide Y (NPY), and many other peptides.

The understanding that the neuropeptides are encoded on mRNAs that are first translated into large preprohormones also led to the examination of all the peptide fragments that are formed during the maturation of these precursors. Starting with the case of the proopiomelanocortin (POMC) preprohormone, the discovery that tissue and cell type-specific processing of the peptide precursors occurs in the central and peripheral nervous systems added to our understanding of the complexity and versatility as well as the physiological specificity of the neuropeptidergic signaling.

The next wave of peptide discoveries came when G-protein-coupled receptors (GPCRs) were discovered by homology cloning using the β-adrenergic receptor as a template; because of a large group of these GPCRs whose ligands were not known, the notion of orphan receptors was adopted. Also, a few years later, the Human Genome Project provided a whole set of GPCR sequences without any indication of the nature of their endogenous ligands as well as the sequences of a whole range of putative prepropeptides with their putative dibasic cleavage points.

These orphan receptors (as well as the peptides in search of their receptors) became highly coveted drug targets – based on *in situ* hybridization-supported mapping of their expression patterns – that showed that these are often in areas of the brain that are associated with normal function and with the pathogenesis of higher functions. Some of the orphan receptors indeed have peptide ligands (e.g., nociceptin/orphan FQ (OFQ), melanin-concentrating hormone, and ghrelin), whereas other orphan GPCRs have been shown to bind lipid transmitters such as the endocannbinoids and sphingosine phosphate derivatives or even to act as pH sensors.

Neuropeptide Signaling as Drug Target

The neuropeptidergic transmission is an attractive area for pharmacological intervention for several reasons.

- We have (almost) all but exhausted the receptors for the classical neurotransmitters – the monoamines, glutamate (Glu), γ-aminobutyric acid (GABA), and acetylcholine (ACh) – as drug targets in our efforts to treat diseases such as epilepsy, major depression, and obesity. We have, however, come to realize that neuropeptides coexisting with these classical neurotransmitters have receptors expressed in brain regions identified as important physiologically and pathophysiologically. This suggests that we should target neuropeptide receptors to modify the activity of neurons in these selected brain regions to achieve therapeutic effects.
- The concentration of (most) neuropeptide receptors is much lower than that of receptors for the classical neurotransmitters, and there are seldom large populations of spare receptors. By the same token, the number of cells producing the corresponding neuropeptides may be as low as only a few thousand in the entire brain.
- The neuropeptide receptor type is a GPCR – a class of drug targets traditionally easier to address chemically.
- The synaptic concentrations of the neuropeptide ligand is several orders of magnitude lower than that of the classical transmitters (nanomolar vs. micromolar or even submillimolar); thus, when antagonists are required, the competition with the endogenous ligand is not that difficult to achieve, and when agonists are sought, there are not large numbers of receptors to saturate. Nevertheless, in both the case of agonists and antagonists, high-affinity (K_D in the nanomolar or subnanomolar range) ligands have to be identified.

The synthesis of neuropeptides depends on gene transcription and translation and is subject to multiple posttranslational modification steps; the ready neuropeptide is often loaded into and stored with adenosine triphosphate (ATP) in large dense-core vesicles. These vesicles release their content under high-frequency

stimulation or at bursting activity, which studies of the periphery on norepinephrine (NE)/NPY and ACh/VIP and in the central nervous system (CNS) on ACh/Gal-containing neurons have shown. This frequency-dependent chemical coding permits at low frequency the ACh/galanin-containing neuron in the septum to release only ACh within the ventral hippocampus, whereas at higher frequencies the same neuron also releases Gal in addition to ACh. Gal, then, in multiple ways, can modify the actions of ACh on pre- and postsynaptic targets in the hippocampus. There are therapeutic possibilities hidden in this scenario; when a given transmitter or neuropeptide is only released at higher frequencies or at specific stimulation patterns, it is a very tempting target of pharmacological intervention because such a mechanism would leave normal synaptic function unaffected but would kick in during runaway discharge and trauma-mediated massive release.

The biosynthesis of neuropeptides can be safely modified chronically, as most transgenic animal models with null mutation of neuropeptides demonstrate. These studies show that there is as strong redundancy of the neuropeptide signaling such that a number of other neuropeptides can take over the role of the one not synthesized. This is good in terms of drug safety, but of course also it indicates that not all chronic neuropeptide targeted actions are necessarily robust or remain robust. For example, the hyperpolarizing neuropeptides in the hippocampus that contribute to control of excitability – somatostatin, NPY, Gal, dynorphin, and so on – can take over, in a compensatory manner, one another's roles to some extent in seizure models. Nevertheless, NPY and Gal receptor subtype selective agonists are sought as anticonvulsant agents (Table 1) because subtle levels of receptor modulation may just do the job.

The selective suppression of neuropeptide gene expression with antisense and/or RNA interference will most likely provide us an important entry into the understanding of neuropeptide (receptor) pharmacology.

Similarly, we may envisage inhibiting the enzymes involved in the processing or transcriptional modification of neuropeptides. When this occurs via a specific enzyme that has one or few neuropeptide substrates, such as the biosynthetic angiotensin-converting enzyme (ACE), successful drugs can result from this approach such as the ACE inhibitors. However, when the enzyme such as that involved in the oxidation of the C-terminal glycine to generate C-terminal amide (necessary for the activity of many neuropeptides) is involved, then no pharmacological selectivity can be expected from the inhibition of this very target.

To slow down, decrease, or altogether stop production and maturation of a neuropeptide seems to be difficult, with only few exceptions (e.g., ACE inhibitors). Furthermore, most neuropeptides bind to several receptor subtypes on different cell types, mediating different actions. Thus, inhibiting the synthesis of neuropeptide agonists has to be evaluated in comparison to the generation of receptor subtype-selective antagonists to the GPCR-type neuropeptide receptors – a process the industry is very familiar with.

Neuropeptide Receptors as Drug Targets

The neuropeptide receptors studied so far belong to the GPCR type and transmembrane domain receptors that, when occupied with agonist, can activate intracellular G-protein-mediated signaling. GPCRs are favorite targets of the pharmaceutical industry, which has produced safe and chronically useful drugs such as antagonists to β-adrenergic or angiotensin receptor for the treatment of hypertension and chronic heart failure, H1 or H2 histaminergic antagonists for allergy or digestive ulcer treatment, and D2 dopaminergic antagonists as antipsychotics. Agonists acting at GPCRs such as serotonin (5-HT_{1A}) receptor agonists anxiolytic and antidepressant drugs, 5-HT_{1B} agonists to treat migraine, or μ- and κ-opiate receptor agonists such as morphine and synthetic analogs for the treatment of several types of pain.

The experience with GPCR antagonists has shown that chronic treatment causes only moderate supersensitivity and that, similarly, treatment with agonists has resulted in moderate desensitization, if any, in most systems. The most notable exceptions are the opiate agonist and muscarinic cholinergic agonists, which caused rapid desensitization. In the fastest documented desensitization (based on rapid internalization of the GPCR), neurokinin (NK)1 was shown, on exposure to the neuropeptide substance P, to rapid internalized within a few minutes. However, the somatostatin receptor agonists used in the treatment of acromegaly, for example, do not cause substantial desensitization of somatostatin receptor, even when constant plasma levels are maintained over months with the current slow release formulations and although *in vitro* data suggest that desensitization occurs under such conditions.

Validation of Neuropeptide Receptors as Drug Targets

The past decade saw the extensive use of molecular, biological, and transgenic techniques to validate neuropeptide receptors as drug targets for the treatment of different diseases. This is a very important development because the time it takes to synthesize

Table 1 Neuropeptides and their receptor subtypes and the links to physiological and pathophysiological actions[a]

Receptor	*Receptor subtypes*	*Endogenous ligands*	*Link to disease, physiological actions*	*Comments*
Angiotensin receptors	AT1, AT2	Angiotensin II, III	Hypertension (AT1), cardiac hypertrophy, congestive heart failure	
Bombesin receptors	BB1, BB2 (GRPR), bb3	Neuromedin B, GRP, GRP(18–27) (aka neuromedin C)	Anxiety (GRPR), cancer, circadian rhythms	
Bradykinin receptors	BK1, BK2	Bradykinin, Lys-bradykinin (kallidin)	Pain, hyperalgesia	
Calcitonin gene-related peptide receptors	Calcitonin, CGRP1, AMY1, -2, -3, AM1, -2	α- and β-CGRP, AMY (aka islet amyloid peptide), AM, AM2/ intermedin.	Hypocalcemia (calcitonin)	Need RAMP 1, 2, 3; AMY 1, 2, 3 = calcitonin receptor + RAMP 1, 2, 3, respectively; CGRP1, AM1, AM2 = calcitonin gene-related receptor + RAMP 1, 2, 3, respectively
Cholecystokinin and gastrin receptors	CCK-A, CCK-B	CCK4, CCK8, gastrin I, gastrin II	Anxiety, panic	
Corticotropin-releasing hormone receptors	CRH1, CRH2	CRH, urocortin 1, 2, and 3	Anxiety, depression, stress	Species differences in splice variants of CRH2
Endothelin receptors	Endothelin 1, -2, -3	ET-A, ET-B	Congestive heart failure, pulmonary hypertension, stroke, kidney failure, hypertension, angioplasty-induced restenosis, asthma, chronic obstructive pulmonary disease, pain, cancer	
Galanin receptors	Gal1,-2,-3	Galanin, GALP	Epilepsy, seizure, anxiety, depression, pain, alcoholism	
Ghrelin receptor	GHSR1	Ghrelin	Obesity, feeding disorders, depression	Obestatin is derived from preproghrelin and was described as acting on GPR39; however, these data have been disputed
Leptin receptor	Leptin receptor	Leptin	Obesity, depression	The receptor is a single membrane-spanning receptor most related to the gp130 signal-transducing component of the growth hormone, IL-6, G-CSF, and LIF receptors, which are part of the class I cytokine receptor family
Melanocortin receptors	MC1, -2, -3, -4, -5	ACTH, AGRP, α-MSH, γ-MSH, γ2-MSH;	Endocrine, metabolic, and feeding disorders; obesity	MC6 has not been cloned; agouti and AGRP are two of the very few endogenous antagonists; haploinsufficiency of the MC4-R is responsible for at least 5% of severe human obesity
Melanin-concentrating hormone receptors	MCH1, MCH2	MCH	Obesity	MCH2 may be nonfunctional in rodents
Neuropeptide S receptor	NPSR	NPS	Anxiety, depression, asthma, COPD, vigilance	SNPs within the NPSR have been associated with an increased prevalance of asthma in a variety of populations

Table 1 Continued

Receptor	*Receptor subtypes*	*Endogenous ligands*	*Link to disease, physiological actions*	*Comments*
Neuropeptide Y receptors	NPY1, -2, -4, -5	NPY, PYY, and PP	Epilepsy, pain, anxiety, depression, obesity	NPY6 is not a functional receptor; NPY3 has been dropped as a true NPY receptor
Neurotensin receptors	NTS1, NTS2	Neurotensin, neuromedin N	Schizophrenia	A third neurotensin receptor, NTS3, was cloned; it is a 100-kDa protein with a single transmembrane domain (i.e., not a GPCR) and is identical to the previously cloned protein sortilin; the status of NT3/sortilin/gp95 as a true neurotensin receptor remains to be established
Neurotropin receptors	TrkA, TrkB, TrkC, p75	BDNF, LNGFR, NGF, NT-4/5	Pain, hyperalgesia, neurodegeneration, depression, schizophrenia	
Opioid receptors	μ, mu, or MOP; δ, delta, or DOP; κ, kappa, or KOP; ORL1	β-Endorphin, dynorphin A, endomorphin 1 and 2, [Leu5]-enkephalin, [Met5]-enkephalin, nociceptin/orphanin FQ	Pain, constipation, autism	
Orexin receptors	OX1, OX2	Orexin A and B (aka hypocretin 1 and 2)	Sleep regulation, obesity	Disruption of prepro-peptide expression or mutations in the gene encoding OX2 receptors result in a narcoleptic phenotype
Somatostatin receptors	sst1, -2, -3, -4, -5	Somatostatin 14 and 28, cortistatin 17 and 29	Acromegaly, GEP tumors, epilepsy, pain, diarrhea, sleep, anxiety, depression, memory	Somatostatins and cortistatins are products of different genes; there no receptor specific for cortistatin
Tachykinin receptors	NK1, -2, -3	SP, NK-A, NK-B	Anxiety, depression, schizophrenia, pain, migraine, COPD, asthma, emesis, IBD, urinary incontinence	
Vasoactive intestinal peptide, pituitary adenylyl cyclase-activating peptide, and related peptide receptors	VPAC1, VPAC2, PAC1	VIP, PACAP(1–27) and (1–38), PHI	Inflammation, injury, circadian rhythms	
Vasopressin and oxytocin receptors	V1a, V1b, V2, OT	Vasopressin and oxytocin	Learning, memory, anxiety, depression, autism, preterm labor, diabetes insipidus, congestive heart failure	

[a]We have not listed following peptide receptors: adiponectin, anaphylatoxin and chemotactic peptide, apelin, chemokine, cytokine family, glucagon and secretin family, glycoprotein hormones, gonadotropin-releasing hormone (GnRH), motilin, neuromedin U, neuropeptides B and W, proteinase-activated, relaxin family, resolvin, thyrotropin-releasing hormone (TRH), and urotensin II.

ACTH, adrenocorticotropic hormone; AGRP, agouti-related protein; AM, adrenomedullin; AMY, amylin; BDNF, brain-derived neurotrophic factor, CCK, cholecystokinin; CGRP, calcitonin gene-related peptide; COPD, chronic obstructive pulmonary disease; CRH, corticotropin-releasing hormone; GALP, galanin-like peptide; G-CSF, granulocyte-colony stimulating factor; GEP, gastroenteropancreatic; GHSR, growth hormone secretagogue receptor; GRP, gastrin-related peptide; IBD, inflammatory bowel disease; IL, interluekin; LIF, leukemia inhibitory factor; LNGFR, low-affinity nerve growth factor receptor; MCH, melanin-concentrating hormone; MSH, melanocyte-stimulating hormone; NGF, nerve growth factor; NK, neurokinin; NT, neurotropin; ORL, opiate receptor-like; PACAP, pituitary adenylyl cyclase-activating peptide; PHI, peptide histidine isoleucine amide; PP, pancreatic polypeptide; PYY, peptide YY; RAMP, receptor activity-modifying proteins; SNP, single nucleotide polymorphism; SP, substance P; VIP, vasoactive intestinal peptide.

adequate agonists to neuropeptide receptors that are able to cross the blood–brain barrier and that are peptidase resistant is measured in years; therefore, the increasing number of examples of transgenic animals that overexpress the neuropeptide in selectively chosen sets of neurons circumvents these problems in studying the pharmacological effects of chronic neuropeptide agonists in disease models. Thus, it was shown that the neuronal overexpression of Gal suppresses seizures in a variety of seizure models. An even faster method is the localized viral vector-mediated expression of a neuropeptide, which informs not only about the effects of an agonist but also about the site of action.

Similarly, null mutations of neuropepitdes have been informative about what antagonists will do in different disease states. The recent surge in the use of antisense oligonucleotides and of small interfering RNA (siRNA) experiments further focuses the answer in terms of the pharmacological effects of an antagonist and the site of action.

The use of receptor knockouts, as in whole pharmaceutical development, has been useful in deciding which receptor subtype is responsible for which effects of the neuropeptide. The usual caveat about compensatory changes occurring in transgenic animals is of particular relevance in the study of neuropeptide systems that are plastic and redundant. Nevertheless, these methods that make use of the fact that neuropeptides, unlike classical transmitters, are gene products and that thus their production can be manipulated by null mutation or overexepression has been very informative and constitutes an important part of the validation process of neuropeptide receptor as drug target.

The Problems of Finding Exogenous Ligands to Neuropeptide Receptors

Agonists

Table 2 summarizes the pharmaceutical development state of numerous neuropeptide receptor-targeting drugs, showing that we seek agonists for several neuropeptide GPCRs. These receptors include: MC4, NPY1, sst2, Gal1, Gal2, OX1, and the search for better μ- and κ-opioid receptor ligands continues.

The problems of finding neuropeptide receptor agonists relate to the nature of the endogenous ligands, which are often large molecules of 20–40 amino acids with possibly large corresponding binding pockets within the receptor. This offers the advantage of high-affinity and high-selectivity binding for the endogenous neuropeptides but makes the discovery of small nonpeptide agonists an almost impossible task. Obviously, the solid phase synthesis of peptides or peptide mimics or the recombinant production of peptides (when large quantities are needed) is not a problem today, but the peptide drugs have a number of inherent problems that make them not well suited as drugs.

1. They have very short half-lives because of peptidolytic degradation by both nonspecific and specific peptidases, although stability can be significantly improved by cyclization.
2. Many of the most sought-after actions for neuropeptides are at receptors expressed in the brain (or in the peripheral nervous system), but the peptide ligands do not cross the blood–brain barrier passively and selective transporters have not been reported (with a very few exceptions, e.g., secretin, thyrotropin-releasing hormone (TRH)) and, in general, oral bioavailability is hardly achievable.
3. The endogenous peptides are pan-ligands to multiple subtypes of receptors, whereas we would prefer to aim at pharmacological actions with receptor subtype selectivity (although such approaches may change again as the number of failed attempts using very selective ligands accumulate).

The synthesis of truncated and L Ala-substituted analogs (called Ala scan) of neuropeptides has shown that the binding epitopes can be well separated from one another in space and thus that it is not easy to reach/mimic these on a small synthetic nonpeptide molecule. Although strong progress has been made in the synthesis of scaffolds such as the β-sheet scaffolds and α-helix mimetics, the design of neuropeptide receptor agonists is not a fully realized task today. The introduction of pseudo-inverse-peptides (e.g., β or β/γ peptides) has addressed some of the peptidolytic stability issues, but it has not fully solved them. Nevertheless, peptidomimetic ligands, particularly for cyclic peptides, have been introduced successfully into clinical practice (cf. somatotstain receptor agonists), and new formulations have been produced that achieve very constant exposure over long periods (weeks).

Nonpeptide agonists to neuropeptide receptors The bright example of morphine keeps us confident that wonderfully important nonpeptidic agonists to neuropeptide receptors can be found. The problem is that drug companies do not work on the timescale of evolution and many have largely stopped or slowed the use of natural product libraries. The other issues, as already listed, are that the large neuropeptides have discontinuous binding epitopes and that, with these, they may also bind to the extracellular domains of the neuropeptide receptor in a polar milieu.

Table 2 Preclinical and clinical development and use of selected neuropeptide receptor ligands in 2006

Receptor	*Receptor subtypes*	*Indications*	*Clinical stage*	*Drugs and drug candidates*
Angiotensin receptors	AT1, AT2	AT1: hypertension, CHF, diabetic retinopathy, anxiety, glaucoma	Marketed AT1 antagonists	Valsartan, Losartan (AT1) launched in hypertension, CHF; ongoing studies in diabetic retinopathy, anxiety, glaucoma
Bombesin receptors	BB1, BB2 (GRPR), bb3	BB2: anxiety, depression BB3: cancer, cardiovascular disease, anxiety	Preclinical	
Bradykinin receptors	BK1, BK2	Pain	BK2 antagonists are developed for chronic pain; no positive data	
Calcitonin gene-related peptide receptors	Calcitonin, CGRP1, AMY1, -2, -3, AM1, -2	Hypocalcemia	Various calcitonins are used for the treatment of osteoporosis	Salmon calcitonin
Cholecystokinin and gastrin receptors	CCK-A, CCK-B	CCK-A: pain, eating disorders, antitumor, small-cell lung cancer, gut motility, schizophrenia CCK-B: anxiety, panic disorder, gastric secretion, sleep	CCK-B antagonists have been tested with negative outcome; however, CCK4 is used in patients/ volunteers to induce panic attacks	CCK-A: Lintitript [SR 27897] for bowel motility and gastric emptying, and biliary tract disease (phase II) CCK-B: GW-150013 in phase II for GAD, but stopped in sleep
Corticotropin-releasing hormone receptors	CRH1, CRH2	CRH1: antagonists developed in pain, depression, epilepsy, Alzheimer's disease, cognition, eating disorders, IBS CRH2: anxiety, eating disorders.	Numerous CRH1 antagonists are being tested in GAD/ depression, one open clinical trial with positive results in depression Combined CRH1/2 or combined CRH1 with SSRIs are considered	CRH1: BMS-562086, SB 723620, NBI-458; NBI-31199; NBI-35583; SSR-125543; also trials of CRH1 with SSRIs CRH1/2: JNJ-19567470 in phase I for anxiety and depression
Endothelin receptors	ET1, ET2, ET3	Pulmonary hypertension	Pulmonary hypertension is a recognized indication for ET antagonist; other indications did not meet proof of efficacy	Bosentan is marketed for pulmonary hypertension
Galanin receptors	Gal1, Gal2, Gal3	Depression, anxiety, pain, epilepsy, Alzheimer's	Gal3 antagonist developed for depression Galanin in open trial had antidepressant effects	Gal3: HT-2157 in depression
Ghrelin receptor	GHSR1	Obesity	A clinical trial with an ghrelin antibody has just been reported to be negative	Cytos ghrelin antibody
Leptin receptor	Leptin receptor	Obesity	No positive human data in obesity so far	
Melanocortin receptors	MC1-5	Mainly obesity MC4: obesity, erectile dysfunction, cachexia, pain, depression, anxiety	Haploinsufficiency of the MC4-R is responsible for at least 5% of severe human obesity	MC4: MCL-0129, preclinical
Melanin-concentrating hormone receptors	MCH1, MCH2	Obesity, anxiety, depression	MCH1 antagonists undergo clinical trials in obesity and possibly anxiety and depression, phase I/II	MCH1: SB-568849 obesity and anxiety, phase I/II; SNAP-7941 preclinical
Neuropeptide S receptor	NPS	Anxiety, sleep	No ligands	
Neuropeptide Y receptors	NPY1, 2, 4, 5	Obesity	Merck reported a very extensive NPY5 antagonists study that is negative, although receptor occupancy was carefully monitored	Ongoing phase II/III

Continued

Table 2 Continued

Receptor	*Receptor subtypes*	*Indications*	*Clinical stage*	*Drugs and drug candidates*
Neurotensin receptors	NTS1, NTS2, NTS3	Schizophrenia	Positive data with NTS3 agonist in schizophrenia phase II	NT-69-L, positive in schizophrenia
Neurotropin receptors	TrkA, TrkB, TrkC, p75			
Opioid receptors	μ, mu, or MOP; δ, delta, or DOP, κ, kappa or KOP, ORL1	μ: pain, diarrhea, anxiety, autism, drug abuse δ: pain, anxiety, depression, cardioprotection κ: pain ORL1: anxiety	Opioid agonists: pain, anxiety, drug abuse Opioid antagonists: opiate poisoning, diarrhea RO 646198 [ipidant] is a nonpeptide orphanin FQ/nociceptin ligand as a potential anxiolytic	μ agonists: morphine, codeine, methadone, fentanyl, and derivatives mixed agonists/ antagonists: buprenorphine, butorphanol, nalbuphine, pentazocine naloxone is a nonselective antagonist; AstraZeneca is developing AZD-2327, a modulator of the enkephalinergic receptor, in anxiety and depression, phase I
Orexin receptors	OX1, OX2	Feeding disorders sleep disorders, narcolepsy	OX1 agonists: feeding disorders, OX2 antagonists: sleep disorders, narcolepsy	Mixed (?) orexin antagonist, phase II (Actelion), sleep disorders
Somatostatin receptors	sst1, sst2, sst3, sst4, sst5	Acromegaly, gastroenteropancreatic tumors, GIT disorders (diarrhea), tumor imaging. Universal agonists: similar indications, transplantation, diabetes, neuropathies, oncology (restenosis), Cushing syndrome.	sst2/sst5 agonists: are marketed for these clinical indication; radioabeled sst2/sst5 agonists for imaging in various cancers; various radiolabeled somatostatin analogs for cancer treatment; universal agonist undergoing clinical trials for the indications listed	sst2/sst5 agonists: octreotide, lanreotide, and vapreotide; [^{111}In] octreoscan; various radiolabeled somatostatin analogs for cancer treatment; SOM230 and other universal agonists
Tachykinin receptors	NK1, NK2, NK3	NK1: pain, migraine, anxiety, GAD, depression, emesis, IBS, overactive bladder, chemotherapy-induced nausea and vomiting and postoperative nausea and vomiting NK2: IBS, COPD, asthma, lower urinary tract disorders, anxiety NK3: schizophrenia, COPD, urinary incontinence	NK1 antagonists registered in emesis, the other indications were eventually dropped; although positive data had been obtained in depression, they were not replicated NK2 and NK3 antagonists still under clinical investigation, phase I/II Combinations: vestipitant (GW-597599), an NK1 receptor antagonist, and paroxetine for depression, phase II	NK1: Aprepitant [MK 869] launched for the treatment of chemotherapy-induced emesis, phase II in GAD, stopped in depression Casopitant (GW-679769) and L 759274 in GAD and depression, phase II/III in other indications NK2: saredutant (SR-48968) and SSR-241586 for IBS, COPD, asthma, lower urinary tract disorders, anxiety, depression NK3: Talnetant (SB-223412) schizophrenia, COPD, urinary incontinence, phase II; SSR 146977 anxiety, depression, psychotic disorders, phase I

Table 2 Continued

Receptor	*Receptor subtypes*	*Indications*	*Clinical stage*	*Drugs and drug candidates*
Vasoactive intestinal peptide, pituitary adenylyl cyclase activating peptide, and related peptide receptors	VPAC1, VPAC2, PAC1	Inflammation, neurodegeneration, sleep	Under investigation	
Vasopressin and oxytocin receptors	V1a, V1b, V2, OT	V1a, V1b: depression V2: diabetes insipidous OT: anxiety, schizophrenia	V1a: depression and menstrual pain; clinical studies under way V1b: positive data reported in depression	V1a: SRX251, depression, premenstrual syndrome V1b: SSR-149415 is in phase II for anxiety and depression

CHF, congestive heart failure; GAD, generalized anxiety disorder; GHSR, growth hormone secretagogue receptor; GIT, gastrointestinal tract; IBS, irritable bowel syndrome; ORL, opiate receptor-like; SSRI, selective serotonin reuptake inhibitors.

The achievement of agonist action by inhibiting the degradation of the neuropeptides has been tested using the synthesis of enkephalinase inhibitors that show effects in pain models, but the robustness of such effects is strongly dependent on the release of the endogenous peptide which is faltering because the peptide stores can be exhausted easier than the stores of classical neurotransmitters that are synthesized at the presynaptic terminal enzymatically. The transcription, translation, and posttranslational modification-dependent peptide synthesis and release can be outstripped by demand.

The other major problem with neuropeptidase inhibitors is that not only specific enzymes such as enkephalinase, but also nonspecific peptidases and dipeptidases can degrade the peptide of interest, in particular if its concentrations rise as result of the inhibition of the selective degrading pathway.

Nonpeptide Antagonists to Neuropeptide Receptors

High-throughput screening (HTS) for neuropeptide receptor antagonists depends on our ability to engineer reporter systems using promiscuous G-proteins to couple almost any neuropeptide receptor to phospholipase C (PLC) activation and Ca^{2+} release from intracellular store or to the production of cyclic adenosine monophosphate (cAMP) and to cAMP responsive element-binding protein (CREB)-dependent transcription of luciferase. Such advances and the availability of additional reporter systems led to the screening of large chemical libraries for ligands to neuropeptide receptors.

Thus, nonpeptide antagonists and allosteric ligands of agonist and antagonist type have been found for many receptors that were screened, although some screens may have been unsuccessful, in spite of the large size of the libraries used. Of course, the chemical space that has been explored so far is very limited, especially given the nature of some of the targets investigated.

However, even when the HTS has identified hits, the subsequent development of drugs by pharmaceutical chemists follows the same slow and difficult path of engineering selectivity for receptor subtypes and for other relevant targets, proper safety, and determination of pharmacokinetic properties to reach the clinical candidate.

Lack of Structural Information on the G-Protein-Coupled Receptors

The lack of x-ray structure data for the GPCRs and for the GPCR–ligand complexes is a major impediment to the rational design of neuropeptide receptor ligands. The models based on rhodopsin have been somewhat useful in the design of monoaminergic GPCR ligands, but the models based on rhodopsin are far from perfect and have very little value when it comes to large neuropeptides. The long-awaited breakthrough in GPCR X-ray structure should make drug development for neuropeptide receptors easier, especially for straight receptor agonists.

Dynamics of Neuropeptide–G-Protein-Coupled Receptor Functions in Drug Development

The GPCR dynamics that can be used in achieving pharmacological effects or modifying such effects –are:

1. Internalization of GPCRs: modification by β-arrestins and receptor-specific kinases.
2. Dimerization of GPCRs: homodimerization or heterodimerization of receptors of the same, or even

different, families; heteroligomerization with receptor activity-modifying proteins (RAMPs), not forgetting the huge reservoir of activity-modifying proteins that seem to interact with almost every single GPCR (called GPCR-interacting proteins (GIPS), e.g., calmoduline, multiple PDZ domain containing protein (MUPP)1, postsynaptic density protein (PSD-)95, channel-interacting PDZ domain protein (CIPP), autocamtide-2-related inhibitory peptide (ARIP-)1, calmodulin-dependent protein kinase (CaMK), Src-homology domain 3 (SH3), synapse-associated protein (SAP), Homer, and 14-3-3).

The various posttranslational modifications of neuropeptide receptors include glycosylation, myristilation, and palmitoylation, each of which is important for the membrane targeting and function of the GPCR, but (apparently) not specifically relevant to neuropeptide receptors. The function-dependent agonist-dependent modification via receptor kinases such as β-arrestin is also very important, but they are not selective targets to achieve the modulation of neuropeptidergic action.

More selectivity can probably be achieved if the homodimerization of neuropeptide GPCRs (as has been reported for several receptors) can be targeted in such a manner that it affects signaling. This has so far been shown with model peptides that are not druglike but that suffice as a proof of the principle that neuropeptide action can be affected by blocking the dimerization of receptors such as μ-opiate, GalR1 or GalR2, or NPY2. Heterodimerization of GPCRs, in particular, among opiate receptors has been demonstrated to provide additional targets.

The most successful and potentially clinically useful example pertains to the blockade of the interaction of the subunits calcitonin receptor-like receptor (CLR) and RAMP of the calcitonin gene-related peptide (CGRP) receptor. The benzimidazole (BI) compound that binds to RAMP and acts as a CGRP antagonist was shown to be effective in migraine and in pain models, although the compound has bioavailability issues.

Allosteric ligands or modulators at neuropeptide receptors are found most easily when HTS is carried out in the agonist mode. The changes in the activity of the receptor-coupled reporter systems can identify allosteric ligands that can be developed into safe and effective drugs.

Perspective

The localization of neuropeptide receptor in important brain areas controlling many functions makes continued interest in neuropeptide receptor ligands certain. The increasing number of genetic studies showing linkage between disorders and neuropeptidergic signaling further emphasizes the view that we will see many neuropeptide receptor ligands as drugs. Finally, we have exhausted the possibilities of using the classical neurotransmitter pharmacology to achieve clinical effects such as control of excitability and treatment of major depression, obesity, and pain, and we are turning to the neuropeptide receptors as drug targets. For these reasons, we expect that many new drugs will target neuropeptide receptors, although some failures are also expected, as with the more classical GPCR ligands (e.g., NPY5 in obesity or NK1 in pain; Table 2).

Summary

The number of genuine neuropeptides and their corresponding receptors has increased steadily over the last 35 years through isolation of the peptides, through deorphanization of several GPCRs, and through the completion the Human Genome Project. Neuropeptides and their receptors show distinct regionally specific distributions in the central and peripheral nervous systems. Neuropeptide signaling is somewhat more distinct spatially than signaling with classical low-molecular-weight neurotransmitters that are more widely expressed, and therefore we assume that drugs acting at neuropeptide receptors will have more specific pharmacological actions with fewer side effects than drugs acting on glutamatergic, GABAergic, monoaminergic, or cholinergic systems. Neuropeptide receptors, which often have multiple subtypes and also multiple splice variants, belong almost exclusively to the GPCR family (also known as seven-transmembrane receptors (7TM)), a favorite class of drug targets in the pharmaceutical industry. Most neuropeptides are co-stored and co-released with classic neurotransmitters, albeit often only at higher frequencies of stimulation or at bursting activity, restricting the neuropeptide signaling to specific circumstances and increasing the expectation that neuropeptidergic drugs will have fewer side effects. Neuropeptides have been shown to possess a wide spectrum of functional roles, ranging from neurohormone to neurotransmitter to growth factor. Much evidence indicates that neuropeptides play crucial and varied roles when the nervous system is challenged by stress, injury, drug abuse, and other types of derangements, such as neuropsychiatric disorders with genetic, epigenetic, and/or environmental components. The ever-increasing number of true neuropeptides and their cognate receptors provide opportunities for us to identify novel drug targets for the treatment of both central and peripheral nervous

system disorders. In fact, receptor subtype-selective antagonists and agonists have been developed, mainly within the framework of the pharmaceutical industry, as illustrated by the success of somatostatin agonists and angiotensin and endothelin antagonists and also by the expected clinical applications of NK-1/2/3 (substance P) receptor antagonists, CRH, vasopressin, NPY, neurotensin, antagonists or neuropeptide receptor modulators which are reported to have efficacy in preclinical or clinical models of pain and neuropsychiatric diseases, such as migraine, chronic/neuropathic pain, anxiety, depression, and schizophrenia.

Neuropeptide Release

F Bergquist and M Ludwig, University of Edinburgh, Edinburgh, UK

Introduction

A main criterion for interneuronal chemical messengers, including neurotransmitters, neuromodulators, and neurohormones, is that their release be regulated and conditioned by neuronal activity. This article discusses the regulated release of neuropeptides, a large class of neuroactive messengers present in both the central nervous system (CNS) and peripheral nervous system. Other characteristics of neuropeptides that are vital for their function as interneuronal messengers, such as receptor effects, synthesis, storage, and breakdown/inactivation are also highlighted here because it is important to understand how neuropeptide release differs from classical neurotransmitter release.

The neuropeptide messenger family is large, and the list of members is still increasing steadily some 70 years after Gaddum and von Euler's discovery of substance P. More than 100 neuropeptides have established messenger properties. For most of these, the mechanisms of release have not been studied in detail, but there seem to be some common themes regarding activity-dependent neuropeptide release that allow some generalizations. The following section discusses some characteristics that are believed to be common to the release of most neuropeptides.

Neuropeptide Release Compared to Classical Neurotransmitter Release

Synthesis

Peptides are synthesized as larger precursors in the cell body but not in axons and axon terminals. The precursors are stored in vesicles where they are broken down by convertases into active peptides, and the vesicles are transported to the release sites. The supply of neuropeptides can, therefore, not be replenished quickly by synthesis at the release site, as is the case with conventional neurotransmitters. Thus there are mechanisms that economize the release of peptidergic vesicles, and transport mechanisms that can deal with changes in demand at particular release sites.

Vesicle Types and Release Sites

Releasable neuropeptides are always stored in and released by exocytosis from large dense-core vesicles (LDCVs). LDCVs differ from the other main class of neurotransmitter vesicles, small synaptic vesicles (SSVs) not only by size and physical density but also by the different composition of membrane proteins involved in the release processes and by a different cellular localization (Figure 1). SSVs are the predominant vehicle for classical neurotransmitter release, although amino acids and acetylcholine are also released from dense-core vesicles to some extent, together with peptides and sometimes amines. As indicated by the name, SSVs are mostly found at synapses, and release from SSVs is restricted to these highly specialized membrane structures (active zones). In contrast, LDCVs are broadly distributed and can release their contents from any part of the neuron, including the cell body and the dendrites. Release of classical transmitters from SSVs is thus restricted spatially, and the action of a classical transmitter is further constrained to the release sites by a highly efficient termination-of-release signal by uptake mechanisms and a fast breakdown. Peptidergic signaling, on the other hand, mostly takes place outside synaptic specializations (Figure 1).

Calcium Dependent Release

All activity-dependent peptide release appears to be triggered by an increase in intracellular Ca^{2+} concentration. The release machinery that mediates neuropeptide release has a higher affinity for Ca^{2+} than that involved in release of classical transmitters. This is necessary because, unlike SSVs, LDCVs are not positioned close to Ca^{2+} channels, and the Ca^{2+} that enters through these channels in response to depolarization is rapidly buffered on its way into the cell. The Ca^{2+} sensor on SSVs is synaptotagmin I, but the identity of the Ca^{2+} sensor on LCDVs is not yet known. When neuropeptides are released from dendrites, the release can be triggered not only by influx of Ca^{2+} via channels in the cell membrane but also by the mobilization of Ca^{2+} from intracellular stores.

Timescale of Neuropeptide Release and the Type of Stimulus Required

The characteristic Ca^{2+} dependence of LDCV fusion influences the speed at which neuropeptides are released. Classical neurotransmitters in SSVs are typically released with latencies of 0.3–1 ms after a Ca^{2+} trigger, whereas the latencies of LDCV release range from 30 to 2000 ms. The long LDCV latencies arise partly from the wider distances between LDCV Ca^{2+} sensors and the sources of Ca^{2+} entry into the cytosol,

Figure 1 Characteristic features of the small synaptic vesicle (SSV) and large dense-core vesicle (LDCV) release mechanisms. The SSV exocytosis (upper-left insert) can be evoked by low-frequency firing or single action potentials. The vast majority of docked SSVs are primed and therefore readily releasable. When an action potential reaches the axon terminal, voltage-sensitive Ca^{2+} channels open and increase the intracellular Ca^{2+} concentration close to the cell membrane to high micromolar levels that trigger SSV release (intracellular Ca^{2+} marked as blue dots). SSVs are found in close apposition to the Ca^{2+} channels and are released with short latencies after the arrival of an action potential. The SSVs can either be integrated into the terminal membrane for later recycling or release their contents by a kiss-and-run mechanism. SSV neurotransmitters are released into a narrow synaptic cleft, where they act on the postsynaptic receptors. Efficient uptake and/or breakdown processes rapidly terminate the signal, and very few transmitter molecules escape the synaptic cleft to act at a distance from the release site. SSVs are refilled by local neurotransmitter synthesis and/or uptake of already released neurotransmitters. The LDCV release of neuropeptides (upper-right insert) can take place from any part of the neuron. LDCVs typically require high-frequency or burst-patterned firing to be released. Compared to SSVs, a much smaller fraction of the docked LDCVs are primed, and only a small fraction of the vesicles present at a release site are available for release. There is no close relationship between Ca^{2+} channels and LDCVs, and LDCVs have a more sensitive Ca^{2+} sensor that responds to the lower Ca^{2+} concentrations that are attained at a distance from the Ca^{2+} source. The release latencies are long, from tens of milliseconds to seconds. Neuropeptides are released outside synaptic specializations and are not recycled into the releasing neuron but are broken down slowly in the extracellular space. Often the breakdown results in one or more active metabolites that require further breakdown to be inactivated. Consequently neuropeptides have a long range of action. Synthesis and packaging of neuropeptides only take place in the cell body, and all LDCVs need to be transported from there to the release sites. LDCVs in transport are captured into the releasable pool of vesicles or the reserve pool at active release sites. The capture of LDCVs is believed to be upregulated when there is increased demand for release at a particular site. Somatodendritic oxytocin release (lower insert) can be triggered by Ca^{2+} from stores in the endoplasmatic reticulum (ER) in addition to the inflow of extracellular Ca^{2+}. In vasopressin and oxytocin neurons, mobilization of intracellular Ca^{2+} can lead to the sustained enhancement of release by promoting recruitment of LDCVs to the releasable pool. Oxytocin cells can autoregulate the dendritic release by the activation of oxytocin receptors (OTRs) that release intracellular Ca^{2+} via an inositol-3,4,5-phosphate (IP3)-mediated pathway.

and partly from differences in the release machineries of SSVs and LDCVs. Neuropeptides require strong stimulation, such as high-frequency firing or burst-patterned firing, to be released, whereas classical neurotransmitters respond also to low frequencies and even single action potentials (Figure 1). The requirement of more intensive stimulation for neuropeptide release is probably linked to the long latencies to release and reflect a need for repeated depolarizations and accumulation of intracellular Ca^{2+}. The reason why neuropeptides play hard to get in this fashion might be that it is disadvantageous to trigger a prolonged and widespread signal too easily, but also it is time- and energy-demanding to refill the neuropeptide stores. Some neuropeptides act in an autoinhibitory fashion, and the restrictive release of such messengers

could serve as an emergency brake that prevents cellular excitotoxic damage or could contribute to cyclic activity in neuronal networks.

Molecular Release Mechanisms – SNARE Machinery

The molecular mechanisms of exocytosis have been studied in some detail over several decades. Some of the cellular systems that have been most useful for these studies examine mainly LDCV fusion; this is the case in adrenal chromaffin cells, from which release of easily oxidized catecholamines can be monitored with high time resolution using carbon-fiber electrodes, and pancreatic β-cells, in which insulin release is usually monitored as changes in cell capacitance. Detailed information about vesicle kinetics and exocytosis has also been obtained by expressing fluorescent tags directed to vesicle membrane proteins or lumen. Less is known regarding exocytosis in peptidergic neurons, but it is usually assumed that LDCVs in neurons fuse with the cell membrane by a mechanism similar to those of peripheral LDCVs because there are many recurring motifs in peripheral and central exocytosis. Here we only briefly describe the characteristics particular for the release of LDCVs.

LDCV exocytosis from endocrine cells occurs from a small fraction of vesicles present near the cell membrane, the releasable pool (~1% of vesicles present at the release site). Some of these vesicles are immediately releasable, but a larger portion requires a longer time to be released. The release process involves several steps and includes the formation of soluble *N*-ethylmaleimide-sensitive factor attached protein receptor (SNARE) complexes consisting of vesicular proteins (vSNARE), cell membrane-bound proteins (target SNARE or tSNARE), and interactions between SNARE complexes and soluble proteins. Before a vesicle can undergo exocytosis, it must be docked to the cell membrane. However, not all docked vesicles are releasable; the docked vesicle needs further preparation, which might involve the binding of Munc13 or Ca^{2+}-dependent activator protein for secretion (CAPS) in a process called priming. The docking and priming processes ensure that only some of the available vesicles are released and that a reserve pool is retained for subsequent release, minimizing the need for newly synthesized peptides (Figure 1). However, in situations of increased demand, it appears that newly synthesized vesicles are released before the already-present reserve pool. The reason for this is unclear, but it might be a way to update the composition of the vesicle content. SSVs also undergo docking and priming before release, but the priming process is more efficient. For example, nearly all docked vesicles are primed and ready to be released in hippocampal neurons. CAPS appears to be essential for the late stages of LDCV exocytosis, but is not necessary for SSV exocytosis, indicating molecular differences in the priming and release processes of the two types of vesicles.

The fusion process is believed to be similar, but probably not identical, for SSVs and LDCVs. In principle, the fusion of vesicle and cell membrane can range from being total, including a flattening and integration of the vesicle membrane into the plasma membrane, to being restricted to a short-lived fusion pore, which may or may not allow the vesicle content to escape. Overall, the fusion times appear to be longer for LDCVs than for SSVs, and although fast retrieval of intact vesicles (called kiss-and-run events) occur with LDCVs, quick recycling of intact vesicles is functionally more important for classical neurotransmitter release, in which the vesicle can be quickly refilled or topped up (Figure 1).

Termination of the Signal

The termination of a signal is critical for information transfer. The simpler the signal is, the more important this is. If we wanted to use a flashlight to send a signal in the dark, a simple solution might be to switch the flashlight on and off in Morse code. However, if we had a box of matches instead of a flashlight, it would be laborious to create a Morse code signal. A better approach might be to write our message on the wall and illuminate it by lighting a few matches. In the brain, neuropeptides signal like illuminating matches, and the message that they convey is dictated by the pattern of receptor expression, which in this metaphor is the writing on the wall. The signaling mode of classical transmitters resembles the Morse code approach, and to achieve this, the action of classical transmitters is both rapidly turned on and rapidly terminated. Efficient uptake mechanisms and fast breakdowns ensure that the signal can be repeated with high frequencies. By contrast, neuropeptide signals are terminated by the slow breakdown of the peptides by extracellular peptidases. The cerebral half-lives for the neuropeptides vasopressin and oxytocin, for example, are ~20 min, whereas fast-acting classical neurotransmitters typically have half-lives of ~5 ms. Because neuropeptides display high-affinity interactions with their receptors (typically in low nanomolar ranges), the action can be widespread in both time and space. This kind of transmission, in which molecules act at a distance from the release site, is sometimes referred to as paracrine, indicating that the message indiscriminately reaches other cells near the site of release. Neuropeptides can, in this respect, be thought of as paracrine messengers in the brain, and an important function appears to be to convey persistent modulating or tuning effects on

neuronal networks rather than to transmit immediate but fugacious messages.

The lack of peptide uptake mechanisms has an important bearing on release dynamics; unlike amines and amino acids, a released peptide cannot be reused but must be synthesized *de novo* whenever it is released. There might be some exceptions; a high-affinity uptake of cholescystokinin has been reported, for example.

Neuropeptide Release Is Not Uniform

Variations between different neurons and over time Although the release of different neuropeptides shares characteristics that are related to the type of vesicle used, there are many variations. Even the morphological appearances of LDCVs indicate differences. LDCVs vary in diameter from 60 to 500 nm. This variation occurs between and within neurons of a population, as well as between different neuron populations. However, it is not clear whether different sizes are associated with differences in release mechanisms other than the obvious difference in released quanta. The content of individual vesicles varies not only between neurons but also within them. LDCVs often contain more than one neuropeptide, and in fact many neurons release a mixture of neuropeptides, sometimes referred to as a neuropeptide cocktail. For instance, vasopressin coexists with dynorphin and galanin in magnocellular neurons of the supraoptic nucleus and paraventricular nucleus and with corticotropin-releasing hormone (CRH) in parvocellular neurons of the paraventricular nucleus. On the other hand, oxytocin in the supraoptic nucleus coexists with enkephalin, dynorphin, cocaine- and amphetamine-regulated transcript (CART), and cholecystokinin. Neuropeptides can also be co-released with classical neurotransmitters such as acetylcholine and γ-aminobutyric acid (GABA) or neuromodulators such as amines, which provide additional flavors to the cocktail. For example, the neuropeptide Y (NPY) neurons also make the classical inhibitory neurotransmitter GABA.

Moreover, most central neuropeptide-releasing neurons appear to have at least one major classical neurotransmitter that sustains fast neurotransmission via SSV release, in addition to the slower effects of neuropeptide release from LDCVs. The amount of co-released and/or co-expressed classical transmitters can also be subject of variation, contributing to the diversity of neuropeptidergic transmission. A dynamic change in neuropeptide expression over time is another factor. Some peptidergic neurons have a relatively stable neuropeptide expression (e.g., some hypothalamic peptides, such as vasopressin, oxytocin, and galanin), but others express neuropeptides only transiently during development or display pronounced upregulation from low levels in response to appropriate physiological stimuli (e.g., vasoactive intestinal peptide (VIP), galanin, or NPY in primary sensory neurons). It is natural to assume that two or more messengers that are released at the same time from the same axon terminal (or even the same vesicle) interact with one another's effects. There are, indeed, several examples both of synergism between co-released neuropeptides and classical transmitters (e.g., acetylcholine and VIP in salivary glands) and of antagonism between co-released transmitters (e.g., galanin and noradrenalin in the brain stem). However, co-released neuropeptides might not always serve as co-transmitters. Because the physical and time-dependent range of neuropeptide action is so large, it is possible that two neuropeptide transmitters released from the same axon terminal or vesicle have completely independent effects, even involving separate receiving neurons. Neuropeptide release is clearly a multifaceted phenomenon in the brain, and we are only beginning to understand the reasons for this complexity. One suggestion which has been put forward is that the co-release of some neurotransmitters constitutes phylogenetic remnants that are no longer linked to function, and it cannot be ruled out that this is, at least sometimes, the case. However, this is not to suggest that the neurotransmitter in question is without biological action. It might just not have a physiological function in every cell and vesicle where it is present.

Variation within neurons – axon terminal versus somatodendritic release Neuropeptides can be differentially released from separate compartments within a neuron. This is the case in hypothalamic magnocellular oxytocin and vasopressin neurons. These neurons release neuropeptides into the bloodstream from axon terminals in the posterior pituitary but also into the CNS from dendrites that are densely packed with oxytocin- or vasopressin-containing LDCVs. The particular anatomical arrangement of these neurons makes it possible to separate the release from axon terminals from the release originating in somatodendritic elements. The magnocellular neurons have virtually no axon collaterals that project back to the dendritic region. Consequently, all axon-terminal release takes place in the posterior pituitary, and conversely, in the supraoptic nucleus, all vasopressin and oxytocin release comes from magnocellular somata and dendrites.

The peripheral action of vasopressin is to promote water retention and increase blood pressure. When magnocellular neurons are activated by systemically increased osmolarity, they respond by releasing vasopressin (and in the rat, oxytocin) from their terminals in the posterior pituitary but also from the dendrites in the supraoptic nucleus. Interestingly, the release from

dendrites and terminals does not occur simultaneously, as might be expected. The dendritic release *in vivo* is delayed by approximately 1 h and persists longer than terminal release. An opposite order of events is observed in lactating rats when oxytocin release in response to suckling is measured *in vivo*; in this case, dendritic release precedes terminal release. Apparently, axon-terminal and somatodendritic release employ distinct activity-dependent release mechanisms. One way in which dendritic oxytocin release differs from terminal release is by its dependence on mobilization of Ca^{2+} from intracellular stores (Figure 1). This is illustrated by the effects of α-melanocyte-stimulating hormone (α-MSH), which, when administered to oxytocin cells, triggers intracellular Ca^{2+} mobilization by activating MC4 receptors. *In vivo* this leads to dendritic oxytocin release but also to decreased firing of the oxytocinergic neurons and thereby decreased axon-terminal release into the blood.

Somatodendritic vasopressin and oxytocin release, furthermore, displays a kind of priming which is not seen with axon-terminal release. Mobilization of intracellular Ca^{2+} from thapsigargin-sensitive stores of the endoplasmic reticulum leads to enhancement of subsequent release. The consequence is a more pronounced somatodendritic release of the neuropeptides in response to a given stimulus. Interestingly, this enhancement of dendritic release is long-lasting, and it is not a direct effect of the increase in intracellular calcium because it develops some time after the intracellular Ca^{2+} concentrations have returned to normal. As might be expected, the lasting enhancement of somatodendritic neuropeptide release is associated with an increased number of vesicles that are closely associated with the cell membrane, reflecting a change in the recruitment of vesicles to the readily releasable pool (Figure 1). The described enhancement (priming) of somatodendritic oxytocin and vasopressin release can be evoked by drugs such as thapsigargin and cyclopiazonic acid (Ca^{2+} mobilizers) but also by endogenous oxytocin. Oxytocin released from the somata and dendrites therefore promotes its own release by a feed-forward mechanism that facilitates recruitment of LDCVs from the reserve pool.

As demonstrated by these examples, axon-terminal and somatodendritic neuropeptide release can occur independently, indicating that neuropeptides can have separate physiological functions depending on which compartment of the neuron they are released from. Vasopressin and oxytocin neurons differ from most other neurons that release neuropeptides in the brain by the unusually high concentration of peptide-containing LDCVs in the dendritic compartments. It remains to be investigated whether differential dendritic and terminal release is also found in other peptidergic neurons. It is, however, already known that dendritic release is not restricted to peptidergic neurons but is a feature of many, if not all, neurotransmitter systems. Dopaminergic cells also display differences between terminal and somatodendritic release that suggest independent release mechanisms, and accumulating evidence favors the concept that dendritic release is a distinct mode of neurotransmission.

Physiological Effects of Neuropeptide Release

We have touched on the characteristics of neuropeptide release that single out this type of transmission from fast classical neurotransmission. The many neuropeptides in the nervous system can have an equally large number of physiological effects. Neurotransmitters generally affect the excitability of other neurons by depolarizing them or by hyperpolarizing them. Peptides have much more diverse effects; among other things, they can affect gene expression, local blood flow, synapotogenesis, and glial cell morphology. Some examples, which illustrate how the characteristic neuropeptide release mechanisms translate into physiological functions, are summarized next.

Neuropeptides have well-established roles in a number of physiological systems such as CNS control of food intake, pain and anxiety, stress, learning and memory, and social behavior. They may also have a role in the pathophysiology of addiction, depression, and eating disorders. Common to the action of neuropeptides in these examples is the long timescale. For example, the CNS control of food intake is not concerned with matching intake and expenditure on millisecond, second or even daily basis but, instead, provides a balance over a week and longer. The action of hypocretins/orexins, ghrelin, NPY, α-MSH, and other appetite-regulating neuropeptides obviously does not last that long *per se*, but they can evidently tune the drive for food intake over time periods of this magnitude. It is easily recognized that fast and spatially precise signals are not needed for this. Even peptides that counteract epileptic seizures, such as galanin and NPY, act on a relatively long timescale. NPY-deficient mice can, in most electrophysiological aspects, not be separated from wild-type mice. When tested with the pharmacological seizure-inducer kainic acid, wild-type and NPY −/− mice display inseparable latencies to electroencephalographic seizure activity, and partial seizures are also similar in behavioral appearance. However, when seizure activity generalizes, wild-type mice seizures end within 30 s, whereas NPY −/− seizures last more than twice as long and ultimately progress into status

epilepticus and death. Thus, it seems that NPY can serve as a brake to stop epileptic seizures. The fact that the major difference between wild-type mice and NPY −/− is that the latter have problems terminating epileptic activity is consistent with the need for intensive stimulation to evoke neuropeptide release, as well as the long latencies to release.

Somatodendritic releases of vasopressin and oxytocin have autoregulatory effects. In the case of vasopressin, this regulation can be either inhibitory or excitatory, depending on the prevailing activity of the neuron. Autoregulation in vasopressin neurons can be amplified by the insertion of κ-opioid receptors, which are present in the LDCV membrane and inserted into the cell membrane on exocytosis. Through such insertions of opioid receptors or other neuropeptide receptors, neuropeptidergic neurons can use LDCV exocytosis to transmit a signal to surrounding neurons and at the same time change their own responsiveness.

One autoregulatory effect of oxytocin is to promote burst activity. Synchronized burst firing of oxytocin neurons is seen during labor and in response to suckling in lactating females but not otherwise. The transition from the normal continuous unsynchronized behavior of oxytocin neurons into synchronized burst-firing response is mediated by central oxytocinergic transmission. By priming somatodendritic oxytocin release using thapsigargin, it is also possible to generate burst-patterned firing in virgin rats, indicating that this network plasticity is mediated by specific dendritic release mechanisms. This kind of functional rewiring of neural networks through paracrine signaling has recently emerged as a mechanism by which dendritically released neuropeptides can alter behavior.

Neurons that release luteinizing hormone-releasing hormone (LHRH) also display dendritic neuropeptide release, in addition to the terminal release into the hypophysial portal circulation. Unlike vasopressin and oxytocin neurons, the LHRH neurons in the preoptic/septal area are scattered throughout a relatively large area. In spite of this, they release LHRH in a synchronized pulsatile manner, and it has been suggested that LHRH autoregulation plays a role in the generation of this pulsatile behavior, which triggers puberty and is necessary for normal ovulatory menstrual cycles in females. Neuropeptide release clearly has widespread physiological effects that stretch beyond the scope of this chapter.

Summary

A large number of different neuropeptides are released from neurons in the periphery and in the brain. In most cases, little is known about the release mechanisms and the regulation of release, but the available information reveals some common themes that distinguish neuropeptide release from the release of classical neurotransmitters. Neuropeptides are always released from LDCVs and have to be synthesized *de novo* for each release event. An economizing transport and recruitment mechanism is therefore needed to prevent depletion. This is mediated in part by a more restrictive priming process, which only allows a small fraction of the present vesicles to be released in response to depolarization, and in part by a spatial separation of LDCV Ca^{2+} sensors and voltage-sensitive Ca^{2+} channels. Typically, neuropeptides are, therefore, released only in response to high-frequency or burst-patterned firing or in response to intercellular messengers that mobilize intracellular Ca^{2+} stores. On the other hand, the action of neuropeptides is prolonged and extended due to slow inactivation and high-affinity receptors. This slow and wide mode of transmission is reflected in many physiological actions of neuropeptides.

Structure and Expression of Neuropeptide S

Neuropeptide S (NPS) was named for its N-terminal serine residue, conserved across all species in which NPS sequences have been found at the genomic level (Figure 1). NPS was isolated as a ligand of an orphan G-protein-coupled receptor and first disclosed in a patent. Similar to other neuropeptides, NPS is encoded by a precursor protein that contains a pair of basic amino acid residues immediately preceding the immature peptide that will likely serve as processing sites for proteolytic cleavage. The NPS peptide is found at the C-terminal end of the precursor protein. The NPS precursor is divided into at least three exons and is located on human chromosome 10. Thus far, DNA sequences encoding NPS have been found in a number of vertebrate species with the exception of fish. The primary structure of NPS has been well conserved throughout evolution. This degree of conservation is indicative of the importance of the N-terminal part for biological activity (Figure 1).

In the rat, NPS precursor messenger RNA (mRNA) is expressed mainly in the brain. A cluster of cells located between the locus coeruleus and Barrington's nucleus in the pontine brain stem shows high expression levels of NPS precursor mRNA (Figure 2). This previously unidentified group of cells defines a novel nucleus in the brain stem. NPS precursor expression is also detected in the lateral parabrachial nucleus, the principle 5 sensory nucleus of the brain stem, and in a few scattered neurons in the amygdala and hypothalamus. Figure 1 Alignment of neuropeptide S (NPS) amino-acid sequences from various species. Sequences were deduced from GenBank resources by searching databases containing expressed and genomic DNA sequences. Residues different from the human NPS structure are shown in red.

Figure 2 Double *in situ* hybridization of the rat brain stem for tyrosine hydroxylase (TH, brown) and neuropeptide S (NPS) precursor (white grains) in the locus coeruleus area. Antisense riboprobes for TH were labeled with digoxigenin, probes for NPS precursor were labeled with ^{35}S-UTP, and hybridizations were carried out. Pictures for TH signals were taken under brightfield illumination, and a separate darkfield image was made from the same section to capture NPS precursor hybridization signals. Both images were combined in Photoshop and adjusted for brightness and contrast. Medial areas are on the left, and lateral areas are located on the right side in the section shown. Scale bar: 200 μm. Experimental conditions are described in detail in Xu YL, Reinscheid RK, Huitron-Resendiz S, et al. (2004) Neuropeptide S: A neuropeptide promoting arousal and anxiolytic-like effects. *Neuron* 43: 487–497.

coeruleus area and the principle 5 sensory nucleus are mainly glutamatergic; the NPS-expressing neurons in the lateral parabrachial nucleus co-express corticotropin-releasing factor. Overall, the expression of NPS precursor is rather restricted in the brain. Peripheral sites expressing NPS precursor include mostly endocrine tissues such as thyroid, mammary gland, salivary gland, and testis.

NPS Receptor

The NPS receptor (NPSR) is a typical G-protein-coupled receptor, also known as GPR135 and vasopressin receptor-related receptor 1. The receptor gene contains at least nine exons and is located on human chromosome 7p14. NPSR has been found to be expressed mainly in the central nervous system of rats by using *in situ* hybridization. NPSR mRNA is widely distributed in many brain areas, with high expression levels in cortex, hypothalamus, amygdala, and multiple midline thalamic nuclei (Figure 3). Many of these areas have been functionally associated with arousal, learning and memory, or processing of emotional behavior.

Physiological Effects of NPS

Central administration of NPS promotes arousal in mice and is able to suppress all stages of sleep in rats. Nanomolar doses of NPS administered centrally induce hyperlocomotion. In addition, NPS appears to produce anxiolytic-like behavior in rodents. This pharmacological spectrum is quite unique since classical psychostimulants either increase anxiety-like behavior or do not affect emotionality. On the other hand, typical anxiolytics normally reduce locomotion and cause sedation. NPS was also shown to suppress feeding although it is currently unclear whether the anorectic effects might be secondary to the behavioral arousal caused by activation of central NPS receptors.

Genetics of NPSR

In 2004, NPSR was identified as an asthma susceptibility gene in a genomewide screen in Finnish and Canadian patients. This study termed the gene "G protein-coupled receptor for asthma susceptibility" but did not provide functional data explaining the physiological role of NPSR in asthma. The study showed that a number of polymorphic variants of NPSR exist in humans and that particular sets of these variants (haplotypes) are associated with an increased risk of asthma and possibly allergic diseases characterized by high immunoglobulin E serum levels. Only one polymorphic site was identified within the coding region, changing asparagine (Asn) to isoleucine (Ile) at amino acid position 107 of the receptor protein. A C-terminal splice variant of human NPSR was found to be overexpressed in human asthmatic airway tissue. Expression of NPSR mRNA was also found upregulated in a mouse model of airway inflammation. These data indicate that NPSR might have important physiological functions in peripheral tissues and could be involved in the pathophysiology of asthma.

A subsequent pharmacological analysis of NPSR variants showed that the coding polymorphism at amino acid position 107 (Asn-Ile) of NPSR produces a gain of function in the receptor protein. NPSR Ile^{107} displays a tenfold increase in agonist efficacy without changing ligand binding affinity. The C-terminal splice variant of human NPSR did not show altered pharmacology.

The involvement of NPSR in the pathophysiology of asthma has recently been challenged by a report

Figure 3 Schematic drawings of neuropeptide S (NPS) receptor messenger RNA (mRNA) expression in the rat brain. Representative regions with high levels of NPS receptor mRNA signals (small triangles) are depicted in the drawings. Strong NPS receptor mRNA expression is found in the anterior olfactory nucleus, endopiriform nucleus, piriform cortex, motor cortex, retrosplenial cortex, and subiculum. Several thalamic nuclei, including the midline nuclei of the thalamus, express high levels of NPSR (thal. midline). Significant expression of NPSR mRNA is also observed in the hypothalamus and the amygdala complex. Amg, amygdala; AON, anterior olfactory nucleus; DEn, dorsal endopiriform nucleus; En, endopiriform nucleus (dorsal and ventral); Hyp, hypothalamus; M2, motor cortex 2; PrC, precommissural nucleus; PVP, paraventricular thalamic nucleus; RSA, retrosplenial agranular cortex; S, subiculum. showing that NPSR-deficient mice did not differ from wild types in their susceptibility to allergic lung disease. Also, the report could not confirm expression of NPSR in human lung or mice with allergic lung disease. The investigators concluded that NPSR might have only indirect influence on lung physiology. This contrasts with a report showing expression of NPSR in human bronchial tissue by *in situ* hybridization. The reason for these discrepancies is currently unclear. Future studies using small molecule agonists and antagonists for NPSR will certainly help define the physiological functions of the NPS system.

Neuropeptide Signaling in Invertebrates

D R Nässel, Stockholm University, Stockholm, Sweden

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Invertebrates constitute the vast majority of all living animals and display an immense variation in nervous system organization and complexity of behavior. However, at all these levels of organization neuropeptides seem to be used for signaling. Thus, basal invertebrates such as cnidarians (e.g., jellyfish and corals) appear to express large numbers of different neuropeptides, and complex peptidergic signaling has been described in the small nematode worm *Caenorhabditis elegans*. This worm, and the fruit fly *Drosophila melanogaster,* have become very useful animal models for the analysis of neuropeptide function. Classically, however, crustaceans (crabs and crayfish), some larger insects (cockroaches, locusts, and moths), and mollusks (e.g., *Aplysia* and *Lymnaea*) were used for endocrinological and molecular studies of neuropeptides and peptide hormones. This article provides a brief and topical overview of neuropeptides and their possible functions in some key groups of invertebrates.

Neuropeptides and Their Precursors in Invertebrates

Invertebrate neuropeptides consist of four to approximately 80-amino-acid residues linked by peptide bonds. Some larger proteins are also known to act as hormones in insects, for example, prothoracicotropic hormone and the heterodimeric cystin knot protein bursicon. Neuropeptides display a great diversity in their molecular structures and display a comparable diversity in their modes of action and functional roles. Invertebrate neuropeptides are known to regulate many aspects of animal development, growth, reproduction, homeostasis, physiology, and behavior. There has recently been a tremendous increase in the number of identified neuropeptides and peptide G-protein-coupled receptors (GPCRs) in several invertebrate species due to the completion of genome-sequencing projects. Thus, we can estimate the number of genes encoding neuropeptide precursors and peptide GPCRs in a given species. For example, in the nematode worm *C. elegans,* there are 98 genes identified that encode putative neuropeptide precursors, including 37 insulin-like genes and approximately 50 genes for predicted peptide GPCRs. In the fruit fly *Drosophila* there are approximately 35 neuropeptide-encoding genes and 48 genes encoding peptide and protein GPCRs.

As in vertebrates, the invertebrate neuropeptides are processed from large precursor proteins with conserved basic features. Some neuropeptides are present in single copies on the precursors, but in invertebrates, more commonly, multiple copies of identical or slightly diversified peptides (isopeptides) can be seen. In mollusks, it has been shown that different peptides that are cleaved from a single precursor can have differential functions and act on different receptors. These peptides are distributed to mutually exclusive populations of neurons by means of alternative splicing of the precursor transcripts. Many of the invertebrate neuropeptides are C-terminally α-amidated and display other posttranslational modifications of structure that generate varying degrees of stability to peptidases.

Invertebrate neuropeptides are localized in neurosecretory cells, interneurons, motor neurons, and sensory neurons. Peptides can also be found in endocrine cells of the intestine and at peripheral locations. Thus, peptides can act as hormones released into the circulation as local neurohormones released nonsynaptically in a paracrine fashion within the nervous system or at muscles or glands. Neuropeptides may also be released at synapses and may act as synaptic modulators or even as co-transmitters, thereby modifying the action of fast-acting neurotransmitters. Each neuropeptide is distributed in a stereotypic pattern in specific neurons, neurosecretory cells, or endocrine cells. Neuropeptides commonly act on different types of GPCRs, but some activate receptor tyrosine kinases or, in the case of molluscan FMRFamide, act on a ligand-gated sodium channel.

Neuropeptides and Their Roles in Some Invertebrates

Cnidarians Provide Information on Basic Neuropeptide Signaling

Cnidarians constitute a phylum of primitive animals, including, for instance, jellyfish, corals, and sea anemones. The basic organization of the cnidarian nervous system is simple, with a plexus of neurons in the basal part of the epithelium that form centralizations in some strategic regions. Analysis of neuropeptide signaling in cnidarians is of evolutionary interest because this phylum has such a basal phylogenitic position.

Neuropeptides are widespread in the cnidarian nervous system and their differential distribution suggests functional specializations (Figure 1). From

Figure 1 *In situ* hybridization of neuropeptides in *Hydra magnipapillata* (Cnidaria): (a) double-labeling *in situ* hybridization with specific cRNA probes coding for preprohormone-A (stained with Fast Red) and prepro-KVamide (stained with BM purple); (b) double-labeling *in situ* hybridization using a probe coding for the Hydra-RGamide preprohormone (stained with BM purple) and one for the Hydra-LWamide preprohormone (stained with Fast Red); (c) hybridization with a preprohormone-C cRNA probe. *In situ* hybridization reveals the localization of various precursors in specific subsets of neurons, suggesting distributed functions of the encoded peptides. In (a), note that co-expression of the two mRNAs occurs in neurons in the peduncle, which now have obtained a brilliant *violet* color. In (b), the resulting color in the neurons indicates that the two prehormone genes are co-expressed. In (c), preprohormone-C neurons occur only in the tentacles. From Hansen GN, Williamson M, and Grimmelikhuijzen CJ (2000) Two-color double-labeling *in situ* hybridization of whole-mount Hydra using RNA probes for five different Hydra neuropeptide preprohormones: Evidence for colocalization. *Cell and Tissue Research* 301: 245–253; Hansen GN, Williamson M, and Grimmelikhuijzen CJ (2002) A new case of neuropeptide coexpression (RGamide and LWamides) in Hydra, found by whole-mount, two-color double-labeling in situ hybridization. *Cell and Tissue Research* 308: 157–165.

a single species of sea anemone (*Anthopleura elegantissima*), 30 peptides, four- to nine-amino acids long, have been identified. These were classified into seven groups based on their C-terminal dipeptides. Molecular cloning has revealed several peptide precursor genes from various cnidarians. These commonly encode many copies of related or identical peptides. There are, for instance, 36 identical copies of antho-RFamide in the predicted precursor from *Anthopleura*. Many of the cnidarian neuropeptides are myostimulatory or myoinhibitory in different muscle groups. Some neuropeptides are morphogenitic factors. For instance, the metamorphosins or LWamides induce metamorphosis in cnidarian larvae and hydra-RGamide stimulates differentiation of neuronal stem cells into neurons.

Except for the RFamide peptides, which are grouped with the FMRFamide-related peptides of other invertebrates, the cnidarian peptides appear unrelated to known peptides of other phyla. A striking finding is that cnidarians possess peptides with multiple types of posttranslational modifications, some of which are unique. This suggests the presence of multiple peptide-processing enzymes even in a simple nervous system.

The Nematode Worm *C. elegans*

Genome sequencing has revealed 98 *C. elegans* genes encoding neuropeptide precursors, of which 37 encode insulin-like precursors. Not less than 29 genes (*flp-1* to *flp-29*) code for multiple FMRFamide-like peptides (FLPs). Nine of these genes contain a single FLP and the others two to nine FLPs each. Together, the 29 *flp* genes may give rise to at least 68 separate FLPs. In addition to the *flp* genes, the worm genome contains 32 other genes encoding neuropeptide-like precursors (*nlp-1* to *nlp-32*). These predicted precursors may produce a total of 151 neuropeptides. Some of these *nlp*-derived peptides appear to be related to neuropeptides known from other invertebrates, for example, peptides with sequence similarity to molluskan APGWamide and buccalin peptides, crustacean orkokinin peptides, and arthropod allatostatin peptides. It is estimated that the *C. elegans* genome has approximately 50 peptide GPCRs, but only a few of these have been paired with peptide ligands, all of which are *flp*-derived.

Making use of the genomics data, it is possible to approach various aspects of neuropeptide biology by the application of sophisticated molecular methods. As an example, systematic RNA interference (RNAi) screens were conducted to search for functions of specific peptide GPCRs. One study of 60 worm GPCRs, including 38 peptide GPCRs, showed that disruption of several of these produced alterations in worm coordination or the rate of egg laying, especially GPCRs of the neuropeptide Y (NPY) receptor group produced clear phenotypes when disrupted.

Genetic analysis of naturally occurring variation in the feeding behavior of *C. elegans,* seen in isolates from different parts of the world, has also shed light

on how neuropeptide signaling may regulate behavior. The receptor NPR-1, related to mammalian NPY receptors, displays a polymorphism that correlates with a striking behavioral difference in response to bacterial food. NPR1–215F and NPR1–215V are the two natural receptor variants with a single amino acid difference at position 215 (in a region where the G-protein couples). These variants are associated with feeding socially (aggregation) or solitarily (dispersion), respectively. Complete *Npr-1* knockouts display aggregation of worms, indicating that the normal role of this receptor is to inhibit social feeding. The ligands of NPR-1 are derived from two FLP-encoding genes, *flp-21* and *flp-18*. These genes are expressed in specific sets of neurons (Figure 2), including sensory neurons, interneurons, and motor neurons known to be involved in feeding and locomotion. The NPR-1 is expressed on neurons that promote social feeding via cyclic guanosine monophosphate (cGMP) signaling and is dependent on environmental oxygen levels.

Mollusks

Neuropeptides in mollusks have primarily been investigated in the pond snail *Lymnaea stagnalis* and the nudibranch slug *Aplysia californica*. Molluskan peptides act as hormones involved in egg laying and sexual behaviors or in growth, renal function, respiration, and circulation. Furthermore, various peptides isolated from nerve terminals in muscles have provided important leads to the roles of peptides in the modulation of muscle and neurons. Approximately 100 peptides have been identified in *Aplysia* and approximately 75 in *Lymnaea*. The molluskan neuropeptides identified so far are to a large extent restricted to this phylum. Some exceptions are the FMRFamide-related peptides, myomodulins, conopressin-like peptides, neuropeptide Y-like peptides, and insulin-like peptides, which are similar to peptides in other invertebrates or even in mammals.

Egg laying in *Aplysia* is a classic example of complex stereotyped behavior initiated and orchestrated by hormonally and locally released neuropeptides. This behavior lasts more than 1 h and involves the release of eggs, specific head movements, increased respiratory pumping, and inhibition of locomotion and feeding. Egg laying is initiated and controlled by two clusters of bag cells in the abdominal ganglion. The bag cells have processes in synaptic neuropil and in hormonal release sites, and they produce nine or more neuropeptides encoded on a single precursor. Four of these participate in regulation of the egg-laying behavior: egg-laying hormone (ELH), and α-, β-, and γ-bag cell peptides (BCPs). The ELH and all three BCPs act nonsynaptically in the abdominal ganglion, and ELH acts as a hormone to induce ovulation. Thus, the peptides encoded on one gene act at different levels – in the central nervous system (CNS) they induce prolonged modulation of circuits controlling egg-laying behavior leading to the inhibition of feeding and locomotion and the stimulation of respiratory pumping; in the periphery the peptides act on the muscles of the hermaphrodite gland and heart.

Complex modulatory action of multiple neuropeptides has been studied in *Aplysia* at synapses between the cholinergic motor neurons and muscles controlling the radula at consummatory biting. In addition to acetylcholine, motor neurons synthesize different neuropeptides that can be co-released with acetylcholine at higher frequencies of stimulation. These peptides act as modulators that extend the dynamic range over which the muscle can operate efficiently and thus maintain an optimal motor output when the intensity and frequency of feeding behavior (biting) change.

Figure 2 Neuronal expression of peptide genes in *Caenorhabditis elegans*: (a) *flp*-18; (b) *flp*-21. These are seen by expression of GFP under control of *flp*-18 and *flp*-21 promoters. The *flp*-expressing neurons in the anterior part of the worm are indicated the acronyms. GFP, green fluorescent protein. All acronyms represent names of identified neurons of the *C. elegans* nervous system. From Rogers C, Reale V, Kim K, et al. (2003) Inhibition of *Caenorhabditis elegans* social feeding by FMRFamide-related peptide activation of NPR-1. *Nature Neuroscience* 6: 1178–1185.

Crustaceans

Decapod crustaceans have been extensively used in classical studies of the endocrinology of reproduction, molting, color change, carbohydrate metabolism, and water and ion balance. They have also been used as models in the analysis of modulation in

neuronal circuits subserving motor rhythms in feeding. A number of hormonal peptides have been isolated from the sinus gland of the eyestalks of crabs and crayfishes; several myotropic neuropeptides have been found in other tissues. In total, more than 20 distinct types of crustacean peptides have been identified. Some of the sinus-gland peptides are large multifunctional hormones, such as crustacean hyperglycemic hormone and molt-inhibiting hormone, which consist of between 72 and 83 amino acids. The remaining peptides have 5–18 amino acids. Many of the crustacean peptides are similar to insect peptides. Actually, some of the peptides first isolated from crustaceans were later identified in insects and found to play major roles in physiology; they are thus the focus of extensive research in *Drosophila*.

The neuronal circuits of the stomatogastric ganglion (STG) of crustaceans constitute a powerful model for mechanisms in neuromodulation. In crabs, the STG consists of 30 endogenous neurons, most of which are motor neurons innervating different muscles of the foregut and stomach. The hard-wired pattern-generating circuitry of the STG is functionally flexible and can produce sets of dynamic output patterns, subserving a repertoire of chewing and filtering behaviors of the foregut and stomach. STG neurons and their output patterns are modulated by several neuropeptides. The neuropeptides act in these circuits by altering intrinsic membrane properties or the synaptic strength of neurons. Most peptides are excitatory and initiate activity in the quiescent STG or increase the frequency of existing pyloric rhythms; some produce a fusion of two rhythms, thus forming a novel pattern.

Drosophila and Other Insects

Many larger insects such as moths, locusts, and cockroaches have long served in studies of peptide hormone signaling. More recently, *Drosophila* has become a tractable model due to the development of appropriate molecular genetics techniques. In *Drosophila,* 35 genes have been identified that encode neuropeptide precursors (Table 1). These include seven genes of insulin-like peptides and three of protein hormones. In total, there may be 70–90 neuropeptides in *Drosophila*. Of the predicted peptides, many constitute closely related peptide isoforms that may be physiologically redundant. Thus, the total number of functionally distinct neuropeptides may be substantially lower. Approximately, 48 neuropeptide, peptide, and protein hormone GPCRs, have been identified in *Drosophila*.

A variety of peptide actions are known in insects: regulation of development, growth and longevity, control of carbohydrate and lipid metabolism, modulation of contractions of the heart, visceral and skeletal muscle, regulation of water and ion transport, activation of pheromone biosynthesis, regulation of the ovary, and regulation of egg maturation. Peptides are also known to trigger and orchestrate ecdysis behavior, to regulate feeding behaviors, and to act as output factors and modulators of the biological clock. Furthermore, some neuropeptides (e.g., allatotropins, allatostatins, and prothoracicotropic hormone) regulate the release or biosynthesis of other hormones. A likely neuropeptide function that has not been explored carefully in insects is as co-transmitters in the central and peripheral synapses. In insects, neuropeptides are distributed in stereotypical patterns of neurons in the CNS (Figure 3).

One of the very exciting and successful areas in *Drosophila* research is the study of the circadian clock. These clocks are endogenous timekeepers that help organize daily rhythms in behavior, physiology, and metabolism. In *Drosophila,* the master circadian clock is located in the brain and consists of several bilateral sets of neurons (~100) that express specific clock genes and exhibit circadian pacemaker properties. Eighteen of these neurons, in two bilateral groups, express the neuropeptide PDF (pigment-dispersing factor) and are critical for the light-induced and circadian rhythmic behavior of flies. There is evidence that PDF is an output factor of these clock neurons both for rhythm generation and synchronizing pacemaker activity in the clock circuitry. Recent identification and knockout of the *Drosophila* PDF receptor confirmed the importance of PDF signaling in the clock.

A signaling system that appears to be well conserved throughout evolution is that of vertebrate NPY and invertebrate neuropeptide F (NPF). The *Drosophila* NPF, expressed in four brain neurons only, consists of 36 residues. NPF is known to specifically activate an NPF receptor (NPFR1) that displays critical sequence similarities to the mammalian NPY receptors and the NPF receptor of *C. elegans*.

Interference with the expression of NPF or NPFR1 has revealed behavioral phenotypes in *Drosophila* that shed light on peptide signaling in feeding, foraging, and social behavior. NPF signaling in third instar larvae of *Drosophila* is important during the behavioral switch from continuous feeding to wandering, food aversion, clumping, and cooperative burrowing. Younger feeding larvae display a strong expression of NPF mRNA, whereas older nonfeeding third instar larvae display very low levels. Transgenic larvae with a deficiency in NPF signaling precociously display food aversion and social behaviors normally only seen in older nonfeeding larvae. On the other hand, when overexpressing NPF or its receptor, larvae exhibited prolonged feeding activity and suppressed the social behavior of older larvae.

Data from Hewes RS and Taghert PH (2001) Neuropeptides and neuropeptide receptors in the *Drosophila* genome. *Genome Research* 11: 1126–1142; Nässel DR (2002) Neuropeptides in the nervous system of *Drosophila* and other insects: Multiple roles as neuromodulators and neurohormones. *Progress in Neurobiology* 68: 1–84; Taghert PH and Veenstra JA (2003) *Drosophila* neuropeptide signaling. *Advances in Genetics* 49: 1–65.

There is a convergence of NPF and *Drosophila* insulin-like peptide (DILP) signaling in the regulation of motivated food ingestion. Food-deprived larvae are more likely to feed on noxious or less accessible food. Overexpression of NPFR1 causes nondeprived (fed) larvae to feed on nonfavorable food, whereas the knockdown of the receptor leads to the opposite. The neural activity in NPFR1-expressing neurons seems to be directly regulated by DILP signaling; the overexpression of DILP signaling components in NPFR1 neurons leads to a decreased feeding response to noxious food, whereas downregulation produced the opposite phenotype.

Another peptidergic system has been implicated in feeding in *Drosophila*, the approximately 20 neurons in the subesophageal ganglion that express the neuropeptide precursor gene *hugin* (*hug*) (**Figure 4**). The *hug* gene can give rise to two neuropeptides both of them activate a GPCR with similarities to the neuromedin U type receptor in mammals. The *hug* transcript is downregulated in starved larvae, correlating with increase in food-seeking behavior. Genetic interference with transmission in *hug*-expressing neurons shows that the *hug*-derived peptides are important for the initiation of feeding, depending on food quality, and that they act in circuitry that modulate feeding

Figure 3 Neuropeptides in the optic lobe and brain of the cockroach *Leucophaea maderae*: (a) neurons immunostained with antisera against the peptide PDH; (b) neurons immunostained with antisera against the peptide FMRFamide; (c) neurons immunostained with antisera against the peptide orcokinin; (d) frontal reconstruction of PDH-immunoreactive neurons with cell bodies near the AMe (arrow) embedded into a three-dimensional reconstruction of the cockroach brain. The images in (a–c) are frontal views. The accessory medulla (AMe) is a circadian pacemaker center in the optic lobe. Acronyms label major neuropils of the brain. AL, antennal lobe; AN, antennal nerve; CB, central body; FMRFa, FMRFamide-like peptide (neuropeptide); La, lamina; LC, lateral calyx; Lo, lobula; MC, median calyx; Me, medulla; ML, median lobe; P, peduncle; PB, protocerebral bridge; PDH, pigment-dispersing hormone; VL, vertical lobe. Scale bar = 100 μm (a–c) and 200 μm (d). From Nässel DR and Homberg U (2006) Neuropeptides in interneurons of the insect brain. *Cell and Tissue Research* 326: 1–34. (d) Originally prepared by T Reischig (University of Marburg, Germany).

behavior based on chemosensory and nutrient signals. Anatomically, the *hug* neurons are well placed in the subesophageal ganglia to integrate chemosensory signals with behavioral output (Figure 4).

Complex interplay between hormonal peptides and neuropeptides in insects has been shown in the cascade of factors controlling molting in *Drosophila* and in the moth *Manduca sexta*. Molting entails the synthesis of new cuticle and the shedding of the old one; the latter requires certain patterns of peristaltic movements, referred to as preecdysis and ecdysis behaviors. Some of the peptides involved, eclosion hormone, corazonin, CCAP, and bursicon, are located in CNS neurons or neurosecretory cells; another ecdysis-triggering hormone is produced by epitracheal cells. These neuropeptide signaling systems act in parallel and in series to coordinate the precise sequence of behaviors that produces ecdysis.

Evolutionary Conservation of Peptide Signaling

Some invertebrate neuropeptides seem to be ancestrally related and can be found in several invertebrate

Figure 4 The *hugin*-derived peptides and feeding in *Drosophila*: (a) drawing of the head region of a *Drosophila* larva; (b) diagram of the larval CNS; (c) model of *hug* as a modulator of feeding behavior. In (a) are shown the external and internal chemosensory neurons in the antennomaxillary complex and internal mouth region innervating the larval CNS (depicted in green). *hug* neurons in the SOG (shown in red) project to the ring gland, pharyngeal muscle region, and the protocerebrum. In (b) are shown the distinct subpopulations of *hug*-expressing neurons projecting to the ring gland (neurohemal organ) only (green), pharynx only (blue), and the remaining targets (red). As shown in (c), the *hug* neurons, which express the neuropeptide gene *hug* and which interconnect gustatory sensillae via the SOG to the pharyngeal muscles, the protocerebrum, and the neuroendocrine organ, modulate chemosensory-dependent feeding behavior. Increased *hug* signaling correlates with decreased feeding, whereas decreased *hug* signaling correlates with increased feeding. phyla from nematodes onward. A few may even be related to vertebrate neuropeptides. Peptide receptors appear even more conserved over evolution, and some ligand-receptor pairs may actually subserve related physiological functions from *C. elegans* to mammals – those of NPF-/NPY-like peptides and the insulin-like peptides. Other examples are insect sulfakinins and mammalian gastrin/cholecystokins and members of the vasopressin/oxytocin superfamily in mollusks and vertebrates. In the following, striking similarities in the insulin pathway are outlined.

There are extensive and functionally important similarities in structure of insulin-like peptides and their receptors in *C. elegans*, mollusks, insects, and vertebrates. The insulin superfamily consists of peptides such as vertebrate insulins, mammalian relaxin, and insulin-like growth factors (IGFs), as well as insulin-like peptides in invertebrates. The typical members of this superfamily consist of heterodimers of A and B chains of approximately 20 and 30 amino acids, respectively. In invertebrates, insulin-like peptides are mostly produced by neurons, by sensory neurons in *C. elegans*, and by neurosecretory cells in mollusks and insects.

The *C. elegans*, *Aplysia*, *Lymnaea*, and *Drosophila* insulin receptors share remarkable structural and functional properties with the insulin tyrosine kinase receptors of vertebrates. In addition, the components of the signaling pathway from insulin receptor substrate to glycogen synthase kinase are also highly conserved among *C. elegans*, *Drosophila*, and mammals. Also some of the signaling functions appear to be conserved during evolution. The mollusk insulin-like peptides (MIPs) are involved in the regulation of growth and associated metabolic processes, in the control of glycogen levels and gonadotropic activity, and in the promotion of neurite growth. Thus, MIPs combine the actions of insulin, IGFs, and relaxin.

In *C. elegans*, insulin signal transduction regulates longevity. There are 38 *C. elegans* genes encoding

insulin-like peptides (*ILP*) but only a single ancestral receptor *daf2*. Mutations in *daf2* produce pleiotropic effects, including increased fat storage, stress resistance, and entry into a diapuase-like dauer state. Available evidence suggests that stressful environmental conditions downregulate insulin signaling, allowing the promotion of a program of longevity.

In *Drosophila,* the insulin-like receptors and insulin signaling components are important in development, cell and organism growth, longevity, and female fertility. The role of insulin signaling components in extension of life span has especially been target of numerous genetic studies. Recent studies showed that interference with insulin signaling affects carbohydrate (trehalose) levels in the fly circulation. Thus, as in mollusks and mammals, the fly insulin-like signaling pathway is important for the control of metabolic carbohydrates.

Summary and Conclusion

A wide variety of neuropeptides has been identified from invertebrates of different organizational levels. In more evolved animals, peptides have defined hormonal roles in the initiation or regulation of specific behaviors or in the regulation of physiological functions critical in development, feeding, growth, reproduction, metabolism, and water balance. Neuropeptides also act as modulators of neuron or muscle properties. In rhythm-generating neural networks peptides trigger or modulate rhythmic patterns, and in muscle they change contractile properties to accommodate for changing patterns of rhythmic contractions. As in mammals, the concerted action of several related or unrelated neuropeptides, often in combination with fast neurotransmitters, is likely to be a common phenomenon in the invertebrate nervous system. We can also see that some signaling pathways are highly conserved throughout evolution. Not only are invertebrate neuropeptide signaling systems of evolutionary interest, some of the conserved ones, such as that of insulin-like peptides, may in fact be more tractable to molecular analysis in animals such as *C. elegans* and *Drosophila*.

Neuropeptide Synthesis and Storage

Introduction

Small, biologically active peptides are crucial to intercellular communication in most multicellular organisms. Both neuropeptides and classical neurotransmitters are secreted at most nerve terminals. Neurons and endocrine cells have the ability to synthesize bioactive peptides, store them for long periods, and secrete them upon command; many other cells in the body also use peptides for communication, although storage in nonneuroendocrine cells is usually minimal. Peptides are used as neurotransmitters, neuromodulators, neurotoxins, autocrine and paracrine agents acting locally, and growth factors and hormones acting long distance. These peptides range in size from three amino acids (TRH) to more complex, disulfide-linked peptides such as insulin, with its A (21 amino acids) and B (30 amino acids) chains. All bioactive peptides share important common features in their biosynthesis, and these features affect the way in which peptides are stored for secretion in a regulated manner.

Steps in Peptide Biosynthesis

Peptides are synthesized as larger inactive precursors with an NH_2-terminal signal sequence that guides the insertion of the nascent chain into the lumen of the endoplasmic reticulum (ER), after which the signal sequence is removed (Figure 1). Peptide synthesis always begins in the cell body and requires the ER and the Golgi complex. This is a critical difference from the biosynthesis of small-molecule neurotransmitters such as glutamate, γ-aminobutyric acid (GABA), acetylcholine, and norepinephrine, which are synthesized at the nerve terminal and can be replenished locally after depletion during neurotransmission.

Some peptide precursors are glycosylated; N-linked oligosaccharide chains are added co-translationally (Figure 1, ER). The NH_2-terminal regions of many promolecules contain Cys residues that form intramolecular disulfide bonds; this process occurs in the ER. As intact promolecules proceed through the Golgi complex, N-linked oligosaccharides are modified, O-linked sugar chains can be added, and other modifications such as sulfation and phosphorylation can occur (Figure 1, Golgi). The same enzymes that carry out these early modifications of peptide precursors are also responsible for modifying integral membrane proteins and other secreted proteins; they are not unique to neuropeptide biosynthesis.

Depending on the promolecule and the cell type, the first enzymatic step unique to neuropeptide biosynthesis, endoproteolytic cleavage, may begin to occur at the distal, or exit, side of the Golgi complex in the *trans*-Golgi network (TGN) (Figure 1). In neurons and endocrine cells, the promolecules and a number of peptide-processing enzymes enter immature secretory granules, where a series of cell-type specific endoproteolytic cleavages proceed more rapidly. As the secretory granules mature, endoproteolytic cleavages continue, along with additional enzymatic modifications of the smaller peptides: COOH-terminal and NH_2-terminal exoproteolytic removal of basic amino acids, α-amidation at exposed COOH-terminal Gly residues, conversion of NH_2-terminal Gln residues into pyroglutamic acid, and NH_2-terminal acetylation. Many of these seemingly minor modifications are essential for biological activity.

For many neuropeptides, closely related precursors produce families of related product peptides; examples include the oxytocin and vasopressin precursors; the three precursors for opiate peptides, β-endorphin, methionine-enkephalin, and dynorphin; substance P; and related tachykinins. The information content encoded by neuropeptides is magnified by several factors. Nearly every peptide precursor is expressed in more than one tissue (e.g., procholecystokinin and proenkephalin in the gut and brain), and different sets of product peptides are often found in each tissue. For example, cholecystokinin (CCK-4) is produced in the brain, whereas larger molecules such as CCK-8 and CCK-33 are more prevalent in the gut; methionine-enkephalin is produced in the brain, whereas larger molecules such as peptides E and F are found in adrenal chromaffin cells.

To add further complexity, several bioactive peptides can be produced from a single precursor. The most widely studied example is proopiomelanocortin (POMC), which can give rise to corticotropin (which stimulates adrenal glucocorticoid production); melanotropins (which cause skin darkening and affect appetite); and β-endorphin, an opiate-active peptide. The anterior pituitary POMC-producing cells (corticotropes) produce corticotropin, but do not make the endoproteolytic cleavages that yield melanotropins or opiate-active peptides. The intermediate pituitary POMC-producing cells cleave corticotropin to

Figure 1 Steps common to the biosynthesis of neuropeptides. The major steps leading from mRNA encoding a preproneuropeptide to its final products are outlined. The subcellular location of step is indicated. <E, pyroglutamic acid; Ac, acetyl; CPE, carboxypeptidase E/H; ER, endoplasmic reticulum; G, glycine; KR, lysine-arginine; NAT, *N*-acetyl-transferase; PAM, peptidylglycine α-amidating monooxygenase; PC, propeptide/prohormone convertase; Q, glutamine; QC, glutaminyl cyclase.

produce melanotropin, and POMC neurons in the arcuate nucleus of the hypothalamus produce both β-endorphin and melanotropins.

Most of the seemingly minor posttranslational alterations of bioactive peptides are essential for full biological activity. Cholecystokinin is inactive on the gallbladder and pancreas unless a specific Tyr residue is sulfated; opiate peptides are inactivated when their NH_2-terminal Tyr residue is N-acetylated. In contrast, NH_2-terminal acetylation activates melanotropin, vasopressin is inactive without its COOH-terminal α-amide group, and gonadotropin-releasing hormone is inactive without its NH_2-terminal pyroglutamic acid residue. Finally, the pattern of precursor processing in a given tissue may be developmentally regulated. Anterior pituitary corticotropes cleave corticotropin to produce melanotropin activity until a time around birth, when adrenocortical function is necessary; at this time, corticotropin cleavage ceases, adrenocorticotropin (ACTH) is produced and glucocorticoid production is stimulated. Transient expression of many peptides and peptide-processing enzymes occurs during development, but the significance of this transient expression is not understood.

Diseases associated with peptide biosynthesis include disorders of protein folding within the ER. Unstable and hypofunctional gene products are produced as a result of mutations impairing prohormone folding. Retention and accumulation of mutant proteins within the ER severely challenges its folding capacity and generates an ER stress response. For example, the $Ins2^{C96Y}$ mutation found in the diabetic Akita mouse prevents the formation of an essential disulfide bond between the A and B chains of insulin, impeding proper folding and the processing of the mutant proinsulin. The misfolded proinsulin is retained in the ER of pancreatic β cells; apoptotic cell death of β cells correlates with the progression of diabetes and is thought to be a consequence of proteotoxicity to the ER. The pathogenesis of the human syndrome hereditary neurogenic diabetes insipidus is similarly thought to be related to ER proteotoxicity, caused by the accumulation of misfolded mutant arginine vasopressin (AVP) in neurons.

Precursor-Processing Enzymes

The enzymes responsible for peptide processing fall into two broad classes: those specific for peptide processing and those that are important in the secretory pathway for many other molecules as well as for bioactive peptides. The latter group includes the enzymes responsible for signal peptide cleavage, oligosaccharide attachment and maturation, O-glycosylation, disulfide bond formation, phosphorylation of luminal Ser and Thr residues, and sulfation of Tyr residues.

Endoproteolytic cleavage of prohormones frequently occurs at pairs of basic amino acids, although single Arg residues are not uncommon as sites of cleavage. The endoproteases responsible for these cleavages include a set of proteins structurally related to the bacterial subtilisins and to the yeast enzyme

Kex2. The members of this propeptide/prohormone convertase (PC) family include PC1/3, PC2, PC4, PC5/6A, PC7/8, paired basic amino acid cleaving enzyme (PACE)4, and furin. The subtilisins are all synthesized as inactive precursors with an NH_2-terminal proregion (Figure 2); the removal of the ~80-residue proregion is necessary for catalytic activity and occurs autocatalytically in several cases. PC1/3 and PC2 are enriched in peptide-containing secretory granules, where they cleave prohormones on the C-terminal side of pairs of basic residues (Lys or Arg). PC1/3 and PC2 cleave secretory granule proteins and are not thought to cleave other proteins in the secretory pathway. There is evidence supporting the participation of aspartyl and cysteinyl endoproteases in the biosynthesis of selected peptides.

Two enzymes expressed in most neurons and endocrine cells mediate the final events in peptide maturation: carboxypeptidase E/H (CPE) removes the basic residues exposed by the PCs; peptidylglycine α-amidating monooxygenase (PAM) converts COOH-terminal Gly residues into α-amide groups. Glutaminyl cyclase (QC), which converts NH_2-terminal Gln residues into pyroglutamic acid residues, modifies a small subset of peptides. Much less is known about the *N*-acetyltransferase (NAT) and aminopeptidase that function in secretory granules. Because they function late in the peptide biosynthetic pathway, these granule enzymes must be active at pH 5–6, the pH of mature secretory granules (Figure 2).

Most of the peptide-processing enzymes require a divalent metal ion for full activity: the PCs are CA^{2+}-dependent; CPE and QC require zinc; bifunctional PAM requires copper, zinc, iron, and calcium. PAM is unusual in that it requires a cofactor, ascorbic acid, which is oxidized as molecular oxygen is consumed in each reaction cycle. Cytochrome b_{561}, an integral membrane protein, shuttles reducing equivalents from the cytosol into the lumen of the secretory granule, replenishing the luminal supply of reduced ascorbate. Tyrosine sulfotransferase requires adenosine 3′-phosphate,5′-phosphosulfate (PAPS) as the active sulfate donor and Mn^{2+}. Neuropeptide expression, which varies in response to many stimuli, is generally controlled by regulating the transcription of mRNA encoding the preprohormone. The expression of peptide precursors is usually tightly coordinated with expression of the relevant peptide-processing enzymes. Thus, when the amount of peptide produced is increased, the pattern of postranslational processing is largely unaltered. Secretory rates can temporarily exceed the synthetic rates for peptides, but mRNA levels usually change in response to changes in secretory demand.

The activity of each PC is controlled by its proregion, by interactions with specific chaperones, and by the pH within different compartments of the secretory pathway (Figure 2). As for bacterial subtilisin, the proregions of PC1/3 and PC2 bind to their active sites. Autocatalytic cleavage of proPC1/3 occurs in

Figure 2 Activation of peptide-processing enzymes. Key steps in the activation of PC1 and PC2 are indicated, as are the various divalent metal ions which much be supplied to the PCs and to CPE, PHM, and PAL. Acidification of the luminal compartment is indicated. 7B2 and SAAS are small proteins that serve a mixed chaperone–inhibitor function for the PCs. AscA, ascorbic acid; CD, cytoplasmic domain; CPE, carboxypeptidase E/H; ER, endoplasmic reticulum; PAL, peptidyl-hydroxyglycine α-amidating lyase; PC, propeptide/prohormone convertase; PHM, peptidylglycine α-hydroxylating monooxygenase; QC, glutaminyl cyclase.

the ER. The proregion of PC2 is not cleaved until proPC2 reaches the immature secretory granules. The activities of PC1/3 and PC2 are also affected by their interactions with naturally occurring inhibitors, pro-SAAS and 7B2, respectively (Figure 2). In the case of PC2, pro7B2 interacts with proPC2 early in the secretory pathway, facilitating its transport from the ER to the TGN. Whereas the NH_2-terminus of 7B2 is essential for PC2 activation, the COOH-terminus of 7B2 inhibits its activity. Like the proregions of PC1 and PC2, the ~10 kDa-propeptide fragment of 7B2 acts as an inhibitor, binding at the active site of PC2. Only when these 8–10 kDa peptides are further cleaved do they lose their affinity for their target PC, allowing it to exhibit activity (Figure 2).

Processing Enzyme Knockouts

Targeted deletion of processing enzymes in the mouse has increased our knowledge of specific PC–substrate pairs. In some cases, redundant activities were identified via the examination of the peptides present in knockout mice. Disruption of the TGN-localized enzymes furin and PACE4 both result in embryonic lethality, with developmental defects associated with the impaired processing of essential inductive signaling molecules (transforming growth factor (TGF)-β, nodal, and bone morphogenetic protein (BMP) family members). In these cases, the mutant phenotypes partially overlap with, but are less severe than the phenotypes of the substrate knockouts, suggesting that a limited degree of processing enzyme redundancy exists. Mice lacking PC1 are viable, but have a severe block in proinsulin cleavage at the B–C chain junction. Although they are hyperproinsulinemic, they do not show abnormalities in glucose tolerance. Dwarfism occurs due to defective cleavage of the growth hormone-releasing hormone (GHRH) precursor. The PC2-null mice also accumulate proinsulin; cleavage at the A–C junction is impaired. Proglucagon processing is completely blocked, with progressive islet hyperplasia and chronic hypoglycemia. Other PC2 substrates accumulate in the brains of mutant animals: enkephalin, CCK, orphanin FQ/nociceptin, and dynorphin. Homozygous mutants for the amidating enzyme PAM die between embryonic day (E)14.5 and E15.5, with severe generalized edema. This phenotype is strikingly similar to the adrenomedullin (AM) knockout phenotype; the AM gene encodes two amidated peptides which function as cardiovascular regulators, and amidation is likely essential for their full bioactivity.

Naturally occurring mutations in processing enzymes are also known. In humans, a syndrome associated with PC1 deficiency has been reported; this syndrome includes extreme childhood obesity, abnormal glucose homeostasis, hypocortisolism, amenorrhea, and impaired gastrointestional (GI) function. In addition, CPE missense mutations have been reported in patients with type 2 diabetes. In mice, another CPE mutation was found (S202P); the mutant CPE ($CPE^{fat/fat}$) is inactive and rapidly degraded. These $CPE^{fat/fat}$ mice are infertile, hyperglycemic, and develop late-onset obesity. The phenotype of the true CPE null mice is similar, although more severe than that of the $CPE^{fat/fat}$ mice. Additional carboxypeptidase family members are probably responsible for the retention of reduced peptide processing that prevents lethality in these animals. Carboxypeptidase D (CPD), which is localized to the TGN and immature granules, probably plays a moderate role because it can only complete reactions initiated at the TGN.

Granule Biogenesis and Storage

Neuroendocrine cells producing proinsulin or POMC generally secrete equimolar amounts of all of the products derived from the promolecule. This means that product peptides with no clearly defined function (e.g., C-peptide derived from proinsulin) are secreted along with the active peptide(s). However, the separation of product peptides into different granules and differential secretionhas been observed in other cell types.

Following the synthesis and translocation of nascent polypeptide chains into the lumen of the ER, secretory proteins are transported through the Golgi complex to the TGN. Once this sorting station is reached, vesicles destined for different subcellular compartments acquire the correct cargo. In all cell types, a constitutive pathway delivers soluble secretory proteins directly to the plasma membrane, where they are released without the need for a stimulus. In addition to the constitutive pathway, a regulated pathway or pathways exist in neurons and endocrine cells; regulated proteins are stored in secretory granules until released in response to an incoming signal. Two models, not mutually exclusive, provide a framework for thinking about the mechanisms by which constitutive and regulated soluble proteins are targeted to their respective pathways for secretion.

One model, known as sorting for entry, suggests that granule content proteins bind selectively to a membrane receptor in the TGN (Figure 3). This could involve either direct binding to a membrane component of the TGN such as cholesterol-rich membrane microdomains (i.e., lipid rafts) or interaction with a specific sorting receptor. Studies on PC2 support a role for lipid rafts in its entry into the regulated

Figure 3 Intracellular sorting of neuropeptides and enzymes to different vesicle populations. Although some sorting begins in the ER/Golgi, most occurs in the TGN and immature secretory granules which undergo significant remodeling. Some cargo is unstructured and mixes with other unstructured cargo; other cargo self-aggregates, excluding other molecules. There is evidence for cargo receptors (proteins and lipid rafts) which steer molecules into regulated granules. A number of proteins present in immature secretory granule membranes must be removed for mature secretory granules to function properly. ACTH, adrenocorticotropin; CgA, chromogranin A; CPE, carboxypeptidase E/H; ER, endoplasmic reticulum; NPY, neuropeptide Y; PC, propeptide/prohormone convertase; PHM, peptide histidine-methionine; TGN, *trans*-Golgi network; VAMP4, vesicle-associated membrane protein 4.

pathway. It has been proposed that CPE binds prohormone aggregates in the TGN and, through its association with lipid rafts, serves as a sorting receptor-mediating prohormone entry into regulated granules. Proteins unable to bind to the sorting receptor enter the constitutive pathway by default.

A second sorting model, known as sorting by retention, is based on the idea that protein entry into immature granules occurs by bulk flow; the retention of regulated cargo is facilitated by the aggregation and condensation of these proteins. Nonaggregating cargo proteins may be retained through membrane interaction. In professional secretory cells, in which over 10% of the total protein synthesis may be one preprohormone, it is difficult to envision a specific receptor with a large enough capacity to accomplish sorting for entry.

Granule trafficking of peptide-processing enzymes with transmembrane domains (PAM, CPD, and PC6) is mediated by signals in their cytoplasmic domains and can be regulated by phosphorylation. Whereas soluble processing enzymes are secreted along with their product peptides, integral membrane-processing enzymes can be retrieved from immature granules during maturation and from the endocytic pathway following exocytosis. Remodeling of the membranes of immature granules is an essential part of the granule maturation process and must occur before secretion can be stimulated. Clathrin is recruited to immature granules by the adaptor protein Golgi-associated γ-ear-containing ADP-ribosylation-factor-binding-protein (GGA), and the selective removal of nongranule proteins occurs via budding of clathrin-coated vesicles. In this manner, the immature granule functions as a more advanced sorting station, succeeding the TGN. Experimental support for this type of remodeling process comes from the progressive removal of transfected exocrine proteins from granules in AtT-20 cells, as well as the transient presence of lysosomal proteins in immature granules.

Although a conserved sorting signal does not exist for regulated secretory proteins, sequence and structural similarities have been found in subsets of proteins. An N-terminal sorting signal comprising a hydrophobic domain, characteristic amino acid content, and amphipathic α-helix has been identified. Structural features of the sorting domain, such as N-terminal disulfide-bonded loops, have been proposed to be important for stabilizing its structure and may contribute to the routing of POMC, chromogranin B, and chromogranin A. Although loop-mediated homodimerization of chromogranin A is required for its sorting into the regulated secretory pathway, there is disagreement on the importance of the disulfide loops of POMC.

A key feature in the sorting of regulated secretory proteins is their ability to selectively aggregate

(Figure 3). Aggregation may begin as early as the ER and may result in homotypic aggregates of secretory proteins. For pancreatic exocrine proteins, the majority of condensation occurs between the ER and *cis*-Golgi; aggregated atrial natriuretic peptide (ANP) has been identified in all layers of the Golgi complex. Other granule proteins, most notably members of the granin family, are known to aggregate when exposed to the slightly acidic (pH <6.5), high calcium (millimolar) conditions in the TGN. Low pH is also important for the aggregation of CPE, insulin, prolactin, POMC, and proPC2; the aggregation of POMC also requires Ca^{2+}, and the aggregation of prolactin requires Zn^{2+}. The aggregation conditions required for each protein may be related to its isoelectric point. Constitutively secreted proteins are excluded from these aggregates. The granins are thought to function as aggregation vehicles and could act by binding or co-aggregating with other secretory proteins. It is in this way that chromogranin A may act as an assembly factor that initiates aggregation. Finally, the ability of some granule content proteins to generate granulelike structures when expressed in cells lacking a regulated secretory pathway is consistent with an important role for aggregation.

The mechanisms by which integral membrane-processing enzymes are targeted to the regulated pathway are fundamentally different from those governing soluble proteins. The cytosolic domains of granule membrane proteins contain information essential for routing. For example, sorting of the vesicular monoamine transporter (VMAT) to secretory granules requires its COOH-terminal extended dileucine motif, suggesting an interaction with adaptor proteins. PAM proteins with a truncated cytoplasmic domain localize to the plasma membrane instead of granules. Cytosolic proteins that interact with PAM and regulate its trafficking include Rho guanosine diphosphate (GDP)/guanosine triphosphate (GTP) exchange factors (kalirin and trio) and a Ser/Thr kinase (P-CIP2). The cytoplasmic domain of PAM is multiply phosphorylated and cycles of phosphorylation/dephosphorylation are essential for normal trafficking within both the biosynthetic and endocytic pathways. Furin enters immature secretory granules, but is excluded from mature granules, returning to the TGN; furin also cycles between the plasma membrane and endosomes. Both the TGN localization of furin and its retrieval from endosomes are mediated by phosphofurin acidic cluster-sorting protein (PACS)-1, which recognizes furin that has been phosphorylated by casein kinase (CK)II. This interaction facilitates binding of adaptor protein (AP-)1, which mediates the entry of furin into clathrin-coated vesicles. PACS-1 also controls the endosome to TGN trafficking of CPD. Like furin, CPD cycles between the TGN and cell surface; the binding of adaptor proteins to its 58-residue cytosolic tail is required for trafficking, which is dependent on the phosphorylation of its CKII sites.

The dynamic regulation of secretory granule membrane composition also plays a role in the acquisition of regulatability. Secretagogue application does not stimulate the exocytosis of immature granules. The maturation of immature secretory granules involves the removal of vesicle-associated membrane protein (VAMP)4 and synaptotagmin IV; removal is an ADP-ribosylation factor (ARF)-dependent process. Remodeling of granule membranes is inhibited by brefeldin A, causing granules to remain in a stimulus-insensitive state. Mature granules acquire the ability to be stimulus responsive. Removal of synaptotagmin IV, a potential inhibitor of Ca^{2+} triggered exocytosis, may be the key to establishing competence to undergo regulated exocytosis. Retrieval of VAMP4 requires phosphorylation-dependent recruitment of AP-1 to immature granules, a process mediated by PACS-1, suggesting that the removal of these inhibitory proteins from immature granules is likely to occur via clathrin-coated vesicles.

Peptides in the Nervous System

Although most work on the synthesis and storage of neuropeptides has been performed in endocrine and neuroendocrine primary cell cultures and cell lines, the general principles apply to primary neurons. In both the central and peripheral nervous systems, neuropeptides have a widespread distribution and are processed primarily by the endoproteases PC1/3 and PC2. The majority of neurons coexpress peptides along with classical low-molecular-weight neurotransmitters such as glutamate, GABA, acetycholine, and biogenic amines. The two types of neurotransmitter are stored in different subcellular compartments within the same neuron. For neuropeptides, secretory granules (also known as large dense-core vesicles) are the only site of storage. These granules are localized to the neuronal cell soma, axons, and dendrites. In contrast to neuropeptides, small-molecule neurotransmitters are localized to small synaptic vesicles, which are concentrated at axon terminals (Figure 4).

One major functional implication of this differential distribution of peptides compared to small-molecule transmitters is that release is selective. Whereas the release of small-molecule neurotransmitters is triggered by a small localized increase in cytoplasmic Ca^{2+}, the release of neurotransmitter from large dense-core vesicles requires a greater increase in Ca^{2+} in the terminal. Low-frequency stimulation may

Figure 4 Peptidergic transmission in neurons. Most neurons contain large dense-core vesicles (secretory granules) and small synaptic vesicles (SSVs). The SSVs can be emptied and refilled at the nerve terminal while the large dense-core vesicles, which contain peptides, cannot be refilled. When two peptide precursors are expressed in one cell, the products can be packaged in the same granules or packaged into separate granules that are trafficked to different parts of the cell. LDCV, large dense-core vesicles; Nuc, nucleus. Adapted from Landry M, Vila-Porcile E, Hokfelt T, and Calas A (2003) Differential routing of coexisting neuropeptides in vasopressin neurons. *European Journal of Neuroscience* 17: 579–589.

release only small synaptic vesicles, whereas high-frequency stimulation releases a combination of peptides and small-molecule neurotransmitters. Consistent with the widespread distribution of peptide receptors, peptide release can occur at a significant distance from any synapse. Peptides can diffuse a significant distance after release and often mediate longer-lasting responses than classical neurotransmitters. Furthermore, depending on the stimulus, peptide release from secretory granules may be axonal or somatodendritic and may occur in either a coordinated or independent manner.

Secretion from axons versus dendrites provides neuropeptides to different target tissues and produces different physiological effects. For example, thyrotropin-releasing hormone (TRH) neurons in the hypothalamic paraventricular nucleus (PVN) project axons to the median eminence, where TRH entry into the hypophysial-portal system stimulates TSH release from the anterior pituitary. Intra-PVN release of TRH from the same neurons may contribute to the regulation of sympathetic outflow during cold stress. In the magnocellular neurons of the supraoptic nucleus (SON), local oxytocin release is stimulated by suckling before a significant peripheral secretion of oxytocin occurs. After osmotic stimulation, the release of oxytocin and AVP within the SON lags behind peripheral secretion.

Neurons often express more than one neuropeptide precursor. The products of the two precursors may be stored in separate granules or may be stored in the same granules; co-storage usually implies co-release and co-transmission. One such example is the primary sensory neurons of the dorsal root and trigeminal ganglia; tachykinins co-localize with calcitonin gene-related peptide (CGRP) in neuronal cell bodies and at the central and peripheral terminals. In this case, there does not appear to be a selective transport mechanism to form different granules to be shipped to functionally distinct processes. CCK and corticotropin-releasing hormone (CRH) are similarly co-stored in the periportal nerve terminals in the rat median eminence. In contrast, in hypothalamic magnocellular neurons, galanin and vasopressin, are only partially co-stored; galanin-containing granules are preferentially targeted to dendrites whereas vasopressin-containing granules are targeted to axons that extend into the posterior pituitary. These neurons have regions of their ER devoted to the synthesis of vasopressin and other regions devoted to galanin synthesis; separation at this early stage may promote packaging into separate granules, which would allow targeting to dendrites versus axons. The bag cell neurons of *Aplysia* contain granules filled with peptides derived from the N-terminal part of the egg-laying hormone precursor and granules filled with peptides derived from its C-terminal region; cleavage of the egg-laying hormone precursor occurs before exit from the Golgi complex. Granules containing N-terminal-derived bag cell peptides are released locally, whereas granules containing C-terminal-derived egg-laying hormone are released into the circulation.

Genes Controlling Expression of Granules and Granule Proteins

That a master gene may control secretory granule biogenesis and the expression of granule proteins has been proposed as a mechanism by which these processes are coordinately regulated. Although the idea is controversial, the acidic glycoprotein chromogranin A (CgA) has been put forth as a candidate master molecule responsible for regulating the initiation of secretory granule biogenesis. Antisense RNA-mediated reductions of CgA expression in PC12 cells result in proportional granule depletion, with a loss of regulation of other content proteins. Consistent with this, a transgenic mouse line with antisense-mediated reduction in CgA expression resulted in aberrant adrenal chromaffin cell granules. In addition, the expression of CgA in nonendocrine cells induced the formation of granulelike structures. However, analysis of one line of CgA knockout mice revealed no

structural abnormalities in adrenal chromaffin cells; vesicle size and number were normal, with upregulation of other granin proteins probably compensating for the CgA deficiency. In an independent line of CgA knockout mice, there were significant changes in chromaffin granule number and appearance, along with marked hypertension, but no general endocrine problems that would be expected if CgA were crucial to the function of all large dense-core vesicles. The fact that not all cells with a regulated secretory pathway contain CgA (e.g., pituitary sommatotropes and mammotropes, which have CgB) also argues against an essential role for CgA for all peptide-secreting cells. CgA may serve as an assembly factor; low pH and Ca^{2+} clearly induce CgA aggregation in the TGN, and aggregated CgA may specifically bind to or co-aggregate with cargo proteins. An additional role for chromogranin A in granule biogenesis may be to protect regulated secretory proteins from degradation by upregulating the expression of protease nexin-1, an endogenous serine protease inhibitor.

In *Drosophila*, the neuropeptidergic phenotype is under the control of the basic helix-loop-helix protein DIMM, a member of the atonal family. DIMM is related to similar molecules in vertebrates such as neuroD, neurogenin, and olig. Recently, dual functionality has been proposed for DIMM. In addition to being a critical regulator of neuropeptide gene expression in differentiating cells, spatiotemporal manipulation of the *dimm* gene revealed that DIMM regulates the expression of neuropeptides and peptide histidine-methionine (PHM) in mature neurons. This ability to regulate secretory protein expression suggests an effective mechanism by which peptidergic signaling may be maintained and dynamically adjusted in fully differentiated cells.

Neuropeptide Y (NP Y) and its Receptors

Introduction

Pancreatic polypeptide (PP) was originally isolated as a contaminant observed during the preparation of insulin. Subsequently, neuropeptide Y (NPY) was isolated from pig brain and named for the presence of C- and N-terminal tyrosines, while peptide YY (PYY) was isolated from pig intestine. While NPY is primarily localized to neurons and PP is found mainly in endocrine pancreas, PYY is found in both endocrine cells and neurons and, therefore, may exhibit neurotransmitter functions as well. While these peptides exhibit diversity in their expression, they share a common three-dimensional structure. Amino acid residues 1–8 form a type II proline helix followed by a loop, after which residues 15–32 form an α-helix, and the four C-terminal residues are in a flexible loop conformation. When comparing the amino acid sequences from a variety of mammals, only 2 of the 36 amino acids of NPY are variable. As such, NPY is one of the most evolutionary conserved peptides known. On the other hand, the PYY sequence exhibits eight variable amino acids between different orders of mammals. PP is one of the least conserved peptides known and appears to have undergone rapid and recent evolution. Despite the limited conservation observed in the PP and PYY amino acid sequences, the general three-dimensional structure (Figure 1) is maintained across a wide variety of species, indicating its potential importance in function.

Expression and Regulation of NPY

The NPY gene is composed of four exons and results in the synthesis of a 97-amino-acid preproNPY and is located on human chromosome 7 at the locus 7p15.1. PreproNPY is proteolytically processed by a prohormone convertase into the C-terminal peptide of NPY (CPON) and NPY1-39. This is further processed by carboxypeptidase to NPY1-37. The processing and C-terminal amidation of NPY is accomplished by peptidylglycine α-amidating monooxygenase and is essential for biological activity. NPY can be further processed to NPY3-36 and NPY2-36 by two enzymes, dipeptidyl peptidase IV and aminopeptidase P, respectively. While the functional significance of CPON is unknown, the C-terminal fragments of NPY have some selectivity for the Y2 receptor subtype.

In the rat brain, NPY is found in numerous brain regions including the hypothalamus, amygdala, hippocampus, nucleus of the solitary tract, locus coeruleus, nucleus acumbens, and cerebral cortex. NPY is colocalized with norepinephrine, γ-aminobutyric acid (GABA), and somatostatin in agouti-related protein (AGRP) containing neurons of the hypothalamus. In addition, NPY is found in peripheral neurons including sympathetic neurons where it is co-stored and co-released with norepinephrine. The adrenal medulla is the primary source of circulating NPY, though it is also expressed in liver, heart, kidney, spleen, pancreas, platelets, and endothelial cells of blood vessels.

The human PYY and PP genes are found 10 kb apart on chromosome 17q21.1. Like NPY, the PYY and PP genes are organized into four exons with three introns. The rat preproPYY sequence is 98 amino acids, consisting of a preceding signal peptide sequence and followed by a 31-amino-acid C-terminal extension peptide called CPOP. PYY is found primarily in the L cells of the gastrointestinal tract, with the highest concentrations found in the rectum, followed by the ileum and the colon. Like NPY, PYY is cleaved by dipeptidyl peptidase to the 3-36 fragment that is thought to be the principal active circulating peptide. PYY and PYY3-36 are stored in the gut mucosal endocrine cells, and both are found in the circulation. Rat preproPP has a signal peptide sequence and a 30-residue C-terminal extension peptide. PP is found primarily in the pancreas and is localized to the islets of Langerhans.

NPY synthesis and secretion are regulated by a number of hormones and neurotransmitters. At the cellular level, activation of either protein kinase A or protein kinase C will result in increased NPY synthesis and secretion. Catecholamines and muscarinic agonists will increase NPY, while GABA agonists will decrease it. Glucocorticoids, growth hormone, ghrelin, and gonadal steroids are hormones that increase NPY synthesis and secretion in the hypothalamus, while insulin, leptin, and retinoic acid will decrease it. NPY synthesis is also increased by a variety of growth factors such as nerve growth factor, insulin-like growth factor-I and brain-derived neurotrophic factor in several brain regions. Of particular interest is the increase in brain NPY observed following treatment of experimental animals with antidepressants, amphetamines, and lithium, indicating that it may play a role in the clinical response to these agents.

Figure 1 Representation of the three-dimensional structure of NPY.

Functional Activities of NPY

When administered directly into the brain, NPY produces marked increases in food intake and a preference for carbohydrate-rich food. This effect has been seen in a number of species ranging from fish to rhesus monkey. Exogenous NPY is the most potent and efficacious orexigenic peptide known. Chronic central administration to rats results in increased adiposity and the symptomology of the metabolic syndrome. Centrally administered NPY also decreases energy expenditure to promote adiposity. Less is understood about the role of endogenous NPY in the regulation of feeding. NPY levels are changed in experimental animals exhibiting a disturbed energy balance such as that seen in anorexia, bulimia neurosa, and diabetes. Starvation increases the concentrations of NPY and NPY mRNA in the hypothalamus, and, when administered centrally to rats, antisense oligonucleotides decrease feeding. NPY produces a number of other centrally mediated effects including anticonvulsant activity, modulation of arousal, anxiolysis, and modulation of cognition. Central administration of NPY produces antidepressant-like effects in animal models, and chronic administration of antidepressant drugs affects hippocampal NPY expression. NPY also acts with the central and peripheral nervous systems to decrease neuronal excitability. NPY has been reported to decrease excitability *in vitro* using hippocampal and dorsal root ganglion preparations. Mice lacking NPY are more susceptible to seizures, and people with temporal lobe epilepsy have increased NPY expression in CA3 regions as well as prominent rearrangements in receptor density and distribution. Furthermore, NPY-deficient mice were found to have an impaired development of neurons in the olfactory epithelium, suggesting a role in neuronal development. Central NPY also regulates ethanol consumption in rodents. In transgenic mice, an inverse correlation between NPY levels and drinking has been shown. Furthermore, a point mutation (leucine[7] to proline) in the preproNPY gene has been associated with higher alcohol consumption in humans and linkage analysis suggesting that dysfunction in the NPY gene locus contributes to ethanol preference in rats.

In addition to its role in feeding, hypothalamic NPY is important in the regulation of reproductive function. NPY acts at both the hypothalamic and pituitary levels to regulate reproductive hormone release. In the presence of estrogen, NPY stimulates leutinizing hormone (LH), while with low levels of estrogen, NPY will inhibit LH release. Continuous central infusion of NPY inhibits LH release in both male and female rats. NPY also exhibits a steroid-dependent regulation of gonadotropin-releasing hormone (GnRH) release. As hypothalamic NPY release is regulated by a vast number of neurotransmitters and hormones, NPY may be an important integrator for the multiple signals that regulate reproductive status.

NPY is frequently co-localized with noradenaline (NA) in sympathetic nerves and in the peripheral nervous system. Exogenous NPY enhances NA-mediated vasoconstriction, especially upon strong stimulation. In addition, NPY appears to stimulate smooth muscle proliferation and is important in angiogenesis and revascularization of ischemic tissues. Centrally administered NPY reduces arterial blood pressure and heart tone in both rats and dogs. Several cardiovascular dysfunctions as well as some tumor diseases are associated with increased plasma levels of NPY. In addition, NPY can act as an antinociceptive peptide, probably through inhibition of substance P release in the dorsal horn of the spinal cord.

PYY and PYY3-36 Function

PYY is the found primarily in the periphery and is released from the gastrointestinal (GI) tract in response to meals. Many of the GI effects described for PP, including inhibition of gall bladder secretion, gut motility, and pancreatic secretion, can also be produced by PYY. Other peripheral effects produced by PYY include the inhibition of fluid and electrolyte secretion in the intestinal tract and direct vasoconstriction. When administered centrally, PYY increases food intake with potency and efficacy similar to that seen with NPY. Via dipeptidyl peptidase IV, PYY is posttranslationally processed to PYY3-36, which appears to be the primary circulating form of the peptide. Peripherally administered PYY3-36 produces a potent decrease in food intake in both human and rodents.

PP Function

PP is almost exclusively expressed in endocrine pancreas and is released in response to meals. PP produces its biological effects mainly in the GI tract, where it inhibits pancreatic secretion, gall bladder activity, intestinal motility, ileum contractions, and gastric emptying and stimulates colon contractions. In addition, PP affects metabolic functions including glycogenolysis and decreases fatty acid levels. However, binding sites for PP have been found in several rat brain regions, including the interpeduncular nucleus, hypothalamus, and brain stem, suggesting that PP may also have direct effects of brain function. This may explain why intracerebroventricular (ICV) injection of PP has been found to stimulate feeding in several different species of experimental animals. In contrast, peripherally administered PP inhibits food intake in humans and rodents.

Receptors for the NPY Family of Peptides

Four functional G-protein-coupled receptors (GPCRs) have been identified that bind the NPY family of peptides, termed Y1, Y2, Y4, and Y5 (Table 1). An additional y6 receptor has been identified as a functional receptor in some species including mice and rabbits; however, it does not encode a functional protein in humans and is absent in rats. Y1, Y2, and Y5 bind NPY and PYY with similar high affinities. PP binds to Y4 with higher affinity than the other peptides. Y1 and Y2 are the predominant brain receptor populations (Figure 2). All the NPY receptors have been shown to couple to Gi and thus mediate inhibition of cAMP synthesis. When expressed in Chinese hamster ovary (CHO) cells, intracellular signaling involves pertussis toxin-sensitive phosphorylation of extracellular signal-regulated protein kinase (ERK)-1 and -2, confirming that these receptors couple to Gi and/or Go. In addition, Y1 activates mitogen-activated protein kinase in gut epithelial cells (IEC-6). Y1, Y2, Y4, and Y5 receptors can couple to phospholipase C to provoke release of Ca^{2+} from intracellular stores.

Table 1 Y receptors and their proposed functions

Receptor	*Agonist actions*
Y1	Angiogenesis, anxiolysis, cellular proliferation, circadian rhythm regulation, endocrine regulation, increase feeding, sedative, vasoconstriction
Y2	Angiogenesis, anticonvulsant, anxiogenesis, cellular proliferation decrease feeding, gastrointestinal motility, and secretion
Y4	Decrease feeding, gastrointestinal regulation
Y5	Anticonvulsant, circadian rhythm regulation, increase feeding

Y1 Receptor

The gene for Y1 is located in a cluster together with Y2 and Y5 on human chromosome 4q31. Y1 is primarily localized to the brain, peripheral nervous system, and peripheral blood vessels. The highest Y1 levels in the brain are found in the anterior thalamus, cerebral cortex, medial geniculate, and amygdala. In the peripheral nervous system, Y1 mRNA is found in the superior cervical and dorsal root ganglion. In the vasculature, Y1 is localized to intramyocardial, colonic, and renal blood vessels with the expression being localized to the intima as well as the media. Y1 mRNA has been detected in a number of peripheral tissues including the colon, kidney, adrenal gland, heart, and placenta. Within the kidney, Y1 mRNA is detected in the renal collecting ducts, loop of Henle, and the juxtaglomerular apparatus.

Y1 receptor is important in the feeding response produced by exogenous NPY. Central injection of Y1-selective agonists increase feeding, while Y1 antagonists can inhibit NPY-induced feeding. Most of the vasoconstriction produced by NPY and PYY is transduced via the Y1 receptor, as shown by the inhibitory affects of various Y1-selective antagonists on NPY-induced vasoconstriction and the absence of effects in Y1-deficient mice. Many of the other central effects of NPY have been attributed to the Y1 receptor, including reduction of blood pressure and heart rate, anxiolysis, and antidepressant activity. Stimulation of brain Y1 receptors inhibits the consumption of ethanol by rodents, inhibits neurogenic inflammation, and is antinociceptive.

Y2 Receptor

The Y2 gene is located near the Y1 gene on chromosome 4 and encodes a 381-amino-acid protein. Y2 has more than 90% amino acid identity within mammals, although Y2 is only about 30% identical to the Y1 and Y4 receptors. Y2 is present in the central and peripheral nervous system, the intestine, and certain blood vessels. Brain Y2 is pronounced in the hypothalamus, lateral septum, hippocampus, and amygdala. In the peripheral nervous system, Y2 is localized to the superior cervical ganglion and dorsal root ganglia. Using polymerase chain reaction (PCR) detection, mRNA encoding the Y2 receptor has been found in a variety of regions of the GI tract, including the crypt, villus, colonic epithelium, and nonepithelial jejunum.

Y2 is predominantly a presynaptic autoreceptor inhibiting further release of NPY and cotransmitters.

Figure 2 Differential autoradiographic localization of Y1 and Y2 receptors in the rat brain. Rat brain sections were labeled with ^{125}I-Leu^{31}-Pro^{34}-PYY (Y1) and ^{125}I-PYY3–36 (Y2) and pseudocolor representations of the receptor distributions obtained. Abbreviations are frontal cortex (FC), accessory olfactory nucleus (AON), claustrum (Cl), lateral septum (SL), lateral dorsal thalamus (LD), CA3 subregion of the hippocampus (CA3), fimbria (fi), and medial geniculate (MG).

An opposing relationship between Y1 and Y2 is evident for the central effects of NPY on blood pressure, as centrally administered Y2 agonists increase blood pressure while central Y1 stimulation decreases it. Given into the brain, Y2 agonists produce anxiogenic responses, presumably by inhibiting the release of NPY and/or GABA from neurons within the amygdala to limit their postsynaptic actions. In the pig spleen, Y2 stimulation evokes potent vasoconstriction that is inhibited by a Y2-selective antagonist. In addition, Y2 is involved in NPY-induced angiogenesis and NPY-induced effects on circadian rhythms. The phenotype of Y2-deficient mice indicates the potential importance of Y2 in feeding responses and bone formation. Peripherally administered PYY3–36 produces a decrease in food consumption by rodents and humans, presumably by activating Y2 receptors in the hypothalamus.

Y4 Receptor

The human Y4 gene is found on chromosome 10 and encodes a protein of 375 amino acids. Of the Y receptors, Y4 is the least conserved across species and is thought to have evolved rather recently. Considerable differences in peptide pharmacology between the rat and human receptors have been noted. For instance, when position 34 of NPY or PYY is replaced by proline, there is an increase in rat Y4 affinity while the human Y4 affinity is unaffected by this change. In contrast to the Y1 and Y2 receptors, the Y4 receptor exhibits a rather restricted distribution within the brain. While mRNA encoding this receptor exhibits a rather broad distribution, studies using radiolabeled PP indicate a high level expression in the interpeduncular nucleus and locus coeruleus in the nucleus of the solitary tract. A lower level of expression is seen within the hypothalamus and thalamus as well as a number of other brain regions. Interestingly, the binding site labeled by ^{125}I-PP in the interpeduncular nucleus does not pharmacologically match the Y4 receptor, indicating that this may be an additional PP binding site. Y4 mRNA is also abundant in the human colon with somewhat lower levels in the prostate and pancreas. In addition, mRNA encoding Y4 has been found in skeletal muscle, thyroid gland, heart, stomach, small intestine, adrenal medulla, cerebral cortex, and nasal mucosa.

Since PP is likely to be the preferred endogenous ligand for Y4, this receptor may mediate many of the GI effects produced by PP, including rabbit ileum contractions. Intravenously administered PP can also reduce food consumption, though the role of endogenous peptide and the Y4 receptor in appetite and body weight regulation has not been established.

Y5 Receptor
