Y5 is encoded by a gene located on chromosome 4 encoding a 446-amino-acid protein. The Y5 receptor is highly conserved (88–90% overall amino acid identity) between orders of mammals. While Y5 mRNA receptor has a broad distribution in the central nervous system, only low levels of Y5 receptor protein are found in the brain using receptor autoradiography and immunohistochemistry. In the periphery, Y5 mRNA is been reported to be present in the intestine, ovary, testes, prostate, spleen, pancreas, kidney, skeletal muscle, liver, placenta, and heart.

The importance of Y5 in NPY-induced feeding has been confirmed by studies involving antisense knockdown, knockout animals, and Y5-selective agonists. Other effects of NPY that are mediated by the Y5 receptor include reproduction through inhibition of LH release and regulation of brain excitability and seizures. Y5 receptor stimulation inhibits neuronal activity in the suprachiasmatic nucleus without generating a phase shift, indicating that Y5 may be indirectly involved in regulation of circadian rhythms.

Regulation of Y Receptors

Internalization and desensitization of NPY family receptors Cell surface expression of Y receptors is regulated primarily by agonist-induced desensitization. This is an important mechanism *in vivo* since NPY knockout mice have a dramatic increase in Y receptor binding when compared to wild-type controls. After agonist stimulation, approximately 20–30% of Y1 expressed in the neuroblastoma cell line SK-N-MC was internalized after stimulation. Y1 internalization follows an endosome pathway followed by rapid recycling to the cell surface. Y4 and Y5 also exhibit rapid internalization after agonist stimulation, while theY2 receptor appears to internalize at a very slow rate. β-Arrestin 2 is an important protein involved in the initial desensitization and internalization of GPCRs. After agonist stimulation, Y1 and Y5 exhibited a rapid recruitment of β-arrestin 2, while Y2 showed a very weak and slow increase in β-arrestin 2 association. Y4 interacts at a rate intermediate to the other receptors.

Dimerization among NPY family receptors It has been recently established that GPCRs form homo- and heterodimers and these complexes have functional implications by altering the signaling, the pharmacology, or the internalization. GPCR dimers can be covalently linked as described for the metabotrophic glutamate receptors or held together by noncovalent interaction like that observed for many of the rhodopsin-like receptors (family A). The Y receptors homodimerize when expressed in HEK293 cells. Y1, Y2, and Y5 homodimers were not affected by agonist treatment, whereas Y4 appears to be assembled as a dimer that dissociates upon agonist stimulation. More recently, Y1 and Y5 were found to heterodimerize when co-expressed. This heterodimer has similar binding properties to what would be expected with a Y1 and Y5 mixture; however, functional coupling and internalization are dramatically altered.

The NPY System and Medication Development

Given the robust effects of the NPY family of peptides on feeding behavior and body weight, there has been considerable interest in the discovery and development of molecules that exploit these effects. In the early 1990s there were a number of efforts by pharmaceutical companies to discover centrally active Y1 and Y5 antagonists. In general, it was difficult to obtain Y1 compounds with suitable properties for clinical development. Adequate oral bioavailability and brain penetration were the consistent challenges observed with a number of chemical series. Several compounds were evaluated preclinically and were able to reduce food consumption and body weight. With the discovery of the Y5 receptor in the mid-1990s, a number of efforts targeted this receptor for drug discovery. While a number of very nice compounds were identified, the highly selective Y5 antagonists produced very modest, if any, changes to food consumption and body weight in preclinical testing and, with one compound, no effect in clinical testing. To date, alternate clinical applications for this class of compounds have not been identified.

In the early 2000s, peripherally injected PYY3–36 was found to decrease food intake through activation of the hypothalamic Y2 receptor. The efficacy was observed in preclinical models as well as several clinical trials. Subsequent efforts have found the potential for improved efficacy using peptides with affinity for both the Y2 and Y4 receptors. Several of these peptides are under clinical development, and an improved understanding of the potential of these peptides to

treat obesity and the metabolic syndrome should be forthcoming.

In addition to body weight disorders, there are substantial opportunities to discover and develop agonists or antagonists for the treatment of a variety of cardiovascular disorders, epilepsy, immune disorders, psychiatric disorders, and substance abuse disorders.

Neuropeptides and Coexistence

General Concepts and Definitions

The term 'neuropeptide' was originally coined to indicate small protein molecules that are contained in neurons and that are composed of 3–100 amino-acid residues. These molecules are usually produced as large, inactive precursors, which are enzymatically cleaved to yield the biologically active peptide. Commonly, precursors contain several molecules of the same neuropeptide and/or more or less structurally related compounds.

Neuropeptides exert several different biological effects, such the regulation of gene transcription, local blood flow, synaptogenesis, and glial cell architecture. Notably, most neuropeptides also influence membrane excitability, and, although this should perhaps not be thought of as their main biological action, this has made them very attractive to neurobiologists. When thinking of neuropeptides as being involved in cell-to-cell communication, the first consideration to be made is that they are about 50 times larger than low-molecular-weight 'classical' neurotransmitters, such as acetylcholine, biogenic amines, and amino acids. As a consequence, neuropeptides possess several more recognition sites for receptors than do smaller neurotransmitters, and thus a higher receptor-binding affinity (about 1000 times greater, with values in nanomoles/liter vs. micromoles/liter) and selectivity. For these reasons neuropeptides can elicit their biological effects even when released at lower quantities. Although large neuropeptide molecules can diffuse and bind slowly to receptors, their half-lives in the brain extracellular space are remarkably long: for example, the half-lives of oxytocin and vasopressin have been estimated to be in the order of about 20 min.

Neuropeptide receptors are usually seven-transmembrane-region G-protein-coupled receptors (GPCRs), which are internalized upon activation as a desensitization mechanism. For example, the neurokinin-1 receptor (the preferred substance P receptor) is internalized 5 min after agonist activation, and is then recycled and restored to the cell membrane within 30 min.

Cellular and Subcellular Sites of Neuropeptide Storage

Localization within Large Granular Vesicles

Identification of the subcellular site of storage of neuropeptides remains crucial to the understanding of their mechanism of action as synaptic (or nonsynaptic) transmitters and of their interaction with other molecules involved in chemical neurotransmission. Neuropeptides are commonly found to be present together with low-molecular-weight classical neurotransmitters in individual nerve cells. However, initial observations indicated that the two classes of transmitter molecules were stored in different subcellular compartments: in large granular vesicles (LGVs) for the neuropeptides, and in small clear synaptic vesicles (SSVs) for the classical transmitters (Figure 1).

In the past, the debate regarding such a compartmentalization was left open, since it could not be excluded that, at least in some cases, LGVs also contained some of the more conventional transmitters, although peptides never seemed to be found in small clear vesicles. Nowadays, the concept that LGVs are the sole site of neuropeptide storage is widely established. The histological demonstration of differential subcellular sites of storage for neuropeptides and low-molecular-weight neurotransmitters is consistent with the possibility that they are selectively released upon specific stimuli. On the other hand, coexisting neuropeptides, even when synthesized from different mRNAs, are usually stored together in LGVs. This has a series of functional implications, since co-stored neuropeptides are not differentially released, and a modulation of biological effects is most readily accomplished by regulating their relative proportions of synthesis.

Synthesis, Storage, and Targeting to Processes

As occurs for all peptide molecules, neuropeptides are synthesized in precursor form within the rough endoplasmic reticulum (RER) and subsequently move to the Golgi apparatus, where they are packaged into LGVs. The primary sensory neurons are a unique class of pseudounipolar neurons; they are grouped outside the central nervous system (CNS) in the sensory ganglia, associated with certain cranial nerves and in dorsal root ganglia (DRGs), and display an extremely abundant and variegated neuropeptide content. Immediately after emerging from the cell body the single process of these neurons divides into a central branch and a peripheral branch that function, respectively, as an axon and a dendrite. Pioneering work carried out with the use of multiple immunogold labeling methods about 20 years ago led to the localization of different tachykinins and calcitonin gene-related peptide (CGRP) to individual LGVs in neuronal cell bodies and central peripheral and branches of DRG neurons. In these cells, virtually

Figure 1 Subcellular localization of neuropeptides and presence within large granular vesicles at central synapses. Calcitonin gene-related factor/substance P (a) and brain-derived neurotrophic peptide/substance P (b) dual immunogold labeling (10 and 20 nm gold particles) in central terminals of a dorsal root ganglion neuron within the substantia gelatinosa of spinal cord. A multisynaptic complex (glomerulus) contains small synaptic vesicles (SSVs) and large granular vesicles (LGVs) with a dense core. Note in both images that SSVs are consistently unlabeled, whereas the majority of LGVs are double labeled. Note also that LGVs are not in proximity of synaptic specializations (arrowheads), unlike SSVs (m, mitochondrion). The arrows indicate the LGV that is shown at higher magnification in the corresponding insets at top right of each panel.

all LGVs are multiple/dual-labeled in both central and peripheral branches, whereas double (multiple)-labeled LGVs in the cell body relatively rare. These observations show that when multiple peptides are produced by one neuron, they are not selectively packaged into different LGV subpopulations, but rather a cocktail of neuropeptides is consistently found within individual LGVs. Moreover, given that LGVs (and therefore the neuropeptides packed therein) are detected at both central and peripheral branches of DRG neurons, it seems reasonable to hold that no selective transport to functionally different neuronal processes (the axons and the dendrites) and/or to different branches of the same process occurs. In neuronal cell bodies, LGVs containing just one component of the cocktail can be regarded as immature vesicles that will probably incorporate the other peptide(s) before being transported to terminals. Studies on nonneuronal cell regulated secretion suggest that peptides are packed into immature LGVs budding from the *trans*-Golgi network, and ultimately transform into mature LGVs. Fusion between immature secretory granules has been demonstrated, and it is thought that after granule–granule fusion, soluble contents condense, and excess membrane are removed by vesicle budding.

Very recent work has shown that an analogous pattern of co-storage is also apparent in central neurons, and that co-stored neuropeptides are quantitatively detected in LGVs with remarkably constant ratios. The ratio might be regulated at the level of neuropeptide synthesis, before packaging in the *trans*-Golgi network (Figure 2).

Coexistence

Coexistence, the concurrent presence of two or more transmitters in a single neuron, is now regarded as a common feature of central and peripheral neurons. Neuropeptides coexist with other neuropeptides, low-molecular-weight fast-acting neurotransmitters, the gaseous transmitter NO, and certain neurotrophins. When multiple neuropeptides are present in neurons, coexistence equals co-localization, since, as discussed earlier, coexisting peptides are co-stored in LGVs.

As a rule, neurons produce a combination of one (or more) low-molecular-weight transmitter(s) and one (or more) high-molecular-weight neuropeptide(s). One remarkable exception seems to be represented by the oxytocin/vasopressin magnocellular neurons that contain a complex cocktail of peptides, but apparently no low-molecular-weight transmitters. When a neuropeptide coexists with a classical transmitter, the latter is generally believed to be the principal messenger, whereas the neuropeptide appears to modulate neuronal response by acting on pre- and/or postsynaptic GPCRs (see the section titled, 'Functional implications of neuropeptide coexistence').

Neuropeptide Co-Localization

Several areas of the CNS are particularly enriched with neuropeptides. In most circumstances, it is common that individual neurons in these areas produce and store more than a single peptide. Relevant examples are given in the following sections.

Figure 2 Packaging of neuropeptides in large granular vesicles (LGVs). For simplicity, only two peptides (indicated by the red and yellow circles) are represented, although there is direct evidence that more neuropeptides can be stored in individual LGVs. Prepropeptides reach the Golgi apparatus from the rough endoplasmic reticulum (RER). They are packaged in granules budding from the *trans*-Golgi network (TGN); the granules subsequently fuse together to give rise to immature LGVs. Immature LGVs are larger and display a more irregular shape compared to their mature counterparts. As maturation of LGVs proceeds, there is a condensation of the granin content, so that the vesicles assume the typical size, shape, and electron density of mature LGVs. When a neuron produces more than a single neuropeptide, it is possible that immature granules budding from the TGN (left) already contain a mixture of cargo molecules. Alternatively, each peptide is singularly packed into individual immature granules (right), which then fuse together to give rise to the mature LGVs. In both cases, the latter contain the cocktail of neuropeptides that are eventually transported to terminals.

Spinal cord The co-localization of tachykinins and CGRP is one of the most widely studied example of peptide co-localization (Figure 1(a)). The cell bodies of the neurons containing these peptides are located in the peripheral nervous system in the DRGs and trigeminal ganglia, and in several autonomic ganglia and intramural plexuses. Galanin is co-localized mainly with enkephalin, but sometimes also with neuropeptide Y (NPY) in some local neurons of the substantia gelatinosa (lamina II) of the dorsal horn. In the same location, the co-localization of tachykinins and enkephalin is also reported. Galanin and substance P are co-localized in neurons of the deeper layers of the dorsal horn. Co-localization of these neuropeptides and neurotensin with galanin has been demonstrated also at the ultrastructural level.

Hypothalamus The hypothalamic hormones oxytocin and vasopressin were the first neuropeptides discovered, and an extensive literature exists on the localization, biological actions, and plasticity of these peptides. The oxytocin- and vasopressin-containing neurons are located in both large (magnocellular) and small (parvocellular) hypothalamic neurons. In the supraoptic nucleus the oxytocin/vasopressin system undergoes a remarkable plasticity under normal and experimental conditions. Although oxytocin and vasopressin neurons usually constitute two separate populations, there are some plasticity inducing conditions, such as parturition and lactation, in which co-localization of the two peptides has been hypothesized on the basis of *in situ* hybridization and single-cell reverse transcription–polymerase chain reaction studies.

Considerable evidence has accumulated that approximately 50% of the corticotropin-releasing hormone (CRH) neurons in the paraventricular nucleus contain vasopressin or its precursors. Moreover, about 30% of the CRH parvocellular neurons in the median eminence contain vasopressin. These neurons are also highly plastic, and the relative proportion of released vasopressin and CRH changes under different physiological and experimental conditions.

Magnocellular oxytocin neurons contain several opioid peptides of the enkephalin family, and magnocellular vasopressin neurons contain dynorphin. In addition, some oxytocin neurons contain either cholecystokinin (CCK) or CRH. Co-localization of CCK and CRH has been demonstrated in periportal nerve terminals of the rat median eminence. It has also been shown that galanin is co-produced in a subpopulation of luteinizing hormone-releasing hormone (LHRH) neurons. The incidence of LGVs immunolabeled for both neuropeptides is high in the female and low in the male rat. Ovariectomy results in a dramatic decline in the number of LHRH/galanin-co-expressing LGVs, which is reversed by the administration of estradiol.

Retina A large number of neuropeptides occur in amacrine cells, and to a lesser extent, in the ganglion cells. These include avian pancreatic polypeptide (APP), enkephalin, neurotensin, NPY, pituitary adenylyl cyclase-activating peptide (PACAP), pancreatic polypeptide (PP), somatostatin, and substance P. Many of these neuropeptides are co-localized within individual neurons.

Coexistence of Neuropeptides and Fast-Acting Neurotransmitters

Acetylcholine Neuropeptides coexist with acetylcholine in numerous areas of the brain. For example, galanin is found to coexist with acetylcholine in the basal forebrain and hippocampus, where the coexistence of somatostatin and acetylcholine has also been described. Coexistence of acetylcholine and CGRP has been reported in neurons of the vestibular nuclei.

Amino acids The coexistence of peptides and aspartate, glutamate, γ-aminobutyric acid (GABA), or glycine is a widespread finding in the CNS. Aspartate coexists with substance P in the spinal cord, and with NPY or galanin in the arcuate nucleus. The coexistence of glutamate and peptides is by far more common. Coexistence of enkephalin and glutamate has been shown to occur in the locus coeruleus. Glutamate and PACAP are localized within the same neurons in the retinohypothalamic tract. Glutamate and substance P coexist in the spinal cord. GABA has been found to be present with several different neuropeptides in various areas of the brain: with enkephalin in the cochlea, striatum, and spinal cord; with somatostatin in the visual and entorhinal cortex, suprachiasmatic nucleus, and basolateral amygdala; with cholecystokinin-8 (CCK-8) and/or vasoactive intestinal peptide (VIP) in the hippocampus dentate gyrus, basolateral amygdala, and suprachiasmatic nucleus; with CGRP in the cerebellum; with NPY in the arcuate nucleus, basolateral amygdala, and dorsal horn; with substance P in the hypothalamus and retinal ganglion cells; with galanin in the dorsal horn; with somatostatin in the entorhinal cortex; with CRH in the hippocampus; and with vasopressin in the suprachiasmatic nucleus.

Biogenic amines Several different neuropeptides have been found to coexist with biogenic amines such as serotonin (5-hydroxytryptamine; 5-HT), and with noradrenaline. The most widely reported combinations are the coexistence of substance P and 5-HT in caudal medullary neurons projecting to the spinal ventral horn, and in dorsal raphe nuclei neurons, and the coexistence of enkephalin or galanin and 5-HT in the dorsal raphe nuclei.

Other combinations have been found with noradrenaline. These include substance P and noradrenaline in the medulla oblongata, NPY and noradrenaline in the hypothalamus, and galanin and noradrenaline in the cerebral cortex and hippocampus. Multiple combinations are possible, and there is strong evidence that more than one neuropeptide may be contained within biogenic amine-synthesizing neurons. Also, these neurons can produce other classical transmitters, such as transmitter amino acids.

Nitric oxide Certain peptides have been found to be present in nitric oxide-producing neurons (detected after NADPH diaphorase histochemistry or nitric oxide synthase immunocytochemistry). Examples include somatostatin in the hippocampus, vasopressin in the hypothalamus, and galanin in the dorsal raphe nucleus.

Coexistence of Neuropeptides and Brain-Derived Neurotrophic Factor

A direct demonstration for the selective storage of brain-derived neurotrophic factor (BDNF) in LGVs has recently been provided by ultrastructural immunocytochemistry (Figure 1(b)), in terminals within the central nucleus of amygdala and spinal cord dorsal horn. These terminals originate from central and peripheral neurons that are capable of synthesizing and anterogradely transporting the neurotrophin. Individual LGVs have been found to contain a cocktail of BDNF, CGRP, and substance P. Such a pattern of cellular storage is compatible with a transmitter function of BDNF in these neuronal populations.

Neurotransmitter Function of Neuropeptides

Despite the enormous amount of literature on neuropeptide distribution in mammals, much of our

knowledge about neuropeptide function comes from studies in invertebrates. Indeed, it is far easier to demonstrate the presence of multiple messengers in neurons than it is to establish their physiological role, or even to show that they have any kind of biological activity at all. Moreover, although an organic framework to describe the function(s) of individual neuropeptides at synapses and/or nonsynaptic sites is now available, relatively little is known about the functional interactions and the control of release of co-stored neuropeptides at central synapses. The existence of synapses can be unequivocally demonstrated only by electron microscopy. Ironically, however, ultrastructural studies have also shown the existence of nonsynaptic transmission. The identification of gases as interneuronal signals or the modulation of neuronal function by lipophilic substances has left no doubt regarding the existence of nonsynaptic information transfer in the CNS. Nonetheless, it is more difficult to accept that vesicle-stored transmitters can be released following quantal mechanisms and operate at distant nonsynaptic sites. This notion applies not only to neuropeptides, but also to certain low-molecular-weight classical neurotransmitters.

Neuropeptides as Slow-Acting Neurotransmitters

Neurotransmitters are consistently packaged in two different morphological types of vesicles at synapses. The most abundant SSVs accumulate fast-acting, low-molecular-weight neurotransmitters. The less frequently observed LGVs store the neuropeptides (Figure 1(a)). The distribution of SSVs and LGVs in typical axodendritic central synapses follows a rather stereotyped pattern. SSVs occupy a variable, but usually large, area of the axon terminal. Some are docked at the presynaptic grid, being ready to be released at the active synaptic zone. LGVs, on the other hand, are localized away from the presynaptic membrane, singularly or in clusters. In addition, electron microscopy has shown that release of LGVs can occur at plasma membranes even in the absence of synaptic specializations. The major functional implication of such an arrangement is that fast- and slow-acting transmitters may be selectively released upon activation of different cellular pathways. Early evidence was obtained showing that the release of coexisting peptides and classical neurotransmitters could be differential and dependent on the frequency and pattern of firing. In general terms, neuropeptide release is triggered by a small increase in the intracellular Ca^{2+} concentration, whereas release of transmitter amino acids from SSVs requires a rise of intracellular Ca^{2+} concentration in the proximity of the Ca^{2+} channels at synapses. Therefore, in terminals with both types of vesicles, a focal increase in Ca^{2+} at the synaptic membrane leads to a preferential discharge from SSVs, whereas a more general elevation of Ca^{2+} inside the terminal favors the release of LGVs. The remarkably short delay in response to fast-acting transmitters (about 1–3 ms) is a close reflection of this mode of discharge from SSVs. On the other hand, the spatial independence from Ca^{2+} channels clustered at synapses explains why neuropeptide release can occur independently from synapses. Among the consequences of the existence of selective mechanisms of release for coexisting peptides and classical transmitters is the possibility that long-lasting intracellular Ca^{2+} elevation may cause the release of neuropeptides to outlast the duration of electrical activity, thus uncoupling release from spiking.

Mode(s) of Release

Even upon prolonged stimulation, not all vesicles at synapses unload their transmitter content. A variable fraction of SSVs and LGVs is readily releasable, but the remaining ones, forming the reserve pool, need further steps to become competent. Two different mechanisms of transmitter emptying have been shown to occur in SSVs and LGVs. These include the slower classical exocytosis, with complete fusion of the vesicle to the plasma membrane, or a faster mechanism whereby vesicles come in close proximity to the membrane and, with the formation of a transient pore, release part of their transmitter content by a process described as 'kiss and run.' The transient pore mechanism allows the quick, simultaneous passage of amine transmitters (and perhaps other small molecules, which may be present in LGVs together with neuropeptides) from LGVs into the extracellular fluid. On the other hand, neuropeptides contained within LGVs remain trapped inside the retrievable vesicle, as a consequence of their higher molecular weight. Therefore, release of most neuropeptides from the LGVs is unlikely to occur through kiss and run, for several reasons. These include the larger size of the peptides relative to the transient pore, and the slow emptying of peptide content from LGVs upon exocytosis. In support, simultaneous capacitance measurements and confocal imaging have shown that peptide release by kiss and run is negligible. On the other hand, complete vesicle fusion is usually required, through a mechanism involving a priming step followed by retrieval of the vesicle as a coated vesicle. A divergence in this respect between peptide-containing LGVs and amine-containing LGVs may merely be additional

to the several differences between these two classes of neurotransmitters. Indeed, neuropeptides do not have a known re-uptake mechanism, as opposed to biogenic amines, so that there is no way locally to refill the peptide-containing LGVs after emptying. Moreover, neuropeptides are synthesized at the rough endoplasmic reticulum in the neuronal perikarya, but not in axon terminals, whereas amines can also be synthesized inside LGVs.

When a neuron produces more than a single neuropeptide (as appears to be the rule), several theoretical possibilities arise regarding their release. It is possible that all co-stored neuropeptides can be released all at once, at all processes. Alternatively, or in addition, individual neuropeptides can be theoretically liberated singularly or in different combinations at different processes. In *Aplysia*, the various neuropeptides derived from a common prohormone seem to be targeted to different neuronal processes. The situation is far less clear in mammals, considering that most studies have been carried out on isolated neurons. Nonetheless, all co-stored neuropeptides can be reasonably assumed to be released together upon exocytosis. For example, the co-release of CGRP and substance P (and other tachykinins) has been demonstrated, and this occurs at both central and peripheral endings of the DRG neurons. Moreover, if the co-release of co-stored neuropeptides is indeed the rule, then it should occur from any neuronal process containing LGVs, although this latter issue also needs further clarification. The major functional implication is that co-released peptides probably act together in determining the response of target cells. A differential release of co-stored peptides (if indeed this occurs *in vivo*) would more likely rely on mechanisms different from those that apply to co-stored biogenic amines and/or coexisting low-molecular-weight neurotransmitters. From this perspective, the relative rate of peptide dissolution from the LGV core might be of primary relevance, since this appears to be the critical determinant of the speed of peptide secretion *in vitro*.

Functional Implications of Neuropeptide Coexistence

For an evolutionary perspective, coexistence of multiple neurotransmitters in neurons has led to substantial advantages. In particular, neuropeptides have a wide diversity of direct or modulatory effects on the electrical responses of target cells, in addition to trophic effects. When they are co-released with other neurotransmitters, the wealth of responses of target neurons increases dramatically. Neurotransmitters produced and released by a single neuron are often defined as cotransmitters. However, it is probably unsafe to consider that cotransmitters must display some kind of interaction, simply because they are co-released, even though such a co-release occurs under physiological conditions. The common existence of a combination of neuropeptides and classical neurotransmitters in neurons enables fast (2–5 ms) and slow (100–500 ms) synaptic communication to take place. Fast- and slow-acting cotransmitters can act on completely independent targets and, therefore, do not interact at all. However, there is a general consensus that when multiple neurotransmitters are released within the extracellular space, they usually display at least some type of interactive actions, irrespective of the finding that such a release occurs from the same neuron – that is, they are true cotransmitters, or from separate sources.

The simplest mode of interaction of two (or more) neurotransmitters occurs when two (or more) distinct receptor complexes are present in the (postsynaptic) membrane of target cells, and a receptor–receptor interaction occurs (**Figure 3**). When neuropeptides coexist with low-molecular-weight neurotransmitters, the neuropeptide usually acts on GPCRs, whereas the low-molecular-weight transmitter generally opens a ligand-gated ion channel. The low-molecular-weight transmitter is generally the principal messenger, and the neuropeptide interacts with it by altering the ion channel gating properties or its response to further signals. This occurs by direct operation on the receptor complex or by the activation of second-messenger systems that, in turn, act on the receptor complex. Hence, one neurotransmitter may alter the number of receptors or the affinity of the receptor to the other(s) simultaneously released. Interestingly, receptor recruitment from the interior of the cell to the plasma membrane may be an additional and ubiquitous mechanism of modulation of signal transduction, leading to receptor sensitization. The interaction of cotransmitters also occurs through presynaptic regulation. This implies the existence of presynaptic receptors for one or more messengers. In this case, one of the neurotransmitters feeds back on presynaptic receptors and thus affects its own release or the release of the cotransmitter(s). This latter possibility has been demonstrated, for example, in the striatum in which tachykinins presynaptically stimulate the release of dopamine, and in the locus coeruleus in which noradrenergic neurons can be activated by the stimulation of neurokinin-3 receptors.

Figure 3 Functional implications of neuropeptide coexistence. For simplicity, only two peptides (indicated by the red and yellow circles) are represented, and only postsynaptic interactions are considered. In purely peptidergic neurons (a), neuropeptides co-stored within large granular vesicles are released together and affect the activity of their target neurons upon binding to their cognate G-protein-coupled receptors. In neurons producing and releasing a combination of neuropeptides and a fast-acting neurotransmitter (b–d), the coexistence of these neuroactive molecules does not necessarily imply that they are acting as cotransmitters. As depicted, in panel (b) only the neuropeptides affect the target neuron that expresses specific G-protein-coupled receptors, whereas in panel (c) the target neuron binds receptors (ion channels) only for the low-molecular-weight transmitter. Only in panel (d) are the neuropeptides and the low-molecular-weight transmitter true cotransmitters. In this case the general rule is that the low-molecular-weight transmitter acts as the principal messenger, whereas the neuropeptides subserve a modulatory role.

Neuropeptides and Receptors in Glia

Introduction

Neuropeptides were originally defined as chemically distinct small proteins (3–100-amino-acid residues) widely distributed in the central and peripheral nervous system and acting as neurotransmitters, cotransmitters, and/or neuromodulators. Initially isolated from different tissues and organs, thanks to their biological properties or by searching for C-terminally amidated fragments, their already large number has further increased over the past 15 years with the advent of molecular cloning and related techniques. New neuropeptides have been found on the basis of messenger RNA (mRNA) sequence, genomic data searching for structural features expected to be intrinsic to neuropeptides, and homology screen approaches applied to G-protein-coupled receptors (GPCRs) (because all the receptors activated by neuropeptides are GPCRs). Today, several tens of small peptide molecules have been identified. They are involved in synaptic transmission, regulation of neurotransmitter recycling and neurotransmitter receptor synthesis (vasoactive intestinal peptide/pituitary adenylate cyclase-activating polypeptide (VIP/PACAP)); ion spatial segregation and, thus, neuronal excitability (NPY, neurotensin); and the complex regulation of energy metabolism coupled to neuronal activation and local vasodilation (VIP/PACAP).

At the same time, the concept of neuropeptides such as neurotransmitters being uniquely synthesized in nerve cells and involved only in synaptic transmission has been severely challenged since the discovery that many neuropeptides can be detected in all main types of glial cells, including astrocyte, oligodendrocyte, NG2-positive oligodendrocyte precursors, microglia, and Schwann cells. Moreover, glial cells are no longer merely likened to the connective cell type of nervous tissue acting as supporting cells: Glial cells play active roles in the development, maintenance, function, and pathology of the nervous system.

It is now clear that glial cells sense and respond to neuronal activity, as indicated by changes in intracellular Ca^{2+} levels that can trigger 'gliotransmitter' release. They possess the molecular machinery necessary for regulated exocytosis, including fusion protein synaptosome-associated protein (SNAP) receptor (SNARE). Astrocytes express synaptobrevin 2, cellubrevin, synthaxin 1, and SNAP 23, associated with electron-lucent (clear), possibly containing classical neurotransmitters, and some dense core vesicular structures, possibly storing peptides. In fact, as soon as astrocytes' ability to release 'neuroligands' was proved, it became clear that not only classical transmitters (i.e., glutamate) but also neuropeptides, such as atrial natriuretic peptides, and aminoacids, such as D-serine, could be released using an exocytotic mechanism from astrocytes, although the lack of evidence in support of an 'active zone' on the plasma membrane makes the site of release uncertain.

Glial cells not only synthesize neuropeptides but are also regulated by them. The early evidence of classic neurotransmitter receptors on glial cells was in fact followed by the demonstration of binding sites and receptor mRNA for many neuropeptides in purified cultures of all major classes of glial cells, and *in situ* hybridization studies on tissue sections have confirmed the presence of neuropeptide receptor mRNA in glial cells in different brain areas. In terms of membrane effects, both hyperpolarization (cholecystokinin (CCK), galanin, neurotensin, VIP/PACAP) and depolarization (neuropeptide Y (NPY)) have been observed. The presence of second messenger systems has also been documented, including generation of cyclic adenosine monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), inositol triphosphate, and intracellular Ca^{2+} transients, and activation of mitogen-activated protein kinase (MAPK), phospholipase A2 and D, and specific G-proteins, as well as transcription factor regulation (induction of immediate early genes and nuclear factor-kappa B (NF-κB)).

Peptides have been shown to participate in the regulation of major processes in glial cells, such as proliferation (e.g., angiotensin, calcitonin gene-related peptide (CGRP), opioids, VIP/PACAP), development and maturation (opioids), energy metabolism (angiotensin), survival (opioids), and in the regulation of the proper function of each glial cell class (e.g., VIP and opioids regulate cytokine production in microglial cells; opioids regulate myelin production in oligodendrocytes; neurotensin and NPY modulate astrocyte reaction during inflammation and after lesions), as is also indicated by regulation of receptor expression, binding properties, and intracellular effects after different stimuli. A completely new chapter has been recently opened in light of the possible role of neuropeptides in gliogenesis and *in vitro* assays based on neural precursor cell technology (*in vitro* neurosphere assay).

Glia expression of peptide and peptide receptors, together with *in situ* detection of molecular markers

Table 1 Peptide expression by different glial cells

Neuropeptide	*Detection level*	*Cell*	*System*

for cell activation and the well-documented role of glial cells in the production and action of growth factors, has defined a new scenario in which neuron-derived neuropeptide regulates glial function and glial-derived neuropeptides regulate neural function and also act in an autocrine-paracrine fashion, thus opening up completely new perspectives for reciprocal neuron–glia interactions in information processing in the nervous system, in brain metabolism, and in the biology of neurodegenerative diseases, migraine, and chronic pain.

This article describes peptide and peptide receptor expression by glial cells, as demonstrated in tissue section, primary cultures, and cell lines using morphological, biochemical, functional, and pharmacological approaches. Available data are listed in Table 1 (neuropeptides) and Table 2 (neuropeptide receptors), and some illustrative peptides are described in the following sections. Just as neuropeptides are heterogeneously distributed among neuronal populations and brain regions, their expression in glia is also highly regional. Several of these neuropeptides are under developmental regulation, and after the postnatal downregulation of glial peptide transcripts, injury in adulthood can cause upregulation again. Thus, data reported in the tables are based on resting conditions of well-characterized *in vivo* (mouse, rat, human) and *in vitro* systems (primary culture and cell lines). Retina is not considered in this article. Different expression profiles, as found studying tissue sections derived from experimental and spontaneous pathologies, mixed cultures, and tumor cell lines, are discussed.

Illustrative Neuropeptides

Angiotensin II

Angiotensin II consists of eight amino acid residues and is the main active substance of the rennin–angiotensin system. It derives from the precursor decapeptide molecule angiotensinogen, a glycoprotein of molecular weight 55 000–58 000, that is converted by renin into angiotensin I. Angiotensin I is converted by angiotensin converting enzyme to angiotensin II. The brain contains an autonomous renin–angiotensin system with all the enzymes and peptides necessary for the biosynthesis of these angiotensins, and astrocytes appear to be the chief source of angiotensinogen in the brain. Large amounts of angiotensinogen mRNA are found in the forebrain medulla; medial thalamus; and hypothalamus, including anterior hypothalamus and the paraventricular, supraoptic, and suprachiasmatic nuclei, as also confirmed by transgenic technology. The presence of immunoreactivity to angiotensin I and II around most brain vessels, presumably in perivascular astrocytes at the surface of astroglial boutons, has also been described in mouse brain tissue.

Angiotensin receptors have been classified into two subtypes, AT1 and AT2. AT1 receptors are expressed on perivascular astrocytes, suggesting that angiotensin

Table 2 Peptide receptor expression by different glial cells

Peptide	*Cell*	*Receptor subtype*[a]	*Effects and effectors*
Angiotensin	Astrocyte	AT1, AT2	Reduction of membrane conductance activation of Na-K-ATPase via PKC delta, activation of PLC e PG release stimulation of PI turnover and reduction of cGMP
			Early genes, glucose uptake and transporter transcription stimulation

may act on astrocytes in an autocrine or paracrine manner. Angiotensin receptors on distinct populations of neonatal rat astrocytes may activate unique signaling pathways and produce different cellular responses. Three different populations have been described: astrocytes containing AT1 subtype coupled to phospholipase C (PLC) activation and prostacyclin release (in the medulla and cerebellum); astrocytes containing high-affinity AT2 receptors which do not activate PLC or release prostacyclin but may be coupled to an additional signaling pathway (in the cerebral cortex); and astrocytes which do not contain high-affinity plasma membrane angiotensin II receptors and do not activate PLC or release prostacyclin (in the thalamic/hypothalamic area).

Most experimental evidence supports the view that brain angiotensin II mediates several classic physiological effects, including blood–brain barrier, body water balance, blood pressure, sodium homeostasis, and blood volume. Beside these classic functions, the brain renin–angiotensin system has more-subtle functions involving complex mechanisms, such as learning, memory, reaction to stress, and control of cerebral circulation.

Atrial Natriuretic Peptide

The family of natriuretic peptides (NPs) comprises atrial, brain, and C-type NPs (ANPs, BNPs, and CNPs), and three NP receptors have been cloned. NP receptor-A (NPR-A) and NP receptor-B (NPR-B) are guanylyl cyclase linked, and they utilize cGMP as intracellular messenger. Both ANP and BNP bind preferentially to NPR-A, whereas CNP binds preferentially to NPR-B. All three NPs bind to the third receptor, known as NP receptor-C (NPR-C). NPR-C is not linked to guanylyl cyclase but appears to act to clear the NPs from circulation. NPs are cardiac and vascular peptides with vasodilatory, diuretic, natriuretic, anti-inflammatory, antifibrotic, and antimitogenic actions. NPs and their mRNA have been localized in forebrain and brain stem regions associated with olfaction, blood pressure regulation, and fluid/electrolytic balance.

ANP has been detected in different types of astrocytes, including glia limitans, and in proximity to microvessels, where the astrocytic bouton processes envelop the vessel wall and play a major role in blood flow regulation. ANP is released from astrocytes through a vesicular exocytotic mechanism in response to cytosolic Ca^{2+} oscillations, as demonstrated by chimeric pro-ANP fused with emerald green fluorescence protein. ANP has a potent vasodilating activity, suppresses the production and signaling of vascular endothelial growth factor, and preserves the functional morphology of endothelial tight junctions. It has been suggested that astrocyte-released ANP might be involved in the development and maintenance of the integrity of the blood–brain barrier, in the regulation of the gliovascular interface and of water and ion homeostasis, and in keeping the brain osmotic microenvironment stable. In pathological conditions, glia-released ANP acts as an anti-vasopermeability factor, which inhibits the development of vascular edema, resulting in protective effects under hypoxic and ischemic conditions.

Astrocytes also express all three types of ANP receptors. In type I astrocytes, it has been shown that ANP decreases Cl^- uptake in a dose-dependent manner. Moreover, astrocyte proliferation is inhibited by NP's binding to C-type receptors, through the inhibition of DNA synthesis associated with inhibition of MAPK activity.

Also microglial cells mRNA coding for ANP receptors (types A, B, and C) and the ANP molecule, thus supporting a possible local paracrine–autocrine regulation. Stimulation of such cells with lipopolysaccharide induces NO and IL-1β production, morphological change in the cells, and the activation of NF-κB and activating protein-1 (AP-1) transcription factors, and all these effects are inhibited by ANP, suggesting that either exogenous or endogenous ANP binds to its receptors on LPS-stimulated microglial cells and thereby inhibits their activities through inhibitions of the transcription factors NF-κB and AP-1.

Calcitonin Gene-Related Peptide

CGRP is a member of the calcitonin peptide family that also includes adrenomedullin (ADM) and two newly isolated peptides, intermedin and calcitonin receptor-stimulating peptide. CGRP and ADM are potent, long-lasting vasodilators, and all major cerebral arteries, small intraparenchymal microvessels, and pial vessels are richly innervated by CGRP-containing nerve fibers. CGRP and ADM have been implicated in cerebrovascular disorders, including migraine headache, vasospasm after subarachnoid hemorrhage, and stroke evolution. While there is no evidence for endogenous synthesis of CGRP, all types of glial cells express CGRP binding sites that function as receptors, forming a complex with the accessory protein from the receptor activity modifying protein family.

In human as well as in rat astrocytes, molecular and pharmacological studies have indicated the presence of type 1 and type 2 receptors and an additional, undefined type. CGRP receptors are also found in the human cerebromicrovascular bed, whereas brain astrocytes, but not microvascular tissue and cells, express functional ADM-R. In view of the suggested importance of astrocytes in the regulation of brain metabolic and ionic homeostasis, local cerebral blood flow, and blood–brain barrier function, CGRP most likely has the ability to modulate some of these various astroglial functions.

CGRP receptors are also expressed by microglia. It has been suggested that neural-derived CGRP from the presynaptic terminals of the neurons, such as motor neuron or primary sensory neurons, activates microglia, leading to immediate early gene and NFκB expression, inducing them to produce proinflammatory cytokines, ATP, and other neuroactive factors, which may further alter neuronal excitability or act on tissue remodeling after lesion. This mechanism has been implicated in, for instance, sustaining hyperalgesia, in which such glial activation could be the driving force, maintaining the pain sensation even after the original injury has healed.

Human oligodendrocytes are also sensitive to calcitonin peptide family stimulation, as indicated by increased cAMP production. ADM and amylin are released by oligodendrocytes, thus suggesting that both peptides act via autocrine/paracrine mechanisms to play functional roles through the elevation of cAMP. It has been reported that some neurons, astrocytes, and brain microvessels have receptors responsive to ADM. ADM released from oligodendrocytes may therefore also affect neighboring cells, such as neurons or astrocytes in the central nervous system (CNS), as a paracrine modulator. The function of CGRP is uncertain in oligodendrocytes, although CGRP has been shown to be an endogenous regulator for modulating cell proliferation in Schwann cells.

Galanin

The expression of galanin in gliallike cells was first reported in colchicine-treated rat brain in NG2- (a chondroitin sulfate proteoglycan) positive cells (Figure 1). NG2-positive cells express properties similar to the oligodendrocyte–type 2 astrocyte progenitor, which can differentiate into oligodendrocyte or type 2 astrocytes and are then classified as oligodendrocyte precursor cells (OPCs). Colchicine-induced galanin expression in OPCs was strongly reduced in hypothyroid rats, suggesting that galanin expression is regulated by the thyroid hormone, possibly via the thyroid hormone-responsive element in the galanin promoter. OPCs express thyroid hormone receptors, and thyroid hormone regulates OPC proliferation and maturation – so galanin may also be involved in these processes. Not only chemical but also electrical stimulation able to activate NG2-positive cells, such as cortical spreading depression (CSD) induced galanin production (mRNA and peptide) in 'activated' NG2-positive cells throughout the entire neocortex, where few or no galanin-positive cells are normally observed. CSD-induced expression of galanin in cerebral cortex may be related to the proliferation of NG2-positive OPCs, as observed after experimental focal ischemia.

Galanin is also expressed by other glial cell types. The peptide and type 2 receptor mRNAs have been found in olfactory ensheathing cells (OECs). OECs are located exclusively in the olfactory bulb, olfactory epithelium, and olfactory nerve. They are specialized glial cells which share some phenotypic characteristics with both the Schwann cells of the peripheral nervous system and the astrocytes of the CNS, serving as a guide to the continuous renewal of olfactory

Figure 1 Galanin may be expressed by NG2-positive cells in the grey and white matter after different lesion stimuli, including intraparenchimal colchicine injection. The micrograph illustrates galanin immunoreactivity (IR; green) in NG2-positive cells (red) in the corpus callosum 24 h after colchicine injection in rat. NG2, a membrane sulfated proteoglycan. From Ubink R, Calza L, and Hokfelt T (2003) 'Neuro'-peptides in glia: Focus on NPY and galanin. *Trends in Neuroscience* 26: 604–609.

axons from the olfactory epithelium to the glomerular layer of the olfactory bulb. GAL and galanin agonists can also significantly inhibit the proliferation of OECs without cytotoxic effects.

Galanin, GalR1 and GalR2 mRNA, and galanin (and GalR1) immunoreactivity are strongly expressed in the subventricular zone and in the rostrally migratory stream of normal adult rat. The observed colocalization of galanin with the neuroblast markers polysialic acid–neural cell adhesion molecule and glial fibrillary acidic protein in these areas suggests that galanin is expressed by the progenitor cells behaving as stem cells *in vitro*. Due to the GalR2 mRNA expression in the same areas, galanin is presumed to regulate stem/progenitor cell activity by autocrine and/or paracrine mechanisms.

Galanin in fact inhibits proliferation of poorly differentiated glial precursors, such as OECs, thus suggesting a direct participation in cell cycle control. Galanin is also expressed in neuroblastomas, gangliocytomas, and pituitary neoplasms, and some of these tumors also express galanin receptors, thus suggesting a possible role of galanin in regulating tumor growth; galanin has indeed been included in triple antitumor therapy in experimental cancer, together with the long-acting synthetic somatostatin analog octeotride and serotonin.

Neuropeptide Y

NPY, peptide YY (PYY), and pancreatic polypeptide (PP) are 36 closely related amino acid polypeptides. Receptors for NPY, PYY, and PP are classified together as 'NPY receptors.' At present, five distinct NPY receptors have been established by receptor cloning studies. With regard to endogenous agonists, the receptors Y1, Y2, and Y5 preferentially bind NPY. Y5 receptor mRNA expression is largely restricted to the CNS.

NPY and NPY mRNA are expressed in astrocytes, and synthesis is highly regulated. For example, phorbol 12-myristate-13-acetate increases NPY protein and mRNA levels, suggesting regulation via the protein kinase C pathway. Interleukin-1b induces NPY expression in human, but not rat, astrocytes; this induction involves early genes. Basic fibroblast growth factor has a similar effect on NPY expression in both rat and human astrocytes, whereas forskolin increases NPY levels only in human astrocytes. These data raise the possibility that growth factors might be endogenous regulators of glial peptide expression, a view supported by their temporal, spatial, and developmental expression. In the nucleus accumbens and median eminence, Y1R was found at astrocyte gap junctions, suggesting that it may influence gap junction permeability. Since NPY takes part in a loop system responsible for feedback mechanism in the CNS control of energy homeostasis, this raises the possibility that NPY, acting on Y1R in astrocytes of the arcuate nucleus and median eminence, may regulate astrocyte coupling and hence influence signaling involved in body mass regulation.

NPY and related receptors are also expressed by glial cells different from astrocytes, microglia, oligodendrocytes, and Schwann cells. NPY has been found in OECs and transiently in Schwann cell precursors, which are present at a time during development when many peripheral axons are growing toward their target. The finding that NPY (both peptide and transcript) is expressed close to the CNS, overlapping with the zone in which incoming axons are

sorted before they enter the CNS, is indicative of a functional role related to growth, pathfinding, and/or trophism.

Opioids

After the biochemical purification and characterization of the three endogenous opioid peptides (the enkephalins, the endorphins, and the dynorphins), a fourth member of the family was isolated and termed simultaneously nociceptin, because of its ability to lower the perception threshold for painful stimuli, and orphanin FQ, as endogenous ligand of the orphan Gi/Go-coupled opioid receptor-like 1 receptor. Pharmacological studies have shown that multiple types of opioid receptors exist, today denoted as mu receptor (MOP), delta receptor (DOP), kappa receptor (KOP), and NOP (for nociceptin or orphanin FQ).

Glial-derived opioid peptides and related receptors play a critical role during development and maturation of oligodendrocyte precursors into myelinating oligodendrocytes, the cell which provides the myelin sheath of the axons in the CNS (Figure 2). Oligodendrocytes arise from OPCs in the ventral regions of the germinal neuroepithelium of the ventricular zones at very early stages of embryonic life. The progression of OPCs to mature oligodendrocytes represents a continuum during which the cells exhibit morphological and biochemical diversity. According to developmental stage-related markers, early oligodendrocyte progenitors, prooligodendroblasts, immature oligodendrocytes, and mature myelinating oligodendrocytes can be identified. Developmentally generated OPCs, as identified by the expression of the surface marker NG2, are also present in the mature CNS, where they account for 3–9% of total cell number in the adult CNS, representing an abundant, slowly cycling population of cells which reenter mitosis after injury. Although these cells have a modest rate of cell division, they represent the major dividing population of the adult CNS and are considered responsible for remyelination, a remarkable repair capability of the mature CNS. It is generally accepted that the process of remyelination represents a recapitulation of myelination during development, so molecular regulators active during development are also likely to guide remyelination.

Opioids participate in most of the critical steps of oligodendrocyte maturation. In culture, β-endorphin acts on the MOP and DOP receptors of hippocampal-derived neuroglial precursors in an autocrine manner, increasing proliferation rate through phosphorylation of extracellular signal-regulated kinase 1/2. Beta-endorphin results in a threefold increase in oligodendrogenesis but no significant change in astrogliogenesis.

Figure 2 Expression of opiate receptors in oligodendrocytes is dependent on developmental stage and cellular system. *In vitro*, primary cultures of oligodendrocytes express mu receptors (MOPs), coupled to mitogenic signaling, in a very early developmental stage (oligodendrocyte precursor cells, as identified by immunoreactive (IR) staining for the membrane sulfated proteoglycan NG2). MOP expression progressively decreases with maturation (see (c), in which 'Rip'-immunostaining recognizes noncompact myelin protein), and kappa receptors (KOPs) predominate in late developmental stages (see (d), in which 2′,3′-cyclic nucleotide 3′-phosphodiesterase (CNPase) positivity identifies mature oligodendrocytes), influencing differentiation. Also, delta receptor (DOP) seems to increase with maturation, but data are conflicting. When oligodendrogenesis is investigated in cultures derived from undifferentiated precursors (as identified in the neurosphere culture system by the immunostaining for nestin, an intermediate filament expressed by undifferentiated precursors of neuroectodermal origin (a)), all receptor subclasses are expressed by Sox2-(self-renewing, pluripotent neural cells, NPCs) and Nkx2.2-immunoreactive glial restricted precursor (GRP), and opioid agonists seems to induce oligodendrogenesis.

Blockade of opioids reduces proliferation, increases neurogenesis, and reduces gliogenesis. Complementary DNA arrays reveal lowered levels of mRNAs expressed in oligodendrocytes. Very immature oligodendrocytes express MOP receptors, whereas KOP receptors become expressed during late development. Selective opioid agonists and antagonists alter the rate of DNA synthesis and the size of myelin-like membranes in developing oligodendrocytes. This time-dependent development of opioid receptors on precursors reflects a possible role of opioids in determining the pool of oligodendrocytes available for myelin repair during adulthood and also myelin production in demyelinating conditions. It is interesting that leucoencephalopathy has been reported to occur during heroin abuse and to be partially reversible after withdrawal, thus supporting the hypothesis that opioids inhibit proliferation and maturation toward myelinating oligodendrocytes. Moreover, β-endorphin increases the mRNA levels of myelin basic protein, and morphine regulates phosphorylation of myelin basic protein in the rat brain.

Substance P

Tachykinins are a family of closely related peptides whose best-known members are substance P (SP), neurokinin A (NKA), and neurokinin B (NKB). NKB is present in the CNS and the spinal cord, and SP and NKA are found in the CNS and in primary afferent sensory neurons supplying a number of peripheral tissues. The three types of tachykinin receptors, denoted as neurokinin-(NK) 1, NK2, and NK3 receptors, are heterogeneously distributed within the tissues in each species.

Tachykinin synthesis by glial cells is not an ancillary phenomenon. SP has also been found to be expressed by human fetal brain microglia, and quantitative analysis of the transcript has indicated that brain microglia express higher levels than do peripheral immune cells, that is, monocyte-derived macrophages and lymphocytes, thus suggesting that brain microglia can be an important source of SP in the CNS.

Emerging evidence indicates that tachykinins regulate the immune functions of CNS glial cells. NK1 receptors have a high affinity for SP and are expressed by a number of resident CNS cell types, including astrocytes and microglia. In the human postmortem brain, the NK3 receptor immunoreactivity was found in the glia limitans at the pial surface, where astrocytes and beaded fibers stained intensely. In the white matter, astrocytes and beaded fibers displayed NK3 receptor immunoreactivity, particularly in areas surrounding blood vessels. SP–NK1 receptor interactions elicit activation of signal transduction pathways in both cell types and can initiate, or augment, inflammatory responses by astrocytes and microglia.

Tachykinins also clearly illustrate how glial cells can participate in pathological events, such as persistent pain resulting from either neuroinflammation or neuroimmune activation. Astrocytes and microglia occurring in the vicinity of the terminals in the dorsal horns of the spinal cord are activated in pain states. Such activation could arise from 'pain transmitters' such as SP, CGRP, glutamate, and/or ATP. It is well known that astrocytes and microglial cells are the main sources of ATP. Glutamate can stimulate ATP release from spinal cord astrocytes, and this release is greatly enhanced when SP is present.

Vasoactive Intestinal Peptide/Pituitary Adenylate Cyclase-Activating Polypeptide

VIP and PACAP are members of a superfamily of structurally related peptide hormones that includes glucagon, glucagon-like peptide, secretin, and growth hormone-releasing hormone. At least three receptors for PACAP exist in mammals, two of which are also high-affinity receptors for VIP, all widely distributed in the nervous tissue: VPAC1 receptor, which responds to VIP and PACAP with comparable affinity; VPAC2 receptor, first cloned from rat olfactory bulb, which also responds to VIP and PACAP with comparable affinity; and PAC1 receptor, which recognizes PACAP with much higher potency than it does VIP.

The classical roles attributed to astrocytes in brain function include cerebrovascular regulation through neurovascular coupling. The active neurons increase energy demand, and this is linked to the local increases in blood flow in the area of elevated neuronal activity. Astrocytes, which are much more numerous than neurons, send processes to synapses and blood vessels and communicate with other astrocytes through gap junctions and by release of ATP. Because of their polarized anatomical structure and of the vicinity of their boutons to contractile elements of blood vessels, such as smooth muscle cells in arterioles and pericytes in capillaries, astrocytes have long been suggested to contribute to the regulation of blood flow during neuronal activity.

In this context, VIP/PACAP peptides offer an example of peptidergic regulation of glia/neuron communication. Originally, VIP was thought to act predominantly by directly modulating neuronal activity. More recently, it has become clear that VIP influences neurons in the cortex through activation of VIP receptors located on astrocytes. VIP and PACAP are also key regulators in glycogen metabolism in

astrocytes, where they regulate expression of a number of genes encoding for enzymes of energy metabolism regulation.

In vivo, astrocytes envelop synapses so intimately that they are thought to compartmentalize the space between cells. One astrocyte may envelop several of the synapses of several neurons, and one neuron may have its synapse enveloped by several astrocytes. Neuron-derived VIP and PACAP are important in regulating astrocyte participation in glutamatergic synaptic function. PACAP increases glutamate uptake by promoting expression of glutamate transporters in astrocytes, and VIP also enhances glutamate uptake by astrocytes, thus decreasing glutamate toxicity.

Moreover, VIP and PACAP participate in the regulation of astroglial precursor proliferation and neural stem cell differentiation and in microglia biology during activation, acting as anti-inflammatory agents.

Future Directions

Neuropeptides represent a highly active area of research in neurobiology and neuropharmacology, and much of the data listed above probably need to be updated in the light of the emerging roles of glial cells in the physiology and pathology of the nervous system. Moreover, there is increasing evidence that GPCRs are present in nuclear or perinuclear membranes. Nuclear localization of NK1, CGRP, and SP has been reported in a subpopulation of dorsal root ganglia cells in rat; AT1 in the kidney, vascular smooth muscle cells, and neural cell lines; and NPY/Y1 in endocardial endothelial cells and opioid receptors in embryonic stem cells. Finally, neurotensin receptor 3, originally defined as sortilin, is a protein for the intracellular trafficking of this receptor, which leads to the internalization of the NT/NT3 complex via the endosomal pathway in different cell types. Potential roles for nuclear signaling pathways activated by neuropeptides/neuropeptide receptors include the regulation of nuclear transport, gene expression, nuclear envelope formation, and cell cycle and cell differentiation regulation.

Neuropeptides in Autonomic Neurons

L Klimaschewski, Medical University of Innsbruck, Innsbruck, Austria

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Autonomic ganglia are widely used as models for studying the establishment and plasticity of neurochemical organization in the autonomic nervous system. They contain well-defined and rather homogenous neuron populations which express a variety of neurotransmitters and neuromodulators (i.e., classical transmitters and neuropeptides in different combinations). The multipolar postganglionic neurons (PGNs) extend 10–15 dendrites and a single, mostly unbranched axon as revealed by silver studies and intracellular dye injection.

The PGNs are classified morphologically and neurochemically by the target they innervate. They regenerate readily, making it possible to study changes in neuropeptide content, for example, in response to axonal lesion. Above all, PGNs may be maintained *in vitro* to investigate effects of neurotrophic factors, cytokines and genetic manipulations on transmitter and neuropeptide expression. In addition, autonomic ganglia contain a variable number of small paraganglionic cells, called small, intensely fluorescent (SIF) cells because of their formaldehyde-induced catecholamine fluorescence. These are mainly located in clusters and ultrastructurally characterized by abundant large granular vesicles containing catecholamines and various neuropeptides.

Neuropeptides differ from classical transmitters with respect to their molecular weight, synthesis, storage, release, action, and metabolism. Peptide precursors are synthesized at the rough endoplasmic reticulum and, after enzymatic cleavage, sorted into large dense-core vesicles (LDV; ~ 100 nm in diameter). This step determines specificity with regard to the neurochemical phenotype and takes place at the level of the *trans*-Golgi network.

Different vesicle populations may be sorted into distinct terminals of the same neuron, suggesting that nerve endings of a particular neuron exhibit different neurochemical codes. Transmitters are stored in small synaptic vesivcles at the presynaptic membrane (active zone) and released rapidly after low-frequency stimulated exocytosis. On the other hand, neuropeptide-containing LDVs are randomly distributed in the nerve terminal, which supports the hypothesis that parasynaptic peptide release requires high frequency stimulation and proceeds in a significantly slower time course. Neuropeptide receptors represent guanine nucleotide-binding protein (G-protein)-linked molecules, consisting of seven membrane-spanning hydrophobic sequences. Neuropeptides are inactivated by proteolysis or by diffusion, whereas the action of classical transmitters is terminated by enzymatic cleavage, specific reuptake mechanisms or by diffusion.

Already at early stages of development, catecholamines and neuropeptides are detectable in autonomic ganglia, with decreasing cell numbers until birth. It appears likely that the restriction of neuropeptide expression to specific subpopulations of autonomic neurons is controlled by extracellular molecules encountered by the growth cone during axon outgrowth and finally by target-derived signals retrogradely transported after organ contact is established. Target tissues, therefore, not only play an important role in regulating the soma size, number, and distribution of neurons but also in determining the species-dependent neurochemical code of individual PGNs. However, we emphasize that no exclusive end organ–mediator relationship exists in autonomic ganglia. Rather, specific tissues (muscle or secretory cells) within the target appear to be the main regulator of neuropeptide synthesis.

Functional subpopulations of pre- and postganglionic neurons (e.g., vasomotor, pilomotor, or secretomotor circuits) are specified by their neuropeptide content (Table 1). During development and adult neuroplasticity, intraganglionic soluble factors derived from satellite cells, macrophages, or neighboring PGNs, as well as electrical activity and cell contact, alter the phenotype of PGNs. It becomes clear that the synthesis of each neuropeptide is regulated by more than one instructive factor or experimental condition and that, vice versa, neuronal differentiation factors induce not just one particular neuromodulator but affect a set of transmitter/peptide genes. In this article, the neuropeptides expressed by pre- and postganglionic autonomic neurons are discussed in alphabetical order regarding their localization, regulation, and function.

Calcitonin Gene-Related Peptide

The 37-amino-acid calcitonin gene-related peptide (CGRP) was shown to be generated by alternative processing of RNA transcribed from the calcitonin gene. CGRP is detected in a population of noncatecholaminergic, mostly vasoactive intestinal polypeptide (VIP)-immunoreactive, and sometimes also substance P

Table 1 The most common neuropeptides expressed in pre- and postganglionic neurons of functionally identified autonomic circuits in various mammals

VIP/PACAP		+ (post)	+ (post)			+ (post)

(SP)-immunoreactive PGNs in different species. Axodendritic synaptic contacts between CGRP-immunoreactive varicosities and PGNs represent links between the pre- and postganglionic efferent pathway. Consequently, CGRP-positive axons are absent from sympathetic ganglia after transection of the sympathetic trunk. Moreover, CGRP-containing nerve terminals provide the morphological correlate for reflex loops between sensory axon collaterals and PGNs. Activin A, a member of the transforming growth factor superfamily, but not leukemia inhibitory factor (LIF) or related cytokines, induce CGRP in sympathetic neurons.

Enkephalins

Two short pentapeptides, Met-enkephalin (ENK) and Leu-ENK, are derived from three different precursors; Met-ENK is included in proenkephalin A and in proopiomelanocortin, whereas Leu-ENK is derived from proenkephalin A or proenkephalin B. The latter is known as prodynorphin. The heptapeptide Met-ENK-Arg-Phe (MEAP) and the octapeptide Met-ENK-Arg-Gly-Leu (MEAGL) are derived from proenkephalin A and converted to Met-ENK. ENK- and MEAP-positive PGN are present in autonomic ganglia. ENK-immunoreactive PGN are catecholaminergic but neuropeptide Y (NPY)- and VIP-negative. Dynorphin is localized in most NPY-immunoreactive and in some NPY-nonreactive PGNs that project to arterioles and piloerector muscles. ENK-immunoreactive axons form pericellular baskets around PGN and establish synaptic contacts with dendrites of PGN. The ENK content increases in response to axotomy but not after decentralization of sympathetic ganglia. However, denervation of the adrenal gland upregulates preproenkephalin mRNA in chromaffin cells. Chronic treatment with the opiate receptor antagonist naloxone elevates ENK levels in the superior cervical ganglion by blocking ENK release from preganglionic nerves.

Mainly inhibitory functions have been assigned to ENK and its derivatives by the inhibition of voltage-dependent Ca^{2+} influx or by opening potassium channels. Physiological studies suggest that the release of acetylcholine from preganglionic nerves is inhibited by MEAP. Compared to the depressant effects of catecholamines on preganglionic acetylcholine release, ENK appears to be up to 100 times more potent. The amplitude of the fast excitatory postsynaptic potential (EPSP) is depressed after application of Leu- or Met-ENK onto PGNs. This effect is prevented by the addition of the opioid antagonist naloxone. ENK does not affect the cholinergic potential induced by the iontophoretic application of acetylcholine onto these neurons. In addition, endogenous opioids mediate inhibition by the activation of postsynaptic opiate receptors. Whereas κ-opioid receptor stimulation inhibits Ca^{2+} uptake through voltage-sensitive channels, δ- and μ-opioid receptors signaling inhibits adenylate cyclase and the activation of neuronal K^+ channels.

Galanin

The 124-amino-acid precursor includes the 29-amino-acid peptide galanin (GAL; the name is derived from the N-terminal glycine and C-terminal alanine residues) and a 60-amino-acid GAL mRNA-associated peptide (GMAP). GAL-immunolabeling is observed in catecholaminergic PGNs which, to a large extent, coexpress NPY. Surgical and chemical denervation (applying acetylcholinesterase (AChE) antibodies) produces a small increase in GAL- and GMAP-immunostaining. Major changes in GAL and GAL mRNA have been found in response to axotomy of autonomic neurons. The signal mainly responsible for increased GAL production in PGNs appears to be LIF because LIF-deficient mice exhibit only a small increase in GAL levels after axotomy. GAL-positive PGNs project to blood vessels of the muscle and skin as well as to the piloarrector muscles. However, compared to the number of positive perikarya, the frequency of GAL-immunoreactive nerve endings in peripheral target tissues is low.

GAL inhibits the release of neurotransmitters by activating a pertussis toxin-sensitive G-protein. Specifically, GAL decreases vagal activity via presynaptic

inhibition of acetylcholine release from parasympathetic nerve terminals, and, in cardiac ganglia, GAL induces a hyperpolarizing potential in the majority of neurons probably due to the activation of a potassium conductance.

Neuropeptide Y

The 36-amino-acid neuropeptide tyrosine (NPY) belongs to a family of structurally related pancreatic polypeptides that include peptide YY. NPY is highly concentrated in large LDVs of sympathetic postganglionic neurons. Scattered, mainly small PGNs exhibit immunolabeling for NPY, and a majority belong to the catecholaminergic neuron population. Some muscle-vasodilator NPY-immunoreactive PGNs in paravertebral ganglia contain co-localized VIP and lack tyrosine hydroxylase (TH)-immunoreactivity. NPY is co-released with noradrenaline upon preganglionic activity to induce long-lasting vasoconstriction (Figure1). Treatment with reserpine or 6-OH-dopamine results in a parallel depletion of both NPY and catecholamines at nerve terminals in the target tissues of PGNs, whereas NPY mRNA and peptide levels increase in the corresponding ganglia. NPY levels decrease in the superior cervical ganglion 1 week after transection of the cervical sympathetic trunk, whereas after axotomy the peptide is elevated but NPY mRNA is downregulated. In genetically hypertensive rats, NPY levels are reduced in the superior cervical ganglion, whereas increased circulating NPY levels are detected in patients with essential hypertension or with pheochromocytoma.

Compared to noradrenaline, NPY-release mainly depends on high-frequency stimulation of PGNs and is facilitated by presynaptic β-receptor activation. NPY apparently is responsible for the α-adrenoceptor antagonist-resistant vasoconstriction in response to stimulation of sympathetic nerves. The large amidated C-terminal part of NPY is necessary for receptor binding, inhibition of cyclic adenosine monophosphate (cAMP) formation, and vasoconstriction caused by stimulation of Y_1 receptors. The presynaptic NPY receptor is of the Y_2 type and mediates the suppression of noradrenaline, serotonin, and NPY release. NPY-mediated suppression of transmitter release from the sympathetic nerve endings by reducing Ca^{2+} influx is due to the selective inhibition of neuronal N-type Ca^{2+} channels. Finally, NPY directly inhibits the catalytic activity of the catecholamine-synthesizing enzymes dopamine β-hydroxylase (DBH) and TH *in vitro*.

Somatostatin

Somatostatin (SOM), the most important inhibitor of pituitary growth hormone secretion, is a cyclic 14-amino-acid peptide isolated from the bovine

Figure 1 Neuropeptides released from autonomic neurons regulate tissue perfusion. Sympathetic vasoconstrictor neurons contain noradrenaline (NA), adenosine triphosphate (ATP), and neuropeptide Y (NPY). They are contacted by cholinergic preganglionic neurons expressing calcitonin gene-related peptide (CGRP). NPY is predominantly acting at small arteries, whereas ATP modulates noradrenergic transmission at larger arteries and fine arterioles within the smooth muscle. Vasodilation is induced by parasympathetic neurons synthesizing acetylcholine (ACh), nitric oxide (NO), and vasoactive intestinal peptide (VIP). Substance P (SP) and enkephalins (ENKs) are neuromodulators expressed in preganglionic neurons innervating them. Adapted from Gibbins IL and Morris JL (2000) Pathway specific expression of neuropeptides and autonomic control of the vasculature. *Regulatory Peptides* 93: 93–107.

hypothalamus. SOM is mainly detected in autonomic neurons throughout development. In adults, only few TH-positive PGNs contain SOM-immunoreactivity. In prevertebral ganglia, for example, these neurons project to the secretomotor neurons in the submucosal ganglia. SOM-immunoreactive axons may be of preganglionic origin because neurons in the nucleus intermediolateralis have been shown to contain SOM-immunoreactivity. SOM serves as a good example of the differential regulation of neuropeptides on mRNA and peptide levels because co-culture of autonomic neurons with ganglionic nonneuronal cells increases prepro-SOM mRNA without altering SOM peptide level. Two different signals derived from satellite cells appear to be responsible for this observation: a soluble factor stimulating the transcription of the prepro-SOM gene and a membrane-associated factor inhibiting peptide synthesis. SOM synthesis is induced by LIF because LIF treatment results in higher SOM mRNA levels. This effect is reversible and appears to be selective because SOM is not increased by this cytokine in sensory neurons. Inhibitory effects of SOM on peripheral noradrenergic neurons include the blockade of a Ca^{2+} current and inhibition of the K^{+}-induced release of acetylcholine.

Substance P

SP belongs to a family of closely related neuropeptides, called tachykinins or neurokinins, which include neurokinin A (NKA), neurokinin B (NKB), neuropeptide K (NPK), and neuropeptide γ (NPγ). Multiple preprotachykinin (PPT) mRNAs arise from a single gene through alternate splicing of the primary transcripts. SP-immunoreactivity has been demonstrated in few sympathetic PGNs, sometimes co-localized with ENK. Whereas the co-localization of SP and CGRP is characteristic of primary sensory neurons, sympathetic PGNs containing both SP and CGRP rarely occur. However, SP/CGRP-positive axons are observed frequently in the autonomic ganglia. They are diminished after postganglionic nerve transection, suggesting that these fibers may represent axon collaterals of sensory neurons. Regarding the origin, distribution, and connectivity of SP-immunoreactive intraganglionic fibers, SP may therefore act as a modulator in local reflex arcs involving PGNs, interconnected SIF cells, or short loop circuits between sensory axon collaterals and PGNs. SP peptide and mRNA are elevated in response to decentralization or axotomy of autonomic neurons. As with VIP, the elevation of SP after axotomy is prevented by dexamethasone, which blocks SP expression induced by interleukin (IL-)1β. IL-1β is synthesized in the sympathetic ganglia and released in response to tumor necrosis factor, which by itself stimulates SP expression in co-cultures of PGNs with nonneuronal cells. Because SP is not elevated in sensory neurons, the effects of IL-1β on SP expression are likely to be selective and, at least in part, mediated by LIF. This suggests that SP expression may be linked to cholinergic development because LIF is identical to cholinergic differentiation factor (CDF). In fact, similarities exist in the regulation of both traits.

SP released from the sympathetic ganglia by depolarization potentiates the amplitude of fast EPSPs, resulting in spike discharge. Physiological studies suggest a role for SP in evoking a slow long-lasting membrane depolarization of PGNs that is influenced by enkephalinergic presynaptic inhibition. SP specifically inhibits the increase in TH activity observed after treatment with nicotinic agonists. However, in cultures of dissociated superior cervical ganglia (SCGs) exogenously applied, SP, like SOM, modulates catecholamine metabolism by increasing TH activity. At the spinal cord level, SP increases sympathetic activity and arterial pressure by activating preganglionic neurons via neurokinin (NK-)1 receptors.

Vasoactive Intestinal Polypeptide and Pituitary Adenylate Cyclase-Activating Polypeptide

VIP, a linear 28-amino-acid peptide, was isolated from porcine gut and is structurally related to the peptides of the secretin–glucagon family. VIP is derived from a larger precursor molecule that contains another biologically active peptide, peptide histidine isoleucin or, in humans, histidine methionine-27. Only few PGNs contain VIP. In contrast, a large proportion of chick lumbosacral sympathetic neurons and 10–15% of mainly cholinergic PGNs in the stellate ganglion exhibit VIP-immunoreactivity. Strongly VIP-positive PGNs occurring in clusters are often localized in the ganglion periphery. They are distinguished from scattered cells exhibiting moderate VIP-immunostaining. The latter cell bodies co-localize CGRP or SP and probably project to the sweat glands. VIP is found in some PGNs containing NPY and projecting to smooth muscle of the airways. Clustered CGRP-nonreactive, but VIP-immunoreactive, PGNs are preferentially apposed by SOM- and CGRP-immunoreactive fibers and probably project to the smooth muscle.

An increase in the number of VIP-immunoreactive cell bodies and nerve fibers is observed after axonal lesion of SCG neurons and in ganglia maintained in organ culture. IL-1β has been found to potentiate

this effect, whereas dexamethason reduces the increase in VIP-immunoreactivity. The increase in peptide content is accompanied by an upregulation of VIP mRNA. As indicated by LIF knockout and antibody studies, LIF/CDF induces VIP mRNA in response to axotomy of the sympathetic ganglia. However, because the induction of VIP after axotomy is reduced only by 60–70% in LIF-deficient mice compared to the lesioned wild-type SCG, other factors are likely to be involved. Although VIP-immunoreactive nerve fibers in the sympathetic ganglia, in part, are derived from preganglionic neurons, an increase of VIP-immunoreactivity is observed after decentralization (i.e., transection of the preganglionic fibers of the SCG).

The cooccurrence of acetylcholine and VIP in sympathetic neurons suggests a cooperative function in the regulation of blood vessels (Figure 1). Indeed, VIP has been found to act as a potent vasodilator. VIP mediates the atropine-resistant vasodilation and increases the secretory response to acetylcholine in the cat submandibular salivary gland. With respect to its possible neuronal functions, VIP induces a voltage-dependent inhibition of N-type Ca^{2+} channels in rat sympathetic neurons. VIP enhances synaptic transmission, probably by increasing acetylcholine release from presynaptic terminals and facilitates the electrophysiological response to muscarinic agonists in the SCG. In parasympathetic ganglia, VIP produces depolarization associated with spontaneously firing action potentials and decreased membrane conductance. Furthermore, the noncholinergic component of the transsynaptic stimulation of TH activity may be due to VIP released from preganglionic fibers. VIP rapidly increases TH activity by elevating intracellular cAMP levels as well as TH mRNA synthesis, followed by an increase in TH activity 2 days later. This long-term neuromodulatory role of VIP may be responsible for the described time course of TH activity after axotomy. Because a significant increase of the intraganglionic VIP content has been observed, a further decrease of TH activity after an initial fall may be prevented by VIP, possibly mediated by a rise in intracellular inositol phosphate. With regard to axonal regeneration after lesion, VIP has been found to induce neurite outgrowth, to stimulate mitosis, and to enhance the survival of sympathetic neuroblasts *in vitro*. Moreover, VIP delays neuronal death for approximately 6 h after nerve growth factor (NGF) deprivation of explanted rat neonatal SCG neurons.

Similar effects on autonomic neurons are mediated by the related pituitary adenylate cyclase-activating peptide (PACAP), which is found in two amidated forms (PACAP38 and PACAP27) and shows a 68% sequence homology with VIP. There is increasing evidence that PACAP acts as a neuromodulator in the autonomic nervous system. In peripheral ganglia, PACAP expression is detected in sensory, vagal, and cranial parasympathetic neurons. In otic and sphenopalatine ganglia, many neurons are positive for both PACAP and VIP. PACAP is upregulated in a subpopulation of PGNs after axotomy and probably participates in neuronal development and nerve regeneration.

The effects of PACAP are mediated by receptors that interact with PACAP and VIP with similar high affinity (VPAC1 and VPAC2), whereas PAC1 is highly specific for PACAP. PACAP/VIP receptors are coupled to adenylate cyclase via G_s and activate downstream signaling molecules, including mitogen-activated protein kinase (MAPK), phosphatidylinositol 3-kinase, and phospholipase C.

Other Neuropeptides

Atrial natriuretic polypeptide is detected in PGNs of the sympathetic ganglia and participates in the inhibition of the carbachol-induced increase in catecholamine synthesis. Bombesin/gastrin-releasing peptide has been demonstrated in axons but not in PGNs or SIF cells of the sympathetic ganglia.

Neurotensin (NT)-immunoreactive nerve fibers occur around CGRP/VIP-immunoreactive PGNs of the SCG and stellate ganglion. Such fibers are probably derived from preganglionic NT-immunoreactive neurons which are found in the spinal intermediolateral nucleus. NT appears to participate in the noncholinergic excitation of PGN.

Vasopressin-immunoreactivity is present in sympathetic PGNs, and a novel neuropeptide, secretoneurin, a cleavage product of secretogranin II, is highly expressed in autonomic neurons and in SIF cells.

Neuropeptides Internalization

J M Jimenez-Andrade and P W Mantyh, University of Minnesota, Minneapolis, MN, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Over the past few decades, numerous neuropeptides and their receptors have been discovered in various regions of the peripheral and central nervous systems. Likewise, an increasing number of studies have revealed that neuropeptides play a significant role in the regulation of nervous system function in normal and pathological conditions.

The biological actions of neuropeptides are mainly mediated by activating either G-protein-coupled receptors (GPCRs), ligand-gated ion channels, cytokine receptors, or receptor tyrosine kinases. In this article, we focus on GPCRs, as the majority of neuropeptides bind to this class of receptor. The GPCRs, once activated, may regulate the function of various protein kinases and enzymatic effectors and modulate the transcription of numerous target genes. An important feature of GPCRs is that the activation of these receptors also triggers 'feedback' mechanisms that protect against both acute and chronic receptor overstimulation. According to SG Ferguson, these mechanisms involve (1) uncoupling of the receptor from heterotrimeric G-proteins (desensitization), (2) the internalization of cell surface receptors to intracellular membranous compartments, and (3) the downregulation of the total cellular complement of receptors due to reduced receptor mRNA and protein synthesis, the lysosomal degradation of preexisting receptors, or recycling of receptors to the cell surface.

A wide variety of neuropeptides and their receptors have been shown to undergo internalization (endocytosis), including angiotensin, neurotensin, bradykinin, corticotropin-releasing factor, somatostatin, vasoactive intestinal peptide, and substance P. In the following discussions we focus on the substance P and neurokinin-1 (SP–NK-1) system to discuss some of the features, functional consequences and the potential therapeutic usefulness of neuropeptide receptor-induced internalization.

Neurobiology of Substance P and NK-1 Receptor

Substance P belongs to the tachykinin neuropeptide family which also includes neurokinin-A (NK-A) and neurokinin-B (NK-B). All tachykinins are characterized by the C-terminal sequence-Phe-Xaa-Gly-Leu-Met-NH_2. Substance P was first identified in 1931 as a component of brain and intestinal extracts which possessed smooth muscle contractile activity. Early studies have shown that substance P is present primarily in the gray matter of the central nervous system (CNS), with the highest levels seen in the hypothalamus and substantia nigra. Substance P was also found to be expressed in the spinal cord, mostly in dorsal areas, as well as in the peripheral nervous system (PNS), particularly in the autonomic nerves, spinal ganglia, and sympathetic trunk.

Comparative analysis of pharmacologic properties of substance P, NK-A, and NK-B has led to the recognition of three distinct NK receptors, each with a preferred ligand: substance P preferentially binds to the NK-1 receptor, whereas NK-A and NK-B show preference for the NK-2 and NK-3 receptors, respectively. While each NK possesses agonist properties at all three receptor types, the biological activity of these systems appears to be governed by both co-localization and affinity of various NKs for different NK receptors. The NK-1 receptor is a G-protein-coupled receptor which, when activated, induces inositol phospholipid hydrolysis and, in some cases, adenylate cyclase.

The SP–NK-1 receptor pathway is an abundant and extensively studied neuropeptide system that is present in the CNS, PNS, and nonneuronal tissues and that regulates a wide variety of functions. Some of the most-studied functions of the SP–NK-1 system include modulation of the signaling of nociception, regulation of chemotherapy-induced nausea and vomiting, and control of respiration.

Localization of Substance P and NK-1 Receptors in the Brain and Spinal Cord

Autoradiographic, immunohistochemical, and messenger RNA (mRNA) expression studies have documented broad distribution of substance P and NK-1 receptors in the CNS. Intense substance P staining has been observed in amygdala, locus coeruleus, hypothalamus, substantia nigra, and peduncular nuclei, whereas moderate labeling has been detected in caudate putamen, nucleus accumbens, and raphe nuclei, as well as in the lamina I of the spinal cord. Relatively low, but detectable, levels of substance P are present in the cerebral cortex, cerebellum, and hippocampus. Substance P has been shown to be expressed in both neuronal cell bodies and dendrites, to be localized to synaptic vesicles, and to be released in a calcium-dependent manner. Taken together, these findings suggest that substance P may be a neurotransmitter involved in regulation of nociceptive transmission as

well as emotional and stress responses. In contrast to receptors for other known neurotransmitters (e.g., serotonin, norepinephrine), which are expressed by virtually all neurons in a given CNS region, NK-1 receptors are expressed by a small percentage (5–7%) of neurons in various regions of the brain and the spinal cord (Figure 1).

Figure 1 Selective expression of the neurokinin-1 receptor in the central nervous system. Confocal photomicrograph showing that only a small proportion of spinal cord neurons (green, neuronal nuclei-positive cells) express the neurokinin-1 receptor (blue). Scale bar = 25 μm.

Figure 3 Internalization of neurokinin-1 receptors following noxious stimulation. Confocal photomicrographs showing the localization of neurokinin-1 receptors in different conditions. (a) On unstimulated neurons, neurokinin-1 receptors are uniformly distributed in the plasma membrane of the cell body and dendrites. (b) Five minutes after noxious somatosensory stimulation, which induces substance P release, neurokinin-1 receptors are internalized into the cytoplasm. Scale bar = 20 μm. Reprinted from Mantyh PW, DeMaster E, Malhotra A, et al. (1995) Receptor endocytosis and dendrite reshaping in spinal neurons after somatosensory stimulation. *Science* 268: 1629–1632.

Figure 2 Model of substance P (SP)-induced endocytosis of neurokinin-1 (NK-1) receptor. NK-1 receptors are localized on the plasma membrane of both cell body and dendrites. Following noxious stimulation, substance P is released from presynaptic terminals and binds to NK-1 receptors present in the postsynaptic terminal. This is followed by a rapid internalization of SP and NK-1 into the cytoplasm in a clathrin-dependent manner via endosomes. Substance P is degraded in the lysosomes and NK-1 receptors are recycled back to the plasma membrane.

Substance P–NK-1 Internalization following Noxious Stimuli

Activation of substance P-containing neurons in response to acute noxious stimuli results in the rapid synaptic release of substance P, which then binds to the closely apposed NK-1 receptors in the immediate vicinity (Figure 2). On unstimulated neurons, NK-1 receptors are localized on the plasma membrane of both the cell body and dendrites (Figure 3(a)), but after stimulation and substance P binding, they are rapidly internalized (within 5 min) into the cytoplasm via endosomes (Figures 2 and 3(b)). This NK-1 receptor internalization in response to substance P binding is reversible, with complete return of internalized receptors to the surface after 30 min, although the kinetics of the internalization and recycling of NK-1 (Figure 2) and other GPCRs may depend on the specific phenotype of the cell expressing the receptor.

Figure 4 Internalization of substance P and neurokinin-1 (NK-1) receptors is proportional to the intensity of noxious stimulus. Adapted from Allen BJ, Rogers SD, Ghilardi JR, et al. (1997) Noxious cutaneous thermal stimuli induce a graded release of endogenous substance P in the spinal cord: Imaging peptide action *in vivo*. *Journal of Neuroscience* 17: 5921–5927.

At least in the spinal cord, the degree of substance P release and NK-1 receptor internalization is proportional to the intensity and frequency of noxious stimuli. More potent stimuli (e.g., either noxious cold or heat) result in a substantially greater release of substance P and internalization of the NK-1 receptor (Figure 4). Similarly, previous exposure to stress amplifies the activity of the SP–NK-1 receptor system, as documented in the rat model of irritant-induced hind paw inflammation, in which the initial decrease in NK-1 receptor activity is followed by a prolonged period ($\geq$8 days) of increased expression. Greater substance P release in response to higher intensity or repeated administration of stressful stimuli not only leads to more potent activation of adjacent NK-1 receptor-expressing neurons, but also permits diffusion of substance P away from the site of release and therefore stimulation of more distant neurons (Figure 5). It has been estimated that approximately three to five times more neurons are activated in response to more potent or more frequent stress stimuli (Figure 5).

Using Receptor Internalization to Deliver Therapies That Target Specific Classes of NK-1-Expressing Cells

A separate line of research has focused on identifying the functional consequences of inactivating the NK-1 receptor by either pharmacological (substance P receptor antagonists, cytotoxic substance P–saporin conjugates) or genetic (NK-1 receptor knockout

Figure 5 Substance P released from sensitized neurons diffuses and activates relatively distant neurokinin-1 receptor-expressing neurons. (a) Confocal photomicrograph showing the internalization of substance P–neurokinin-1 in neurons with cell bodies in lamina V of the spinal cord. (b) Higher power magnification. Adapted from Abbadie C, Trafton J, Liu H, Mantyh PW, and Basbaum AI (1997) Inflammation increases the distribution of dorsal horn neurons that internalize the neurokinin-1 receptor in response to noxious and non-noxious stimulation. *Journal of Neuroscience* 17: 8049–8060.

Figure 6 Mechanism of cytotoxic action of the substance P (SP)–saporin complex. The SP–saporin conjugate is internalized via the neurokinin-1 receptor endosomal pathway, and saporin subsequently escapes from *trans*-Golgi network to inhibit ribosomal protein synthesis and thereby induce cell death. Localized application of SP–saporin effectively leads to ablation of neurons containing the neurokinin-1 receptor.

mice) means. The substance P–saporin (SP–SAP) conjugate exploits the internalization of the NK-1 receptor to achieve selective killing of NK-1 receptor-expressing neurons by SAP, which inhibits ribosomal protein synthesis (Figure 6). Localized application of SP–SAP promotes selective pharmacologic ablation of neurons expressing the NK-1 receptor (Figure 7) and thereby allows the examination of the role of the SP–NK-1 receptor pathway in various regions of the brain and spinal cord. Injection of the SP–SAP complex into the dorsal horn of the spinal cord results in a marked attenuation of responses to highly noxious stimuli, mechanical and thermal hyperalgesia, and chronic neuropathy and inflammation, suggesting that the SP–NK-1 receptor pathway in the spinal cord may be involved in nociception.

Summary

The SP–NK-1 receptor pathway is involved in the neural processing of a range of noxious and stressful stimuli, and it represents the most abundant and the most thoroughly studied neuropeptide system in both the CNS and PNS. To ensure that extracellular stimuli are translated into intracellular signals of appropriate magnitude and specificity, most signaling cascades are tightly regulated. One of the major mechanisms involved in the regulation of GPCRs involves their

Figure 7 Internalization and cytotoxicity of substance P–saporin in primary cultures of neonatal spinal cord neurons. Confocal photomicrograph showing neurokinin-1 receptor immunofluorescence at different time points (a, c, d) following substance P–saporin treatment. Areas of concentrated neurokinin-1 receptor immunofluorescence appear yellow. Two hours after substance P–saporin, neurokinin-1 internalization was visualized with an antibody against neurokinin-1 (a), and intracellular accumulation of saporin was observed with an antibody against saporin (b). While neurokinin-1 receptor is recycled back to the plasma membrane following substance P alone (data not shown), neurokinin-1 receptor immunofluorescence is localized within intracellular endosomes 1 day after substance P–saporin (c). At day four posttreatment, neurokinin-1 receptor-positive neurons show shrunken cell bodies and diffuse neurokinin-1 immunoreactivity throughout the cytoplasm (d). Scale bar = 25 μm. Reprinted from Mantyh PW, Rogers SD, Honore P, et al. (1997) Inhibition of hyperalgesia by ablation of lamina I spinal neurons expressing the substance P receptor. *Science* 278: 275–279.

endocytic trafficking. GPCR endocytic trafficking entails the targeting of receptors to discrete endocytic sites at the plasma membrane, followed by receptor internalization and intracellular sorting. Thus, internalization of neuropeptide-receptors can regulate the level of cell surface receptors, the sorting of receptors to degradative or recycling pathways, and in some cases the specific signaling pathways.

Neuropeptides Phylogeny and Evolution

Introduction

Neuropeptides comprise a large and diverse set of intercellular signaling molecules in the nervous system of most, if not all, animal phyla. Many of the neuropeptides also function as hormones or have evolutionarily related peptides that do so. Due to the small size of many neuropeptides, often below 15 amino acids with the shortest consisting of only three amino acids, their phylogenetic relationships have been difficult to study across distantly related animal groups.

Neuropeptides are generated by proteolytic cleavage of larger precursor peptides (prepro-peptides) that consist of a signal peptide and one or several spacer peptides, in addition to the biologically active mature neuropeptides. These spacer peptides usually diverge much more rapidly than the neuropeptides, thereby obscuring evolutionary relationships. Several neuropeptides show similarities between vertebrates and insects or mollusks (Table 1), thus demonstrating their origin prior to the divergence of deuterostomes and protostomes. In addition to sequence comparisons, some genetic criteria are considered here that have proven useful in determining gene orthology, most significantly conserved synteny (i.e., the same location of the gene, relative to other genes, across species).

Vertebrate genomes may encode well over 100 distinct neuropeptides and possibly considerably more. Analyses of the presently available sequenced genomes are probably far from exhaustive because of the difficulties in identifying short peptides and their precursors. Several additional genes encoding neuropeptides or endocrine peptides are expected to be discovered in these genomes because many orphan receptors exist that are likely to have peptide ligands. The genome of the fruit fly *Drosophila melanogaster* has been reported to contain about 35 genes encoding neuropeptides, and the nematode worm *Caenorhabditis elegans* has at least 109 genes encoding a total of more than 250 potential neuropeptides.

Many neuropeptides make up families of related members (see Table 1) that have arisen by tandem duplications within a single gene or by duplications of entire genes, either locally within a chromosomal region, by retrotranscription and reinsertion into a chromosome, or by duplication of a chromosomal segment. Neuropeptides usually act through G-protein-coupled receptors (GPCRs), and the diversity and relationships of neuropeptides are reflected in the multiplicity and relationships of their receptors. A few examples are known in which neuropeptides and their corresponding receptors have coevolved structurally and functionally. This article describes in general terms the evolution and phylogeny of neuropeptides, with several examples taken from well-studied families in vertebrates and invertebrates.

Duplications within Genes

Some neuropeptides are generated from simple prepro-peptides that contain only a single mature peptide, for instance neuropeptide Y (NPY) and galanin, whereas others may harbor a few or several biologically active peptides, such as the famous precursor proopiomelanocortin (POMC), which encodes corticotropin (ACTH) and β-endorphin as well as a few related copies of melanocyte-stimulating hormone (MSH). Additional copies of a peptide within a single precursor may arise by duplication of the DNA segment that encodes the mature neuropeptide.

One common type of duplication is tandem duplication within the same exon of a gene, as exemplified by thyrotropin-releasing hormone (TRH), the first neuropeptide to be purified and sequenced. TRH is present in vertebrates and has the sequence (pyro) Glu-His-Pro-amide, generated from the sequence Gln-His-Pro-Gly flanked by proteolytic cleavage sites in the precursor. TRH is present in six copies within the same exon in the human prepro-TRH gene (Figure 1(a)), seven copies in the frog *Xenopus tropicalis,* and eight copies in goldfish. Chicken prepro-TRH contains four copies flanked by canonical cleavage sites and includes three more TRH-like motifs that may no longer be excised. Several other prepro-peptides contain multiple copies within the same exon, for instance, six identical copies of Met-enkepahlin (Tyr-Gly-Gly-Phe-Met) and one copy of Leu-enkephalin in prepro-enkephalin (Leu-enkephalin differs only in the last amino acid from Met-enkephalin), and two similar copies of orexin in prepro-orexin orexin A and B (also called hypocretin-1 and -2), share approximately 50% of their amino acid positions.

The most impressive examples of tandem duplications in the same exon of a prepro-peptide gene are probably the precursors of FMRF-amide-like peptides in invertebrates. *D. melanogaster* has three precursors for FMRF-amide-like peptides, one of which contains information for 13 such peptides encoded by a single exon. Even more extreme is the FMRF-amide

Table 1 Selected families of vertebrate/chordate neuropeptides and endocrine peptides[a]

Neuropeptide family	*Proposed protostome homologs*
Neuropeptide Y (NPY) Peptide YY (PYY) Pancreatic polypeptide (PP)	Neuropeptide F (NPF)
Cholecystokinin (CCK) Gastrin (cionin in the tunicate *Ciona intestinalis*)	Sulfakinins
Oxytocin Vasopressin (isotocin, mesotocin, vasotocin in nonmammalian vertebrates)	Cephalotocin, octopressin, Lys-conopressin
Insulin Insulin-like peptides Insulin-like growth factors I and II Relaxins	Insulin-like
Somatostatin Cortistatin (somatostatin 2) Urotensin II	
Urotensin II-related peptide	
Tachykinins: Substance P Neurokinins A and B Hemokinin-1 (physalaemin, kassinin in frogs)	Tachykinin-related
Opioid peptides: Met-enkephalin Leu-enkephalin dynorphins A and B α-neoendorphin β-endorphin orphanin FQ (= nociceptin)	
Galanin Galanin-like peptide	
Glucagon Glucagon-like peptides 1 and 2 (GLP-1, GLP-2) Vasoactive intestinal peptide (VIP) Peptide histidine-methionine (PHM) Secretin Gastric inhibitory peptide (GIP) Growth hormone-releasing hormone (GHRH = GRF) Pituitary adenylate cyclase-activating peptide (PACAP) PACAP-related peptide (PRP)	
Melanocyte-stimulating hormones (MSH): $\alpha, \beta, \gamma, \delta$	
Corticotropin-releasing hormone (CRH) Urocortins II and III	Diuretic hormone (DH44)
Gonadotropin-releasing hormones (GnRH = LHRH)	
Neuropeptide FF Neuropeptide AF	
Orexins A and B	
Prolactin-releasing peptide (PrRP)	
Calcitonin Calcitonin gene-related peptide (CGRP) Amylin Adrenomedullins Intermedin Calcitonin receptor-stimulating peptides (CRSPs)	Diuretic hormone 31 (DH31)
Neuromedin U	Hugin
Neuromedin B (NM-B) Gastrin-releasing peptide (GRP) (bombesin in frogs)	
Galanin Galanin-like peptide (GALP)	

[a]Some family members function as neuropeptides, others function as endocrine peptides, and some serve dual roles.

Figure 1 Schematic outline of the genes encoding three peptide precursors: (a) human prepro-TRH (242 amino acids); (b) *Aplysia californica* FMRF-amide precursor (597 amino acids); (c) human precursor for glucagon, GLp-1, and GLP-2 (179 amino acids). The precursors for TRH (a) and FMRF-amide (b) contain all copies of the mature peptide within the same exon, whereas the precursor for the related peptides glucagon, GLP-1, and GLP-2 (c) has the three peptides on separate exons as a result of exon duplications. Note that the FMRF-amide precursor in (b) has a different scale. The intron sizes are not drawn to scale, as indicated by the parallel diagonal lines. aa, amino acid(s); GLP, glucogon-like peptide; TRH, thyrotropin-releasing hormone.

precursor from the marine snail *Aplysia californica*, with no less than 28 copies of the same FMRF-amide motif (Figure 1(b)). The nematode *C. elegans* has 29 genes encoding more than 70 FMRF-amide-like peptides.

On numerous occasions, multiplication of a peptide- encoding segment has occurred by duplication of an entire exon that contains the coding information for a mature neuropeptide. This difference in duplication mechanism relative to the within-exon duplications already described is worth noting because exon duplication need not occur with the same precision as a duplication within a coding segment that must maintain the translational reading frame; this is because the splicing machinery connects duplicated exons to generate a continuous coding sequence as long as their splice junctions are located in the same phase of the codons. One example of a gene with exon duplication is the gene for the glucagon precursor, which also encodes, on separate exons, the glucogon-like peptide (GLP)-1 and GLP-2 (Figure 1(c)). Likewise, the precursor for tachykinin-1, encoding substance P and neurokinin A, and the precursor for vasoactive intestinal peptide (VIP), encoding VIP and peptide histidine-methionine (PHM), have expanded by exon duplication to encode additional structurally related peptides.

Over time, the duplicated peptides may accumulate amino acid differences, leading to more or less different functional roles. Examples of this are the peptides GLP-1 and GLP-2, which have found separate receptors from that of glucagon (due to duplications of the glucagon receptor gene), and prepro-tachykinin-1, whose peptides substance P and neurokinin A also-have separate receptors due to a receptor gene duplication.

A more complicated result of an exon duplication is displayed by the gene encoding calcitonin and calcitonin gene-related peptide (CGRP). These two structurally related peptides arose by an exon duplication, and the primary gene transcript is alternatively spliced to use either of these exons. Whereas endocrine C cells in the thyroid gland splice the pre-mRNA to include the calcitonin exon, neurons generate a splice variant that contains the CGRP exon and an additional exon (Figure 2).

Gene Duplications

A common form of duplication involves entire genes. Such duplicates are often located adjacent to one another in the same chromosomal region, either in tandem (i.e., in the same orientation) or with opposite orientation relative to one another. One example of tandem duplication of a prepro-peptide gene is the duplication of the peptide YY gene (expressed in endocrine cells and a few neurons in mammals) to generate the pancreatic polypeptide (PP) gene

(see Figure 3), a duplication that seems to have taken place early in tetrapod evolution. The genes are located only 10 kb apart in the human genome. Another example is the duplication that generated the oxytocin and vasopressin precursor genes from a common ancestral gene, probably at an early stage in vertebrate evolution. These two peptide genes are also located close to one another and seem to differ in their orientation relative to one another due to gene inversion in some lineages (the frog *Xenopus laevis* has the genes in tandem; mammals have them tail-to-tail). In these two examples, the exon–intron organization is the same for the two copies, indicating that the genes were duplicated at the DNA level, possibly by unequal crossing-over due to repeated DNA elements flanking the ancestral gene.

Figure 2 Human gene for the calcitonin–CGRP precursor. Alternative splicing of the Pre-mRNA leads to the production of either calcitonin (endocrine cells in the thyroid) or CGRP (neurons). CGRP, calcitonin gene-related peptide.

Figure 3 Gene duplication scheme for the vertebrate NPY family. The gene duplication that gave rise NPY and PYY from a common ancestral gene occurred early in vertebrate evolution through the duplication of a chromosomal region or an entire chromosome (probably in a tetraploidization event), which preceded the origin of jawed vertebrates (gnathostomes). Subsequently, the PYY gene was duplicated locally to generate PP, probably in an early tetrapod ancestor because PP is present in amphibians, reptiles/birds, and mammals. After these gene duplications, PP accumulated considerably more amino acid changes than NPY and PYY. NPY, neuropeptide Y; PP, pancreatic polypeptide; PYY, peptide YY.

In other instances, the introns are missing from one of the copies, suggesting that duplication occurred via mRNA that was retrotranscribed to DNA and then reinserted into the genome. This seems to be the case for the second insulin gene found in the rat. This duplicate retains one of the two introns present in the original gene, suggesting that the DNA copy was retrotranscribed from a partially spliced mRNA intermediate. Retrotranscription also may explain the origin of the gonadotropin-releasing hormone (GnRH)-1 gene in the tunicate *Ciona intestinalis,* which lacks the two introns present in the GnRH-2 gene.

Proposed Vertebrate Chromosome or Genome Duplications

Many families of neuropeptide genes in vertebrate genomes have their family members distributed on different chromosomes. It has been proposed that this is due to duplications of large chromsomal regions or entire chromosomes, or even of the entire genome (tetraploidization). This has most convincingly been demonstrated for the fish lineage, which underwent a tetraploidization before the radiation of teleost fishes (which make up more than 99% of the extant fish species). At least one and possibly two such tetraploidizations also seem to have occurred before the divergence of gnathostomes (jawed vertebrates). More recently, additional tetraploidizations have occurred independently in several vertebrate groups, for instance *xenopus* frogs, salmonid fishes, cyprinid fishes, and sturgeons. The tetraploidizations have generated additional gene copies for a huge number of gene families, including several families of neuropeptides, endocrine peptides, and their receptors. This mechanism of duplication means that new peptides and receptors arose concomitantly for several peptide–receptor systems, thereby probably facilitating novel peptide–receptor partnerships.

One well-studied example of family expansion by chromosome duplication is the NPY family, in which NPY and peptide YY (PYY) arose from a common ancestral gene (Figure 3). Subsequently, PYY was duplicated locally to generate PP on the same chromosome, as already mentioned. The teleost fish tetraploidization generated duplicates of both NPY and PYY. All four peptide genes are present in the genome of the pufferfish fugu (*Takifugu rubripes*), but one of the NPY copies seems to have been lost from the genome of the zebra fish (*Danio rerio*). Assignment of the fish peptides as either NPY or PYY has been difficult to achieve by sequence analyses only, but has been possible by comparison of the chromosomal location of the genes. Thus, gene neighborhood (conserved synteny or location in the same chromosomal region) is a useful criterion for the identification of gene orthology (i.e., species homologs).

Also, the receptor family for NPY has expanded by chromosome duplications, although here a local gene triplication preceded the chromosome duplications. Another peptide family that has grown by this mechanism is the tachykinin family, whose three prepro-peptide genes are located in three related chromosome regions. Likewise, the receptors for the tachykinins have also received additional copies by chromosome doubling.

Another peptide family that seems to involve both a local duplication and a chromosome-segment duplication is the family consisting of somatostatin 1, cortistatin (= somatostatin 2), urotensin II, and urotensin II-related peptide. A combination of local and chromosomal duplications also explains the complex insulin/relaxin family, which has 10 members in humans, some of which are expressed in the nervous system. Detailed gene-linkage information for distantly related vertebrates is required to determine whether additional peptide families have expanded by chromosome duplication.

Phylogenetic Sequence Analyses

The primary criterion for assignment of different peptides to a family is, of course, that they display some degree of amino acid sequence identity (shared positions). If the degree of identity is significantly higher than can be expected from chance events, it is presumed to be due to common ancestry. However, the shortness of neuropeptides and endocrine peptides often make detailed sequence-based phylogenetic analyses ambiguous. Furthermore, some positions in a neuropeptide may be crucial for function and may, therefore, have been maintained constant by conservative selection pressures over long evolutionary periods (e.g., cysteine residues involved in disulfide bonds), whereas other positions are less important and therefore tolerate evolutionary changes to a considerable extent. For these reasons, it has been pointed out that short peptides are risky to use for phylogenetic studies. However, to understand the evolution of the peptides themselves, sequence comparisons are, of course, of crucial importance.

Even more problematic for phylogenetic analyses are positions that may switch back and forth between a few amino acid alternatives, often involving residues with similar properties such as positively charged Lys-Arg or negatively charged Asp-Glu. Spacer peptides may evolve so rapidly that they sometimes cannot even be aligned when comparing animal groups as distantly related as tetrapods and bony fishes or insects and crustaceans, not to speak of deuterostomes

versus protostomes. Nevertheless, some neuropeptides show similarities between, for instance, vertebrates and insects, thus demonstrating their origin prior to the divergence of protostomes and deuterostomes. Such examples seem to include the vertebrate peptide families for NPY, cholecystokinin (CCK)/gastrin, oxytocin/vasopressin, tachykinins, insulin, corticotropin-releasing hormone (CRH), calcitonin, and neuromedin U (see Table 1).

Among vertebrates, sequence comparisons usually allow the unambiguous assignment of a peptide to a family, although detailed relationships within a peptide family may be more complicated to resolve across species. A particularly problematic example is the family of peptides comprising oxytocin and vasopressin in mammals, which usually differ in only two of the nine positions. Similar peptides have been identified in all gnathostome groups investigated and have been given names such as isotocin, mesotocin, and vasotocin, along with several additional variants identified in cartilaginous fishes (sharks, rays, skates, and chimaeras). It is not obvious if these are orthologs (species homologs) to mammalian oxytocin or vasopressin. In situations such as these, additional comparative criteria may be helpful, such as chromosomal location and conserved synteny.

Some peptides have dramatically uneven rates of evolutionary change across animal phyla. Also, rates of change may differ considerably among peptide members of the same peptide family. Some of the most intriguing examples are provided by peptide/protein hormones because information is available for a very large number of species, but sequence information is emerging also for several neuropeptides. For instance, the protein hormones prolactin and growth hormone (sizes just under 200 amino acids) differ greatly in their evolutionary rate across orders of mammals. Both of these hormones have evolved extremely rapidly in primates. Growth hormone has remained almost constant in, for instance, the pig, dog, horse, and elephant since their respective lineages diverged from the common mammalian ancestor shared with primates. In contrast, prolactin has changed extensively in the elephant. It is not yet obvious how the rates of change correlate with any physiological functions. Another peptide hormone with a rapid rate of change is PP. Interestingly, the replacement rate of PP seems to have been highest shortly after its origin (i.e., its duplication from PYY; Figure 3), after which it slowed down in the different tetrapod lineages.

Short peptides tend to be highly conserved, probably because each position has a relatively greater impact on the peptide's structure and interactions with receptors. Strongly conserved short peptides include, for instance, GnRH, somatostatin, oxytocin, and vasopressin. Among the longer peptides, some of the most highly conserved during vertebrate evolution are NPY (36 amino acids) and CRH (41 amino acids). But even for such long and well-conserved neuropeptides, the phylogenetic trees diverge from the established species trees due to uneven rates, back mutations, and extremely strong conservative selection pressure.

Different parts of the same peptide may also display considerable differences in the rate of change. One such peptide is galanin (29 amino acids), whose N-terminal 14 residues are well conserved, whereas the C-terminus has accumulated several changes. These internal-rate differences seem to correlate well with the conservative selection pressure imposed by receptor interactions, such that the conserved part of the peptide is most important. For the NPY family peptides, the C-terminal part is much more strongly conserved than the N-terminal part.

One particularly challenging neuropeptide family from the evolutionary perspective is the GnRH family, which consists of two to three highly similar copies in most vertebrates. These decapeptides share four identical positions and have another three highly conserved positions across all vertebrates investigated as well as tunicates. The remaining three positions, on the other hand, are quite variable. This has made it difficult to determine the orthology relationships across species. The terminology is further complicated by the fact that a particular GnRH sequence is often named after the species in which it was first discovered. Thus, chicken GnRH-II is used to refer to a particular GnRH sequence that can be found in many different species.

Naturally, the accuracy of the phylogenetic trees will improve as the list of species for which neuropeptide sequences are known grows, particularly when information becomes available for species that represent distantly related and crucial evolutionary branches. The genome projects offer the great advantage of being able to provide sequences for most or all of the members of each neuropeptide and receptor family within a species, thereby facilitating a more accurate assignment of orthologs across species.

Evolutionary Change of Neuropeptide Functions

The functions of a particular neuropeptide may shift during evolution, but the definitive assignment of ancestral versus derived functions is risky until detailed information has been collected for several species from different evolutionary lineages. Neuropeptides that have clearly distinct roles in different animal groups include some of the peptides that exist both in protostomes and deuterostomes.

Functional differences have been observed also among more closely related lineages, although some of these differences are still in the process of being explored. For instance, the role of prolactin-releasing hormone is thought to differ between mammals and birds (chicken), as is of course the role of the protein hormone prolactin itself. It may also be that the role of oxytocin for olfactory reproductive memory in rodents is not as prominent in humans.

Likewise, changes in function after a gene duplication are difficult to determine and require functional data for species that diverged prior to the gene duplication as well as for species that have the duplication. It is expected that neuropeptide duplicates may undergo either of the same fates that have been reported for other gene families: a new gene copy may find new functions (neo-functionalization), it may be severely mutated and be lost (nonfunctionalization), or it may split the mother gene's functions with the other daughter gene (subfunctionalization).

Numerous examples exist in which structurally related neuropeptides have quite different functional roles in some respects, yet partially overlap to some extent. In mammals, oxytocin and vasopressin both seem to be involved in neuronal aspects of reproductive and social behavior, but have more distinct roles in mammary and renal endocrinology. Even duplicated peptides generated from the same precursor may evolve different functional roles, as shown by substance P and neurokinin A from the prepro-tachykinin-1 precursor.

In mammals, the two related neuropeptides pituitary adenylate cyclase-activating polypeptide (PACAP) and VIP influence the circadian pacemaker system in the suprachiasmatic nucleus (SCN) of the hypothalamus. Whereas PACAP acts on two receptor subtypes, PAC1 and VPAC2, VIP acts only on the latter. The difference in receptor preference along with differences in anatomical expression of these components within the SCN explains how the two peptides have evolved distinct roles in the regulation of the mammalian circadian clock. Whereas VPAC2 (responding to both neuropeptides) is involved in both maintenance and synchronization of the clock, PAC1 seems to be involved in light-induced phase shift, as suggested by experiments with knockout mice.

Another example of rather distinct functions for gene duplicates, not least with regard to sites of production, is the NPY family, which in mammals involves NPY produced in neurons and PYY made in intestinal endocrine cells. PYY is also produced in some brain stem neurons in the rat and more extensively in the nervous system of the zebra fish and lamprey, in addition to endocrine cells. Possibly, the ancestral NPY/PYY gene was expressed in both neurons and endocrine cells.

An intriguing functional difference between NPY and PYY is that NPY is released before meals in the hypothalamus and stimulates appetite, whereas PYY is released postprandially (after meals) from the intestine and reduces appetite via the hypothalamus. Some evidence suggests that the function of the ancestral peptide was appetite stimulation and that the appetite inhibition induced by PYY is a result of receptor Y2 expression in a different cell type than those that stimulate appetite (subtypes Y1 and Y5). The time for this functional switch in evolution is not yet known.

One type of evolutionary change concerns how a peptide and a receptor subtype may evolve preference for one another leading to the (partial) exclusion of other related peptides and receptors. This can also be exemplified by the NPY family, in which PP and receptor Y4 have stronger preference for one another in mammals, particularly in rodents, than they have in the chicken. This preference is a derived feature because PP is a copy of PYY and therefore must once have bound to the same receptors as PYY. One function of PP in humans seems to be the inhibition of appetite after meals (like PYY), albeit the two peptides exert this effect via separate receptor subtypes.

Additional mechanisms that may lead to altered peptide structures during evolution are posttranslational modifications and changes in peptide processing and degradation. Although detailed functional data are more scarce for these types of evolutionary changes (because they usually cannot be predicted from gene sequences or predicted protein sequences), some observations suggest that, for instance, somatostatin, peptide YY, and bradykinin may be processed differently among classes of vertebrates. Sequence differences in prepro-peptides suggest that precursor processing may differ among species for several additional peptides.

Summary and Conclusion

The evolutionary history of neuropeptides and related endocrine peptides is replete with gene duplications, involving parts of genes or entire genes by a variety of mechanisms, that have resulted in a plethora of peptides. The large number of neuropeptides and their corresponding GPCRs influence a broad range of functions and have presumably contributed greatly to the diversification and refined regulation of neuronal and endocrine processes such as reproduction, food intake, and circadian rhythm, as well as many other physiological processes and behaviors. The duplications have paved the way for more specific functions for some neuropeptides and novel functions for

others. The phylogenetic relationships of neuropeptides have in some cases been difficult to resolve due to their small size and uneven rates of change. Novel types of information from the many genome projects such as gene location (gene neighborhood), along with information from additional species representing important evolutionary branches, will make it possible to sort out neuropeptide and receptor phylogenies with much greater precision.

Neuropeptides: Discovery

Introduction

Chemically, neuropeptides are molecules composed of short stretches of covalently linked amino acids. Neuropeptides are messenger molecules that transfer information from one cell to another in the central nervous system (CNS). They accomplish this by being released from a cell as 'first messengers' and by interacting with specific receptors found on the membrane of a recipient cell. This induces a second messenger response that will change the chemistry of the recipient cells and that, after a cascade of events, results in a physiological or behavioral change. All neuropeptide receptors are G-protein-coupled receptors (GPCRs). Consequently, the expression of a particular peptide GPCR in the CNS indicates that this peptide should be classified as a neuropeptide.

Neuropeptides are numerous and, in general, structurally diverse; they form the largest family of first messenger molecules in mammals. They are small in size when compared to proteins, ranging from 3 to less than 100 amino acids. They are all synthesized in the form of large, inactive precursor polypeptides, which need to be cleaved by processing enzymes to yield the final peptides. These are often enzymatically modified to be rendered bioactive.

These characteristics, which today specify the nature of neuropeptides, were not found easily. They have resulted from years of work searching for different neuropeptides, their modes of synthesis, and their modes of action. It all started with the discovery of neuropeptides.

The Discovery of Neuropeptides

At first neuropeptides were discovered via their functions. A particular physiological response would be observed to be regulated by some tissue extract. Upon further analysis, which often took years, it would be found that a peptide was responsible for this regulation. Later, when more had been learned about them, neuropeptides were also discovered on the basis of similarities expected to exist in their structures. Recently, this line of research has involved genomic analyses. Finally, neuropeptides have been discovered as the natural ligands of orphan GPCRs (see Table 1).

The Organ Bath-Based Approaches

One approach relies on the use of the 'organ bath' introduced by Rudolph Magnus in Utrecht at the beginning of the twentieth century. A freshly harvested organ (e.g., intestine) is bathed *ex vivo* in a physiological salt solution linked to a force transducer that records changes in muscle activity. Using such a bath, it is possible to monitor smooth muscle contractions and vasodilator properties. This approach led to the discovery of many neurotransmitters, in particular, the biogenic amines and acetylcholine. It was also used to test synthetic drug effects, and that led to the idea that it could be used for testing extracts of natural origin. This approach opened the door to the discovery of the first neuropeptides.

The first neuropeptide and the enkephalins In the 1930s, von Euler and Gaddum characterized 'preparation P' from extracts of horse brain and intestine that stimulated the contraction of intestinal tissues *in vitro*. This activity was not inhibited by atropine, evidence that the responsible agent was not acetylcholine. One notable aspect of this activity was revealed when it was shown to be protease sensitive. This was the first evidence for the existence of peptides active in the CNS and gave birth to the concept of neuropeptides. This active peptide was later named substance P; its structure was finally resolved in 1971.

But the discovery that, possibly, more than any other established the role of neuropeptides in neurotransmission was that of the enkephalins. They were discovered, in brain extracts, as agents able to mimic the action of morphine in a bath assay. Because morphine is the standard analgesic and an addictive molecule, these peptides created an immediate interest in research fields dealing with pain management or drug abuse. Their names (literally, endogenous brain peptides) indeed helped prove the validity of the neuropeptide concept.

Two families of hormones that became neuropeptides At the beginning of the 1950s, du Vigneaud et al. isolated, from posterior pituitary lobes, oxytocin and vasopressin on the basis of their uterus-contracting and pressor activities, respectively. These peptides act primarily on peripheral tissues, namely, the uterus for oxytocin and the kidney for vasopressin. We know now that their receptors are expressed in the CNS and that some of their activities are brain related. They are therefore neuropeptides.

Table 1 Dates in the discovery of neuropeptides

Date	*Discovery*
1902	Secretin, discovered as a hormone, now classified as a neuropeptide
1930	Substance P, the first neuropeptide, sequenced in 1971
1950–51	Oxytocin and vasopressin, found as hormones, now classified as neuropeptides
1969	TRH and the other hypothalamic releasing factors
1975	The enkephalins, proof of concept for the neuropeptides
1960s–1990s	The major schools of neuropeptide discovery:
	Mutt and Tatemoto: Discovery of C-amidated neuropeptides
	Erspamer and Melchiorri: Discovery of neuropeptides in amphibian skin
	Matsuo, Minamino, and Kangawa: Discovery of neuropeptides involved in muscle contraction or relaxation
1979	γ-MSH, the first neuropeptide found not on the basis of its activity but by sequence analysis
1983	CGRP and neurokinins, found as products of alternative splicing
1995	OFQ/N, first neuropeptide found as ligand of an orphan GPCR
1995–97	Urocortin and cortistatin neuropeptides found by homology screening and RNA subtraction analyses
1995–2000s	The orphan receptor strategy leads to the discovery of 12 neuropeptides
	A major school: Takeda chemical industry
2000	hRFRP-1–3, the first neuropeptides found by bioinformatics

TRH, thyrotropin-releasing hormone; MSH, melanocyte-stimulating hormone; CGRP, calcitonin gene-related peptide; OFQ/N: orphanin FQ/nociceptin; hRFRP, RFamide-related peptides.

The releasing factors are also among the first neuropeptide discoveries. Work by Harris had specified that there exist hypothalamic substances that regulate pituitary function. The concept was validated with the isolation and characterization, from tens of thousands of hypothalami, of one of these messenger substances, thyrotropin-releasing factor (TRH). This was followed by the identification of releasing factors for each of the pituitary glycoprotein hormones. Although isolated as hormones, these releasing factors can be now classified as neuropeptides since their receptors have also been shown to be expressed in the CNS.

Three schools of neuropeptide discovery Some biological activities related to intestinal motility and pancreatic secretion had been detected since the beginning of the twentieth century, and some of them had been linked to the action of 'hormones,' which proved to be peptides. Indeed, the term hormone was invented as a consequence of the discovery of such a bioactive peptide, secretin.

From the 1950s to the 1980s, Victor Mutt and coworkers determined the sequence of several of these bioactive peptides, in particular, secretin, cholecystokinin, and vasoactive intestinal peptide. They also realized that C-terminal amidation is a hallmark of many bioactive peptides and used this chemical principle to isolate randomly potentially active peptides from large quantities of intestines or brains. This search ultimately led to the discoveries of novel bioactive peptides such as peptide histidine isoleucine (PHI), peptide tyrosine tyrosine (PYY), neuropeptide tyrosine (NPY), and galanin. Again, we can classify these peptides as neuropeptides since their receptors are expressed in the CNS.

Another school of neuropeptide discovery, under the direction of Erspamer and Melchiorri, took advantage of the fact that amphibian skin proved to be a nearly inexhaustible mine of bioactive peptides. While the structures of the frog skin peptides are specific to that species, related representatives can often be found in the brain or the gut of mammals. This is how bombesin and its counterparts in mammals were found.

While researchers from these two schools of neuropeptide discovery went about finding neuropeptides in a random manner, under the supervision of Matsuo, Minamino, and Kangawa, those from a third school used biological assays to find peptides that exhibit tachykinin-like effects. At the end of the 1970s and in the 1980s they discovered the neoendorphins, adrenomedullin, and the different neuromedins.

The Nucleic Acid-Based Approaches

The identification of novel neuropeptides has also resulted from experiments involving not peptide extractions but instead mRNA sequence analyses.

Neuropeptides discovered as part of precursors With the cloning of neuropeptide precursors at the end of the 1970s and in the 1980s, it became clear that most neuropeptide sequences are flanked by pairs of basic amino acid residues in the nonprocessed

precursors. In-depth studies on the processing of proopiomelanocortin (POMC) showed the importance of trypsin-like enzymes in the maturation of neuropeptides. Indeed, the first neuropeptide identified solely on the basis of its genomic sequence was γ-melanocyte-stimulating hormone (γ-MSH), found in the POMC precursor in 1979; this may be the first success of 'bioinformatics,' years before the introduction of the personal computer. The existence of several neuropeptides has been postulated on the basis of this principle.

Neuropeptides resulting from alternative splicing Because many neuropeptide precursors are transcribed from multiexonic genes, alternative splicing can give rise to new peptide sequences from a single gene. In 1983, calcitonin gene-related peptides (CGRPs) and the neurokinins were discovered as products from the alternative splicing of the calcitonin and substance P genes, respectively. Other neuropeptides have also been detected as alternatively spliced products of a known neuropeptide precursor; some, however, remain only putative neuropeptides as they have not been matched to a specific receptor.

Neuropeptides found by subtractive hybridization Another approach, which has its roots in the search for brain-specific mRNAs, uses subtractive hybridization to enrich for tissue-specific mRNAs. Applied to the search for mRNAs specific to different CNS tissues, it has led to the discovery of cortistatin and the hypocretins.

Neuropeptides found by homology screening Taking advantage of possible sequence similarities between different neuropeptide precursors is another way to discover new neuropeptides. In this case, genes or mRNAs are screened in nonstringent hybridization conditions with a nucleic acid probe derived from the sequence of a known precursor. Identified clones may be sequentially related to the probe and thus may encode a protein similar to the original precursor, that is, possibly a new neuropeptide precursor. This approach is applicable only to products that belong to gene families. While there are precursors that show an evolutionary relationship, the vast majority of them are not closely sequence related (especially when compared to the neuropeptide receptors). Urocortin, however, is an example of a neuropeptide discovered on the basis of its sequence similarities to the urotensin I precursor.

Neuropeptides found in silico With the genome sequence, bioinformatics has also been applied to the discovery of neuropeptides. Taking advantage of the facts that neuropeptides are often C-terminally amidated, that some contain conserved sequence, such as the RFamide sequence, and that they must be encoded by a precursor protein harboring a signal sequence, it is possible to design computer programs that can fish new neuropeptides from data banks. The hRFRP-1–3 peptides and the pyroglutamylated RFamide peptide (QRFP) were discovered using this approach.

The Orphan GPCR-Based Approach

Because neuropeptides exert their actions by activating GPCRs, some GPCRs that have not been matched to any known first messenger molecules, the so-called orphan GPCRs, have been used as targets to discover new neuropeptides. Orphan GPCRs are expressed in eukaryotic cells which are tested against tissue extracts, often brain extracts. Receptor reactivity is monitored by quantifying changes in second messenger levels. The tissue extracts showing reactivity are fractionated until the active component is purified to homogeneity.

The first success of the orphan receptor strategy was the discovery of a novel neuropeptide, named orphanin FQ or nociceptin (OFQ/N). This strategy has since led to the discovery of 13 neuropeptides: the orexins/hypocretins, prolactin-releasing peptide, apelin, ghrelin, metastin, neuropeptide B/W, the prokineticins, relaxin 3, neuropeptide S, and neuromedin S.

The advantage of this approach is that because it is based on the use of receptors, it ensures biological activity of the discovered peptides. It offers the most promise for finding new neuropeptides since several dozen GPCRs that may bind peptides are still orphan receptors.

How Many Neuropeptides Are Yet to Be Found?

By the mid-1990s, some 65 neuropeptides had been discovered. Other peptides, potentially neuropeptides, had also been found, in particular as processing products of known precursors. Some exhibit regulatory roles on particular responses. But according to the definition stating that a neuropeptide is a peptide that acts on a specific receptor expressed in the CNS, as long as these peptides are not matched to specific receptors they fall outside of the neuropeptide classification. There is a caveat associated with this neuropeptide definition, however, which has to do with receptor specificity. A GPCR can exhibit different affinities for structurally distinct ligands. Two unrelated peptides may bind the same GPCR because

they share some topological motif that permits activation. Of course, these two peptides will exhibit different affinities for the GPCR. As a rule of thumb, one can expect neuropeptides to activate their receptors with affinities in the low nanomolar range or lower. However, it is possible that low-affinity peptides activate the GPCR *in vivo* under particular circumstances, and thus the number of bioactive neuropeptides may be significantly larger than can be currently evaluated.

The surest way to go about predicting how many neuropeptides are yet to be found is to count the potential receptors. The application of the orphan receptor approach has led to the discovery of a dozen neuropeptides. As defined previously, if a neuropeptide is a peptide whose receptor is expressed in the CNS, then one can turn to the remaining orphan GPCRs to ask how many more may be found. There exist some 100 orphan GPCRs that, on the basis of their sequences, may bind ligands that are not chemosensory (olfactory, gustatory, chemoattractants, or chemokines). There is thus far no algorithm that can ascertain whether these orphan receptors may bind peptides or ligands of other chemical classes. Yet if one considers that about half of the first messengers that direct interneuronal signaling are neuropeptides, it can be extrapolated that half of the remaining nonchemosensory orphan GPCRs may bind peptides and thus that some 50 neuropeptides may still remain to be discovered.

Neuropeptides versus Classical Neurotransmitters

There are several main differences between neuropeptides (3–100 amino acid residues) and classical neurotransmitter molecules such as glutamate, γ-aminobutyric acid (GABA), dopamine, noradrenaline, glycine, and acetylcholine with respect to their synthesis, storage, and signaling function. Because classical transmitters can be rapidly synthesized in nerve terminals and stored in small synaptic vesicles they maintain a fairly constant level, whereas neuropeptide transmitters, which are synthesized in the cell body and stored in large dense-core vesicles transported to the terminal, may be more rapidly depleted. Neuropeptides, which are up to 50 times larger than classical neurotransmitters, display a complex three-dimensional structure, and some possess several recognition sites with nanomolar affinity for their receptors.

Neuropeptides are typically well conserved across species and outnumber the classical neurotransmitters. They are present in numerous neurons, together with one or even two small classical neurotransmitters (coexistence), which may affect their target neurons differentially. In cases of co-localization the peptide transmitters are often released at higher firing rates and particularly under burst-firing patterns from afferent fibers (Figure 1). In general, it is unlikely that neuropeptides participate in rapid integrative functions in a neuronal assembly.

Volume Transmission

In contrast to classical neurotransmitters, which interact with receptors linked to elaborate pre- and postsynaptic specializations, neuropeptides, once released, diffuse and may activate receptors far from their release site, a mechanism termed volume transmission (Figure 2). Thus, in contrast to conventional synaptic transmission neuropeptides may influence large ensembles of neurons in a divergent gating function rather than mediating rapid local point-to-point communication. The effective concentrations of neuropeptides needed for this mode of signaling are much lower than for synaptic transmission mediated by classical neurotransmitters, which reach much higher concentrations at their receptors, due to the small volume of the synaptic cleft. The diffusion of the neuropetide depends on the size of the extracellular space, its tortuosity, and the degradation encountered. After diffusing, the neuropeptide binds more slowly, but with much higher binding affinity and selectivity, to its receptor than classical transmitters confined to the synaptic cleft. Peptide-induced receptor trafficking and redistribution of heterogeneous extrasynaptic receptors (Figure 3), spontaneous release and specific regional inactivation mechanisms, and information transfer via glia cells add to the complexity of this mode of delocalized signaling.

Neuropeptides: Synthesis, Release, and Degradation

Neuropeptides occur in a bewildering range of shapes and sizes in the animal kingdom. Neuropeptides are found in all types of neurons and glia cells of the mammalian central nervous system (CNS). Genes that code for a neuropeptide family are generally not clustered and are spread out all over the mammalian genome. Duplications and point mutations in old primordial genes are probably the origin of the presently known members of the family of a neuropeptide. Because the precursors for neuropeptides are encoded in the genome, their functions can be detailed in transgenic animal models that do not produce or that overexpress the neuropeptide. However, the deletion of one neuropeptide gene often shows no noticeable effect because the action of the coded neuropeptide may be too subtle or is compensated by related neuropeptides.

Significantly, even if the gene that encodes the precursor is identified, it is not clear what particular peptide it will create because neuropeptide precursors undergo extensive posttranslational processing. The proneuropeptides are processed into active forms in large dense-core vesicle precursors by the concurrently packaged enzymes. Although certain peptidases may produce a variety of biologically active fragments, most commonly the peptide that is stored in vesicles and then released is considered the transmitter.

After trafficking into the presynaptic compartment, they may dock and fuse with the plasma membrane after a specific priming process at sites different from the synaptic vesicles containing classical neurotransmitters. The release from dense-core vesicles is probably regulated by specific protein kinases, and they are replenished after exocytosis by anterograde

Figure 1 Co-localization and co-release of classical neurotransmitters and neuropeptides. Classical transmitters are synthesized in nerve terminals and stored in small synaptic vesicles (SV), released, and recycled (1 and 2). They interact with subsynaptic receptors, including metabotropic receptors (3). Neuropeptides are synthesized in the cell body and transported to the terminal (4), stored in large dense-core vesicles (DCV; 5) and released at nonsynaptic sites (6). Neuropeptides interact with pre- and postsynaptic receptors (7). Voltage-gated Ca^{2+} channels control the release of classical transmitter and neuropeptide (8). Activation of a neuropeptide receptor induces, e.g., the phosphorylation (P) of an ionotropic receptor (9). Peptide transmitters are often released at higher firing rates, particularly under burst-firing patterns (10 and 11).

Figure 2 Point-to-point vs. volume transmission. Neuropeptides, once released (1 and 2), diffuse and activate receptors (3) far from their release site (volume transmission). Classical neurotransmitters mediate local point-to-point communication (2). Co-released neuropeptides participate in signaling at nonsynaptic and synaptic somatic and dendritic sites.

transport of new secretory granules from the *trans*-Golgi network. Classical neurotransmitters are packaged into small clear synaptic vesicles that are clustered near release sites at synaptic terminals where they undergo repeated rounds of exocytosis, endocytosis, and refilling with neurotransmitter.

The function of neuropeptide-encoding mRNAs in neuronal processes beyond the perikaryon still remains to be elucidated. Neuropeptides participate in signaling at nonsynaptic and synaptic somatic and dendritic sites of the target neuron, and there is evidence that they also exert trophic actions. The dendritic release of neuropeptides is partially independent from axon terminal release, and the exocytosis machinery at the two sites seems to be different (Figure 4). Action potentials backpropagating from the axon hillock into the dendritic tree probably open high-voltage-activated Ca^{2+} channels to trigger and modulate dendritic release. Synapses located on dendritic spines are probably important sites for the plastic changes produced by such a retrograde signaling, which questions the classical point of view of synaptic transmission and short-term modifications of excitatory and inhibitory synaptic efficacy. The invasion of the dendritic tree by the backpropagation of action potentials is subtly controlled by, for example, dendritic voltage-sensitive Na^{+}- and K^{+}-conductances, and it appears to be highly dynamic. It remains to be shown whether the dendritic release of neuropeptides and classical transmitters is, in addition, differentially

Figure 3 Receptor localization and trafficking on a dendritic spine. Transmitter release from synaptic vesicles (SV; 1); some dense-core vesicles (DCV) carrying receptors for the neuropeptides (2); presynaptic receptors (3) and postsynaptic receptors (7). Receptors moving from extrasynaptic sites to subsynaptic sites to join subsynaptic receptors (receptor trafficking; 4, 5, and 6); postsynaptic density in a dendritic spine (8); dendritic release (9).

Figure 4 Release sites of neuropeptides. Neuropeptides are synthesized somatically (1) and dendritically (2). Dendritic release (5) is triggered by action potentials backpropagating (3) from the axon hillock (4) into the dendritic tree. Peptides are also released from presynaptic terminals (6) and glia cells (7) and may act in concert on remote receptors (volume transmission; 8).

regulated by the release of Ca^{2+} from intracellular pools. New experimental approaches employing novel techniques will soon lead to a better understanding of the dynamics of dendritic computation and its contribution to neuronal signal processing.

The release of a neuropeptide is, like that of classical transmitters, Ca^{2+}-dependent, but requires higher frequencies of discharge in afferent fibers and is considerably slower because neuropeptides cannot diffuse through the diffusion pore. There is evidence that neuropeptides may come into play as messengers mainly when the nervous system is trying to respond to a pathological challenge such as nerve injury, seizure, or stress. Under these conditions, neurons and glia cells change their phenotype in regard to neuropeptides and their endowment with neuropeptide receptors. This phenotypic switch may be seen as an attempt to promote survival and regenerative mechanisms in a neuronal system.

After release, peptide transmitters appear to be inactivated enzymatically or by diffusion. With few exceptions (e.g., cholecystokinin), they lack a high-affinity reuptake process that removes the transmitter from the extracellular space. The introduction of *in vivo* push–pull cannulae and microdialysis has been useful for the measurement of extracellular concentrations of neuropeptides. Another successful *in vivo* approach has been to insert electrodes coated with antibodies into the specific area of the brain for a short period. The removed probes are then exposed to a radiolabeled peptide, which binds to receptors that are not already occupied by the peptide that was released in the brain tissue. Without these techniques, the release of some neuropeptides may not have been detected because they were present at too low a concentration or only during particular developmental stages.

Neuropeptide Receptors

Neuropeptides bind more tightly than classical neurotransmitters to their receptors, which are with few exceptions G-protein-coupled receptors (GPCRs). The receptors for neuropeptides belong to different families (rhodopsin-like, glucagon-vasoactive intestinal peptide/calcitonin). Several GPCRs form homodimers or heterodimers, and most commonly several receptor subtypes exist for a given peptide ligand. Furthermore, there is evidence that so-called receptor activity-modifying proteins can alter the pharmacological profiles of a single receptor.

Most neuropeptide receptors are rapidly ($\sim$5 min) desensitized after agonist activation. The receptor–neuropeptide complexes are internalized, and the receptors are then recycled and restored to the cell membrane within $\sim$30 min. It remains to be shown to what extent this recycling process is brought about by metalloendopeptidases affecting intracellular degradation of signaling peptides. Conjugation of the toxin saporin to the neuropeptide (e.g., substance P) can be used to selectively destroy neurons involved in pain processing in the dorsal horn of the spinal cord. Animal models show that this selective targeting technology prevents the formation of hyperalgesia and can reverse established neuropathic pain behavior.

The action of an endogenously released neuropeptide may depend on the local circuitry as well as the strategic location of the receptor subtypes. In addition to actions at neighboring neurons, neuropeptides can regulate the excitability of the neuron from which they are released via an autoreceptor function. The release of some neuropeptides seems to be regulated in a reciprocal fashion by autoreceptors of coexisting classical neurotransmitters such as dopamine.

Peptidergic Interneurons

The interneuronal system, often classified according to neuropeptide content, is crucial for maintaining appropriate brain function under normal and pathophysiological conditions. It is widely accepted that the effects of neuropeptides can be very distinct at the network level and that neuropeptides released from interneurons can trigger diverse K^+ currents such as the voltage-sensitive K^+ current I_M or the voltage-insensitive K^+ leak current I_{LK}. Both currents hyperpolarize the neuron and shunt excitatory synaptic potentials and can markedly affect neuronal excitability. The augmentation of the nonselective cation current I_H and the reduction of voltage-sensitive N-type Ca^{2+} channels have been suggested as mechanisms underlying pre- and postsynaptic peptidergic signaling.

Electron-microscopy studies have shown neuropeptide-immunoreactive terminals localized to the dendritic shafts and spines of principal neurons. There is evidence from recent studies that dendritic spines undergo an activity-dependent structural remodeling and that memories are created by alterations in glutamate-dependent excitatory synaptic transmission on dendritic spines. In the past, electrophysiological recordings were often limited to short-lasting impalements of the soma of only vaguely identified neurons. The advent of novel recording techniques for synaptic potentials and single-channel activity from dendritic sites remote from the soma under visual control and its combination with extremely targeted stimulation techniques in which the active transmitter is uncaged from a larger molecule by an ultraviolet (UV) laser has opened the possibility that we can detail these processes. Electrophysiological investigations into the acute effects of neuropeptides suggest that

they interfere not only with short-term alterations in synaptic efficacy but can also affect neuronal plasticity in neuronal circuits in a long-lasting way through indirect effects on release mechanisms of excitatory or inhibitory classical transmitters. The inhibition of glutamate release decreases the frequency of spontaneous glutamate-mediated events and the amplitude of evoked excitatory postsynaptic responses. Such a reduction in glutamate release and co-released GABA could act in concert to reduce the likelihood of neuronal firing and the generation of long-term potentiation. It has been shown for central neurons that the early and the late components of a GABAergic inhibitory postsynaptic potential (IPSP) are mediated by $GABA_A$ and $GABA_B$ receptors, respectively.

Synaptic strength at glutamatergic synapses shows a remarkable degree of use-dependent plasticity. This dynamic regulation of synaptic efficacy plays a crucial role in experience-dependent modification as well as in the formation of neuronal connections in neural circuitry as physiological correlates to learning and memory.

Some neuropeptides may be considered as endogenous antiepileptic agents because they reduce excitatory synaptic transmission in the CNS. Their application elicits a long-lasting decrease in evoked excitatory postsynaptic current (EPSC) amplitude and a delayed, long-lasting increase in the amplitude of an evoked monosynaptic inhibitory postsynaptic current (IPSC). Like opioid peptides, substance P and other neuropeptides of the tachykinin family also can indirectly affect pyramidal neurons via an effect on neighboring hippocampal CA1 interneurons. Neurokinin (NK)-1 receptors are located both on presynaptic terminals and at somatodendritic sites of GABAergic neurons. By increasing the excitability of CA1 GABAergic interneurons, tachykinins can powerfully facilitate the inhibitory synaptic input to pyramidal neurons. This indirect inhibition could play a role in regulating short-term and long-term synaptic plasticity, promoting neuronal circuit synchronization or influencing epileptogenesis. Because tachykinins do not alter the frequency or amplitude of miniature inhibitory synaptic currents and are without effect on evoked inhibitory synaptic currents, these neuropeptides probably act at the somatodendritic membrane of GABAergic interneurons rather than at their axon terminals. In the hippocampus, opioid peptides increase the excitability of CA1 pyramidal neurons via a reduction of GABAergic inhibition from neighboring interneurons (disinhibition).

Peptidergic Synaptic Potentials

Most of our knowledge about peptidergic transmission and most therapeutically used drugs is based on exogenous application in which substances may diffuse in the extracellular space and evoke their actions, for example, via the simultaneous activation and/or inhibition of ensembles of neurons or glia cells. Even when highly selective agonists and antagonists are available or transgenic mice expressing antibodies to the neuropeptide under study are combined with state-of-the-art single-unit recordings in *in vitro* preparations, these studies are still notoriously hard to interpret.

Most of the information that has been gathered so far about the actions of neuropeptides in the CNS *in vivo* derives from extracellular recording of single-unit activity in combination with iontophoretic or pneumatic administration from multibarreled micropipettes in regions containing a high density of specific binding sites. Most of these *in vivo* studies do not attempt to differentiate a presynaptic site of action from overlapping postsynaptic effects or to characterize the role of single neurons in an ensemble of neurons.

There is evidence that endogenously released neuropeptides shift membrane permeability and can directly cause postsynaptic inhibition and elicit peptide-mediated IPSPs. These findings indicate that neuropeptides may not just alter the response of a target neuron to classical neurotransmitters without interfering directly with neuronal excitability. However, such consistent postsynaptic effects on neuronal excitability are documented only for few neuropeptides. Such a shift of the membrane to a more hyperpolarized level directly reduces the voltage-dependent glutamatergic transmission mediated by *N*-methyl-D-aspartate (NMDA) receptors involved, for example, in cognition or epileptogenesis and shift glutamatergic transmission preferentially to α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor-mediated mechanisms in the whole neuron. The generation of excitatory postsynaptic potentials (EPSPs) by neuropeptides has been reported in neurons of the peripheral nervous system and a few neurons in the CNS.

Growth Factors

Some of the known growth factors such as brain-derived nerve growth factor (BDNF), which are secreted from neurons and glia cells, fulfill the neuropetide criteria and may act like neurotransmitters or get indirectly involved in the interneuronal communication by affecting, for example, ion transporters, which control the intracellular concentration of chloride in neurons. It has recently been shown that BDNF released from activated glia cells reduces the chloride transport out of the target neurons. The increase in intracellular chloride concentration shifts the commonly inhibitory effects of $GABA_A$ receptor activation toward excitation in these GABAergic

neurons, and thus dramatically affects acute functioning and plasticity in these neuronal circuits.

Conclusion

Considerable progress has been made in the field of neuropeptide research, and fascinating detailed insights into novel signaling modes in the nervous system have been gained through the advent of new technologies. New neuropeptides were described, and a multitude of receptors for neuropeptides have been characterized and cloned. Nevertheless, there is still only little information available on their role in humans. Because numerous neuropeptides are involved in mammalian brain functions under normal and pathological conditions, it was predicted that many agonistic and antagonistic drugs, as well as peptidase inhibitors preventing peptide breakdown and thus strengthening the peptidergic transmission, would rapidly be developed for therapeutic use. To date, this prediction has not yet materialized. Only substance P has secured a position in the field of psychopharmacology. It was shown that substance P (NK-1) antagonists have an antidepressant activity comparable to the most commonly prescribed serotonin reuptake inhibitors but are associated with less pronounced side effects. There is no doubt that peptidergic signaling mechanisms in the human brain will remain important targets for drug development and novel therapeutic algorithms.

Neuropeptides: Endocrine Cells

Introduction

Neuropeptides can be defined as peptides that are expressed in neurons and have a transmitter or cotransmitter function. However, it is common knowledge that many neuropeptides are not restricted to neurons, but occur also in other cells, endocrine cells in particular (Table 1). It should be mentioned that the opposite is also true; several peptides first discovered as hormones produced by endocrine cells were later shown to be neuropeptides, since they were expressed in neurons as well. The close relationship between peptide hormone-producing endocrine cells and neurons, and also between central and peripheral neurons, with regard to peptide expression has fostered an array of concepts and terms, such as neurohormonal peptides, brain–gut (or gut–brain) peptides, and the more neutral term regulatory peptides. There are several other histochemical and morphological characteristics that endocrine cells and neurons have in common (Table 2). Based on these similarities it was long held that endocrine cells in the gut, the pancreas, and the airways, together with the thyroid C cells and the adrenal medullary cells, all were embryologically of neuroectodermal origin. However, it is now quite firmly established that endocrine cells in the gut, pancreas, and airways originate from the endoderm (i.e., of the same embryonic origin as the epithelial cells that surround them), while C cells and adrenomedullary cells do have neuroectodermal origin. The following discussions represent a survey of the main lines of development in this field, focusing on those peptide genes that display a dual expression in neurons and endocrine cells.

Hormones Later Becoming Neuropeptides

The very first hormone described, thereby giving rise to the concept of hormones and thus forming the origin of endocrinology, was secretin. More than 100 years ago this substance was functionally defined in duodenal extracts by virtue of its stimulating effect on pancreatic fluid secretion. Around 70 years later secretin was chemically identified as a peptide. Still later the secretin-producing endocrine cells could be identified by immunocytochemistry (ICC) in the epithelium of the upper small intestine. However, not until quite recently was secretin gene expression described in the brain, and, in fact, much of current secretin research centers around the possible role of the peptide in the pathogenesis of brain disease, autism in particular.

Other peptides have a longer history as brain–gut peptides. One example is cholecystokinin (CCK), also long known as a gut hormone. However, rather soon after its chemical characterization, and the ensuing development of antibodies for radioimmunoassay (RIA) and ICC, it was found that CCK was also a neuropeptide with a wide distribution in both central and peripheral neurons.

The inevitable trend is that, as new techniques are developed, and as those already available become more and more sensitive, increasing numbers of peptide hormones turn out to have a neuronal localization as well. One recent example is the intestinal hormone GIP, initially named gastric inhibitory peptide but later renamed with the physiologically more appropriate descriptor, glucose-dependent insulin-releasing peptide; GIP recently has been found to be discretely expressed also in the brain. Correspondingly, certain pituitary hormones, such as proopiomelanocortin-derived hormones (adrenocorticotropic hormone, α-melanocyte-stimulating hormone, β-endorphin), and also growth hormone, have become to be viewed as neuropeptides in that they have been demonstrated in neuronal systems in the brain.

Neuropeptides Entering Endocrine Cells

Over the years a steadily increasing number of newly discovered peptides have first been localized to neurons in the central and/or peripheral nervous systems, and have later been found to exist also in endocrine cells. Thus, calcitonin gene-related peptide (CGRP), a product of an alternative calcitonin pre-mRNA splicing, was, apart from a low level of co-expression with the parent mRNA in C cells, initially thought to be expressed more or less exclusively in central and peripheral neurons: However, a few years after its discovery, CGRP was detected also in islet endocrine cells and in endocrine cells of the airways. Another example is gastrin-releasing peptide (GRP), a bombesin-like peptide first established as a neuropeptide with a wide distribution in the enteric nervous system (ENS), but soon found to occur also in endocrine cells in the airways and elsewhere. Neuropeptide Y (NPY), a major peptide in both central and peripheral neurons, was quite rapidly localized also to endocrine cells of the adrenal medulla, and later to islet endocrine cells. One more recent example is cocaine- and

Table 1 Peptides expressed in both neurons and endocrine cells in mammals

Peptides regarded as principal hormones, with their own cell type:
Propiomelanocortin derivatives (adrenocorticotropic hormone, melanocyte-stimulating hormone, β-endorphin, and other processing products)
Growth hormone (some evidence of neuronal expression)
Ghrelin (some evidence of neuronal expression)
Secretin (some evidence of neuronal expression)
Cholecystokinin
Glucose-dependent insulin-releasing peptide (some evidence of neuronal expression)
Motilin (some evidence of neuronal expression)
Somatostatin
Proglucagon derivatives (glucagon-like peptides GLP-1 and GLP-2 and other processing products)
Neurotensin
Co-expressed peptides in endocrine cells:
Enkephalins (adrenal medulla and gut)
Dynorphins (islets)
Neuropeptide Y (adrenal medulla and islets)
Peptide YY (gut and islets)
Calcitonin gene-related peptide (thyroid, islets, and airways)
Islet amyloid polypeptide (islets and stomach)
Thyrotropin-releasing hormone (islets during development)
Substance P and other tachykinins (gut enterochromaffin cells and carcinoid tumors)
Pituitary adenylate cyclase-activating peptide (adrenal medulla)
Galanin (adrenal medulla)
Chromogranins, and their processing products – e.g., pancreastatin from chromogranin A, secretoneurin from secretogranin II (many different endocrine cell types)
Cocaine- and amphetamine-regulated transcript (islets, gut, and adrenal medulla)
Gastrin-releasing peptide/bombesin (airways)
Orexin[a] (islets and gut)
Vasoactive intestinal peptide (endocrine tumors)
Growth hormone-releasing hormone (endocrine tumors)

[a]Claimed but not verified.

Table 2 Features common to peptide-producing endocrine cells and neurons

Endogenous amines and other 'classical' neurotransmitters stored in secretory granules/dense-cored vesicles
Capacity to form amines from endogenous or exogenous precursor amino acids, so-called APUD (amine precursor uptake and decarboxylation) mechanism
Vesicular monoamine transporters (V-MATs)
Certain 'neuron-specific' enzymes and other marker proteins (e.g., cholinesterases, neuron-specific enolase, protein gene product 9.5, neurophysin)
Granule-stored chromogranins and related proteins and their processing products
Granule-stored peptide-processing enzymes

amphetamine-regulated transcript (CART) peptides, which were first identified as abundantly expressed peptides in both central and peripheral neurons. CART was subsequently found to be expressed in endocrine cells of the adrenal medulla, the pancreatic islets, and the intestine, and, at least in rats, also in antral gastrin cells of the stomach.

Messenger Coexistence in Endocrine Cells and Neurons

One feature that is characteristic of a peptide, whether occurring in endocrine cells or in neurons, is that it is not the one and only hormone/transmitter in these cells, but rather is co-localized with other peptides and/or 'classical' neurotransmitters (Table 3). This feature of co-localization is sometimes referred to as 'chemical coding.' In fact, the chemical coding, which can be extensive in certain neurons of the ENS, is quite remarkable in its extent also in certain endocrine cells, such as in insulin-producing beta cells in pancreatic islets. The frequent co-existence of peptides indicates an even higher complexity to the way the target cells are regulated. Unraveling of the functional significance of co-expression of peptides and of peptides and other messengers in endocrine cells is still in its infancy, but some interesting advances have been made in the nervous system. Thus, the concept

Table 3 Releasable substances in granules of both endocrine cells and neurons

Low-molecular-weight messengers:
Amines (e.g., serotonin, melatonin, dopamine, noradrenaline, adrenaline, histamine)
Amino acids (e.g., γ-aminobutyric acid, glutamic acid)
Adenosine triphosphate
Nitric oxide
Carbon monoxide
Peptides and proteins:
Messenger peptides
Other propeptide processing (silent?) fragments
Acidic proteins (chromogranins and related proteins)
Peptide-processing enzymes

Table 4 Possible advantages of multiple messengers in endocrine cells

Coordinated effects at close range (paracrine or autocrine actions) and at a distance (endocrine actions)
Coordinated effects over time: immediate effects and delayed (e.g., trophic) effects

Activity dependent

of cotransmission (i.e., cooperation at the target cells of co-stored and simultaneously released messengers) was fueled by a series of observations on sympathetic nerves co-storing NPY and noradrenaline, in regulating vascular tone and blood flow, and on parasympathetic nerves co-storing vasoactive intestinal peptide (VIP) and acetylcholine, in regulating secretion from exocrine glands. It is not inconceivable that similar mechanisms operate also in the endocrine system; co-stored and co-released peptides (hormones and other regulatory peptides) may cooperate at the target cells. Some of them may, alternatively or additionally, have paracrine or autocrine functions by targeting neighboring cells or the cell of origin.

To be able to understand the full physiological significance of messenger coexistence in endocrine cells, we need to address a number of questions:

- What is the messenger mix (chemical coding) of each individual population of endocrine cells?
- How is the expression of the co-stored messengers controlled?
- What advantages do co-storage and co-release offer?

Detailed answers to these questions cannot yet be given. Possible functional advantages of the coexistence and co-release of messengers are listed in Table 4. It is clear, however, that the number of messengers – including peptides – in certain endocrine cells is high, and that some peptides are not permanent residents, but are rather transiently expressed during development and in pathophysiological conditions, as illustrated by islet beta cells (see later). One notable observation regarding coexisting peptides is the variation among species in the peptide constellation in a given cell type. Consequently, data obtained in common laboratory animals, such as rats and mice, may not in all details be valid for other mammals. Hence, caution is needed when extrapolating data from experimental animals to humans. The main aspects of peptide plasticity in endocrine cells are summarized in Table 5. An emerging issue in this context is that in tissues harboring both nerves and endocrine cells, a peptide may in one species be located preferentially in nerve fibers, while in another species the primary site of expression is in endocrine cells. It may then be asked whether a peptide can play the same paracrine role regardless if it is released from a nerve fiber or from an endocrine cell. Possibly, a neuronal localization of the messenger gives the potential of a more rapid release – and response of the target cell.

Adrenal Medulla

As more and more information has been gathered, the catecholamine-producing endocrine cells of the adrenal medulla have turned out to be a virtual storehouse of neuropeptides. Some of these peptides may occur exclusively in endocrine cells, whereas others are, in addition, present in neuronal elements. Many of the peptides are known to participate in the regulation of the secretory activities of the gland, presumably by paracrine or autocrine mechanisms. It cannot be excluded, however, that some peptides reach the circulation to join the battery of amines and peptides that function as hormones. Among peptides known to be produced in adrenomedullary cells are enkephalins, NPY, galanin, somatostatin, CGRP, VIP, pituitary adenylate cyclase-activating peptide (PACAP), and CART. Although not studied in detail, it is evident that many peptides coexist in the same cells. It should also be mentioned that the exact cellular localization (adrenaline- vs. noradrenaline-producing cells), the extent of expression (all cells of a given type or a subpopulation of them), and the presence in endocrine cells versus in neuronal elements are to some extent species dependent.

Islet Beta Cells

Beta cells, in addition to insulin, and the second proinsulin-derived C-peptide, invariably produce islet amyloid polypeptide (IAPP, or amylin). Insulin and IAPP are known to be co-stored in the same secretory granules and co-released at secretion. However, the two encoding genes may not always be co-regulated. Beta cells, in addition, express a plethora of neuropeptides during development and under pathophysiological conditions. Such peptides include CART, NPY, and thyrotropin-releasing hormone (TRH), as studied mostly in rodents to date. Thus, CART, NPY, and TRH are strongly upregulated pre- and neonatally, but are then gradually downregulated to very low levels of expression, or no expression, in the adult beta cell. It is notable that the upregulation of CART during development is not limited to beta cells but occurs in several of the other islet endocrine cell types (Figures 1(a)–1(d)). Interestingly, upon severe and long-standing challenge of the beta cells in adults, as in states of insulin resistance (i.e., in animal models of type 2 diabetes), expression of CART (Figures 1(m)–1(p)) and NPY is again heavily upregulated, particularly during the phase of islet expansion when beta cells are capable of compensating for the increased insulin demand by cell hypertrophy and hyperplasia.

Intestinal L Cells

An important population of L cells (defined by their comparatively large secretory granules) express the glucagon gene. However, in these cells proglucagon processing yields glucagon-like peptides (GLP-1 and GLP-2) rather than glucagon, which remains embedded in a larger peptide, glicentin, lacking glucagon

Figure 1 (a–d) Fetal (embryonic day 20) rat islets. Double immunostaining for cocaine- and amphetamine-regulated transcript (CART; red in all images) and each of the four major islet hormones, illustrating that CART is expressed in all of these islet cell types during a period around birth. (a) Double staining for CART and glucagon (blue). (b) Double staining for CART and insulin (blue). (c) Double staining for CART and somatostatin (green). (d) Double staining for CART and pancreatic peptide (green). CART is to a varying degree co-expressed (violet or yellow) with all four islet hormones in a subpopulation of each cell type. (e–h) Distal ileum of mouse (e, f) and pig (g, h). Double immunostaining for proglucagon (e, g) and peptide YY (f, h). The two peptides coexist in the L cells. (i–l) Human gastric fundus – oxyntic mucosa (i, j) and duodenal villi (k, l) – double immunostained for ghrelin (i, k) and motilin (j, l). Ghrelin and motilin are co-localized in the same cells in the duodenum (k, l), while gastric ghrelin cells lack motilin (i, j). (m–p) Rodent islets double immunostained for CART (red) and insulin (blue). (m) Low magnification of normal mouse islets and islets of an ob/ob mouse (n). CART is robustly upregulated in many beta cells of the ob/ob mice, whereas the normal islets have no detectable CART in islet cells. Note also the bundle of CART immunoreactive nerve fibers in panel n. (o) Higher magnification of normal rat islet and diabetic GK rat islet (p). CART is restricted to delta cells in the normal islet, while it is upregulated in many beta cells of the GK rat islet. Co-expression is represented by violet staining.

bioactivity. These L cells predominate in the distal intestine and, in addition to proglucagon, they express peptide YY (PYY), as documented in several mammals (Figures 1(e)–1(h)).

Coexistence of Peptides with Overlapping Functions

Evidence is emerging that certain peptides that have, at least in part, overlapping functions also overlap in their cellular localization. Thus, it has been shown in the human intestine that a significant population of the GIP-producing endocrine cells, the K cells, also express GLP-1. Both of these peptides are known to stimulate insulin secretion and belong to the group of incretin hormones. Furthermore, ghrelin and motilin, both of which stimulate gastric emptying and are implicated in the regulation of gut motility via the generation of migrating motor complexes (MMCs), also partly overlap in their cellular localization. Although a majority of gastrointestinal ghrelin cells are located in the stomach in human adults, a significant population is present also in the mucosa of the upper intestine, and a vast majority of these latter cells are, in fact, identical with motilin cells (Figures 1(k) and 1(l)). It is notable that gastric ghrelin cells do not express motilin (Figures 1(i) and 1(j)), nor do the ghrelin cells present in the pancreatic islets. This partial coexistence arrangement not only indicates phenotypical differences, but suggests also functional differences among subpopulations of ghrelin-producing cells, adding further complexity to the functional characterization of endocrine cells and their hormones.

The peptides coexisting in the islet beta cells may also have overlapping functions. IAPP and NPY are known as inhibitors of insulin secretion. In rats, CART is also an inhibitor of basal insulin secretion, but differs from the other two peptides by its potent augmenting effect on secretion stimulated by glucose and cAMP activating agents such as GLP-1.

Do peptides GLP-1 and PYY, coexisting in intestinal L cells, also fit into this concept (keeping in mind that PYY1–36 is known to be orexigenic, whereas GLP-1 is an acknowledged anorexigenic peptide)? It is not unlikely that they do, since PYY1–36 is rapidly converted to PYY3–36, which is also anorexigenic. This property of PYY3–36 is presumably due to its high selectivity for Y-2 receptors known to inhibit the release of the orexigenic peptide NPY in the hypothalamus.

Peptides with Dual Localization in Endocrine Cells and Neurons – Ontogeny and Phylogeny

It has gradually been realized that the distinction between true neuropeptides(i.e., peptides restricted to neurons) and peptides with a dual localization in neurons and endocrine cells is not crystal clear. Some peptides may be exclusively expressed in neurons or endocrine cells in adults under normal conditions, but have a dual localization during ontogeny and in pathophysiological conditions.

Phylogenetic studies have complicated things even further. Thus, it seems that certain peptides expressed exclusively in endocrine cells in mammals are produced in neurons, or have a dual localization in nerves and endocrine cells in lower vertebrates. The opposite seems also to be true; a neuronally localized peptide in mammals may be produced by endocrine cells in submammalian vertebrates. Thus, for instance, VIP, a well known neuronally localized peptide in mammals, is present in a large population of endocrine cells in the distal intestine of cartilaginous fish.

Role as Principal Hormone or as Co-Expressed Peptide

One note of consideration is the actual status of a neuropeptide when it is expressed in endocrine cells. It may be the principal hormone, like secretin and CCK. More often, however, it is co-produced with the principal hormone. In this latter instance the coexisting peptides as a rule are co-stored within the same secretory granules, as revealed by, for example, immunogold staining, at the electron microscopic level.

Another note of consideration is the propeptide processing and the size of the resulting fragments. This has been quite extensively studied for pro-CCK, for example, and, in general it seems that the precursor processing is more advanced – that is, the final processed fragments are smaller – in neurons than in endocrine cells. Thus, the short fragment, CCK-8, predominates in neurons, whereas the longer fragments, CCK-58 and CCK-33, predominate in endocrine cells.

The chromogranins and related peptides form, in this context, a special group. The first of these acidic proteins, chromogranin A, was originally described in the secretory granules of endocrine cells in the adrenal medulla. Chromogranins were soon found to form a considerable proportion of the granule matrix of very many endocrine cells, and of many neurons as well. It was also demonstrated that chromogranins are subjected to proteolytic processing at specific cleavage sites, to yield fragments of different size, and that this processing mirrors that of hormone and neuropeptide precursor processing. Furthermore, it has turned out that many of the chromogranin fragments display biological activity, and that they,

being stored in the secretory granules, are released together with the main hormone or neurotransmitter upon exocytosis.

Pathophysiological Aspects

The islet beta cells have been studied quite extensively with respect to coexisting peptides and the plasticity of peptide expression during development of experimental type 2 diabetes, particularly in rat models. In the early phase of this process the beta cells accelerate insulin (and IAPP) expression in order to compensate for the increased need of hormone, to avoid hyperglycemia. At the same time the beta cells upregulate their CART and NPY expression severalfold, from very low, or no expression, to high levels. This is suggested to reflect, on one hand, an attempt of the cell to boost the rate of insulin secretion, since CART is capable of augmenting an already stimulated secretion. On the other hand, there is, at the same time, a need to prevent cell exhaustion, and eventual cell damage, by upregulating also inhibitors of insulin secretion, such as IAPP and NPY, to act as local breaks. It may be added in this context that the islet parasympathetic innervation, containing CART and VIP in addition to acetylcholine, becomes denser, as studied in rats, during diabetes development, thereby providing more insulin secretagogues to the beta cell environment.

Tumors arising from peptide hormone-producing cells in the gastro–entero–pancreatic region, the airways, or the thymus (adenomas if benign, or carcinoids if malignant) are on the whole infrequent, but may give rise to severe symptoms due to hormone overproduction, even if the tumor is benign. It is not uncommon that endocrine tumors are composed of several cell types, producing a number of different peptides (multihormonal tumors). Nevertheless, it is usually the predominating cell type that produces the hormone causing the main symptoms. Occasionally, the tumor releases counteracting hormones, or hormone release inhibitors, which may result in a delay of symptoms, and thereby a delay in diagnosis and in treatment as well. Further, it is not uncommon that metastases produce a different spectrum of peptides than the primary tumor. These general features also apply to endocrine tumors arising in the adrenal medulla (pheochromocytoma) or from the thyroid C cells (medullary thyroid carcinoma). Pheochromocytomas may host a great number of peptides, but are usually diagnosed on the basis of the overproduction of catecholamines.

Finally, one feature that is pertinent to mention is that endocrine tumors may occasionally produce peptides that are not normally expressed in endocrine cells in mammals, at least not in adulthood. Such peptides include VIP, which causes the watery diarrhea, hypokalemia, and anacidity (WDHA) syndrome, and growth hormone-releasing hormone (GHRH), which may give rise to acromegaly. Further, the tachykinin substance P, which in the human gut is expressed in but a small subpopulation of the serotonin-producing enterochromaffin (EC) cells in the ileum, is present in almost all ileal carcinoids, by far the most common intestinal endocrine tumor. The appearance of unexpected peptides in endocrine tumors may be related to a broader ontogenetic and phylogenetic messenger programming of certain peptide hormone-producing cells.

Concluding Remarks and Future Directions

Studies of peptides as hormones and neuropeptides have witnessed both ups and downs over the years. These types of peptides were the basis of the very start of endocrinology (secretin), and constitute by now a dominating category of hormonal and neuronal messengers. Their functions cover a wide spectrum; it has, in this context, become an intriguing fact that many hormonal peptides expressed in the gastro–entero–pancreatic region are engaged in the regulation of feeding, in addition to having other more specified functions (Table 6). However, since many of these peptides are expressed also in the brain, the exact origin of the orexigenic and anorexigenic signals is in some instances not yet resolved. When gene technology provided the possibility to knock out such peptides, or their receptor(s), one by one, the resulting generally meager phenotype, or total lack of it, represented one 'down.' Redundancy became a reality in this research area, and is one conceivable explanation. In retrospect, we have to admit that it is certainly a good strategy for survival not to be dependent on a single messenger to handle vital functions, such as feeding.

It is to be expected that, with techniques becoming more and more sophisticated and sensitive, more neuropeptides, including those expressed at low levels, will be detected in endocrine cells, and, conversely, more hormonal peptides will be detected in neurons. Furthermore, new peptides with a cell-to-cell messenger function are still regularly discovered (e.g., as ligands of orphan G-protein-coupled receptors). It is therefore to be expected that new peptides will continue to appear for quite some time in the future. To this end, there are still endocrine cells (e.g., along the gastrointestinal tract) that lack a peptide hormone, and a host of orphan receptors that need a ligand.

Table 6 Hormones and regulatory peptides in gastro–entero–pancreatic endocrine cells thought to be involved in feeding regulation

Peptide	*Sites of production*	*Actions*
Islet amyloid polypeptide/ amylin	Islet beta cells and delta cells, gastric endocrine cells	Inhibit insulin secretion, inhibit feeding
Cocaine- and amphetamine-regulated transcript peptides	Islet delta cells and antral G cells, many islet cell types neonatally(rat), islet beta cells in diabetes models	Regulate islet hormone secretion, inhibit feeding
Cholecystokinin	I cells, upper small intestine	Stimulate pancreatic enzyme secretion and gallbladder contraction, inhibit feeding
Enterostatin	Endocrine cells (mostly enterochromaffin cells) in upper gut	Inhibit feeding
Ghrelin	A-like or P/D1 cells in stomach, Mo cells in upper intestine and islet ghrelin cells	Stimulate feeding and gastric emptying, inhibit insulin secretion
Glucagon-like peptide-1	L cells (major population), distal small and large intestine	Stimulate insulin secretion glucose dependently, inhibit feeding
Motilin	Mo cells, upper small intestine	Stimulate interdigestive gut motility, stimulate feeding
Neurotensin	Neurotensin (subpopulation of L) cells, distal small intestine	Inhibit gut motility, acid secretion, and feeding
Neuropeptide Y	Islet beta cells during development, adrenal medulla	Inhibit insulin secretion, gut motility, and secretion; stimulate feeding
Oxyntomodulin	L cells, distal small and large intestine	Inhibit gastric acid secretion and feeding
Pancreatic peptide	Islet pancreatic peptide cells, gut (few)	Inhibit exocrine pancreatic secretion, inhibit feeding
Peptide YY (PYY3–36)	L cells, distal small intestine and large intestine, islet alpha and delta cells	Inhibit feeding, gut motility, exocrine pancreatic secretion
Somatostatin	D cells in islets and along the entire gut	Inhibit numerous gut and islet functions, inhibit feeding
Thyrotropin-releasing hormone	Islet beta cells during development	Stimulate gastric secretion and motility, inhibit feeding

Neuropeptides: Enteric Nervous System

M Costa and S Brookes, Flinders University, Adelaide, SA, Australia

Neuropeptides in the Enteric Nervous System

The enteric nervous system (ENS) comprises all neurons embedded within the digestive tract and their connections with extrinsic neurons originating in sympathetic, parasympathetic, and sensory ganglia. The ENS is involved in controlling movements of the digestive tube, in mucosal transport, in controlling the local blood supply and in modulating cellular defense mechanisms. The process of unraveling the neural circuits of the ENS has progressed significantly over the past few decades, with the major classes of enteric neurons being identified in some experimental animals. A relatively small number of functional classes have been characterized on the basis of their neurochemistry, projections, biophysical properties, and effects of their activation.

Enteric circuits mediating the different functions usually work in concert. For instance, neurally mediated changes in motility are usually associated with appropriate alterations of secretion and blood flow. Although extensive analysis of enteric neural circuits is well advanced, how the circuits give rise to integrated enteric motor, circulatory, and secretory behaviors is less well understood. Consequently, the role of the neuropeptides contained in individual classes of enteric neurons, or in specific circuits, remains largely uncertain. We present here a critical perspective of the role of neuropeptides in the neural circuits underlying the major functions controlled by the ENS.

Neuropeptides are relatively short sequences of amino acids, synthesized in the nerve cell body by cleavage from larger precursor peptides and transported to the nerve endings, where they are stored and released from vesicles. Neuropeptides cleaved from the same or similar precursors have been classified into families. All neuropeptides give rise to effects mediated via G-protein-coupled receptors (GPCRs). Neuropeptide receptors also form subgroups with a range of molecular forms and with varying affinities for the native (endogenous) or synthetic ligands.

The discovery of neuropeptides in enteric neurons was reported nearly 30 years ago. The list of peptides expressed in the enteric nervous system has grown in parallel with the burgeoning list of new peptides identified in other parts of the nervous system. There seems to be a fundamental agreement in the literature that nearly all classes of enteric neurons contain one or more neuropeptides. Despite the vast amount of information that has been accumulated on the nature and distribution of peptides in the ENS, relatively little progress has been made in achieving a real understanding of their neuronal role.

In the gastrointestinal mucosa there are many classes of enteroendocrine cells containing a wealth of peptides, similar to those contained in enteric neurons. This adds to the difficulty of investigating the actual role of neuropeptides in the enteric nervous system. Some of the peptides released from enteroendocrine cells play a hormonal role, but may also act as mediators for transducing luminal signals to intrinsic and extrinsic afferent neurons. Peptides are also present and released from other nonneuronal sources – for example, calcitonin gene-related peptide (CGRP) can be released by mast cells.

Since the 1970s, almost every class of biologically active peptides discovered in mammalian brain has also been found in enteric neurons. Indeed, some peptides were first discovered in the gut. At the time, it was expected that neuropeptides could be used to distinguish different functional classes of enteric neurons. This rapidly created an inflated number of potential functional classes. The discovery that several peptides could coexist in the same enteric neuron, and that neurons with similar shapes (axonal projections) contained unique combinations of peptides and other neurochemicals, led to the idea of 'chemical coding.' It was also proposed that neurons with different 'chemical coding' are likely to be functionally distinct. This concept opened a new era in investigations of the ENS. It has helped identify the major classes of enteric neurons, making it possible to place these classes within functional circuits and to identify the neurons in functional studies. Nearly 20 functional classes of enteric neurons have been identified using 'chemical coding' principles, including excitatory and inhibitory motor neurons, ascending and descending interneurons, secretomotor neurons, vasomotor neurons, and intestinofugal and intrinsic afferent neurons.

An important corollary of these studies was recognition that the same peptide may be present in very different classes of neurons. The concept of 'one enteric peptide, one function' had to be abandoned. The discovery that enteric neurons utilize multiple transmitter mechanisms also meant that the idea that a neuron can be named after one transmitter also had to be abandoned. Thus terms such as 'peptidergic,' 'VIPergic,' and 'tachykinergic,' often used to describe classes of enteric neurons, must be regarded

as inaccurate and inappropriate. First, the mere presence of a peptide in a neuron does not prove that it is used as transmitter. Second, even if this is the case, neurons usually contain and utilize several other transmitters. To avoid confusion, enteric neurons are mentioned here according to their functional classes (e.g., inhibitory motor neurons) and as 'peptide containing' – for example, vasoactive intestinal peptide (VIP)-containing inhibitory motor neurons. The classes of enteric neurons and their circuitries should be regarded as scaffolds on which different messenger substances play their relative roles as modulators or cotransmitters.

Another implication of the chemical coding concept is that each class of enteric neurons may utilize multiple transmitter substances. This led to the concept of plurichemical transmission, whereby individual classes of enteric neurons use different cotransmitters affecting different mechanisms of recipient cells, over a range of time courses. Detailed knowledge of chemical coding of enteric neurons has enabled more direct and meaningful comparisons of enteric circuitries in different species.

Identification, Quantification, Localization, and Biological Actions of Neuropeptides

The discovery of the presence of a neuropeptide in the ENS usually involved extraction and purification, testing for biological activity, followed by sequencing of the peptide and its eventual localization by immunohistochemistry. For example, the original extraction of the tachykinin, substance P, from horse intestine preceded by decades its sequencing in central tissue. It led to the identification of different members of the tachykinin family in mammalian gut, with detailed localization in different classes of enteric neurons. More recently, new peptides and their receptors are being increasingly discovered through bioinformatics and by molecular biological methods.

The main technique for localizing neuropeptides over the past three decades has been by histological staining using antibodies raised against a part of or the whole neuropeptide sequence or its precursor. Although immunohistochemical techniques are relatively simple, the interpretation of the results need some attention. For example, only if tissue labeling is prevented by inactivating the antibody with its synthetic antigen ('preabsorption') can the localization be said to show 'peptide-like' immunoreactivity. Further identification of the actual molecular form requires additional analytical techniques, including sequencing and Western blots.

The effort to study localization of neuropeptides in the gut has blossomed since the early studies of immunohistochemistry in the 1970s. Somatostatin was the first neuropeptide visualized in enteric neurons, in 1977 (Figure 1). Since then, methods to visualize entire enteric circuits in whole-mount preparations has permitted characterization of the shapes, projections, and proportions of enteric neurons containing particular peptides. In 1979, Tomas Hokfelt and colleagues published the first evidence of co-co-localization of peptides in enteric neurons. Since then, a large number of reports have revealed the presence of new peptides in enteric neural tissue, providing a large and sometimes contradictory database on the diversity of enteric neurons. With a patient systematic study of the multiple localization of peptides and other markers, much of

Figure 1 Descending cholinergic interneuron in the myenteric plexus of the guinea pig small intestine was filled with biotinamide (green) after intracellular recording. The same neuron was immunoreactive for the peptide, somatostatin (blue), and shows distinctive, filamentous dendrites in the camera lucida drawing on the right.

this information was crystallized into a comprehensive and simplified account for the enteric circuits in the guinea pig small intestine, by the mid-1990s. It is fair to say similar attempts to identify all classes of enteric neurons have been attempted in only a few other regions of gut or species. The literature is still surprisingly full of isolated and unrelated observations of single immunohistochemical labeling of one or other neuropeptide, which cannot yet be put into a meaningful functional context.

Establishing Physiological Functions of Enteric Neuropeptides

Investigations on the role of neuropeptides in enteric neurons is part of the general problem of demonstrating a transmitter role for any proposed substance. A classic list of prerequisites that a putative transmitter must fulfill includes transmitter synthesis, storage, and release, and a demonstration of an effect mediated via specific receptors that mimics a biological mechanism. However, too often publications merely demonstrate the presence of a peptide in the gut by histological means, present evidence that the exogenous peptide (or an agonist) produces an effect, and from this incomplete evidence conclude too eagerly that the peptide is an enteric transmitter.

A critical piece of evidence for identifying a transmitter role is to show that interfering with the transmission mechanisms of the endogenous peptide results in some change of function, usually through the use of a specific and selective antagonist. This has only been achieved in a very few instances. Partly this is due to the relative lack of effective antagonists to peptide receptors. Even when good antagonists are available, as for the tachykinin receptors, the multiplicity of receptors involved demands the use of cocktails of antagonists. For example, it was less than a decade ago that the role of tachykinins in motor behavior of the intestine (peristalsis in the distal colon of the guinea pig) was established. This was long after antagonists for the three classes of tachykinin receptor (NK-1, NK-2, and NK-3) became available. Marcello Tonini and co-workers used simultaneously antagonists to all three tachykinin receptors, to demonstrate that the propulsive contractions of the guinea pig colon are mediated by tachykinins, probably released from excitatory motor neurons, which are also cholinergic. The nature of inhibitory transmission from enteric inhibitory motor neurons has been subject of extensive research and long debate. The original descriptive term 'nonadrenergic noncholinergic' (NANC) gave way to the more specific 'purinergic,' 'VIPergic,' and 'nitrergic' to describe ATP, VIP, or nitric oxide (NO) as the transmitter substance, respectively. It is now well accepted that most inhibitory motor neurons contain and utilize all three classes of substances (see later), with variations in their relative contributions.

The localization of peptide receptors has assisted the understanding of the role of neuropeptides in the gastrointestinal tract. By and large, receptors were localized where they were expected. The visualization of opioid receptors on some enteric neurons by immunohistochemistry confirmed that this was the main site at which opiates inhibited intestinal motility (Figure 2). Before immunohistochemical localization of receptor proteins, the effects of agonists comprised the main way to establish the potential action if the endogenous peptides were to be released. For example, endogenous tachykinins act on enteric neurons via NK-3 receptors. Senktide, a specific agonist, evokes contraction of intestinal muscle solely by an action on enteric neurons. The use of selective

Figure 2 Single confocal section through a myenteric ganglion of guinea pig ileum shows several neurons with immunoreactivity for the mu opioid receptor (μOR; red), which is concentrated at the cell membrane, with some granular background labeling throughout the ganglion. Two of the neurons are also immunoreactive for nitric oxide synthase (NOS; green), a marker for inhibitory interneurons and descending interneurons.

antagonists to NK-3 receptors confirmed that endogenous tachykinins, probably released by enteric primary afferent enteric neurons, act on other neurons via slow synaptic mechanisms involving NK-3 receptors.

When receptors are found at cellular sites not predicted by previous pharmacological studies, new sites of action may be suggested. Fluorescently labeled agonists have proved useful to follow the dynamics of peptide receptors during their activation. Recycling of opioid and tachykinin receptors in functional studies has provided evidence of the release of the endogenous peptides. For example, a fluorescently labeled NK-3 agonist supported previous evidence that endogenous tachykinins mediate slow synaptic transmission between enteric primary afferent neurons, interneurons, and motor neurons.

Targeted mutations in the gene encoding a peptide or its receptor (yielding 'knockout' animals) have also been useful, although compensatory mechanisms during development may complicate interpretation of the results. There are, however, relatively few experiments of this type that have shed light on the enteric peptides. Mice lacking the VIP gene (−/−) show significant alterations in intestinal morphology and structure as seen by light microscopy. The length of the bowel is decreased compared to wild-type (WT) controls and the smooth muscle layers are thicker, with impaired intestinal transit. A significant percentage of VIP(−/−) mice die in the first postnatal year, with overt stenosis of the gut.

Another way to investigate transmitter function, which has been useful for many nonpeptide transmitters, is to experimentally alter the endogenous mechanisms of inactivation. However, this has been rather less successful for neuropeptides. For example. the enzyme aminopeptidase A is known to inactivate cholecystokinin (CCK-8) and selective inhibitors are available, but other peptides are also substrates of the same enzyme. The neutral endopeptidase inhibitor, thiorphan, has been shown to enhance and prolong inhibitory transmission to the smooth muscle, and this has been taken as indication for inhibitory peptides involvement.

Functional Role of Peptides in Enteric Circuits

The restriction of neuropeptides to specific functional populations of enteric neurons has made it easier to identify their roles in transmission. A few families of neuropeptides appear to play major roles, but the roles of most other peptides still remain to be established.

Tachykinins are a family of peptides; members include substance P (SP), neurokinin-A (NK-A), and neuropeptide-γ (which lacks residues 3–17 of neuropeptide K). They are cleaved from preprotachykinin A (PPT-A), which occurs in several forms (preprotachykinin mRNA species, α, β, and γ). Preprotachykinin B (PPT-B) encodes neurokinin-B (NK-B) and peptide 2 (P2), a nontachykinin peptide sequence. The discovery of a third preprotachykinin gene (*TAC4*) has more than doubled the number of tachykinins through the discovery of several new species-divergent peptides. These include hemokinin-1 (HK-1) in mouse and rat, endokinin-1 (EK-1) in rabbit, and EK-A, EK-B, human HK-1 (hHK-1), and hHK(4–11) in humans. Each exhibits a remarkable selectivity and potency for the NK-1 receptor, similar to SP. These recently cloned mammalian tachykinins are primarily expressed in nonneuronal cells. The biological actions of all of the tachykinins are mediated through three types G-protein-coupled receptors denoted NK(1), NK(2), and NK(3).

Tachykinins are present in excitatory motor neurons both to the circular muscle and longitudinal muscle layers. They are released with the major transmitter, acetylcholine, and act on muscle cells via NK-2 receptors and on interstitial cells of Cajal via NK-1 receptors. Tachykinins appear to be released by higher frequency firing of motor neurons, compared to acetylcholine, and elicit more prolonged responses. Tachykinins are also contained in the enteric primary afferent neurons and are released to provide the main slow synaptic transmission to neighboring primary afferent neurons, interneurons, and motor neurons, mostly via NK-3 receptors. Tachykinins are also co-transmitters with acetylcholine in secretomotor neurons.

In 1970, SI Said and V Mutt isolated a novel peptide from porcine intestinal extracts; the peptide, which had powerful vasoactive properties, was named vasoactive intestinal peptide, and it is now known to belong to the secretin/glucagon family, along with peptide histidine isoleucine (PHI), peptide histidine valine (PHV), and pituitary adenylate cyclase-activating polypeptide (PACAP). These are all cleaved from different precursors from two genes. Behavioral and neurological tests on transgenic mice reveal some functional distinctions between the two genes. These findings suggest that PACAP and VIP evolved to possess distinct biological activities and that they do not compensate each other effectively when one is absent in a knockout mouse. Molecular cloning of PACAP receptors has shown three distinct receptor subtypes: the PACAP-specific PAC1 receptor, which is coupled to several transduction systems, and the two PACAP/VIP-indifferent VPAC1 and VPAC2 receptors, which are primarily coupled to adenylyl cyclase.

In addition to VIP (**Figure 3**), enteric inhibitory motor neurons use PACAP as a transmitter to relax intestinal smooth muscle by eliciting slow hyperpolarization. They act via receptors located on both smooth muscle cells and interstitial cells of Cajal;

Figure 3 Motor neurons to the circular muscle of the guinea pig ileum were retrogradely labeled with the carbocyanine dye, DiI (red). One motor neuron close to the DiI application site was immunoreactive for substance P (SP) but not for vasoactive intestinal peptide (VIP). The other motor neuron (lower red profile, slightly out of focus) was one of a very sparse population of enteric neurons, immunoreactive for both SP and VIP.

Figure 4 Neurons in a submucous ganglion of guinea pig ileum, showing typical chemical coding. A single neuron was retrogradely labeled by the carbocyanine dye, DiI, applied to a myenteric ganglion (red). The same neuron, probably a noncholinergic secretomotor neuron, was immunoreactive for the peptide vasoactive intestinal polypeptide (VIP; green) but not for neuropeptide Y (NPY; blue). In fact, there is no coexistence of VIP and NPY; these peptides are found in separate populations in submucous neurons of the small intestine in this species.

a receptor antagonist for both VIP and PACAP reduces inhibitory transmission. The same inhibitory motor neurons also utilize nitric oxide as transmitter, relaxing muscle cells via the guanylate cyclase/3′,5′-cyclic guanosine monophosphate pathway. Nitric oxide and vasoactive intestinal polypeptide also interact; NO enhances the release of VIP from nerve terminals and vice versa. ATP co-released from these same neurons also inhibits smooth muscle over a shorter time course. In some parts of the gastrointestinal tract, there is evidence that other inhibitory peptides may contribute to inhibitory transmission, in some species. For example, a neurotensin receptor antagonist has been shown to reduce inhibitory transmission in jejunal and ileal segments of rats.

VIP is also a major transmitter of secretomotor neurons (Figure 4), where it may also interact with NO; each potentiates the other's effect in stimulating intestinal fluid secretion. The role of VIP in some descending interneurons is less clear; it may partially mediate slow

synaptic transmission from these cells. Similarly, VIP contained in intestinofugal neurons may contribute to slow transmission in prevertebral sympathetic ganglia.

The discovery of the presence of opioid peptides in enteric neurons led to extensive studies of their roles. These peptides include leu-enkephalin (leu-ENK) and met-enkephalin (met-ENK), cleaved from preproenkephalin; dynorphin (DYN), cleaved from predynorphin; and the recently discovered heptadecapeptide, nociceptin, also known as orphanin FQ, which is the endogenous ligand for the 'orphan' opioid receptor-like $(ORL)_1$ receptor. They all inhibit enteric neurons directly, with little or no effect on smooth muscle or secretory cells. Opioid peptides are present in enteric excitatory motor neurons, where they are co-released with acetylcholine and tachykinins. Under physiological conditions, they appear to exert little effect. However, when neural activity is intense, such as during peristaltic work against an obstruction, the opioids play a braking role by inhibiting the neurons from which they are released. Opioid peptides are also present in inhibitory motor neurons, where their role is less certain. Nevertheless, as the nerve endings of inhibitory and excitatory neurons run in the same bundles, opioids released from inhibitory neurons may inhibit the release of excitatory transmitters from excitatory motor neurons. The role of opioid peptides in interneurons is likely to be similar. This suggests a widespread phenomenon in which transmission involves autoregulatory mechanisms that limit excitability during sustained or excessive activation. The action of opioid peptides is mediated by all three known opioid receptors: the mu, kappa, and delta receptors. Both tolerance to and dependence on opiates have been demonstrated in enteric neurons, leading to significant interest by neuropharmacologists on the cellular bases of drug addiction.

Neuropeptide Y (NPY) and galanin are also contained in some interneurons and inhibitory motor neurons, where they probably act as 'brakes,' similar to opioid peptides, rather than as transmitters in their own right. NPY and peptide YY (PYY) are structurally related peptides that mediate inhibitory actions on gastrointestinal motility, secretion, and blood flow. Several receptor subtypes have been identified and the Y1, Y2, Y4/PP1, Y5, and Y5/PP2/Y2b receptors have been cloned. The selective Y1 receptor antagonist BIBP 3226 augments ascending reflex contractions, suggesting that endogenous NPY is co-released to autoregulate excitatory transmission. Galanin's effects are mediated by three distinct G-protein-coupled receptors, (galanin receptor 1 (GalR1), GalR2, and GalR3), which activate different intracellular signaling pathways. All three Gal receptor mRNAs have been detected in the gut. Galanin inhibits transmitter release from myenteric neurons through inhibition of voltage-dependent Ca^{2+} channels via a $G_{(i/o)}$-coupled GalR. Evidence for a physiological role of Gal is still lacking, as receptor antagonists do not affect peristalsis either in normal conditions or when efficiency is reduced by partial nicotinic transmission blockade with hexamethonium.

Similar to NPY and galanin, somatostatin is likely to act by inhibiting neural activity either presynaptically or postsynaptically. It has been localized in some descending cholinergic neurons as well as in secretomotor pathways. An excellent example of the functional relevance of chemical coding is the differential expression of NPY in postganglionic sympathetic vasoconstrictor neurons to the intestine. Somatostatin is present in the sympathetic neurons that inhibit secretion, through actions on submucosal secretomotor neurons. In contrast, the sympathetic neurons that inhibit motility by acting on myenteric neurons contain neither NPY nor somatostatin. These three classes of sympathetic neurons are activated independently by physiological stimuli.

Although CGRP is widely distributed in several classes of enteric neurons, its role in these neurons is unclear. However, CGRP is also a sensory peptide that is released, together with tachykinins, from the collaterals of extrinsic spinal sensory neurons, and its actions on blood vessels, on muscle, and on enteric neurons are well established. Other peptides present in enteric interneurons and motor neurons have been shown to be able to excite other enteric neurons. These include CCK, gastrin-releasing peptide (GRP), corticotropin-releasing factor (CRF), neurotensin, neuromedins, ghrelin, endothelins, and atrial natriuretic factor. CCK antagonists reduce slow excitatory synaptic potentials in myenteric neurons, suggesting that neurally released CCK is involved in synaptic transmission in some enteric pathways. However, its role in physiological conditions remains to be established. GRP is a 27-amino-acid peptide and is closely related to bombesin, sharing all but one of the last ten amino acids at the C-terminal end. Endogenous GRP is released during motor activity, and antagonists to the bombesin receptor (BB_2) inhibit propulsion of artificial fecal pellets through isolated segments of guinea pig distal colon.

None of the other peptides have been shown directly to mediate synaptic transmission and thus their role remains obscure. The more recently discovered peptide, cocaine- and amphetamine-regulated transcript peptide (CART), has been shown to be present in some enteric motor neurons. However, this peptide has not been shown to have a detectable role, apart from a possible modulatory effect on NO transmission. Similarly, the more recently discovered peptides, ghrelin and orexins (orexins

A and B), are present in some enteric neurons and are capable of stimulating motor neurons, interneurons, and secretomotor neurons, but their role remains to be determined. A hint that orexin may serve as an excitatory transmitter in ascending excitatory reflexes comes from a study in which antagonists to the orexin receptors reduced ascending reflex contractions in the mouse small intestine.

Changes in Peptide Levels and Their Receptors

Measurements of neuropeptide transmitters and their receptors have accompanied studies of their localization. Radioimmunoassay (RIA) and enzyme-linked immunoassy (ELISA) tests have been widely used to quantify peptides in the intestine, largely replacing the quantitative bioassays used in earlier times. Immunoblots have been used to determine protein levels in tissues, and expression of messenger RNA indicates the potential production of neuropeptides or their receptors. Messenger RNA can be used for cellular localization, when detected with *in situ* hybridization. Messenger RNA for neuropeptides and their precursors and receptors can be assessed by real-time quantitative reverse transcription–polymerase chain reaction (qRT-PCR).

Using such methods (often with immunohistochemical methods), the changes in tissue contents of precursors, peptides, and their receptors have been explored in a range of physiopathological conditions. Changes in gene expression of neuropeptide precursors or receptors are taken as indications of up- or downregulation – as either adaptive or maladaptive responses to the disease state. A major problem with such studies is that it is not clear if changes are a primary cause of the correlated symptom or if they are an effect, or whether they are the result of plastic changes of tissues. For example, inflammation of the human ileum results in changes in substance P and NK-1 expression, even at distant sites in the body. Whether this contributes to the symptoms or is an adaptive response to minimize damage is not entirely clear. What is becoming apparent is that the chemical coding of enteric neurons can be readily modified in physiopathological conditions, with neuropeptides likely to be primarily or secondarily involved in plastic adaptive changes.

New Advances

The effects of neuropeptides on less well-studied functions, such as modulation of gene expression, cell proliferation, cell migration, differentiation, and (generically) morphogenesis and maintenance of tissue morphology, are all likely to become more important in future studies. Neuropeptides are also likely to play roles in wound healing, antiapoptosis, and responses to injury and inflammation, and, in ontogenetic functions, on proliferation/differentiation from early stages.

In disease states, such as inflammatory bowel disease, inhibition of myocyte proliferation by VIP and PACAP may serve to control smooth muscle hyperplasia. CART may be neuroprotective, playing a role in the survival and maintenance of enteric neurons. Undoubtedly, systematic analysis of plasticity in neuropeptides and their receptors will be enhanced by the application of microarray techniques and targeted molecular approaches. The study of transgenic animals and knockdown techniques, using RNA interference or synthetic oligonucleotides, also has enormous potential to clarify the roles of neuropeptides in gastrointestinal function under normal or abnormal conditions. We can also foresee the discovery of new peptides, possibly new families, and certainly the identification of new receptors. A large number of 'orphan' G-protein-coupled receptors exist: these comprise a large class of receptors with unknown cognate ligands. Finding the known neuropeptides that may act on them, or identifying novel neuropeptides that fulfill this role, will be a productive endeavor for years to come. There is no shortage of intestinal functions and malfunctions that may involve subtle roles of old and new enteric neuropeptides. The challenge will remain how to match the increasing pharmacopoeia of peptides expressed by a finite population of enteric neurons with their range of highly subtle roles and functions.

The wealth of neuropeptides in enteric neurons is still puzzling, three decades after they were first described. For most of them, there is currently little indication that they play much more than a minor, secondary role. Yet evolutionary theory tells us that the preservation of such molecular mechanisms is likely to indicate that they play a significant role in the organism's life. The experimental conditions under which they have been studied so far may not simulate adequately the complex range of environmental conditions in which specific peptides are likely to play their important evolutionary role. It remains for the investigators to use their inventiveness to identify the physiological conditions under which this can be demonstrated.

Dale's Principle versus the Concept of Coexistence: Implications for Epilepsy

The pathophysiology of epilepsy is typically viewed as the shift in the balance between the inhibitory (γ-aminobutyric acid (GABA)) and the excitatory (glutamate) neurotransmission, in favor of the latter. This shift occurs due to both selective loss of inhibitory GABA-ergic neurons after precipitating epileptogenic insults (e.g., status epilepticus, stroke, and traumatic brain injury) and the reorganization of neuronal circuits that favor hypersynchrony of neuronal populations (e.g., aberrant connections formed by the axons of dentate granule cells of the dentate gyrus, known as mossy fiber sprouting). Deficit in GABA-mediated signaling and augmentation of glutamatergic transmission that have been documented in many (although not all) types of epilepsy represent the basis for the pharmacotherapy of the disease.

The glutamate–GABA hypothesis of epilepsy is based on Dale's principle, the assumption that the neuropharmacological profile of every single neuron is defined by certain single neurotransmitter. However, Dale's principle has been proven wrong, so it has become obvious that the neuropharmacological basis of epilepsy is far more complex and multifaceted.

In contrast to Dale's principle, the concept of coexistence postulates that individual neurons produce, store, and release more than one messenger molecule. Indeed, a diverse group of biologically active substances has been shown to coexist with classic neurotransmitters in the same neuron and to regulate many aspects of neuronal functioning. Originally, the functional role of these substances was not clear; hence, in order to emphasize their putatively secondary, supporting role they were named neuromodulators. Today, however, the difference between the two classes of neuronal messengers is merely semantic; it has been well established that many neuromodulators are as important in shaping neuronal activity and in defining the biochemical profile of neurons and neuronal networks as classic neurotransmitters and, in fact, often play primary, rather than secondary, role in the pathophysiology of brain diseases.

Neuromodulator neuropeptides constitute a large and diverse group. Along with classic neurotransmitters, neuropeptides have been implicated in the mechanisms of many brain disorders, including epilepsy.

The basic properties of neuropeptides make them particularly important players in the mechanisms of epilepsy. As established during early stages of peptide research, neuropeptide release from neurons is activity dependent; particularly, neuropeptides, in contrast to classic transmitters, are released only at high frequencies of neuronal firing. Because on single-neuron-level epilepsy is characterized by an abnormally high firing rate, it is conceivable that neuropeptide release occurs in epileptic, rather than in normal, neurons. This assumption, if true, has several important ramifications. Seizure-induced increase in neuropeptide release might contribute both to the further progression and to the arrest of ongoing seizure activity; that is, it may represent either a maladaptive or an adaptive component of epileptic process, depending on the peptide involved. This, in turn, suggests that neuropeptide receptors may represent targets for antiepileptic therapy in addition to or in lieu of targeting classic neurotransmitters.

Temporal Lobe Epilepsy

Epilepsy is not a single disease but rather is a diverse group of diseases, each of which has distinct etiology, pathophysiology, and clinical characteristics. Temporal lobe epilepsy (TLE), which is primarily associated with hippocampal pathology, is one of the most commonly occurring forms of the disease. TLE bears several features that make it a particularly important object of epilepsy research. TLE develops after a variety of precipitating insults, such as status epilepticus, traumatic brain injury, infection, prolonged febrile seizures in the childhood, and stroke; it is not linked to any definite genetic trait and thus might affect practically anyone. Most important, TLE is frequently refractory, that is, resistant to currently available antiepileptic drugs; drug resistance represents a major challenge in managing the disease in at least one-third of patients.

Along with classic neurotransmitters, the hippocampus, which represents the neuroanatomical and neurophysiological substrates of TLE, expresses multiple peptides and peptide receptors. To date, a significant body of evidence has been accumulated to prove that peptidergic modulation represents both an important mechanism of TLE and a promising target for the development of novel antiepileptic drugs. Although both clinical and experimental studies have implicated neuropeptides in the mechanisms of

several forms of epilepsy, this article focuses on peptidergic modulation of TLE. On the one hand, basic principles of the regulation of limbic seizures by neuropeptides are applicable to other seizure types; on the other hand, the hippocampus, due to its anatomical organization, neurochemical profile, and a variety of neurodegenerative and neuronal plastic changes that mark epileptic process, represents a convenient model for examining the role of neuropeptides in the pathophysiology of the disease.

Most of the data on the role of neuropeptides in TLE comes from experimental studies that employed animal models. Among experimental models of TLE (also referred to as limbic epilepsy), two have been most widely used. Poststatus epilepticus chronic epilepsy closely resembles the evolution of human TLE, starting with precipitating insult (status epilepticus induced by chemical convulsants or electrical stimulation of the brain); followed by the silent period, which is characterized by neuronal degeneration and synaptic reorganization; and finishing with epilepsy *per se*, that is the occurrence of spontaneous recurrent seizures. Kindling is another model of limbic epilepsy which is characterized by the progressive development of seizures in response to repeatedly applied initially subconvulsive epileptogenic stimulus (e.g., electrical stimulation of the brain). In contrast to status epilepticus, neuronal degeneration is not a major factor in kindling process; instead, the chronic remodeling of neuronal circuits plays a primary role. The two models therefore allow us to focus on different mechanisms that underlie epileptic process, with an emphasis on neurodegeneration and neuronal plasticity, respectively.

Several Lines of Evidence Implicate Neuropeptides in the Mechanisms of Epilepsy

Expression of Peptides and Their Receptors Are Altered in Epileptic Brain

Immunohistochemistry, Western blot, *in situ* hybridization, polymerase chain reaction, and ligand binding assays revealed both the increase and the reduction of neuropeptide and/or peptide receptor expression in epileptic hippocampus. Increased expression was reported for enkephalins, orphanin FQ (nociceptin), neuropeptide Y, substance P, and neurokinin B; the expression of dynorphin and galanin was reduced. Changes in somatostatin depended on the epilepsy model used. Thus, somatostatin expression was elevated in the hippocampus of kindled animals, whereas status epilepticus-induced epilepsy led to the loss of somatostatin-containing neurons (which is also the case in human TLE). In addition to a mere increase or reduction of peptide expression, seizures can lead to qualitative changes; for example, status epilepticus induced *de novo* expression of neuropeptide Y in the inhibitory interneurons of the hippocampus and of substance P in all hippocampal subfields, that is, in neuronal populations that normally contain neither of these peptides.

Neuropeptide receptors also undergo plastic changes in epileptic brain. For example, status epilepticus increased the expression of μ-opioid receptors and Y2 receptors of neuropeptide Y; it also reduced the expression of orphanin FQ receptors, galanin type 2 receptors, Y1 receptors of neuropeptide Y, and somatostatin receptors sst2, 3, and 4.

The observed changes in peptide and peptide receptor expression are difficult to interpret on their own. Do they represent merely surrogate markers of epilepsy, or do they play certain role in epileptic process? If the latter is true, do these changes promote or counteract seizures?

Exogenously Administered Neuropeptides Modify Seizures

The answers to these questions come, in part, from experiments that examined how the exogenous administration of neuropeptide receptor ligands (both agonists and antagonists) modify seizures.

Anticonvulsant activity, both in *in vivo* (status epilepticus, kindling) and *in vitro* models of epilepsy, was shown for agonists of κ-opioid receptors (dynorphin), galanin type 1 and 2 receptors (galanin (1–29), galanin(2–11), and M617), orphanin FQ, neuropeptide Y receptors Y2 ([ahx5–24]NPY) and Y5 (Ala-Aib-NPY), somatostatin sst2 (octreotide and seglitide), antagonists of neurokinin 1 receptor (spantide II and RP 67,580), and the blocker of receptor Y1 BIBP3226. At the same time, κ-antagonist norbinaltorphimine and galanin antagonists chimeric peptides M35 and M40 facilitated seizures. Further, agonists of SST4 (L-803087) μ-(enkephalins) and neurokinin 3 (neurokinin B) receptors exerted proconvulsant effects. The agonist of neurokinin 1 receptors, substance P, exacerbated status epilepticus *in vivo*, but was shown to have anticonvulsant effect in an *in vitro* seizure model.

Although the exogenous administration of neuropeptides can provide certain answers about their role in seizures, such an approach has its drawbacks. Particularly, it is not known what final concentration of the peptide reaches the receptor; the amounts of peptides used are high compared to their endogenous concentrations and, thus, may not relevantly reproduce their physiological effects. At the same time,

saturating amounts of peptide receptor antagonists can hardly be achieved. Progress in molecular biology and the related introduction of transgenic animals into the routine of research laboratories has helped to overcome some of these and other possible pitfalls.

Animals with Altered Peptide/Peptide Receptor Expression Have Altered Seizure Phenotypes

Enhanced susceptibility to and increased severity of seizure responses have been reported for neuropeptide Y knockout mice and for the animals lacking the neuropeptideY receptor Y5. Mice lacking somatostatin exhibited exacerbated seizure responses; however, sst2 receptor knockout mice showed enhanced seizure resistance. The elimination of the preprotachykinin A gene, which encodes both substance P and neurokinin A, mitigated both status epilepticus-associated seizures and hippocampal neuronal injury. In contrast, both seizures (status epilepticus and kindling) and neuronal injury (status epilepticus) were exacerbated in galanin knockout and in galanin receptor type 1 and 2 knockout mice; at the same time, overexpression of galanin under both β-hydroxylase and platelet-derived growth factor B promoters decreased the severity of kindled- and status epilepticus-induced convulsions. Orphanin FQ knockout animals showed increased resistance to seizures, despite the fact that exogenously administered orphanin FQ was anticonvulsant.

The use of animals with peptide or peptide receptor mutations has its limitations as well. For example, the studies employ mice, but the patterns of human TLE are better reproduced in rats; the approach cannot be applied to all peptides because functional deletion of some of them might be lethal. Furthermore, a high degree of neuronal plasticity might result in the compensatory changes (e.g., overexpression of receptor sst2 in somatostatin knockout mice), which in turn may mask the effects of the peptide or peptide receptor in question.

Other Evidence

Other approaches have been employed to study the role of neuropeptides in epilepsy. For example, chronic adeno-associated virus vector overexpression of both neuropeptide Y and galanin in the hippocampus inhibited limbic seizures. Knockdown of galanin receptors 1 and 2 using peptide nucleic acid antisense targeting respective RNA exacerbated status epilepticus-associated seizures and neuronal injury.

Clinical Data

Studies in TLE patients documented polymorphism of prepro-dynorphin gene; hippocampal overexpression of substance P, dynorphin, and enkephalins; and the loss of somatostatin-positive neurons.

Table 1 represents a compilation of data on the role of several neuropeptides in epilepsy based on alterations in peptide and/or peptide receptor expression; the effects of exogenously administered ligands; and seizure phenotype in mutant mice.

Other Neuropeptides

Regulation of seizures is not limited to the neuropeptides listed in Table 1 and discussed above. Virtually every single neuropeptide known to date has been examined with regards to its role in epilepsy. These peptides include thyrotropin-releasing hormone, cholecystokinin, corticotropin-releasing factor, bombesin, δ-sleep-inducing peptide, neurotensin, kyotorphin, atrial natriuretic peptide, angiotensin, and vasopressin, although in many cases reports on their effects in epilepsy lack systematic approach and mechanistic studies.

Seizure-Induced Neuropeptide Plasticity: Maladaptive and Adaptive Changes in Epilepsy

For obvious reasons, research reports generally focus on the role of a single peptide in epilepsy; however, as we see from the data presented so far, seizures lead to multiple modifications in peptide and peptide receptor expression, which occur both simultaneously and sequentially. A synthesis of observations accumulated from experimental studies allows us to define a broader role of peptidergic modulation of epileptic process. Based on the pharmacological effects and seizure phenotype in mutant animals, peptides can be divided in two groups: anticonvulsant, that is, those that counteract epilepsy, and proconvulsant, that is, those that facilitate seizures (it should be emphasized that such a division is not completely accurate, keeping in mind that in certain cases the same peptide may exhibit opposite effects on seizures in different models and that the same peptide acting on different receptor subtypes may have the opposite effects). Therefore, some changes in the peptide and/or peptide receptors expression observed in epileptic brain can be interpreted as adaptive, that is, those that counteract seizures and that include the seizure-induced overexpression of anticonvulsant peptides or the downregulation of proconvulsant peptides. At the same time, other alterations are apparently maladaptive because they favor seizure progression; the latter include the downregulation of anticonvulsant peptides or overexpression of proconvulsant peptides (Figure 1). When applied to

Table 1 Role and possible mechanisms of seizure modulation by neuropeptides

Peptide	*Changes in peptide expression (hippocampus)*	*Changes in peptide receptor expression (hippocampus)*	*Role in epilepsy based on the effects of peptide receptor ligands*	*Seizure phenotype in mutant mice*	*Mechanism of action*
Dynorphin	Decrease (status epilepticus; kindling)	No data available	Anticonvulsant (kappa)	No data available	G-protein-coupled inward rectifier K^+ channels (GIRK) – activation; Sub-threshold voltage-gated K^+ channels (KCNQ2/KCNQ3) – activation
Enkephalins	Increase (poststatus epilepticus; chronic epilepsy)	Increase (Mu-opioid receptors, poststatus epilepticus)	Proconvulsant	No data available	Ca^{2+} influx – facilitation KCNQ2/KCNQ3 channels – inhibition (through delta receptor) GIRK – activation
Orphanin FQ	Increase (kindling; status epilepticus)	Decrease (status epilepticus)	Anticonvulsant (0 Mg^{2+} in hippocampal slices; kindling)	Increased resistance (peptide knockout, kindling; status epilepticus)	KCNQ2/KCNQ3 channels – activation
Galanin	Decrease (poststatus epilepticus)	No change (GalR1, poststatus epilepticus)	Anticonvulsant (GalR1/Gal2)	Increased susceptibility (peptide knockout); increased resistance (peptide overexpression)	ATP-sensitive K^+ channels (KATP) – activation
		Decrease (GalR2, poststatus epilepticus)	Proconvulsant (GalR2)	Spontaneous seizures (Galanin receptor 1 knockout); increased susceptibility (galanin receptor 1, galanin receptor 2 knockouts)	GIRK – activation
Neuropeptide Y	Increase (kindling; poststatus epilepticus; chronic epilepsy); ectopic expression	Increase (Y2, poststatus epilepticus and kindling, TLE)	Anticonvulsant (Y2; Y5)	Increased susceptibility (peptide knockout)	GIRK – activation
		Decrease (Y1, poststatus epilepticus and kindling)	Proconvulsant (Y1)	Increased susceptibility (Y5 receptor knockout)	
Somatostatin	Increase (kindling)	Decrease (SST2, kindling; SST3, SST4, poststatus epilepticus)	Anticonvulsant-SST2 (rats)	Increased susceptibility (somatostatin knockout, SST2 knockout, kindling, status epilepticus);	KCNQ2/KCNQ3 channels – activation
	Reduced release; loss of SOM interneurons (poststatus epilepticus, human TLE)		Proconvulsant-SST4 (mice)	Increased resistance (SST2 receptor knockout, status epilepticus in mice)	
Substance P	Increase (poststatus epilepticus)	No data available	Proconvulsant (status epilepticus);	Increased resistance (pre-protachykinin knockout	Facilitation of NMDA-mediated transmission
			Anticonvulsant (kindling; entorhinal cortex *in vitro*)		Facilitation of GABA-mediated transmission KCNQ2/KCNQ3 – inhibition
Neurokinin B	Increase (kindling; status epilepticus)	No data available	Proconvulsant	No data available	GABA-A receptors internalization

Figure 1 The role of seizure-induced plasticity of neuropeptides in seizure regulation. Based on the effects of exogenously administered neuropeptides and/or changes in seizure susceptibility in neuropeptide/peptide receptor mutant mice, neuropeptides can be described as either anticonvulsant or proconvulsant. Hence, seizures-induced alterations in the expression of certain neuropeptides and/or their receptors can be interpreted as adaptive, that is those that counteract seizure activity (e.g., upregulation of anticonvulsant and downregulation of proconvulsant peptides), or maladaptive, that is those that favor seizure progression (e.g., downregulation of anticonvulsant and upregulation of proconvulsant peptides). Examples of adaptive and maladaptive changes for selected peptides are provided in italics; more information is given in Table 1.

neuropeptides, the concept of adaptive and maladaptive changes might have important clinical implications, as it would become a central principle for the development of peptide-based anticonvulsant therapies.

Same Neuropeptide Can Be Both Anticonvulsant and Proconvulsant

Apparently controversial results obtained in various experimental studies revealed that the same peptide may both inhibit and facilitate seizures. Although there are many reasons for such opposite effects, the following three scenarios are most important in evaluating the overall effects of neuropeptide of interest.

In the Same Brain Area, the Neuropeptide Acts at Different Receptor Subtypes

The effect of neuropeptide Y in the hippocampus exemplifies this scenario (Figure 2). In the hippocampus, neuropeptide Y is expressed in a subset of inhibitory interneurons, where it coexists with the classic neurotransmitter GABA. Three types of receptors for neuropeptide Y are expressed in the hippocampus: Y5, Y2, and Y1. Y5 receptor is located on the axons projecting from the dentate granule cells into the CA3 area (mossy fibers); the activation of Y5 by neuropeptide Y inhibits the propagation of epileptic discharge from the dentate gyrus further into the hippocampus and beyond. Y2 receptors are expressed on excitatory interneurons, mossy cells, that are driven by and project back to dentate granule cells, thus providing feedback excitation; the activation of Y2 disrupts reverberation of the excitation between the dentate granule and mossy cells. Y1 receptors are located on the neuropeptide Y-containing interneurons, which are also driven by and project back to the dentate granule cells, thus providing feedback inhibition; the activation of Y1 by neuropeptide Y released from the same neuron inhibits further neuropeptide release.

The differences in the localization of neuropeptide Y receptors explain why both Y5 and Y2 agonists acted as anticonvulsant (through the interference with feed-forward and feedback excitation, respectively), whereas the Y1 agonist facilitated seizures (attenuation of the effects of the peptide on receptors Y5 and Y2 due to the inhibition of peptide release). Furthermore, differential localization of receptors Y5 and Y2 implies that the correspondent agonists will inhibit epileptic activity through different modes – whereas the former primarily interfere with the seizure spread, the latter are particularly important in suppressing seizure activity within the epileptic focus.

Figure 2 Regulation of hippocampal excitability and seizures by neuropeptide Y (NPY) and its receptors. Seizure discharge originating from the entorhinal cortex (EC) spreads through perforant path (PP) to the dentate granule cell of the dentate gyrus (GC). Excitation of GC involves three pathways: (1) feed-forward excitation through mossy fibers (MF) to the CA3 pyramidal cells and further through Schaffer collaterals (SC) to the CA1 pyramidal cells; (2) feedback inhibition through the excitation of GABAergic inhibitory interneurons (IN), including those that contain NPY; and (3) feedback excitation through glutamatergic excitatory interneurons mossy cells (MC). In addition to the direct projection of granule cells, inhibitory interneurons receive positive drive from mossy cells (4). Positive drive to NPY-positive interneurons is accompanied by the release of NPY that acts on three types of receptors: Y5 receptors (5), located on mossy fibers (the activation of Y5 interferes with the spread of seizure activity from granule cells into the CA3); Y2 receptors (6), expressed on mossy cells (the activation of Y2 blocks reverberation of seizure discharge between mossy cells and granule cells); and Y1 autoreceptors (7), located on NPY-positive interneurons (the activation of Y1 inhibits NPY release).

In Different Brain Areas, Activation of the Same Receptor Subtype May Have Opposite Effects on Seizures

In this scenario, galanin acting at galanin receptor type 1 (GalR1) may both inhibit and facilitate seizures of hippocampal origin (Figure 3). The activation of GalR1 in the hippocampus, achieved by the local infusion of GalR1 agonist, inhibits the release of the major excitatory neurotransmitter glutamate and exerts the end anticonvulsant effect. At the same time, local activation of GalR1 in the dorsal raphe inhibits serotonin release and blocks serotonergic projection from this area into the hippocampus. Because hippocampal serotonin itself inhibits seizures through the activation of postsynaptic receptors 5HT1A, which in turn interferes with glutamate release, the end effect of GalR1 agonist applied locally into the dorsal raphe is to facilitates seizure response.

Figure 3 Regulation of limbic seizures by galanin type 1 receptors (GalR1s). Activation of GalR1 in the hippocampus inhibits seizures through presynaptic inhibition of glutamate (Glu) release from principal hippocampal cells (1). Another mechanism that counteracts seizures is an ascending serotonergic pathway originating from the dorsal raphe (DR) and projecting into the hippocampus (HIPP) (2); it inhibits glutamate release through hippocampal 5HT1A receptors. The activation of GalR1s in the DR (3) inhibits serotonin (5-HT) release and facilitates seizures through attenuating the serotonergic inhibition of excitatory transmission in the hippocampus.

Same Peptide Acting at the Same Receptor Subtype Has Different Species-Dependent Effects

In rats, somatostatin has been shown to inhibit seizures through receptor sst2. At the same time, sst2 agonists failed to modify seizures in wild-type mice. Moreover, sst2 knockout mice exhibited a surprising attenuation of seizure severity compared to wild-type animals. This phenomenon has been explained by the fact that sst4 receptors, which by themselves facilitate seizures, are coupled to sst2; thus, in sst2 knockout mice the loss of function of the proconvulsant somatostatin receptor subtype leads to the reduced seizure susceptibility.

Mechanisms of Seizure Modulation by Neuropeptides

Neuropeptide receptors belong to the family of G-protein-coupled receptors (GPCRs), with a variety of downstream mechanisms; some of these mechanisms play an important role in epilepsy and thus represent possible targets for both the pro- and anticonvulsant effects of neuropeptides (Table 1).

G-Protein-Coupled Inward Rectifier K^+ Channels

G-protein-coupled inward rectifier K^+ channels (GIRKs) represent a target for the anticonvulsant effects of such neuropeptides as dynorphin, galanin, and neuropeptide Y. The activation (opening) of GIRKs depends on the coupling of GPCRs to $G_{\beta\gamma?}$ subunit of G_i-protein. Depending on whether the GIRK is pre- or postsynaptic, the resulting inwardly rectifying K^+ current interferes with either neurotransmitter release on the presynaptic level or with the postsynaptic effects of transmitter through neuronal hyperpolarization.

Proconvulsant effects of enkephalins, which also have been shown to activate GIRKs, might be explained by the hyperpolarization of inhibitory interneurons in the hippocampus and with the ultimate interference with the release of GABA (a phenomenon known as the inhibition of inhibition).

Adenosine Triphosphate-Sensitive K^+ Channels

Adenosine triphosphate-sensitive K^+ channels (KATPs) are another type of inward potassium rectifier and represent an apparent target for galanin. The function of KATPs is mainly controlled by the metabolic status of the neurons, in which a decrease of the adenosine triphosphate (ATP) : adenosine diphosphate (ADP) ratio leads to the channel opening. In addition, the opening of KATPs occurs through an active G_α subunit of G_i protein and results in inward rectifying K^+ current, which interferes with both pre- and postsynaptic aspects of neurotransmission. Thus, the end effects of KATPs activation is similar to that of GIRKs.

Subthreshold Voltage-Gated K^+ Channels

The subthreshold voltage-gated K^+ channels KCNQ2 and KCNQ3represent a substrate for a noninactivating, slowly deactivating, subthreshold current known as M-current and are activated in the presence of such neuropeptides as orphanin FQ, somatostatin, and dynorphin. In contrast, it has been suggested that substance P and δ-opioid receptor agonists inhibit M-current. M-currents play a critical role in controlling neuronal excitability and have been implicated in the mechanisms of epilepsy. The novel, clinically available antiepileptic drug retigabine inhibits seizures through enhancing KCNQ2/KCNQ3 currents.

Other Mechanisms

In addition to the mechanisms discussed so far, facilitation of seizures by enkephalins may occur through the stimulation of Ca^{2+} influx and the consequent increase of neuronal excitability. Substance P and neurokinin B exhibit a unique effect on classic neurotransmission – they stimulate trafficking of *N*-methyl-D-aspartate (NMDA) receptor from inside the cell into the membrane and thus facilitate excitatory neurotransmission via the increase in the availability of target receptor for glutamate (at the same time, electrophysiological data found facilitation of GABA-ergic transmission by substance P, which may explain its anticonvulsant effect *in vitro*).

Can Neuropeptides Be Turned into Antiepileptic Drugs?

The ability of neuropeptides to modulate seizures raises the question of whether peptide receptor ligands can be used as antiepileptic drugs. Physical-chemical and biological properties of native neuropeptides determine their low bioavailability and thus prohibit their use in clinical practice. Such properties include digestion in the gut, poor permeability through the blood–brain barrier, and a very short half-life due to quick inactivation by peptidases. Furthermore, reported opposite effects on seizures exhibited by the same peptide acting on different receptor subtypes (e.g., neuropeptide Y acting at Y1 vs. Y5 and Y2) implies that a peptide-based antiepileptic drug may have to possess receptor-subtype selectivity; at the same time, native peptides do not discriminate among their receptor subtypes.

We consider three approaches have been used to modify peptide receptor ligands to optimize their pharmacokinetic and pharmacodynamic properties: nonpeptide ligands, peptide modification, and alternative routes of delivery.

Nonpeptide Ligands for Peptide Receptors

This approach pursues three major goals: reducing the size of the active molecule and increasing its permeability through the blood–brain barrier, reducing biodegradation, and enhancing receptor subtype preference.

Several nonpeptide low-molecular-weight ligands of peptide receptors have been synthesized and examined for their anticonvulsant efficacy. Particularly, a

selective κ-opioid agonist U-69,593, mixed galanin type 1 and type 2 receptor agonist galnon, preferential galanin receptor type 1 agonist galmic, sst2 agonists BIM 23120 and L-779976Y1, and Y1 antagonist BIBP3226 exhibited anticonvulsant effects upon systemic administration under conditions of experimental seizure models. Ligands for other neuropeptides receptors are available and, based on the effects of native peptides, have antiepileptic potential (e.g., neurokinin 1 antagonist M869), but have not been yet studied for anticonvulsant efficacy.

Peptide Modification

Nonpeptide approaches worked well for some peptides, but it was not as successful for others. For example, currently available nonpeptide galanin agonists have only moderate affinity toward galanin receptors, compared to native peptide, and one of them (galnon) has interaction sites outside the peptide receptor. An alternative approach in developing peptide-based drugs consists of preserving peptide structure but modifying it in such a way as to enhance bioavailability. For example, the 8 amino acid synthetic peptide octreotide exhibits high affinity toward receptor sst2 and exerts potent anticonvulsant effects when given systemically.

Alternative Routes of Delivery

The ubiquity of neuropeptide targets both in the brain and in peripheral tissues and organs, such as the gut, heart, and pancreas, may lead to side effects. Thus, it represents a substantial challenge for using peptides as antiepileptic drugs.

The nasal route of delivery of neuropeptides has the potential to avoid peripheral side effects along with other important advantages, such as bypassing the peptide digestion in the gut and the liver first-pass effect. This approach has been applied to thyrotropin-releasing hormone (TRH) to inhibit experimentally induced convulsions.

Viral vector-mediated transduction and expression of anticonvulsant factors in select neuronal populations affords direct delivery and continuous production of anticonvulsant peptides in the epileptic brain. This strategy has been applied to neuropeptide Y and galanin in experimental epilepsy models.

Presently, peptide-based anticonvulsant therapy is at its early preclinical stage, although several peptide receptor ligands with proven or prospective anticonvulsant potential have been approved for clinical use, for example, the sst2 agonist octreotide for the therapy of certain hormone-secreting tumors and the substance P antagonist MK869 for treating chemotherapy-induced emesis.

There is a rich network of interrelated factors controlling feeding behavior and body weight. These include the status of energy stores and metabolic demand, the availability of diet and circulating nutrients, and the palatability of ingested foods. This network functions through a wide variety of neurochemical systems in the brain, which are either stimulatory or inhibitory in nature. Those that increase feeding and weight gain include the peptides neuropeptide Y (NPY), agouti-related protein (AgRP), melanin-concentrating hormone (MCH), galanin (GAL), orexins (ORX), and the opioids enkephalin (ENK) and dynorphin (DYN). Those that inhibit feeding are peptides such as proopiomelanocortin, cocaine-activated regulatory transcript, and corticotropin-releasing hormone, in addition to the monoamine serotonin. This article focuses on the seven peptides that increase feeding. It summarizes a large body of information related to the anatomical distribution of these peptide systems, the endocrine signals of energy abundance or insufficiency or diet and nutrient signals that control their activity, and the behavioral and physiological effects produced by peptide injections, antagonists, or mutations of the peptide and receptor genes (see Table 1). In addition to their considerable redundancy, these peptide systems show great diversity and specialization in their actions that allow them to maintain energy and nutrient homeostasis under a variety of physiological states and environmental conditions that occur over a lifetime.

Neuropeptide Y

NPY is expressed in neurons concentrated in the arcuate nucleus (ARC), which send their projections to different areas of the hypothalamus. These include the paraventricular nucleus (PVN) and perifornical area/lateral hypothalamus (PFLH), where NPY is believed to act through different receptor subtypes (Y1R, Y5R and possibly Y2R) to control energy homeostasis.

This peptide in the ARC and PVN is highly responsive to states of negative energy balance and increased metabolic demand. It is markedly stimulated by food deprivation and the adrenal steroid corticosterone (CORT), which is released in states of energy deficiency to maintain glucose availability. Both NPY and this glucocorticoid exhibit a strong circadian peak at the onset of the natural feeding period, when gluconeogenesis and glycogenolysis are elevated. The gut hormone ghrelin, also an indicator of energy insufficiency, rises before fasting or meal initiation and activates NPY neurons in the ARC. These positive relationships between NPY and both CORT and ghrelin contrast with this peptide's inverse relation with the adiposity-related hormones insulin and leptin, which provide a signal of energy abundance and have a potent inhibitory effect on NPY. These findings illustrate the homeostatic principle of negative feedback, whereby a rise in insulin or leptin and/or decline in CORT or ghrelin with food consumption and increased body weight suppresses anabolic peptides, like NPY, that promote further eating and weight gain.

In addition to these hormones, dietary nutrients as well as circulating and intracellular nutrients can affect endogenous NPY in the ARC and PVN. This peptide is consistently higher in subjects consuming a low-energy, carbohydrate-rich diet. Together with CORT, NPY peaks at the onset of the active feeding cycle or around the time of weaning, when carbohydrate is the strongly preferred macronutrient and energy stores are low. This relationship to carbohydrate intake confirms that NPY is positively linked to signals reflecting a deficiency of glucose availability or utilization. This is supported by evidence that NPY is increased after pharmacological blockade of glucose utilization and is inversely related to glucose levels, declining immediately after the ingestion or injection of glucose when circulating glucose is high and rising subsequently as glucose levels drop toward or below the baseline and CORT rises.

Injection studies demonstrate that NPY functions in states of negative energy balance to stimulate the ingestion and metabolism of carbohydrate to maintain glucose homeostasis and promote fat synthesis. Exogenous NPY has a potent, stimulatory effect on feeding, with a preferential increase in the ingestion of carbohydrate or sucrose, and it stimulates body fat accrual. Its endocrine and metabolic effects include a rise in circulating levels of both CORT and insulin, which together promote *de novo* lipogenesis, and a reduction in energy expenditure, sympathetic nervous system activity, and fat utilization in favor of carbohydrate metabolism. Thus, by suppressing inhibitory postingestive feedback, NPY both replenishes carbohydrate stores and gears excess carbohydrate towards fat storage.

Mice models with a deletion of the *npy* or receptor genes show little change or even an increase in daily

Table 1 Summary of peptides

Orexigenic peptides	*Responsive to negative energy balance?*	*Responsive to dietary fat?*	*Primary functions*
Neuropeptide Y	Yes	No	Stimulate food intake during periods of negative energy balance and increased metabolic demand
Agouti-related protein	Yes	No	Reduce signaling through catabolic pathways during periods of negative energy balance, thereby stimulating food intake
Melanin-concentrating hormone	Yes	Yes	Maximize intake of energy-rich foods and storage of excess calories as fat
Galanin	No	Yes	Restore carbohydrate balance under conditions of excess dietary fat intake
Orexins	Yes	Yes	Coordinate motivated behaviors with sleep/wake cycle
Enkephalin Dynorphin	No	Yes	Stimulate intake of palatable, fat-rich diets

food consumption or body weight. However, closer examination of these genetic mutants reveals a phenotype consistent with the proposed function of NPY in states of negative energy balance. This phenotype includes a decrease in fasting-induced refeeding, diabetes-induced hyperphagia, weight gain in leptin-deficient mice, and utilization of carbohydrate relative to lipids. Further, transgenic mice with NPY overexpression exhibit an obese phenotype, specifically on a sucrose-loaded diet, which is accompanied by overeating, hyperglycemia, hyperinsulinemia, and increased NPY receptor expression.

In summary, these investigations demonstrate that NPY neurons in the ARC are stimulated under conditions of negative energy balance and increased metabolic demand. This peptide rises in response to changes in various hormones, including elevated levels of CORT and ghrelin and reduced levels of leptin and insulin, and it responds positively to signals related to a need for carbohydrate, decline in glucose levels or storage, or disturbance in glucose utilization. The anabolic functions of endogenous NPY are to promote food intake, replenish carbohydrate stores, reduce fat oxidation in favor of carbohydrate, and stimulate the utilization of excess glucose to promote *de novo* lipogenesis. These NPY effects involve reciprocal interactions with neural systems that inhibit feeding, such as the melanocortins in the ARC, corticotropin-releasing hormone in the PVN, and serotonin in the midbrain; and this peptide may be a downstream mediator of the feeding-stimulatory effects of orexigenic peptides, such as ORX and MCH.

Agouti-Related Protein

AgRP is expressed in the ARC in neurons that also produce NPY. It forms part of the central melanocortin system, which comprises α-melanocyte stimulating hormone, an agonist of both melanocortin receptor 3 (MC3-R) and receptor 4 (MC4-R), in addition to AgRP, an endogenous competitive antagonist of these receptors. Whereas AgRP cell bodies are restricted to the ARC, AgRP fibers project to multiple areas of the hypothalamus and brain, and all of these AgRP terminals contain NPY.

Studies indicate a close functional relationship between AgRP and NPY because the expression of these peptides is similarly modulated under various physiological conditions. This is evident in states of negative energy balance or increased energy demand, such as food deprivation or lactation, which have reduced leptin and insulin levels, increased ghrelin or CORT levels, and elevated AgRP together with NPY. Like NPY, AgRP shows a strong circadian rhythm, rising with CORT at the onset of the nocturnal feeding cycle, and it is suppressed under conditions of positive energy balance, when leptin and insulin levels are elevated and ghrelin levels are reduced. The activity of NPY/AgRP neurons is excited by orexigens, such as ghrelin and ORX, but decreased by leptin.

Dietary studies reveal further similarities between these two peptides. As described for NPY, AgRP gene expression is higher in rodents consuming a high-carbohydrate low-fat diet, and it decreases as the fat content of the diet increases. It peaks in rat pups at weaning and is associated with peak circulating CORT and a strong preference for dietary carbohydrate. Thus, AgRP is stimulated by low energy status and by periods of reduced fat consumption, such as the transition to weaning, when glucose, insulin, and leptin levels are falling.

As with NPY, AgRP has a potent stimulatory effect on food intake. Chronic administration of AgRP increases food intake and decreases metabolic rate, leading to increased body fat accrual. Both peptides appear to mediate the orexigenic effect of ghrelin and

suppress the hypothalamic–pituitary–thyroid axis. They are additive in their effects on feeding, suggesting that they represent redundant components of a parallel circuit.

A large number of genetic studies have been devoted to identifying the role of AgRP in physiological settings. Overexpression of the *Agrp* gene in transgenic mice produces hyperphagia and obesity. However, young AgRP-deficient mice, similar to NPY-deficient mice, are normophagic with normal body weight under *ad libitum* feeding conditions, indicating that these peptides do not function tonically when food is freely available. However, following brief food deprivation, AgRP knockout mice, like the NPY mutants, exhibit impaired reflexive hyperphagia. This supports the physiological data implicating AgRP in processes geared toward restoring energy homeostasis when food sources are low. Interestingly, as AgRP knockout mice age, they maintain a leaner body composition, in contrast to the progressive adiposity seen in aging wild-type mice, and this is associated with increased metabolic rate, possibly due to the increased thyroid hormone seen in these mice.

Taken together, this evidence demonstrates that AgRP in the ARC is similar to NPY in being stimulated by conditions of energy deficiency. Under these conditions, AgRP is required to stimulate hunger, reduce lipid oxidation in favor of carbohydrate, and, when food deprivation is prolonged, reduce locomotor activity and metabolic rate via inhibition of the hypothalamic–pituitary–thyroid axis in order to conserve energy. These anabolic effects are mediated, in part, via inhibitory projections to catabolic melanocortin cells in the ARC. These two parallel systems, AgRP and NPY, probably evolved to ensure the signaling of hunger during food scarcity and to enable the body to endure long periods of negative energy balance.

Melanin-Concentrating Hormone

MCH is an orexigenic peptide which acts via a specific receptor, MCHR1. This peptide is heavily expressed in the hypothalamus, predominantly in the PFLH and zona incerta but also in the ARC and ventromedial hypothalamus (VMH), suggesting a role in feeding and energy homeostasis. It is even more heavily expressed in areas of the forebrain which are involved in the rewarding aspects of motivated behaviors.

Studies of MCH provide support for this peptide's role in energy balance. Fasting, which reduces leptin, stimulates the expression of MCH, and although leptin injection suppresses MCH, this fasting-induced increase in MCH can be seen in leptin-deficient mice. Further, rats that become obese on a fat-rich diet and have markedly elevated leptin levels show no difference in MCH expression. This indicates that MCH is regulated by other hormonal factors, such as the glucocorticoid CORT and gonadal steroids.

There are limited data regarding the sensitivity of MCH neurons to circulating nutrients. The firing frequency of MCH neurons increases in response to rising concentrations of glucose. Also, MCH expression in the PFLH is stimulated by the administration of an inhibitor of fatty acid oxidation or fatty acid synthase. This evidence indicates that MCH responds to a deficiency in fat oxidation or fat synthesis.

Central administration of MCH stimulates food intake but also increases the consumption of alcohol and sucrose. Further, this peptide impacts metabolic processes that contribute to weight gain. It enhances the secretion of CORT and suppresses the release of thyroid stimulating hormone. Chronic administration of MCH or an MCHR1 agonist induces hyperphagia and increases body fat mass, particularly on a highly palatable diet, and these effects occur in association with reduced fatty acid oxidation and thermogenesis. Conversely, MCHR1 antagonists decrease body weight and adiposity, due to both a reduction in food intake and an increase in energy expenditure. Together, these findings indicate that MCH acts through metabolic as well as behavioral mechanisms to promote weight gain.

Genetic studies support a physiological role for MCH in energy homeostasis. Transgenic mice that overexpress MCH exhibit hyperphagia and obesity on a fat-rich diet. Targeted ablation of the MCH gene leads to a lean phenotype associated with hypophagia and an increased metabolic rate, and it attenuates the marked obesity of leptin-deficient mice through increased energy expenditure and locomotor activity, effects that become more apparent on a high-fat diet. Similarly, mice lacking functional MCHR1 gain less weight than wild-type littermates on a high-fat diet, due to an increase in locomotor activity that stimulates metabolic rate and thermogenesis. These mice become leaner despite a significant increase in food intake, suggesting that MCH plays a more prominent role in regulating energy expenditure and activity than feeding behavior.

Together, these results indicate that MCH has an important role in energy homeostasis. Whereas MCH responds to negative energy balance and is anatomically and functionally linked to NPY neurons in the ARC, this peptide can function independently of leptin and is unresponsive to nutrient-sensing signals indicative of reduced glucose metabolism. The evidence that the orexigenic effect of MCH is most prominent with palatable diets and that MCH neurons project to reward centers in the brain suggests that this peptide recognizes energy-rich foods and functions to maximize the intake of the energy source

and its storage as fat. These effects should allow the efficient storage of energy during periods of food excess and better equip animals for ensuing periods of food deprivation.

Galanin

GAL is expressed in a number of neuronal populations within the hypothalamus, including the PVN and PFLH, as well as ARC. These neurons, which send projections throughout the hypothalamus where the GAL receptor subtypes, GALR1 and GALR2, exist, are believed to have a role in feeding behavior and energy homeostasis. Investigations of endogenous GAL or GAL injection reveal marked differences between this peptide system and the orexigenic peptides, NPY and AgRP, already described.

In the different hypothalamic nuclei, GAL is found to be relatively unresponsive to signals related to energy deficiency, including food restriction, CORT, and the blockade of glucose oxidation. Further, leptin is relatively weak in its effects on endogenous GAL, with GAL expression in the PVN consistently elevated in obese rats on a high-fat diet. Also, GAL is particularly sensitive to the stimulatory effects of the gonadal steroids, which are increased by dietary fat. Thus, GAL in the PVN functions through distinct mechanisms and in different physiological states or conditions than NPY and AgRP in the ARC.

Endogenous GAL also responds very differently from NPY to manipulations of diet and nutrient metabolism. In the PVN but not the ARC, GAL in rats on pure macronutrient diets is positively related to the amount of fat but not carbohydrate consumed. It is stimulated by acute and chronic periods of high-fat diet consumption, and it peaks toward the middle of the natural feeding cycle, when fat is the preferred macronutrient. Also, it is strongly, positively related to circulating levels of triglycerides, in addition to measures of fat uptake and oxidation in muscle, and it is reduced by pharmacological blockade of fat oxidation, which suppresses fat intake. Thus, GAL, unlike NPY, appears to function specifically under dietary conditions rich in fat and respond to signals related to the metabolism of fat rather than carbohydrate.

The effects of GAL injection also differ from NPY, indicating that it functions under different conditions and physiological states. The GAL-induced feeding response is smaller in magnitude and shorter in duration, but it is stronger and more prolonged, leading to increased weight gain, specifically in animals that are on a mixed high-fat diet or that naturally prefer fat when given a choice of macronutrients. It is greatly reduced when fat is removed from the diet or after injection of the pentapeptide enterostatin and GAL antagonist, both of which reduce fat consumption. In some cases, GAL's physiological effects are diametrically opposite to those of NPY, including a suppression of insulin, CORT, and vasopressin release and an increase in gastric acid secretion. Also, GAL, unlike NPY, has no effect on respiratory quotient and increases the capacity of muscle to metabolize carbohydrate. Thus, when stimulated on a high-fat diet, GAL's primary function may be to restore carbohydrate balance, compensating for or reversing the diet-induced drop in carbohydrate metabolism while contributing to the hyperphagia that provides more dietary carbohydrate to replenish liver glycogen stores.

Mice with mutations of the *gal* gene or GAL receptor genes or that overexpress GAL are found to normally defend their food intake and body weight when fasted or fed *ad libitum* on a low-fat chow diet. Thus, in contrast to NPY, endogenous GAL is not a critical component in the metabolic response to starvation and has little function under dietary conditions low in fat and high in carbohydrate. There is evidence, however, to support the idea that GAL functions specifically under conditions when dietary fat is in excess. Repeated PVN injections of antisense oligonucleotides to GAL mRNA suppress fat consumption in association with a reduction in endogenous GAL, and the deletion of the *gal* gene causes a marked reduction in fat consumption. Further, GAL knockout mice exhibit increased sensitivity to the inhibitory effects of leptin on body weight, indicating that endogenous GAL plays a role in counteracting the actions of leptin as it rises on a fat-rich diet.

In summary, GAL-expressing neurons in the PVN have very different properties and functions from the other orexigenic peptides described so far. This peptide is relatively unresponsive to states of energy deficiency and conditions where food is scarce or rich in carbohydrate. In contrast, GAL functions in close relation to dietary fat, mediating specific functions that allow animals to adapt to these conditions of positive energy balance and abundant fat intake. Through behavioral and metabolic actions, it restores carbohydrate balance under conditions of excess dietary fat that compromise the utilization, storage, and intake of carbohydrate. To perform these functions, GAL may act through other peptide systems in the brain, including the opioid peptides, which show a similar relationship to dietary fat.

Orexins

The orexin peptides, ORX A and ORX B (also referred to as hypocretin 1 and 2), share 46% identity,

are coded by the same gene, and are localized in neurons of the PFLH. These ORX neurons project within the hypothalamus and throughout the brain, and the two ORX receptors, OX1R and OX2R, display similar widespread distribution patterns.

The ORX neurons are controlled by changes in circulating nutrients that link feeding behavior to arousal and physical activity. For example, ORX expression is stimulated by a high-fat diet, and this increase in ORX expression is positively related to levels of circulating triglycerides. Consistent with this relationship is the circadian rhythm of ORX peptides, which, like GAL, show peak levels several hours after onset of the feeding cycle, when rats exhibit a rise in their preference for dietary fat. This association between ORX neurons and circulating lipids suggests a possible contribution of this peptide system to the acute hyperphagia associated with consumption of a high-fat diet.

The ORX neurons are also controlled by changes in circulating glucose. They exhibit tonic spontaneous firing, which is inhibited by signals related to food ingestion and by physiological or experimentally induced increases in glucose, and they are stimulated when plasma glucose falls and food is withheld. Based on evidence linking the ORX peptides to the sleep–wake cycle, these findings led to the proposal that this peptide system is a key player in coupling nutrient homeostasis to states of consciousness.

Central administration of the ORX peptides, particularly ORX A, stimulates food intake. This peptide produces a stronger feeding response on a high-fat diet compared to a low-fat diet, supporting the idea that ORX contributes to the hyperphagia induced by a high-fat diet. The ORX peptide system is also implicated in the sleep–wake cycle and is thought to play a role in maintaining periods of wakefulness. Further, ORX A stimulates spontaneous physical activity independently of its effects on food intake. These effects of ORX substantiate the proposed role of this peptide system in regulating energy balance and suggest that a primary role for ORX may be synchronizing feeding and activity with the sleep–wake cycle.

Genetic studies support a role for the ORX peptides in energy balance. Orexin-deficient mice show hypophagia and inactivity compared to control littermates, which may contribute to their unexpected late-onset obesity, and they fail to exhibit the increase in arousal induced by food deprivation. Their phenotypes are similar to narcolepsy, a human sleep disorder. These findings support the idea that the obese phenotype in ORX-deficient mice reflects an underlying decrease in energy expenditure, due to reduced locomotor activity, and in foraging behaviors. They indicate that this peptide system regulates both food intake and physical activity, but in the absence of ORX, the effect on activity predominates. Thus, rather than arising from greater hunger *per se*, the feeding-stimulatory effect of ORX may be attributed to an increase in wakefulness and locomotor activity that is optimal for food-seeking behavior.

In conclusion, these results indicate that ORX neurons are highly responsive to changes in circulating nutrients. The ORX peptides sense negative energy balance, predominantly through a decrease in circulating glucose, and they act to stimulate feeding by increasing arousal and the motivation to seek food. They also sense positive energy balance induced by a high-fat diet and rise with circulating lipids, possibly contributing to the hyperphagia and activity-based energy expenditure associated with a fat-rich diet. Through their interactions with NPY/AgRP and melanocortin neurons in the ARC, the ORX peptides may provide a critical link between energy balance and brain mechanisms coordinating sleep–wakefulness and motivated behaviors.

Opioid Peptides

Opioid peptides have long been known to have a role in stimulating feeding behavior. This article focuses on the peptides ENK, which acts through μ and δ receptors, and DYN, which acts on κ receptors. These two peptides and their receptors are heavily expressed in the different hypothalamic nuclei and also in various forebrain structures, such as the nucleus accumbens (NAc), which have an important role in mediating the rewarding properties of food.

Similar to GAL, these opioid peptides are very different from NPY in their response to energy deficiency. In the ARC as well as NAc, ENK and DYN are either unaffected or reduced by food deprivation, and DYN in the ARC is actually stimulated by leptin. Whereas there are few studies of these opioids in relation to the adrenal and gonadal steroids, those that do exist show little effect of estradiol on DYN in the hypothalamus, in contrast to its potent stimulatory effect on GAL.

Palatability and sensory attributes of preferred foods that signal high energy density are particularly important in driving caloric consumption in excess of metabolic demand, thus promoting obesity. Opioid signaling in the brain is believed to control food intake, specifically through the modulation of neural processes related to palatability and hedonistic impact of energy-dense foods. Whereas the effects of sucrose drinking on the endogenous opioids and their receptors remain unclear, acute or chronic consumption of palatable,

fat-rich foods (compared to less palatable, low-fat foods) increases ENK and DYN in the hypothalamus, and this effect is strongest and most consistent in the PVN but opposite in the NAc. This occurs independently of the palatability and caloric density of the diet and is also seen after injection of a lipid emulsion, which bypasses the ingestion process and thus avoids stimuli related to palatability. These findings suggest that postingestive factors, such as circulating lipids, may be important in determining the expression level and functions of these peptides in the PVN. Consumption or injection of a fat-rich diet invariably produces a marked increase in circulating levels of triglycerides, and these lipids, in turn, are positively related to ENK and DYN and produce an increase in neuronal activity in the PVN, specifically in fat-responsive neurons that express ORX peptides.

Although there is little evidence supporting a role for these opioid peptides in glucose or lipid metabolism and body fat accrual, pharmacological studies with behavioral measures consistently demonstrate a potent stimulatory effect of the opioids on food intake, with the opposite pattern observed with opiate antagonists. The effect of the agonists is particularly strong after injection into the PVN and NAc, and it is largest with palatable diets rich in fat or sugar. In addition to their close relation to signals of diet palatability, the opioids appear to function in relation to the specific macronutrients of the palatable diets, switching preferences from a high-sucrose to a high-fat diet. Evidence suggests that the opioids in the forebrain are more closely related to signals of diet palatability, whereas those in the hypothalamus have a closer relation to the specific macronutrient in the palatable diet.

Mutant mice with a deletion of the opioid genes or their receptors fail to show consistent changes in daily food intake and body weight. However, more subtle changes in behavior are evident. These include a reduced preference for saccharine in opioid receptor-deficient mice and a reduction in willingness to work for palatable food in ENK knockout mice.

These results suggest that these orexigenic opioid peptides play a key role in mediating excess feeding induced by palatable food. Although relatively unresponsive to states of energy deficiency, these opioids, similar to GAL and ORX, are closely, positively related to fat intake and circulating lipids, which promote hyperphagia. These peptides, in turn, potently stimulate the consumption of palatable energy-dense diets, having a stronger effect on a high-fat than a low-fat diet. Their functions are mediated by a broadly distributed network of structures within the hypothalamus and forebrain, with the former related more to macronutrient content of the palatable diet and the latter related to the palatability itself. These opioids are found to be involved in mediating the feeding-stimulatory actions of the other orexigenic systems, including NPY, AgRP, MCH, GAL, and ORX.

Conclusion

The study of eating behavior and obesity from the perspective of the brain is clearly a burgeoning field, with many technological advances that are allowing investigators to make new and exciting discoveries while defining specific functions of the peptide systems in energy homeostasis. These orexigenic systems exhibit considerable diversity and redundancy in their actions, which involve not only the stimulation of food intake but effects on more intricate behavioral and physiological processes related, for example, to the circadian rhythm of meals, arousal of food-seeking behavior, diet palatability, energy expenditure, and nutrient metabolism in different tissues. The studies reviewed here have clearly advanced our understanding, at the level of the hypothalamus, of the complex systems involved in energy homeostasis. Such complex regulation is made possible by the large number of circulating hormones and nutrients that manipulate neuronal function and the diverse anatomical and functional relationships existing among the different peptides within the hypothalamus. It is also made possible by neural mechanisms that extend from the gut and other peripheral organs to the hindbrain and forebrain. A major miscalculation at any step within this complex circuit can lead to overeating and obesity. Whereas the unfolding of the beauty and intricacy of the neural and humoral systems involved is a thing of awe, its application in modern times is impossible without a parallel appreciation of the enormous impact of environment, in terms of food availability and diet composition. The complex systems of energy homeostasis evolved in an environment of scarcity. Thus, in a society where food is superabundant and diets are rich in fat or carbohydrate, we need sociopolitical help in coping with problems of body-weight regulation. An understanding of the neuroscience of eating behavior and obesity, although critical to the discovery and development of future anti-obesity agents, must bring with it a sensible food distribution and education system. Otherwise, it will just be science for the sake of treatment, without all the benefits that could accrue from the prevention of overeating.

Neuropeptides: Mental Disease

F Holsboer, Max Planck Institute of Psychiatry, Munich, Germany

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In the 1970s, David de Wied formulated the neuropeptide concept, which states that these molecules synthesized and released from nerve cells in the brain exert behavioral effects. Before then, it was well established that central neuropeptides are involved in pituitary hormone secretion and are, in turn, regulated by peripheral hormones via feedback mechanisms, mostly at the hypothalamic nuclei. It was also documented that neuropeptide-containing hypothalamic cells project to extra-hypothalamic targets and, further, that neuropeptides are copackaged with neurotransmitters belonging to the class of biogenic amines. It were Tomas Hökfelt and Jan Lundberg who spearheaded the view that neuropeptides are in contrast to biogenic amines released under conditions in which homeostatic control needs to be established (Figure 1). This view was based on the finding that, in contrast to biogenic amines, neuropeptides are released only at higher neuronal firing rates. This opened the possibility of expanding the time range at which synaptic communication can occur.

In the context of mental disorder, the hypersecretion of neuropeptides can be viewed as the attempt of the brain to adapt to a specific demand, such as coping with a stressor or stimulating hunger in the case of energy loss. If adaptation fails, the continuous neuropeptide hyperdrive may ultimately result in a clinical condition. These neuropeptides are particularly suited for carrying out complex tasks, such as behavioral adaptation because they contain more chemical information and feature more recognition sites for the receptors to which they bind with much higher affinity (10^{-6} vs. 10^{-3} M) than biogenic amine neurotransmitters. Along with the rapidly evolving refinements in measuring neuropeptides and their molecular control mechanisms, we also see a rapidly developing pharmacology that offers small chemical molecules suited for interfering with neuropeptide signaling pathways. In particular, neuropeptide receptors are preferred drug discovery targets because their cognate ligands bind selectively and tightly and they promise to exhibit fewer side effects.

In this article, I take some examples from psychiatry research that demonstrate how our advanced understanding of neuropeptide physiology can be translated into the development of new drugs and where the field is now.

Substance P and Neurokinin Receptor 1 Antagonists in Depression

Substance P, the most abundant neuropeptide in the brain, is a C-terminal amidated, 11-amino-acid residue. When injected into a rodent's brain, substance P induces anxiety-like behavior, which is counteracted by blocking neurokinin receptor type 1 (NK1), to which the neuropeptide binds. This corresponds with studies in mice in which the *Tac1* gene was deleted. These mouse mutants do not produce substance P and show decreased anxiety- and depression-like behavior. Neuroanatomical studies revealed that substance P is present in brain circuits thought to be involved in the processing of anxiety. These include the amygdala, septum, mid-brain, periaqueductal gray, hippocampus, and hypothalamus. There are also connections between biogenic amines and substance P. Central administration of substance P increases neuronal firing in the locus coeruleus, an area in the brain stem reticular formation on the floor of the fourth ventricle, on which norepinephrine fibers project into all areas of the cortex. Thus, substance P-induced increase of neuronal firing in the locus coeruleus results in the activation of many brain areas involved in arousal, affect, and anxiety. In turn, stress exposure results in increased locus coeruleus firing. A direct effect of substance P in the brain stem area is also suggested by the presence of NK1s on tyrosine hydroxylase – positive cell bodies in the locus coeruleus. Based on these and on corresponding findings, NK1 antagonists were developed as drugs to be used when failed stress adaptation is implicated in pathogenesis.

Studies relating pharmacological interventions at NK1s revealed that blocking substance P signaling prevents the stress-induced activation of the ascending noradrenergic projections. Also, the serotoninergic system is intertwined with substance P because, in contrast to rodents, many serotoninergic neurons in the dorsal raphe express substance P. In this brain stem area, most cell bodies of serotoninergic neurons are located. Administration of NK1 antagonists in mice results in decreased anxiety-like behavior in parallel with a selective desensitization of serotonin inhibitory autoreceptors (5-HT_{1A}), which resembles the effect of sustained antidepressant treatment.

Some studies exist that suggest an association between the central release of substance P and depression.

Figure 1 Tomas Hökfelts's hypothesis submits that in synaptic transmission (right), unlike biogenic amine and amino acid neurotransmitters (T), neuropeptides (P) are secreted only at a high firing rate or bursting activity (left).

Some studies found elevated substance P concentration in the cerebrospinal fluid (CSF), and one study reported decreased NK1 binding. Because continuous overexposure of NK1s to substance P results in their internalization, the decreased NK1 binding can be viewed as reflecting a desensitizing mechanism secondary to overabundant substance P exposure.

After the first report of clinical efficacy of NK1 antagonist NK869 in depression, several studies attempted to confirm this novel pharmacological principle but achieved mixed results. Although, there is currently some disillusionment; the jury is still out on whether NK1s will become targets for future antidepressant drugs.

Growth Hormone-Releasing Secretagogues – Multitasking Neuropeptides

There is literally no mental disorder, including dementia, in which sleep is not affected. Thus, it is of interest to explore to which degree changes of neuropeptide signaling are involved. As shown by many investigators, nocturnal sleep is a period of high endocrine activity, and in turn several hormones have the capacity to affect sleep. For example, the onset of sleep is characterized by a steep increase of growth hormone (GH) secretion. During this part of sleep, called slow-wave sleep, low frequencies and high amplitude in the sleep electroencephalogram (EEG) predominate. GH secreted from the pituitary is controlled by a number of neuropeptides:, growth hormone-releasing hormone (GHRH) and ghrelin, which stimulate GH secretion, and somatostatin, which inhibits GH secretion.

GHRH, produced in the hypothalamus, not only governs GH secretion from somatotrophs but also provides the subcortical mechanism synchronizing sleep and GH secretion. Because the GH secretion is highest when we sleep most deeply, it was suggested that GHRH is a key promoter of deep (slow-wave) sleep in humans, as well as the sleep physiological equivalent in animals. This is often termed nonrapid eye movement (non-REM) sleep, sleep episodes during which eye movements are absent. As first demonstrated by Axel Steiger, repeated pulsatile injections of GHRH are important for observing a GHRH-induced effect on the sleep EEG in humans. When GHRH is systemically administered in a pulsatile mode, slow-wave sleep is enhanced in young male subjects; however, women do not respond in this way. Elderly people suffer from fragmental sleep with many awakenings and exhibit much less slow-wave sleep compared to younger people. Therefore, activating GHRH-mediated signaling pathways promised the restoration of sleep in people of advanced age. Indeed, GHRH promotes sleep continuity, but it fails to increase slow-wave sleep in this age group. When we block GH secretion by administering somatostatin, which acts at the somatostatin receptor 2 (sst2), we would expect an effect on sleep opposite to that of GHRH. In fact, when the longer-acting somatostatin analog octreotide, which stimulates sst2 (together with the sst5), is given to animals, both non-REM sleep and GH secretion are suppressed. It is of note that somatostatin receptor-mediated effects fulfill many tasks in the brain. For example, angiotensin-like response, such as prompt drinking, blood pressure rises, and vasopressin surges, were also elicited by octreotide. The effects of sst2 stimulation, however, seem to be independent of octreotides actions on angiotensin because pretreatment with angiotensin-converting enzyme inhibitor did not interfere with octreotide-induced sleep (Figure 2).

A different situation emerged with a third GH-regulating peptide, ghrelin, which exerts its action via the GH secretagogue receptor type 1a (GHS1a) Ghrelin is an acylated peptide predominantly produced by the stomach and has received considerable interest as a molecule with orexigenic effects. Originally, ghrelin, produced in the gastrointestinal tract, was thought to regulate food intake and energy homeostasis by reaching the GHS1a via blood circulation. In that capacity, ghrelin can be viewed as a factor complementary to leptin, which is produced and released from adipocytes and signals satiety. More recently, ghrelin has also been found to be expressed in a previously uncharacterized group of neurons adjacent to the third ventricle between the dorsal, ventral, paraventricular, and arcuate hypothalamic nuclei, which send efferents to a number of nuclei known to be involved in the control of appetite and energy balance. In accordance with this, it was found that ghrelin enhanced appetite and increases food intake in humans.

The ghrelin receptor was recently shown to exhibit a high constitutive activity, probably providing a set

Figure 2 Balance of GHRH, somatostatin (SRIF), and CRH determines sleep regulation and hormonal activity during sleep: (a) young normal control; (b) patient with depression; (c) senior normal control. CRH, corticotropin-releasing hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; REM, rapid-eye movement sleep.

point for signal transduction activity against which all the inhibitory mechanisms act. Leptin, for example, when lowered is a key signal for an increased food intake and decreased energy expenditure, probably mediated through the decreased inhibition of the constitutive ghrelin receptor signaling. Unsurprisingly, the ghrelin receptor is viewed as an intriguing target for developing drugs that regulate eating behavior. More specifically, ghrelin receptor antagonists are long sought-after antiobesity drug candidates. The induction of sleep by GHRH in males and the impairment of sleep by somatostatin receptor activation raised interest in how ghrelin may act on sleep. Pulsatile injections of ghrelin to young healthy volunteers showed that this peptide enhances not only GH secretion but also slow-wave sleep. From this exploratory study, it was surmised that in addition to its effect on GH secretion, food intake, and weight gain, ghrelin is a sleep-promoting neuropeptide. Whether stimulating the GHS receptor is a pharmacological route for future sleep medicines is not yet easy to predict because via the same receptor hunger is induced, which is an undesired side effect for a sleep-promoting drug.

Modulating the Vasopressin System – A Yet Unexploited Therapeutic Strategy for Treating Anxiety Disorders and Depression

Arginine vasopressin (AVP) is a nonapeptide, and this system serves two purposes:

1. Parvocellular neurons of the hypothalamic paraventricular nucleus (PVN) secrete AVP into the portal blood, where it synergizes the actions of corticotropin-releasing hormone (CRH) on the anterior pituitary to control secretion of corticotropin (ACTH) and corticosteroids.
2. Magnocellular neurons of the nucleus supraopticus and PVN project to the posterior pituitary, where they enter the blood circulation and contribute to the regulation of blood pressure (via renal water reabsorbtion) and hepatic glycogenolysis.

In this article, the focus is on behavioral effects of AVP, particularly those related to coping with stress and to anxiety and depression. Abundant literature exists showing that centrally released AVP has many effects on memory processing, social affiliation, and affective conditions in rodents. The possibility that AVP plays also a role in human clinical conditions was hinted at by neuroendocrine studies in which depressed dexamethasone-pretreated patients responded to intravenous injections of CRH with increased ACTH and cortisol secretion. The hypothesized underlying mechanism submits that depressives,when pretreated with dexamethasone, have suppressed ACTH, and subsequently cortisol, concentrations. Thus, their brains are deprived of cortisol, the negative feedback signal, which cannot be compensated by dexamethasone because of its poor blood–brain barrier penetration. In response to this cortisol depletion, central CRH-stimulating neuropeptides are activated. The most powerful of them is AVP, which is supposed to be overexpressed in depression and which synergizes at the pituitary level with injected CRH, overriding the dexamethasone suppression at pituitary corticotrophs. The ACTH and cortisol hypersecretion as seen in depressives following the administration of the combined

dexamethsone–CRH test gradually normalizes prior to the resolution of depressive psychopathology. Clinical studies measuring AVP in the PVN of suicide victims and basic science experiments using rats with innate high anxiety confirm this view. The latter animal model generated by Rainer Landgraf by selectively breeding animals according to the degree of their anxiety-like behavior, was of particular interest because it showed that the rats' AVP hypersecretion is associated with abnormal test results in the combined dexamethasone–CRH test and because treatment with an antidepressant normalized this neuroendocrine abnormality. The mechanism causing central AVP hypersecretion in these high-anxiety rats was shown to be a polymorphism in the AVP gene promoter, which disrupts the cognate binding of a transcriptional repressor leading to unrestrained AVP overexpression (see Figure 3).

Whether a comparable mechanism is also causally related to depression and anxiety in humans is unclear. Measurements of AVP in the CSF and plasma provided mixed results, and whether plasma and CSF concentrations of AVP reflect the release of the neuropeptide at specific brain sites is arguable. Nevertheless, animal studies in combination with neuroendocrine and postmortem neuropathological studies provided an argument that AVP receptors (V_{1A} and V_{1B}) are potentially interesting drug targets. The V_{1B} antagonist SSR-149415 was shown to induce antidepressant- and anxiolytic-like effects in rodents. This compound also reversed the stress-induced suppression of neurogenesis in the dentate gyrus in a mouse model of depression. Neurogenesis is currently viewed as a surrogate marker for antidepressant-like activity and is suppressed by corticosteroid hypersecretion. A number of other V_{1A} and V_{1B} antagonists are currently under consideration for clinical development.

The Role of Neurotensin in Causality and Treatment of Schizophrenia

A number of neuropeptide and other neurotransmitter systems have been implicated in the pathophysiology of schizophrenia and antipsychotic mechanisms of drug action. Aside from the hypothesized mesolimbic hyperdrive of dopamine, the strongest case for a neuropeptide has been made for neurotensin, a tridecapeptide.

1. Pathophysiological approaches suggest that the primary disturbance in schizophrenia lies in neurocircuits that converge in the dopaminergic projections from the ventral tegmental area to the nucleus accumbens. Many afferents implicated in schizophrenia, including glutamatergic afferents from the prefrontal cortex, hippocampal areas, or the amygdala terminate in this nucleus from which projections to cortical areas emerge. All these circuits are closely associated with neurotensin systems.
2. It was repeatedly confirmed that patients with schizophrenia had lower CSF neurotensin concentrations and, further, that these changes are secondary to lowered neurotensin secretion in the brain and do not stem from peripheral sources.
3. When antipsychotic drugs are given and the psychopathology is resolved, CSF neurotensin concentrations increase. This accords with preclinical studies showing that antipsychotic drugs increase neurotensin mRNA and neuropeptide concentration and secretion at the nucleus accumbens.

These findings indicate that the antipsychotic effect of drugs given for the treatment of schizophrenia work via enhanced neurotransmission with neurotensin as messenger. Specifically, it was demonstrated in two animal models of antipsychotic drug activity that the blockade of neurotensin signaling by neurotensin receptor antagonists prevented the haloperidol-elicited behavioral effect. Haloperidol is an antipsychotic drug (APD) that primarily acts at dopamine type 2 receptors (DA2s). Mapping APD actions in the brain using immediate early gene expression allowed the identification of brain regions and neurotransmitter systems that are potentially involved in mediating the actions of these drugs. In fact, this technique corroborated the predominant role of the nucleus accumbens because all APDs increased *FOS* expression in this locus. Currently, the first-line treatment of schizophrenia is the use of atypical antipsychotics,

which are different from typical APDs in that they actively block DA2 less but also antagonize $5HT_{2A}$. It is remarkable that only typical (e.g., haloperidol), but not atypical, APDs activate *FOS* expression in the dorsolateral caudate/putamen; this is probably related to the development of extrapyramidal side effects produced by typical, but not atypical, APDs. In contrast, atypical APDs, which are superior to typical APDs with regard to the improvement of negative symptoms of schizophrenia (e.g., deficiency in emotional response, hedonia, and spontaneous speech and motivation), increase *FOS* in the medial prefrontal cortex, specifically in the deep layers of the infralimbic and ventral prelimbic cortices. Many data point to the possibility that neurotensin may be involved in the antipsychotic mechanism of action of APDs. Increased neurotensin neurotransmission following APD administration may also contribute to APD-induced *FOS* expression. A recent extension of this approach also studied the interaction of haloperidol and a neurotensin antagonist (SR14 2948A) and measured APD-induced *FOS* expression as endpoint. In essence, this study did not find a consistent effect on APD-induced *FOS* expression in all brain areas investigated. However, on the behavioral level there was a clear effect in that the neurotensin antagonist was able to prevent the APD-induced restoration of prepulse inhibition of the acoustic startle reflex in isolation-reared rats. This paradigm is taken as a predictive test for antipsychotic-like activity. The reported effect of the neurotensin antagonist is believed to be mediated by inhibited neurotensin neurotransmission in the nucleus accumbens. Based on these findings, it had been suggested that neurotensin receptor agonists may be an interesting opportunity for a new class of antipsychotic drugs.

Corticotropin-Releasing Hormone Signaling – New Targets for Drugs for the Treatment of Stress-Related Disorders

The impaired regulation of plasma stress-hormone secretion is frequently observed in major depression, depressive episodes in the context of bipolar disorder, and psychotic depression. This finding links stress and traumatic experiences to genetic vulnerability to affective disorders. Stressors of all kinds, and particularly those that occur early in life during the critical phase of brain development, can facilitate the development of depression among those carrying a genetic disposition. This relationship between external factors (stressors) and genetic disposition has advanced research exploring how the stress hormone system is regulated. The original finding among depressive patients was hyperactivity of the hypothalamic–pituitary–adrenocortical (HPA) system as reflected by elevations of the stress hormones (ACTH and cortisol), whose secretary pattern was characterized by a flattening of the diurnal rhythm, and increased cortisol release at any secretory burst. In fact, although only a fraction of depressives shows this HPA hyperactivity, disturbed regulation also becomes apparent when refined neuroendocrine function tests are administered. Today, the most sensitive test to identify impaired HPA regulation is the combined dexamethasone–CRH test, which administers a low (1.5 mg) dose of dexamethasone at night (23.00 h) and injects a dose of 100 μg CRH intravenously the next day at 15.00 h. The elicited plasma ACTH and cortisol concentrations are strikingly different between normal controls and depressives (Figure 4).

Because the exaggerated response to this test normalizes weeks before depressive symptomatology resolves, the combined dexamthesone–CRH test is now considered a biomarker of treatment outcome. However, all these results reflect the activity of the HPA system and do not necessarily inform us about the central stress hormone system. In other words, the absence of a peripherally documented stress hormone abnormality does not rule out a still-existing central stress hormone disturbance. Whereas CRH released from the neurons of the hypothalamus may produce hypercortisolism via the HPA system, CRH released from other brain loci and binding at the prefrontal cortex, amygdala, hippocampus, locus coeruleus, and so on can induce behavioral changes unrelated to HPA changes. A key role for CRH, a 41-amino-acid neuropeptide, in mediating the signs and symptoms of human depression came from studies showing an elevation of CRH in the CSF of depressives along with decreased CRH binding sites in the prefrontal cortex of depressed suicide victims and from neuroendocrine test results such as blunted ACTH response to an intravenous dose of CRH. A decrease of CRH in patients responding to antidepressant treatment is well documented.

A large body of evidence from basic research corroborated the view that CRH is a key mediator of anxiety and depression (see Figure 5). For example, intracerebroventricular administration of CRH produced behavioral changes in rats that are analogous to the cardinal symptoms of depression. This was also the case for mice which transgenically over- or underexpress CRH. Transgenic mice overexpressing CRH show behavioral changes that include increased anxiety-like behavior, decreased sexual activity, deficits in learning, and impairment in sleep. In contrast, mouse mutants in which the CRH gene has been silenced do not exhibit a behavioral phenotype,

Figure 4 Among depressives (red), the combined dexamethasone–CRH test results in increased HPA activity because AVP is increased at many CNS sites and also at the pituitary (controls = black). ↑, increased; ↓, decreased; +, stimulates; −, inhibits; ACTH, corticotropin; AVP, arginine vasopressin; CNS, central nervous system, CRH, corticotropin-releasing hormone; Dex, dexamethasome; GR, glucocorticoid receptor; h, human; HPA, hypothalamic–pituitary–adrenal; mdr, multidrug resistance gene; MR, mineralocorticoid receptor.

Figure 5 Signs and symptoms induced by CRH and AVP resemble many features common in affective disorders. ↑, increased; ACTH, adrenoscorticotropin; AVP, arginine vasopressin; CRH, corticotropin-releasing hormone; icv, intracerebroventricular; LC, locus coeruleus.

indicating that CRH is only important when needed to adapt to a stressor. Also, the effect of early trauma has been reproduced in animal models. Prolonged separation in neonatal rats, for example, produced depression-like symptoms along with increased CRH mRNA and CRH expression in the hypothalamus, locus coeruleus, and amygdala; decreased CRH receptor binding in the pituitary; and increased CRH concentrations in the median eminence, portal blood, and CSF. Similarly, chronic stress in adult mice produces persistent behavioral changes reminiscent of depression. It is of note, however, that not everyone exposed to a stressor or trauma develops depression, neither acutely nor later in life, inasmuch as not every patient who suffers from a depressive episode has experienced a major stressor that would explain his

or her clinical condition. Genetic disposition seems to be an important determinant, and stressful experiences, which via epigenetic modulation have often longstanding effects on gene activity, act in concert on liability or resilience to depression.

All these findings led to the question: through which pathway is the CRH signal conveyed? Until now there are two CRH receptor subtypes identified, which display distinct anatomical localizations and pharmacology. Both subtypes of G-protein-coupled receptors (GPCRs) belong to the class B family, and they have been termed CRH_1 and CRH_2, with CRH_2 existing in three identified splice variant isoforms: $CRH_{2(a)}$, $CRH_{2(b)}$, and $CRH_{2(c)}$. Both receptor subtypes are found in the human pituitary and throughout the neocortex of primates. In the rodent brain, only the CRH_1 is expressed at the pituitary and neocortex. Not only CRH but also the urocortins activate the CRH receptors. Urocortin (UCN-) I has equal affinity for both receptor subtypes, whereas-UCN II (often termed stress copin-related peptide) and UCN III (often termed stresscopin) have higher affinity and selectivity for CRH_2. In the light of these differences and because human CRH binds at the CRH_1 with 15-fold higher affinity over CRH_2, the drug discovery process targeting CRH signaling in the brain focused on CRH_1.

This development was supported by studies in rodents, in which suppressed CRH_1 gene expression via antisense or interference RNA directed against CRH mRNA revealed decreased anxiety-like behavior when the rodents were exposed to the elevated-plus maze test. Also, genetically engineered disruption of CRH signaling in CRH_1-null mutants showed decreased anxiety-like behavior. Over the last 15 years, a number of small-molecule CRH_1 antagonists have been developed, but until now none of them has entered clinical practice. In an animal model in which rats were selectively bred for high anxiety, a clinical candidate drug (R121919) reduced anxiety-like behavior, whereas in nonanxious rats with the same genetic background the drug failed to alter their level of anxiety. The anxiolytic effects of R121919 in rats were independent of the dose-dependent attenuation of stress hormone secretion. This corroborates the hypothesis that behavioral alterations and peripheral levels of stress hormones are not always closely linked. The first series of clinical studies used R121919 as CRH_1 antagonist and demonstrated a clinical profile consistent with antidepressant activity. In an exploratory small open-label study, patients responded to R121919 in a similar way as treated with paroxetine, a selective serotonin reuptake inhibitor. As in animals, in depressed patients no direct relationship between hormonal effects and changes in psychopathology was observed. Because CRH hyperactivity in the brain has been implicated in sleep disturbances associated with depression, it is remarkable that R121919 improved sleep in these patients. Although R121919 had been discontinued because of safety concerns, some other CRH_1 antagonists are now under study. One of these is NBI-34041, an orally available heterocyclic compound with a chemical structure distinct from other related compounds. When higher dosages were given to rats, stress-elicited ACTH levels were suppressed. This compound was also tested clinically in normal volunteers who underwent a psychosocial stress test, called the Trier Social Stress Test (TSST). In the TSST, the hormonal response to a public-speaking and a mental-arithmetic stress situation is measured. Although the CRH antagonists failed to change hormonal response at baseline or after an intravenous stimulation with CRH, markedly decreased hormonal responses to the TSST were observed. This finding confirms that neither central stress hormone regulation at baseline nor CRH-elicited responsivity is attenuated by the CRH_1 antagonist. However, the administration of this drug does protect the central stress hormone system from overshooting in response to an emotional challenge. Blocking all CRH_1 that fulfill many diverse functions in the brain and the periphery may, nevertheless, be harmful. Therefore, the discovery that CRH, when administered to the brain induces a specific pattern of signaling pathway activation is of interest. Beyond CRH_1 receptor, stimulation of mitogen-activated protein kinase (MAPK) occurs. This pathway depends on protein kinase A (PKA) activity involving phosphorylated extracellular-signal-regulated kinase (ERK)1/ 2. These kinases are only activated in limbic areas, such as CA_3–CA_1 hippocampal cell layers and the basolateral complex of the amygdala, two brain areas involved in the neuroanatomy of depression and anxiety. Because ERK1/2 are pleiotrophic kinases, their brain-area-specific activation by CRH_1 signaling suggests that they can be used as bait for finding downstream partners that, through their specific cellular context, can be explored as targets for drugs with restricted effects to relevant brain loci.

Conclusion

It is obvious that neuropeptides have functions in the brain that are distinct from their roles as regulators of peripheral homeostasis under stress exposure. Significantly, peptides may play only a minor role under normal circumstances and the absence of defined phenotypes of many neuropeptide-null mutant mice points in this direction. Therefore, neuropeptide receptors are interesting future targets because blocking

their function may not result in major effects as long as there is no potentially pathological condition. Thus, neuropeptide signaling pathways provide an opportunity for the discovery of drugs to treat mental illness specifically with a low risk of side effects.

Neuropeptides: Pain

X-J Xu and Z Wiesenfeld-Hallin, Karolinska Institutet, Stockholm, Sweden

© 2009 Published by Elsevier Ltd.

General Aspects of Neuropeptides and Pain

The possibility that substance P (SP) could be a nociceptive transmitter was raised by Lembeck in the early 1950s based on the finding that there is higher concentration of SP in the dorsal roots and dorsal horn than in the ventral roots and ventral horn. But it was not until the 1970s that the role of neuropeptides as pain modulators, both in excitatory and inhibitory capacities, began to be seriously considered. This was sparked mainly by the identification of SP as an undecapeptide and the localization of SP in small-diameter, nonmyelinated afferent fibers. Subsequently, several other neuropeptides were also found in dorsal root ganglia (DRG) neurons, including neurokinin A (NKA), calcitonin gene-related peptide (CGRP), somatostatin, vasoactive intestinal peptide (VIP), pituitary cyclase-activating peptide (PACAP), neuropeptide Y (NPY), and galanin. The receptors for these peptides have been localized in the dorsal horn and, in many cases, in the terminals of afferents and on dorsal horn interneurons, which s also express a large number of neuropeptides. This has made the dorsal horn of the spinal cord an interesting area to study the role of peptides in pain transmission.

Like in other areas of the nervous system, peptides often coexist with each other and with classical neurotransmitters in the DRG and dorsal horn. Neuropeptides are generally stored in large dense-core vesicles and are released from these vesicles optimally by higher frequency of stimulation than that required for the release of classical neurotransmitters. The excitatory effect of neuropeptides such as SP and CGRP on postsynaptic neurons is often delayed in onset, but with a prolonged duration of action. This suggests that neuropeptides, in contrast to classical transmitters, play more of a modulatory role in sensory transmission. Further, expression of peptides and peptide receptor undergoes marked changes in the DRG and spinal cord after injury to the nervous system or inflammation, suggesting that some of the neuropeptides may also be involved in adaptive changes and plasticity and may have trophic effects.

Tachykinins

Distribution, Receptors, and Plasticity

The mammalian tachykinin SP is the first neuropeptide to be implicated in pain transmission. SP, together with tachykinin NKA, is present in a subpopulation of DRG cells, primarily with small somata. In addition, SP-like immunoreactivity has also been localized in the fiber network of the dorsal horn, mainly in the outer laminae, but also in bulbospinal tract fibers and in dorsal horn interneurons. In the DRG, SP and NKA are also co-localized with other peptides, such as CGRP and galanin, and with classical neurotransmitters, such as glutamate. Neurokinin B (NKB), on the other hand, appears to be present mainly in dorsal horn interneurons, but not in the DRG.

Three subtypes of tachykinin receptors have been identified and cloned. The NK-1 receptor is concentrated in the superficial laminae of the dorsal horn, particularly in lamina I, where internalization of this receptor has been shown to occur after noxious stimulation. NK-2 receptor-like immunoreactivity has also been observed in the outer part of lamina I and in the area around the central canal. These receptors are, however, exclusively astrocytic. NK-3 receptor-like immunoreactivity has been localized in laminae I, II, and X.

SP is markedly downregulated in the DRG after axotomy. Such downregulation occurs primarily in small-sized DRG neurons, and the loss of target-derived nerve growth factors is believed to be responsible for this effect. Paradoxically, it has been reported that nerve injury triggers a *de novo* synthesis of SP in large DRG neurons. Moreover, NK-1 receptors are upregulated in the dorsal horn after nerve injury. In contrast to nerve injury, inflammation appears to be associated with a moderate increase in the synthesis of SP and NKA in the DRG. The synthesis of NK-1 and NK-3 receptors is also increased in the dorsal horn after peripheral inflammation.

Release and Function

In vitro or *in vivo* release of SP in the spinal cord upon noxious peripheral stimulation has been repeatedly shown by a number of methods. Release occurs primarily at the superficial laminae of the dorsal horn. NKA is also released in the spinal cord following noxious stimulation, and – unlike SP, the release of which is confined in the superficial laminae – released

NKA appears to spread into deeper laminae and persists much longer than does SP. This has lead to the suggestion that NKA may be responsible for more prolonged increase in spinal excitability, compared to SP.

SP excites dorsal horn neurons and produces behavioral reactions indicative of pain upon intrathecal administration in rodents. Intrathecal SP has also been consistently shown to produce hyperalgesia in many nociceptive tests and to increase the excitatory effect and the release of other excitatory transmitters, such as glutamate. However, NK-1 receptor antagonists are not antinociceptive in classical pain tests, such as the hot plate or tail flick tests, and these compounds also have minimal effect on baseline responses of dorsal horn neurons to noxious stimulation. Thus, SP is unlikely to be involved in transmission of basal nociception. On the other hand, activation of NK-1 receptors has been shown to be a critical component in the activity-dependent increase (central sensitization) in spinal cord excitability after intense nociceptive stimulation. Furthermore, NK-1 receptor antagonists are also able to reduce hyperalgesia in rodent models of inflammatory pain. This activity profile of NK-1 receptor antagonists has been confirmed in studies with knockout mice lacking genes for the NK-1 receptor or preprotachykinin.

Possible Clinical Application

Several clinical trials have been conducted to examine the analgesic efficacy of NK-1 receptor antagonists in humans in various pain conditions, such as postoperative dental pain, osteoarthritis, diabetic neuropathy, postherpetic neuralgia, and migraine, and the results have been largely disappointing. There may be several reasons for this apparent discrepancy between animal and human studies, including species differences in the distribution and function of the NK-1 receptors, the relevance of the human clinical pain model used, or the redundancy of pain involving large numbers of transmitters and modulators and the complex interactions among them.

More recently it has been suggested that SP may also be involved in neuropathic pain after peripheral nerve injury. This is primarily based on the finding that nerve injury causes increased synthesis and release of SP in and from large-diameter sensory neurons. It is, however, important to note that nerve injury is associated with downregulation of SP in small-diameter C-afferents, and the role of SP in mediating central sensitization was diminished after nerve injury. Functional studies examining the effect of NK-1 antagonists in rodent models of neuropathic pain have produced mixed results, and NK-1 antagonists are ineffective in human neuropathic pain conditions. Depleting the NK-1 receptor does not influence the development of neuropathic painlike behaviors. Overall, it is unlikely that NK-1 receptor antagonists could be useful as analgesics in neuropathic pain.

Calcitonin Gene-Related Peptide

CGRP is the most abundant peptide in mammalian primary afferents, where it is present in sensory neurons of all sizes. CGRP is released from primary afferents at their peripheral and central terminals. The role of CGRP in peripheral neurogenic inflammation is well established, whereas in the spinal cord CGRP is also believed to have an excitatory role. CGRP depolarizes dorsal horn neurons with a very slow onset and long duration of action. In both behavioral and electrophysiological studies, CGRP has been found to markedly enhance the excitatory effect of SP and other neuropeptides. Mice lacking CGRP genes fail to develop heat hyperalgesia after inflammation and have reduced spinal sensitization and diminished responses to pain-causing agents. Similar to SP, the synthesis of CGRP is downregulated after nerve injury and upregulated after inflammation.

Recently, a direct role for CGRP in heat pain sensitivity has been established using a genetic approach. It was shown in mice that robust strain differences in behavioral sensitivity to noxious heat are due to genetic differences in CGRP expression and sensitivity. Such CGRP dependence is also reflected in differential responsiveness of primary afferent thermal nociceptors to heat stimuli.

Somatostatin

Somatostatin is present in a subset of small-diameter sensory neurons; these neurons do not express SP, but coexist with CGRP. Several subtypes of somatostatin receptors are also expressed in the DRG and dorsal horn. The synthesis of somatostatin is downregulated after nerve injury.

Somatostatin and its analogs have been shown to induce pain relief in a number of clinical conditions. This effect of somatostatin is believed to be related mostly to its peripheral effect and/or to its direct effect on the disease process. In the spinal cord, somatostatin produces complex effects on neuronal activity; a previously reported antinociceptive effect following intrathecal administration appears to be due to a neurotoxic action of this peptide in the spinal cord.

VIP, PACAP-27, and PACAP-38

Three structurally related peptides, VIP, PACAP-27, and PACAP-38, have limited presence in small to

medium-sized DRG neurons under normal conditions, but are markedly upregulated after nerve injury. Some reports also suggest an upregulation of PACAPs following peripheral inflammation.

Upon application to the spinal cord, VIP and PACAP produce primarily an excitatory effect on dorsal horn neurons, increase spinal nociceptive reflexes, and produce behavioral hyperalgesia. The relative physiological roles played by these peptides are increased after nerve injury, replacing tachykinins as important mediators of central sensitization. Furthermore, antagonists of receptors for these peptides inhibit neuronal responses to noxious stimulation in the dorsal horn, particularly after nerve injury. Thus, the receptors for VIP-related peptides may be a drug target for development of analgesics in neuropathic pain.

Galanin

Like the VIP family of peptides, galanin is expressed in few sensory neurons in rat DRG under normal circumstances, although the number of neurons that express galanin is higher in monkeys. The galanin-positive sensory neurons are mainly of small size and also contain SP and CGRP. Galanin-like immunoreactivity has also been localized in dorsal horn neurons, mainly in lamina II, where it coexists with γ-aminobutyric acid (GABA), enkephalin, and neuropeptide Y.

Behavioral and electrophysiological studies have shown that galanin produces complex effects with a predominantly inhibitory action on spinal nociception. Electrophysiological studies using the flexor reflex model suggest that galanin may be particularly effective in reducing central sensitization through neuronal hyperpolarization and in blocking the facilitatory effect of SP and CGRP. However, spinal administration of galanin also produces an excitatory effect on nociception under some circumstances. Recent evidence suggests that the complex effects of galanin may be mediated by subtypes of galanin receptors, with R1 receptor being inhibitory and R2 receptor being excitatory.

The inhibitory effect of galanin on dorsal horn neuronal activity and nociceptive reflexes is increased after nerve injury, and intrathecal application of galanin alleviated neuropathic painlike behaviors in rodents. Galanin may also be tonically active in suppressing painful input from injured sensory fibers. Chronic intrathecal infusion of galanin receptor antagonist increases autotomy behaviors in axotomized rats, representing a putative animal model of neuropathic pain. Furthermore, application of galanin antisense oligonucleotide to the distal stump of the transected sciatic nerve effectively reduces the upregulation of galanin in sensory neurons and exaggerates autotomy behavior. In the Bennett nerve constriction model, it has been reported that the extent of galanin upregulation is inversely correlated to the severity of painlike behavior among individual rats. An inhibitory effect of galanin on nociception after nerve injured has also been supported by studies in mice overexpressing galanin or lacking the R1 galanin receptors. Thus, agonists of galanin receptors, possibly of the R1 subtype, deserve to be further evaluated for their analgesic potential for treating neuropathic pain.

Neuropeptide Y

In normal conditions, NPY is rarely present in DRG neurons in rats, whereas in the dorsal horn it is found in interneurons in the superficial laminae, where it coexists with GABA. Peripheral nerve lesion induces a dramatic increase in the expression of NPY in the DRG, mainly in the medium/large-sized neurons.

Similar to galanin, NPY also produces a complex effect on spinal pain mechanisms, with predominantly inhibitory action. It has been shown that the inhibitory effect of NPY is mainly mediated by the activation of the Y1 receptor in normal rats, but by both Y1 and Y2 receptors after nerve injury. On the other hand, NPY has been shown at the level of the nucleus gracilis to mediate tactile hypersensitivity after nerve injury, in accordance with an upregulation of NPY in large fibers.

Opioid Peptides

The opioid peptides (endorphins, enkephalins, dynorphins, endomorphins, and nociceptin) are present mainly in dorsal horn interneurons, but not in sensory neurons. Enkephalins and endorphins are well-established mediators of the endogenous antinociceptive system activated by placebo treatment, chronic pain, stress, acupuncture, etc. The action of endomorphins and nociceptin, by activation of μ and opioid receptor-like (ORL) receptors, is also primarily inhibitory in the spinal cord, whereas dynorphins appear to produce a more complex effect in pain modulation.

Cholecystokinin and Other Antiopioid Peptides

It is well established that the antinociceptive and/or analgesic effect of opioids can be reduced by a range of nonopioid peptides, including cholecystokinin (CCK), Phe-Met-Arg-Phe-NH_2 (FMRF-amide)-related peptides, angiotensin II, and melanocyte-inhibiting factor (MIF)-related peptides. Among these, the antiopioid effect of CCK is best studied. In general, there is an overlap in the anatomical distribution of CCK,

opioids, and their receptors in the spinal cord and brain; this overlap may underlie the documented interaction between the opioid and CCK systems. In the spinal cord, CCK is found in dorsal horn interneurons but not in sensory neurons in the DRG, and only a small number of rat DRG neurons express CCK-B receptor mRNA under normal conditions. After nerve injury, the level of CCK and CCK-B receptor mRNA is upregulated in the DRG.

A large body of literature has accumulated that indicates that upon local, systemic, intrathecal, or intracerebral injection, CCK reduces the effect of exogenous as well as endogenous opioids. The inhibition by CCK on opioid antinociception appears to be tonic, as blockade of endogenous CCK by receptor antagonists results in an enhancement of opioid-induced antinociception. Importantly, CCK may be involved in determining opioid sensitivity under pathological conditions. Thus, the antinociceptive effect of opiates is enhanced in animals with acute inflammation, which is associated with a decreased release of CCK. In contrast, opiates have reduced effect after nerve injury, which has been shown to be related to enhanced activity of the endogenous CCK system. Furthermore, repeated administration of opiates induces a gradual reduction in their ability to induce analgesia, a condition known as tolerance, which is also related to the CCK system. Hence, blockade of CCK receptors may have potential clinical applications in pain management by increasing the effect of opioids and reducing tolerance.

Neuropeptides: Sensory Systems

J V Priestley, Queen Mary University of London, London, UK

Introduction

The somatosensory system carries information from the body surface (skin), viscera, muscles, and joints. Specialized neurons, referred to as primary afferent or primary sensory, respond to events that arise from outside the body or inside the body and convey information to second-order neurons within the spinal cord and brain stem. All primary sensory neurons use the fast-acting transmitter glutamate, but, remarkably, many also contain multiple neuropeptide transmitters. This is particularly true of the subpopulation of neurons that respond to tissue damage, known as nociceptors. These neuropeptides function as neurotransmitters within the spinal cord, conveying information about both acute pain and the chronic pain associated with nerve injury and inflammation. In addition, they act as neurohumeral factors in the periphery, regulating blood flow and the tissue response to injury. This article briefly reviews the organization and subtypes of primary sensory neurons, their regulation by growth factors, the changes that take place after nerve injury and inflammation, and the functional role of primary afferent neuropeptides.

Biochemical Characterization and Anatomy of Primary Sensory Neurons

The majority of the body surface and most muscles and joints are supplied by primary sensory neurons whose cell bodies are located in ganglia just lateral to the spinal cord, referred to as spinal or dorsal root ganglia (DRGs). The face, and the muscles of facial expression, is supplied by primary sensory neurons in the trigeminal and petrosal (glossopharyngeal) cranial ganglia; however, their properties are generally similar to those of DRG neurons. This article therefore focuses mainly on the DRG neurons. However, many viscera receive innervation not only from DRG neurons but also from specialized primary sensory neurons located in the nodose and jugular ganglia. Those neurons have distinct properties and are not considered in detail. Most information comes from studies in rat, but similar principles seem to apply to other species, although there are many differences in detail.

DRG neurons do not possess dendrites, but have an axon that divides into a peripheral branch which has receptor, and possibly also effector, properties and a central branch that synapses with second-order neurons within the spinal cord (Figure 1). They can be divided into various subpopulations based on their neurochemistry (Figure 2), anatomy, and physiology. Large and medium-size neurons (25–60 μm in diameter) form a group that can be distinguished by their high content of phosphorylated heavy-chain (200 kDa) neurofilament and that make up approximately 40% of the lumbar DRG neurons. These cells have mostly myelinated axons that conduct in the Aα/β range (12–31 m s^{-1}, rat lumbar DRG neurons), and their peripheral axons have specialized encapsulated endings and are mainly low-threshold mechanoreceptors. Many subtypes exist, defined according to their stimulation and adaptation properties, such as Pacinian corpuscles and Merkel touch domes in the skin, and Ia spindle afferents in muscle. Aβ high-threshold mechanoreceptors (nociceptors) also exist, but are less common than Aδ and C fiber nociceptors.

Nociceptive Dorsal Root Ganglion Neurons

The remaining DRG neurons are small in size (10–30 μm), express the intermediate filament peripherin, have unmyelinated axons (C fibers, <1.3 m s^{-1} conduction velocity), and have unencapsulated nerve endings that function as nociceptors and/or thermoreceptors. Several subtypes exist and include low-threshold mechanoreceptors (e.g., 12% of rat saphenous C fibers), warming receptors and cooling receptors, and silent receptors (11%, insensitive or unexcitable). However, most C fibers (70%) are polymodal nociceptors and respond to noxious mechanical, thermal, and chemical stimuli. This property is largely due to the fact that their peripheral terminals express transient receptor potential (TRPV)1, a nonselective cation channel that is a member of the vanilloid subfamily of TRPV ion channels. TRPV1 has been described as a molecular integrator of pain-producing stimuli. It is activated by temperatures above 43 °C; by molecules that possess a vanilloid moiety (e.g., capsaicin, the pungent component of capsicum peppers); and by a range of factors associated with tissue damage, including the endocannabinoid anandamide, the leukotriene hydroperoxyeicosatetraenoic acid (HPETE), and low pH (<5.9). Another TRPV member, TRPV2, responds to noxious heat (>52 °C) and is an important receptor expressed by finely myelinated Aδ mechano-heat nociceptors (type I AMHs, also known as Aδ high-threshold mechanoreceptors). In addition, nociceptive DRG neurons express a range of receptors for

Figure 1 Diagram showing afferent and efferent properties of a typical cutaneous DRG neuron. The cell bodies of DRG neurons are located in dorsal root ganglia, and each neuron has an axon which divides to form a peripheral and a central branch. The peripheral branch runs in a peripheral nerve and forms specialized receptors in the dermis and epidermis of the skin. The central branch runs in a dorsal root and synapses with second-order neurons in the dorsal horn of the spinal cord. The normal flow of information and direction of action potential propagation is from the periphery to the spinal cord (orthodromic) and, in the case of DRG neurons that use neuropeptides, the neuropeptide is released at the central synapses and acts as a neurotransmitter. However, some DRG neurons (shown in blue) have collateral branches that innervate blood vessels. In their case, action potentials can also be conducted antidromically and neuropeptides may be released from their peripheral terminals to control vasculature. DRG, dorsal root ganglion.

Figure 2 Pie chart summarizing the main neurochemical populations of DRG neurons. One population comprises large cells which give rise to myelinated axons and have high levels of neurofilament (NF200). Small cells, which have mainly unmyelinated axons and are predominantly nociceptors, comprise two populations. One population consists of cells that constitutively synthesize the neuropeptide CGRP. The other population is characterized by cells that bind the lectin *Griffonia simplicifolia* IB4. An overlap between the NF200 and CGRP populations corresponds to Aδ nociceptors. There is also some overlap between the IB4 and CGRP populations. Neurotrophin receptors and GDNF receptors expressed by small and medium-size cells (predominantly nociceptors) are indicated around the periphery of the chart, together with molecules found in each major population. The percentages reflect the situation in lumbar (L4 and L5) ganglia of the rat. Similar populations exist at other segmental levels (cervical, thoracic, and sacral), but the exact percentages vary. BDNF, brain-derived neurotrophic factor; CGRP, calcitonin gene-related peptide; DRG, dorsal root ganglion; FRAP, fluoride-resistant acid phosphatase; GDNF, glial cell line-derived neurotrophic factor; GFR, glial cell line-derived neurotrophic factor receptor; IB4, isolectin B4; TRPV, transient receptor potential. inflammatory mediators and/or products of tissue damage, including purinoceptors, bradykinin receptors, serotonin (5-hydroxytryptamine (5-HT)) receptors, acid-sensing ion channels (ASICs), the CB1 cannabinoid receptor, the H1 histamine receptor, the transient receptor potential A1 (TRPA1) receptor, and prostanoid receptors. Some of these receptors are, like TRPV1, ion channels that lead to the direct activation of nociceptors by causing membrane depolarization and the firing of action potentials. Others, such as the

bradykinin B2 receptor, are G-protein-coupled receptors (GPCRs) that modulate TRPV1 and other ion channels via second messengers. Nociceptive DRG neurons also possess specialized voltage-gated sodium channels, which generate action potentials with distinctive propagation and firing properties. Such channels include $Na_V1.7$ (tetrodotoxin (TTX)-sensitive sodium current), $Na_V1.8$ (sensory neuron specific (SNS), TTX-resistant) and $Na_V1.9$ (sodium channel NaN, TTX-resistant).

Peptidergic and Nonpeptidergic Nociceptors

In addition to the functional diversity outlined so far, neurochemical studies have revealed that small DRG neurons can be divided into two main subgroups depending on whether or not they constitutively express neuropeptides. Just over half of all small DRG neurons (50–60%) constitutively express the neuropeptide calcitonin gene-related peptide (CGRP) and may also express other neuropeptides, including substance P (a tachykinin derived from preprotachykinin-A), somatostatin, vasoactive intestinal polypeptide (VIP) and galanin (Table 1), and the neurotrophin brain-derived neurotrophic factor (BDNF). Many of these neuropeptides coexist not only within single DRG neurons but also within individual dense-core vesicles. Histochemical and functional studies have shown that the majority of CGRP neurons (59–65%) possess TRPV1 and are likely to be polymodal nociceptors. Neuropeptides are generally not found in the large-diameter mechanoreceptive cells, but CGRP is present in many medium-size 200 kDa neurofilament-rich neurons which are also mainly nociceptors (AMHs). The other half of the small DRG neurons either do not contain neuropeptides or contain only low levels that can be identified using a variety of markers. These include staining by the lectin *Griffonia simplicifolia* isolectin B4 (IB4), expression of a nonlysosomal fluoride-resistant acid phosphatase (FRAP), expression of the purinoceptor P2X3, and expression of a subtype of sensory neuron-specific GPCR referred to as Mas-related G-protein-coupled receptor subtype d (Mrgprd). The majority of these cells also express TRPV1 (75% of IB4 cells), and thus polymodal nociceptors appear to have two subtypes: one which constitutively expresses neuropeptides and one which does not. There is good evidence that the neuropeptides serve as neurotransmitters and/or neuromodulators (see the section titled 'Function of sensory neuropeptides'), and so I refer to these two populations as peptidergic and nonpeptidergic. Note that the thermoreceptors have not been characterized as thoroughly as the nociceptors and that it is not known whether they also comprise peptidergic and nonpeptidergic populations. It is also not known whether such a dichotomy applies to visceral afferents. Many nodose and jugular ganglion neurons are peptidergic and express TRPV1. In addition, there are many P2X3/IB4 neurons in the nodose ganglion which are nonpeptidergic. However, at least in the lung, these appear to be myelinated mechanoreceptors and not capsaicin-sensitive.

Table 1 Neuropeptides synthesized by small and medium-size DRG neurons[a]

	DRG cells (%)
Calcitonin gene-related peptide (CGRP)	32–50
Substance P and neurokinin A	18–38
Cholecystokinin (CCK)	0–3
Galanin	0–5
Somatostatin	5–15
Vasoactive intestinal polypeptide (VIP) and Peptide histidine isoleucine (PHI)	0–5 (mainly in visceral afferents)
Neuropeptide Y	0
Bombesin/gastrin-releasing peptide	0–8
Dynorphin	0–3
Enkephalin	0–3

[a]DRG, dorsal root ganglion.

From the material reviewed so far, it can be seen that neuropeptides in sensory neurons are predominantly associated with nociceptors but that not all nociceptors express neuropeptides. Nociceptive DRG neurons can basically be divided into three main populations (Figure 3): (1) medium-diameter TRPV2-expressing peptidergic (CGRP) cells that have finely myelinated (Aδ) axons; (2) small-diameter TRPV1-expressing peptidergic (CGRP and substance P) cells that give rise to unmyelinated axons (C fibers); and (3) small-diameter TRPV1- and P2X3-expressing and IB4-binding nonpeptidergic cells that give rise to unmyelinated axons (C fibers). Among cutaneous afferents, all three nociceptive populations have peripheral processes that form free nerve endings in the epidermis, but peptidergic C fibers (population 2) terminate more superficially than nonpeptidergic axons and also give rise to perivascular endings in epidermis and dermis. This population also has proportionally more visceral projections than the nonpeptidergic DRG neurons (population 3). The central projections of these three populations have slightly different termination patterns. The peptidergic C fibers terminate predominantly in the lamina I and outer lamina II (IIo), nonpeptidergic axons terminate mainly in the inner lamina II (IIi), and Aδ fibers terminate predominantly in lamina I and laminae III–V.

The significance of having two populations of polymodal nociceptors (peptidergic and nonpeptidergic) is not known, but one possibility is that they signal different types of pain (e.g., acute and chronic). It is also possible that each population targets distinct central pathways. For example, recent studies

Figure 3 Diagram showing the three main populations of nociceptors: (1) medium-diameter peptidergic (CGRP) cells (red) that have finely myelinated axons that function as mechano-heat nociceptors (AMHs), respond to NGF and NT3, and innervate predominantly laminae I and III/IV; (2) small-diameter peptidergic (CGRP and substance P) cells (blue) that function as polymodal nociceptors, respond to NGF, and innervate predominantly laminae I and II outer (IIo); and (3) small-diameter IB4-binding nonpeptidergic cells (green) that function as polymodal nociceptors, respond to GDNF, and innervate predominantly lamina II inner (IIi). BDNF, brain-derived neurotrophic factor; CGRP, calcitonin gene-related peptide; FRAP, fluoride-resistant acid phosphatase; GDNF, glial cell line-derived neurotrophic factor; GFR, glial cell line-derived neurotrophic factor receptor; IB4, isolectin B4; NF200, 200 kDa neurofilament; NGF, nerve growth factor; NK1, neurokinin 1; NT3, neurotrophin 3; SP, substance P; TRPV, transient receptor potential. Adapted from McMahon SB and Priestley JV (2005) Nociceptor plasticity. In: Hunt SP and Koltzenburg M (eds.) *The Neurobiology of Pain*, pp. 35–64. Oxford: Oxford University Press.

indicate that peptidergic C fibers innervate dorsal horn neurons that project to traditional central nervous system (CNS) pain relay sites, such as the parabrachial nucleus and the ventrolateral thalamus, whereas nonpeptidergic C fibers may activate neurons that project to limbic and striatal sites including the bed nucleus of the stria terminalis and the globus pallidus. Thus, the nonpeptidergic cells may innervate pathways that convey primarily the affective component of pain rather than the sensory-discriminatory component and may also activate brain centers that control motor responses to pain.

Target-Derived and Injury-Derived Growth Factors

The organization reviewed so far is true of the normal, healthy nervous system, but major changes take place after tissue or nerve injury, particularly as regards neuropeptide expression. It appears that both the normal phenotypes of DRG cells and the changes after injury are regulated by growth factors that arise either from peripheral tissues (target-derived) or from the local glial and immune response to injury (injury-derived). This regulation will now be briefly reviewed because it helps to explain the neurochemical subtypes (see the section titled 'Biochemical characterization and anatomy of primary sensory neurons') and the changes after tissue or nerve injury (see the section titled 'Neuropeptide plasticity following inflammation or nerve injury').

Target-Derived Neurotrophins

During development, the survival of DRG neurons depends on nerve growth factor (NGF), which binds to a receptor tyrosine kinase called trkA, and neurotrophin (NT)-3, which binds to trkC; and virtually all DRG cells express trkA or trkC. In the adult, DRG neurons no longer require neurotrophins for survival, and there are postnatal changes that establish a new pattern of receptor expression (Figure 2). The peptidergic population of polymodal nociceptors expresses predominantly trkA, and low-threshold mechanoreceptors express either trkB the receptor for BDNF or trkC. AMH nociceptors express both trkA and trkC. All DRG neurons that express trk receptors also express p75, a nonselective neurotrophin receptor that is a member of the tumor necrosis factor (TNF) receptor superfamily. p75 acts as a trk coreceptor, but can also signal directly by recruitment of various adaptor proteins. The expression of trkA by the peptidergic population of nociceptors suggests that this population responds to NGF, and this is borne out by experimental studies in which animals were treated

with exogenous NGF. In healthy animals, NGF has a range of direct effects that are mediated by trkA, including an acute sensitization leading to thermal hyperalgesia and a longer-lasting effect on gene expression. The chronic effects are mediated by the internalization of trkA and retrograde transport to the cell body, where the activation of the mitogen-activated protein kinase (MAPK) pathway leads to induction of transcription factors such as c-Myc, Elk-1, c-Fos, and c-Jun and either positive or negative regulation of a large number of different target genes. Positively regulated genes have their expression increased by NGF and include substance P, CGRP, BDNF, TRPV1, and P2X3. Negatively regulated genes have their expression suppressed by NGF and include galanin and activating transcription factor (ATF)3. Regulation by endogenous NGF is most evident when there are large changes in NGF levels, such as occurs in nerve injury or inflammation (see the section titled 'Neuropeptide plasticity following inflammation or nerve injury'). However, regulation can also be seen in normal healthy animals, indicating that the adult phenotype of the peptidergic nociceptors is maintained by NGF derived from cells in peripheral targets, such as keratinocytes in the epidermis of the skin. This interpretation is supported by studies in which NGF has been sequestered or blocked in normal animals. This produces a thermal and chemical hypoalgesia; a reduction in the sensitivity of individual nociceptors; a downregulation of substance P, CGRP, and $Na_V1.8$; and a reduction in the innervation density of the epidermis. NGF blockade also results in an upregulation of injury-associated markers such as c-Jun, VIP, and galanin (see the section titled 'Inflammation').

Glial Cell Line-Derived Neurotrophic Factor and Cytokines

NGF is the most thoroughly studied growth factor that regulates neuropeptide expression in DRG neurons, but it is not the only one. Two other important families are the glial cell line-derived neurotrophic factor (GDNF) family and the neuropoietic cytokines. Low-threshold mechanoreceptors and the nonpeptidergic population of nociceptors respond to GDNF and express GDNF receptor components such as the tyrosine kinase RET and the accessory subunits GFRα1, GFRα2, and GFRα3. GDNF treatment *in vivo* has acute effects on DRG neurons that are due to sensitization of TRPV1. However, GDNF also increases the expression of proteins such as P2X3 and somatostatin in nonpeptidergic cells and protects nonpeptidergic cells from some of the effects of axotomy (see the section titled 'Nerve injury'). The peptidergic C fiber nociceptors do not express RET, but some do express GFRα3 and this expression increases after nerve injury. GDNF is thought to regulate nonpeptidergic cells as a targetderived factor, but a more important role is probably as a local injury-derived factor. GDNF is synthesized by Schwann cells and by DRG satellite glial cells, and synthesis is increased further by axotomy. The neuropoietic cytokines can also be classed as injury-derived factors, produced by resident and infiltrating inflammatory cells. Their members include ciliary neurotrophic factor (CNTF), oncostatin M (OM), leukemia inhibitory factor (LIF), and interleukin (IL)-6. Galanin, which is strongly upregulated after nerve injury, is regulated by LIF and IL-6.

Neuropeptide Plasticity Following Inflammation or Nerve Injury

The organization and neurochemistry of DRG neurons are not stable, and major changes take place in response to alterations in levels of growth factors and cytokines. This is seen most dramatically following tissue inflammation and nerve injury.

Inflammation

In inflammatory conditions, such as rheumatoid arthritis or cystitis, the peripheral terminals of DRG neurons become exposed to a complex cocktail of algesic chemicals released from injured cells, from resident mast cells, and from infiltrating macrophages and lymphocytes (Figure 4). This inflammatory milieu activates ligand-gated ion channels (e.g., TRPV1, activated by a fall in tissue pH) and GPCRs (e.g., histamine H1, bradykinin B1 and B2, and P2X3) and leads to an acute activation and sensitization that is evident as a thermal hyperalgesia. However, growth factors and cytokines are also released from Schwann cells, keratinocytes, and inflammatory cells and act on the receptors we reviewed previously to produce both acute and chronic effects. For example, NGF contributes to the acute sensitization of peptidergic nociceptors by a pathway that involves the activation of phospholipase C by trkA and the activation of multiple downstream pathways, including the phosphorylation of TRPV1 by protein kinase C. In addition, internalization and retrograde transport of trkA drives long-term changes in genes related to many aspects of DRG function, including neurotransmitters and neuropeptides, receptors, ion channels, and cytoskeletal proteins. Increased expression of TRPV1 and bradykinin B1/B2 receptors, for example, maintain the sensitization of peptidergic nociceptors, whereas increases in substance P and CGRP expression augment transmission in the dorsal horn (see the section titled 'The role of sensory neuropeptides in the spinal

Figure 4 Diagram summarizing the changes that occur in nociceptors as a consequence of tissue inflammation. Inflammatory mediators act on the peripheral endings of primary sensory neurons to produce both acute sensitization and chronic changes in the phenotype of DRG neurons. These chronic changes include increased expression of neuropeptides (substance P and CGRP) and of the neurotrophin BDNF. The changes in the primary sensory neurons lead to secondary changes in the dorsal horn (central sensitization). 5-HT, serotonin; BDNF, brain-derived neurotrophic factor; CGRP, calcitonin gene-related peptide; DRG, dorsal root ganglion; Glu, glutamate; NGF, nerve growth factor; NK1, neurokinin 1; NO, nitric oxide; TRPV, transient receptor potential.

cord') and contribute to vasodilatation and plasma extravasation via their peripheral release (see the section titled 'The role of peripherally released sensory neuropeptides').

Nerve Injury

Following nerve injury, there are even greater changes in gene expression by DRG neurons than are seen in inflammation. For example, microarray studies showed that the expression of 240 different genes change after axotomy. Many of the changes that take place are opposite to those seen in inflammation and due not to the increased production of growth factors in the periphery but to the axotomy causing a disconnection of DRG neurons from their peripheral targets and consequently a reduction in supply of growth factors. Here I focus on changes in such axotomized neurons (Figure 5). However, note that nerve injury often leaves some DRG neurons whose axons remain intact but which intermingle with those degenerating in the distal nerve and target tissue. These intact axons may actually be exposed to increased levels of growth factors and show changes that are opposite to those of their axotomized neighbors. This is partly because Schwann cells and inflammatory cells respond to the axotomy by increasing growth factor production; it is also because target-derived trophic factors are usually made in limiting amounts. When a significant number of sensory neurons lose contact with their target, the remaining innervation has less competition for these factors. The overall effects of a nerve injury therefore depends on the proportions of axotomized versus intact axons.

Many of the neuropeptides constitutively expressed by peptidergic nociceptors, such as substance P, CGRP, somatostatin, and BDNF, are downregulated in axotomized DRG neurons (Figure 5). These changes develop over a few days and persist for many months, and they appear to be due to loss of the NGF that normally positively regulates neuropeptide expression. Nonpeptidergic cells are also affected by axotomy and, in response to the loss of GDNF, downregulate IB4 binding sites and FRAP. Treatment of the damaged nerves with NGF prevents the downregulation in the peptidergic population, and GDNF prevents it in the nonpeptidergic population. In addition, there are increases in gene expression that appear to be due either to loss of a target-derived factor that negatively regulates neuropeptide expression or to the local production of an injury-derived factor. For example, galanin is dramatically upregulated in a large number of axotomized DRG neurons, including both the peptidergic and nonpeptidergic nociceptive populations and many of the large cells.

Figure 5 Diagram summarizing the range of phenotypic changes that take place in DRG neurons that are axotomized as a consequence of a peripheral nerve injury. The neuropeptides substance P and CGRP and the neurotrophin BDNF are downregulated in small-diameter (predominantly nociceptive) DRG neurons, whereas CCK is upregulated in small-diameter DRG neurons and substance P, NPY, and BDNF are upregulated in large-diameter DRG neurons. The neuropeptides VIP and galanin are upregulated in both small and large neurons. Note that a different set of changes occurs in DRG neurons, whose axons remain intact after a partial nerve injury. BDNF, brain-derived neurotrophic factor; CCK, cholecystokinin; CGRP, calcitonin gene-related peptide; DRG, dorsal root ganglion; NPY, neuropeptide Y; VIP, vasoactive intestinal peptide.

This upregulation starts very rapidly, within a day and well before the downregulation of neuropeptides can be detected. Experimental studies indicate that the galanin upregulation is partly due to the loss of target-derived NGF and partly due to gain of IL-6 or LIF. Thus, NGF treatment can partially offset galanin upregulation, and NGF deprivation has been reported to induce it. In addition, the application of LIF or IL-6 induces galanin expression.

Function of Sensory Neuropeptides

DRG neurons are capable of releasing neuropeptides from both their central and peripheral processes (Figure 1), and at the two sites the neuropeptides have quite different roles. There is also evidence that neuropeptides can be released from DRG cell bodies, but this has been much less studied and its significance is unclear.

The Role of Sensory Neuropeptides in the Spinal Cord

As already reviewed, the central axons of peptide-containing C fibers terminate mainly in laminae I and II of the dorsal horn, where they make synapses on second-order neurons. In this location, neuropeptides are thought to act as neurotransmitters or neuromodulators, coexisting with the fast-acting neurotransmitter glutamate. Thus, they are released from terminals in response to depolarization by an action potential, and they act on GPCRs to cause slow excitatory postsynaptic potentials (EPSPs) or inhibitory postsynaptic potentials (IPSPs). However, unlike glutamate, which is stored in agranular vesicles and released exclusively into the synaptic cleft to act predominantly on *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors concentrated at the postsynaptic density, neuropeptides are thought to be released also from extrasynaptic sites and to diffuse locally (referred to as paracrine or volume transmission). Thus, their site of action is determined more by the distribution of their receptors than by the synaptic circuitry, and the anatomical range of their action is determined by the quantity of neuropeptide released and the presence of extracellular peptidases (which degrade the neuropeptide and hence limit diffusion). In addition, neuropeptides differ from glutamate in requiring a higher frequency of action potentials to evoke their release.

The main neuropeptides that are constitutively expressed by C fiber nociceptors are CGRP and substance P, and of these the most fully characterized as a dorsal horn neurotransmitter is substance P. Thus, many spinothalamic and spinobulbar projection neurons in lamina I are innervated by substance P-containing primary afferents and possess the substance P (neurokinin (NK)1) receptor. Additional projection neurons are located in laminae IV and V, but have dendrites that extend ventrally into laminae I and IIo, where they are innervated b substance P-containing primary afferents (Figure 3). Substance P is released on high-frequency C fiber stimulation, binds to and causes internalization of NK1 within projection neurons, and leads to the activation of inositol triphosphate (IP_3)- and protein kinase A-mediated signaling pathways. This leads to the generation of slow EPSPs, possibly via phosphorylation and inhibition of potassium channels, but it can also activate the transcription factor c-fos and lead to changes in gene transcription. Although primary afferent-evoked and substance P-mediated EPSPs can be detected in the normal dorsal horn, it appears that substance P does not make a significant contribution to transmission in pain pathways until the substance P levels are increased and/or the primary afferent firing is increased, such as occurs with inflammation (see the section titled 'Inflammation'). The strongest evidence for this comes from studies of preprotachykinin-A and NK1 knockout mice, both of which show normal thresholds for acute pain but reduced responses to intense noxious stimuli. In inflammation, increased peripheral NGF sensitizes peptidergic nociceptors

and increases substance P synthesis, both of which lead to increased substance P release from central terminals. This, in turn, leads to acute and chronic changes in the activation of second-order neurons and contributes to central sensitization, a state in which spinal cord neurons become more excitable (Figure 4). Acute changes include membrane depolarization, which leads to further depolarization via the release of Mg^{2+} block of NMDA receptors and the activation of voltage-gated Ca^{2+} channels. Chronic changes include transcriptionally mediated increases in the expression of the NK1 receptor and of neuropeptides expressed by dorsal horn neurons, such as dynorphin. Dynorphin is thought to either suppress or facilitate the activity of nociceptive dorsal horn neurons, depending on the type of cells that express it. The neurotrophin BDNF, which is constitutively expressed in nociceptive C fibers and positively regulated by NGF, is thought to be co-released with substance P and CGRP and to also contribute to central sensitization. Thus BDNF, via its receptor trkB, causes protein kinase-dependent phosphorylation of NMDA and AMPA receptors, as well as long-term changes in gene transcription.

The changes that take place after nerve injury also lead to profound changes in neurotransmission within the dorsal horn. Upregulation of substance P, CGRP, and BDNF in spared afferents can lead to central sensitization by similar mechanisms to those already reviewed. In addition, the dramatic changes in peptide expression within damaged primary afferents (Figure 5) mean that neuropeptides such as VIP, neuropeptide Y, and galanin take over from substance P and CGRP as the neurotransmitters used by injured afferents. Galanin, which is the neuropeptide that is most dramatically increased (approximately 120-fold), has predominantly inhibitory effects on spinal cord processing (mediated via receptors GalR1), and this has been proposed to reduce nociceptive transmission after nerve injury. Consistent with this interpretation, galanin overexpressing mice show reduced pain responses. However, galanin also has neurotrophic actions, and this may explain why galanin knockout mice, which have a loss of peptidergic nociceptors, show reduced pain in nerve-injury models. In addition, in some situations galanin may act at presynaptic receptors GalR2 to promote the release of primary afferent transmitters and increase pain transmission. Cholecystokinin (CCK) is also upregulated after nerve injury and, because CCK acts as a functional opioid antagonist, may contribute to the relative refractoriness of neuropathic pain to morphine analgesia.

The Role of Peripherally Released Sensory Neuropeptides

In addition to release from central terminals, CGRP and substance P are released from peripheral terminals, where they play a key role in the tissue response to injury in a process referred to as neurogenic inflammation. This can be seen, for example, in the triple response that accompanies injuries such as insect bites or nettle stings: a wheal (due to edema), local reddening (due to increased blood flow), and a flare (visible for several centimeters around the injury site due to a spread of the increased blood flow). CGRP, released from sensory endings, is thought to be the major vasodilator contributing to the increased blood flow (acting via receptor CGRP1), and substance P, released from sensory endings, is one of several mediators that increase vascular permeability and lead to plasma extravasation and edema. The substance P effects are both direct (via receptors NK1 on endothelial cells) and indirect (via the activation of mast cells and subsequent release of edema-inducing amines). Classically the triple response has been regarded as an axon reflex, due to the activation of nociceptors and antidromic propagation of action potentials leading to the release of neuropeptides from perivascular endings (Figure 1). However, there is evidence that neurogenic inflammation does not require propagation of action potentials, which suggests that sensory receptor activation and local peptide release are closely linked.

In some situations, peripherally released neuropeptides may contribute to tissue repair and the resolution of inflammation. Substance P acts as a mitogen for fibroblasts and endothelial cells and has been proposed as playing a role in angiogenesis. However, it is clear that sensitization of peptidergic primary afferents, and the associated neurogenic inflammation, can also contribute to chronic inflammatory conditions. This is the case, for example, in asthma. Sensory fibers participate in regulatory reflexes within the airways, and their sensitization increases the activation of parasympathetic efferent pathways, which in turn contribute to coughing, mucus hypersecretion, and bronchoconstriction. This is exacerbated by the antidromic release of substance P and neurokinin A (another tachykinin derived from preprotachykinin-A), which are potent inducers of airway smooth-muscle contraction, vasodilatation, bronchial edema, and mucus hypersecretion. Neuropeptides can also contribute to local inflammation by direct effects on inflammatory cells, in addition to promoting neutrophil and lymphocyte recruitment indirectly by their

effects on vasculature. For example, substance P enhances lymphocyte proliferation and immunoglobulin production, and it enhances cytokine secretion from lymphocytes, macrophages, and mast cells.

Neurophysiology: Past and Present

S Jacyna, University College London, London, UK

Introduction

The term 'neurophysiology' is essentially a twentieth-century coinage. It was only after 1900, moreover, that the discipline acquired a distinct institutional identity, with appointments, university departments, and journals dedicated to its cultivation. Examples of the hyphenated version 'neuro-physiology' and the cognate term 'nerve physiology' can, however, be found in the nineteenth century. Despite the recent provenance of the name, it is nevertheless commonplace for those wishing to delineate the history of neurophysiology to venture far into the past.

Thus the American physiologist and medical historian John Farquhar Fulton (1899–1960), in 1933, declared that: "It is not difficult to trace the history of neurophysiology prior to 1885 for fundamental discoveries were few and can be enumerated on the fingers of two hands." Nonetheless, he then went on to enumerate the efforts of the ancient medical writer Galen (129–200 AD) in the field. Galen had, Fulton claimed, promulgated a theory of nervous conduction that was to last largely unmodified until the end of the eighteenth century. According to Fulton, there was then something of a lengthy hiatus in the history of neurophysiology until the early nineteenth century, when the doctrine of reflex action was formulated.

Underlying histories of this kind is the assumption that a thread of common endeavor is discernible in the history of Western science and medicine. Since antiquity individuals have – largely unwittingly – made contributions to a field that ultimately came to be known as neurophysiology. The fact that they might not have recognized this characterization of their activities, or would, more probably, have classified what they were doing under some other rubric, is seen as irrelevant. This 'discernible thread' assumption permits a curious kind of collegiality to arise between 'neurophysiologists' past and present. The efforts of earlier workers are to be judged in relation to currently accepted understandings of nervous function. They may be deemed to have contributed in some positive way, to have been mistaken, or even to have retarded the advance of knowledge. Thus the seventeenth-century English physician Thomas Willis' (1621–73) 'concepts of neurophysiology' may receive a mixed appraisal. His ideas on the localization of function in the brain are dismissed as 'fanciful,' and based on clumsy experimental technique and anatomical ignorance. On the other hand, Willis is acknowledged as "a pioneer in the development of our knowledge of autonomic function." He was, in fact, as Meyer and Hierons wrote, "very close to our modern ideas of the cerebral control of the autonomic system." One might note in passing that these comparisons are made in language that would have been alien to Willis. The term 'autonomic nervous system' was coined only in 1898 by JN Langley.

Modern historians of science are apt to dismiss historiography of this kind as naive or 'whigish.' On the other hand, imposing this kind of retrospective unity on a disparate body of writings from different periods and places does provide a rationale of sorts for historical investigation, especially for those who see themselves as heirs to this heritage. In order to understand fully our current knowledge of the workings of the nervous system, it is necessary to grasp how we attained it. The perceived failures, as well as successes, of previous generations of investigators may be instructive to those seeking to advance knowledge in the present. It should be noted that what might be characterized as 'practitioners' history' has, moreover, often served a range of polemical goals. Fulton, for instance, was, through historical exposition, keen to demonstrate the intimate relations between clinical and experimental work in advancing the field of neurophysiology. Others have written the history of a particular aspect of the subject with the view of denigrating certain theories, approaches, and conclusions while highlighting the advantages of others. Henry Head's highly partisan history of aphasia studies, published in 1926, comes to mind.

On the other hand, a 'presentist' approach to the history of neurophysiology – as of any other science – is subject to serious criticism. In particular, this perspective on the past runs the risk of seriously distorting the views of the authors under consideration by detaching them from their context. Thus it might be argued that the political and religious circumstances in which Thomas Willis worked, along with the clinical goals that he pursued, are of more relevance to understanding his work than the correctness or otherwise of his doctrines from a modern perspective. More generally, the endeavor to translate the terms in which the body has been understood in the past into a modern idiom runs the risk of obscuring the profound differences involved. Even when similar terms are in use, the meaning is often utterly different. This is true even of as basic a term as 'nerve.'

It is possible to strive for a middle way – that is, to try to chart the development of a modern neurophysiological concept while remaining sensitive to shifts of meaning and to context. An excellent example of such history is Roger Smith's account of the emergence of the concept of physiological inhibition over the past two centuries. In particular, Smith casts important light upon the interdependence of the various settings – both technical and lay – in which the meanings of inhibition evolved during this period.

In view of these issues, any attempt to establish the most salient points in the history of neurophysiology must be undertaken with great caution. This article is mostly confined to the period after 1800, on the grounds that the nineteenth and early twentieth centuries saw the emergence of new ways of understanding the structure and function of the nervous system that differ from those of previous epochs and yet appear to us as distinctively modern. With this in mind, the following discussion is organized under three headings: the reflex, microstructure, and localization of function.

The Reflex

The predominant theory of nervous action from the time of Galen until at least the middle of the eighteenth century revolved around the doctrine of 'animal spirits.' These subtle liquids were elaborated in the brain and then transmitted through the nerves. Their centripetal motion produced sensation; their centrifugal action caused muscular movement. One of the implications of the doctrine of animal spirits was thus that the brain was the sole central organ of the nervous system: it alone received impulses from the outside world, and it was only from the brain that bodily movement was initiated.

The observation that movements, often of a complex and coordinated kind, took place in decapitated animals led a number of authors to reconsider this doctrine. Some speculated about the existence of a 'spinal soul' that would continue to operate after the cerebral soul was detached. While the doctrine of the spinal soul retained advocates even in the nineteenth century, it was challenged by an alternative, purely mechanistic, explanation for the evident capacity of the spinal cord for functional autonomy. The figure most closely associated with this development was the English physician and experimentalist Marshall Hall (1790–1857). In a series of papers Hall argued for the existence of a separate "excito-motor system of nerves" located in the spinal marrow, which subserved reflex action. Hall originated the term 'reflex arc' to designate this mechanism. Hall insisted that the operations of this system, although apparently purposive, were entirely mechanical and involved no psychic component. Although at first controversial, Hall's views on the existence of reflex action were eventually to gain general recognition.

Hall insisted that reflex action was confined to the spinal cord and basal ganglia. However, in 1863 the Russian physiologist Ivan Mikhailov Sechenov (1829–1905) argued that the functions of the cerebral hemispheres could also be understood in terms of reflex action. This was at the time a bold assertion (attempts were made to censor Sechenov's publication), but one that laid the foundation for a unified conception of nervous function in its simplest as well as in its most complex manifestations. Sechenov's work inspired, among others, Ivan Pavlov (1849–1936), who maintained that reflexes could be acquired or conditioned as well as innate.

At the turn of the twentieth century another English investigator, Charles Scott Sherrington (1857–1952), was to elaborate the theory of the reflex in important ways. Sherrington placed the concept of the reflex within a more general biological context. In his monograph, *The Integrative Action of the Nervous System* (1906), he maintained that the simple reflex represented the most primitive instance of the general property of the nervous system to coordinate the body's responses to external and internal stimuli. More complex reactions were to be understood as compounds of such basic reflexes.

Microstructure and Function

The 1830s saw the promulgation of the theory that all bodily structures were composed of 'cells' and their processes. Jan Evangelista Purkyně (1787–1869) and his collaborator Gustav Gabriel Valentin had by 1836 declared that this theory applied to the nervous system, which was, they claimed, composed entirely of globules and fibers. In 1838 Robert Remak (1815–65) announced that in nervous tissues cells and fibers were continuous, the latter originating from the body of the former. By analogy with other organs it might be concluded that the cell body was the active portion of the nervous system, while the fibers performed a commissural function.

These insights, however, left open the issue of how the different nerve cells communicated. This question was to be the source of much controversy throughout the later nineteenth century. On the one hand there was the so-called reticularist theory, which maintained that the nerve cells formed a continuous network. The best known reticularist was the Italian histologist Camillo Golgi (1843–1926), who devised new staining techniques designed to reveal the microscopic structure of the nervous system with

unprecedented clarity. He nonetheless maintained that the fibers that emerged from cell bodies possessed processes that ultimately merged with those of other cells.

Golgi's staining techniques were adopted and refined by the Spaniard Santiago Ramón y Cajal (1852–1934). Working in relative isolation from the main schools of scientific research, he was less influenced by prevailing orthodoxies, including the reticularist theory. Whereas Golgi insisted to the end of his life on the continuity of the nervous system, when Cajal looked through the microscope he saw the nerve cells as discrete anatomical entities. Rather than studying specimens derived from adult organisms, Cajal made use of embryonic tissue in which the structure was less complicated and the nerve fibers remained unmyelinated.

Cajal found it difficult to gain acceptance for his claims. A crucial moment came at the 1889 meeting of the German Anatomical Society in Berlin. Cajal was, through direct demonstration of his specimens, able to convince a number of scientists, including the highly influential Albrecht von Kölliker – previously a reticularist – of the truth of his claim that the processes of nerve cells approximated to but never merged with those of others. In 1891 another convert, Wilhelm von Waldeyer (1836–1921), proposed the name 'neuron' for this functional unit. As a highly regarded professor in the University of Berlin, Waldeyer was able to propagate and gain acceptance for this new conception of the microstructure of the nervous system.

Sherrington came to know of Cajal's work and relied upon these morphological assumptions when formulating his theory of the integrative action of the nervous system. The notion of the neuron as anatomically autonomous made it possible to conceptualize the orderly and unidirectional transmission of impulses through the nervous system in a way that was impossible in the reticularist hypothesis. Sherrington in 1897 coined the term 'synapse' (derived from the Greek word 'to clasp') to describe the junction between one nerve cell and another. He was, however, careful to insist that the existence of this junction, as well as the mode of transmission, remained hypothetical.

Electron microscopy in the second half of the twentieth century made it possible to visualize synaptic junctions in far greater detail than was permitted by the light microscope. Chemical theories of transmission had been suggested as early as 1905. An alternative electrical theory was, however, upheld by some, including for a time Sherrington's student, John Carew Eccles (1903–97). The researches of Bernard Katz (1911–2003) in the 1950s, however, demonstrated the existence of a synaptic delay in neuromuscular transmission, which could not be accounted for in the electrical hypothesis but which implied the action of a chemical neurotransmitter. The agent concerned was identified as acetylcholine. Reversing his earlier position, Eccles in 1964 showed the existence of a comparable delay in transmission between afferent and motor neuron, suggesting that chemical transmission at synaptic junctions was a general phenomenon.

Localization of Function

For much of the nineteenth century, physiology remained closely connected to anatomy. This bias was especially marked in Britain and has been explained in terms of a national aversion to conducting experiments on living, conscious beings. A leading exponent of this anatomical approach was the Scottish surgeon Charles Bell (1774–1830), who became involved after 1822 in a controversy with the French physiologist François Magendie (1774–1842) over priority of discovery in the matter of the functions of the spinal nerve roots. Magendie worked in a context where far less stigma was attached to extensive use of animal experimentation. His exhibition of his techniques on a visit to Britain, however, caused outrage.

The convoluted and somewhat sordid details of the controversy between Bell and Magendie need not be detailed here. What should be noted is that the so-called Bell–Magendie law that was ultimately adopted recognized that the posterior and anterior roots of the spinal nerves possessed distinct functions: while the former were sensory the latter were motor in nature. This simple dichotomy was called into question by later research that identified some sensory fibers in the anterior root. From an historical perspective, however, this 'law' was a significant moment in the movement that gathered momentum in the first half of the nineteenth century, to assign particular functions to distinct portions of the nervous system.

Another important contribution to this tendency came from the work of Franz Josef Gall (1758–1828). Gall was a skilled anatomist who pioneered new techniques for the dissection of the brain and spinal cord. He was, however, the author of an ambitious project, which Gall called 'organology,' but which became better known as 'phrenology.' According to this system, the brain was not, as had been generally assumed, a unitary entity, but a congeries of organs, each with its distinct function. Gall further surmised that the size of an organ was directly related to the strength of a particular trait in an individual. These characteristics could be read by means of a

craniological examination, thus providing insights into character and aptitude.

While Gall's system excited considerable interest and support, it never gained general acceptance. His work was, moreover, subjected to what was seen as a devastating critique by the French experimentalist Pierre Jean Marie Flourens (1794–1867), who advocated a more holistic understanding of cerebral function. Flourens maintained that the cerebral hemispheres, cerebellum, and medulla each possessed distinct functions. The hemispheres served as the center for volition and cognition, the cerebellum regulated equilibrium and coordination, and the medulla controlled the vital functions. Flourens, however, insisted that each of these areas of the brain performed its operations as a whole. It was therefore impossible to assign particular offices to circumscribed portions of the cerebrum. Flourens based these conclusions on ablation experiments performed on birds as well as on small mammals. Flourens' views on cerebral function enjoyed the status of orthodoxy until the second half of the nineteenth century.

Gall's suggestion that the cerebral cortex might be composed of functionally distinct areas was not, however, entirely forgotten. When after 1860 new theories of cerebral localization began to circulate, his name was often invoked as an important, if flawed, precursor. As Herbert Spencer (1820–1903) declared in 1870:

> [I]t seems to me that most physiologists have not sufficiently recognized the general truth of which Phrenology is an adumbration. Whoever calmly considers the question, cannot long resist the conviction that different parts of the cerebrum must, *in some way or other*, subserve different kinds of mental action. Localization of function is the law of all organization whatever; and it would be marvellous were there here an exception.

This was just a particular instance of the general law that Spencer called the physiological division of labor.

The 'New Phrenology' that developed after 1860 relied on two principal sources of evidence: clinical observation and animal experiment. The former source derived inferences about normal brain function from the symptoms presented by patients suffering from brain lesions. A particularly important event occurred in 1861 in the course of a debate at the *Société d'Anthropologie* of Paris. The *Société* was known as a center for advanced materialist ideas and included a number of unreconstructed supporters of Gall's views. The members of the *Société* were engaged in a debate on the relationship, if any, between cranial size and intelligence when, in April 1861, a surgeon and anatomist named Pierre Paul Broca (1824–80) made a particularly momentous intervention.

Broca presented the case of a patient named Leborgne who had for several years been unable to utter any words save for the syllable 'tan.' At autopsy Broca had discovered a lesion of the third frontal convolution of Leborgne's brain. On the basis of this and subsequent observations, Broca proposed that the posterior part of this convolution was the seat of articulate language. In 1863 Broca tentatively advanced the view that the speech center was located in the 'dominant' hemisphere of the brain and that there was thus a correlation with handedness.

These claims provoked widespread interest throughout the medical world as practitioners sought out cases of acquired language deficit and attempted to correlate these symptoms with injury to determinate parts of the cortex and its underlying structures. An important contribution to this literature was made in 1874 by the German psychiatrist Carl Wernicke (1848–1905). Wernicke described a form of 'sensory' aphasia in which the ability to comprehend words was impaired, and correlated this condition with injury to the temporal lobe. His observations again supported the hypothesis of hemispherical dominance.

Some scientists, such as Friedrich Goltz (1834–1902), continued to maintain the view that the cerebral hemispheres performed their functions as a unitary organ. There was, moreover, much controversy about the validity of particular localizations. Nonetheless, by the last decades of the nineteenth century the principle of cerebral organization had, as a result of extensive clinical evidence gathered in the aftermath of Broca's initial announcement, received widespread acceptance. If the various aspects of language could be assigned a seat on the cerebral cortex, then there seemed every reason to suppose that the other higher functions of the brain might also be localized.

These clinical findings were supplemented by a series of experimental results that emerged in the later nineteenth century. In 1870, the psychiatrist Eduard Hitzig (1838–1908) and the anatomist Gustav Fritsch (1838–1927) published the results of experiments in which they had applied an electric current to various parts of the cerebral cortex of a dog. These investigations appeared to show that stimulation of specific sites upon the cortex elicited movements of particular parts of the body; there was thus a 'motor cortex.' This result overthrew Flourens' doctrine that the cerebral hemispheres were not motor in function, as well as supplying further confirmation of the reality of cerebral localization.

Fritsch and Hitzig's results were corroborated by the British physician David Ferrier (1843–1928), who, working on the brain of monkeys, produced more detailed maps of the motor cortex. Ferrier also proposed cortical sites for some of the special senses.

The doctrine of cerebral localization received further support from the aforementioned developments in the histology of the nervous system. If each neuron was a distinct unit – an "absolutely autonomous canton" (Cajal) – then it became much easier to conceive the structural basis of functional specialization. Developments in cytoarchitectonics, which appeared to show the existence of histologically distinct areas in the cerebral cortex, were also seen to provide further support for localization.

By the end of the nineteenth century a 'mosaicist' view of cerebral function was thus in the ascendant. Around 1900, however, the contention that particular functions could be assigned to ever more specific zones within the brain was challenged. A number of neurologists, such as Henry Head (1861–1940) and Kurt Goldstein (1878–1965), argued that a proper study of clinical cases revealed evidence that was incompatible with any strict notion of cerebral localization. They cited the fact that cortical injury led to global behavioral disorders and pointed to the apparent ability of the brain to recover functional integrity despite the destruction of portions of the cortex. Shepherd Ivory Franz (1874–1933) came to similar conclusions on the basis of both clinical and experimental work. The American psychologist Karl Lashley (1890–1958) derived the doctrine of cortical 'equipotentiality' from his own experiments. According to this theory, any part of the cortex could substitute for the functions of the other in case of local injury. Lashley was, however, willing to accept a limited form of localization for sensory and motor functions.

The middle decades of the twentieth century saw, however, a reassertion of the reality of cortical localization based upon the use of increasingly sophisticated experimental techniques. Working at Johns Hopkins University, Clinton Nathan Woolsey (1904–93) employed electrophysiological methods to show that specific areas of the cortex responded to the stimulation of small cutaneous surfaces. The British physiologist Edgar Douglas Adrian (1889–1977) also developed techniques that made it possible to record the discharge of single nerve fibers. This methodology was used, in conjunction with refined ablation techniques, to map the functional divisions of the mammalian cortex with far greater precision than had previously been possible. More recently, brain-imaging techniques, such as positron emission tomography, have apparently provided striking visual evidence that specific areas of the brain are active during certain cognitive states. Thanks to the wide dissemination of such images through the media, the doctrine of cerebral localization has now entered popular culture.

Introduction

Experience-dependent changes in the efficacy of synaptic connections between different neurons is believed to be a basis for learning memory and various forms of development. In 1949 Donald Hebb postulated that when one neuron persistently drives the activity of another neuron, the synaptic connection between these neurons is potentiated. This activity-dependent synaptic potentiation could account for various forms of learning. Theoretical analysis indicates that not only Hebbian-like synaptic potentiation is necessary but also depression between two neurons that are not sufficiently coactive. If depression did not exist, all synapses would tend to saturate at their maximal allowed values, neurons would not be selective, and they would respond to different stimuli in a similar manner. The experimental correlates of these theoretically proposed forms of synaptic plasticity are called long-term potentiation (LTP) and long-term depression (LTD). Significant experimental evidence has accumulated to support the hypothesis that synaptic plasticity is indeed a basis for learning memory and various forms of development.

The cellular and molecular machinery responsible for synaptic plasticity is complex. Hundreds of different molecules are involved in the induction and maintenance of synaptic plasticity, and this complexity has raised doubts about the ability to truly understand these mechanisms. The role of computational modeling is to start from a set of assumptions about underlying mechanisms, in this case about the underlying physiology and molecular biology, formalize them as a set of equations, and use simulations to obtain the unambiguous consequences of this set of assumptions. Therefore, for complex systems, computational modeling is an indispensable tool for gaining a true understanding of how they operate.

Two broad classes of synaptic plasticity models can be described: (1) Phenomenological models are very simple models that are typically based on an input–output relationship between neuronal activity and synaptic plasticity. Phenomenological models are typically used in simulations to account for higher-level phenomena such as the formation of memory or the development of neuronal selectivity. (2) Biophysical models are more-detailed models that incorporate more of the cellular and synaptic biophysics of neurons and are typically used to account for controlled synaptic plasticity experiments. This article focuses on biophysical models.

Synaptic plasticity has an early induction phase in which external signals rapidly cause a biochemical cascade that results in a change in synaptic efficacy. This change in efficacy is expressed by changing either pre or postsynaptic variables that control synaptic transmission, such as the number of postsynaptic receptors or the probability of presynaptic release. There is also a late phase of synaptic plasticity in which these efficacy changes are maintained over long periods of time. These two phases can be partially separated physiologically and pharmacologically. The section titled 'Biophysical models for the induction of synaptic plasticity' reviews models describing the induction of synaptic plasticity, and the section titled 'Models for maintaining synaptic plasticity' reviews models accounting for the maintenance of synaptic plasticity.

Different Induction Protocols for Bidirectional Synaptic Plasticity

LTP was first described in 1973 by Bliss and Lømo, and since that time many different induction paradigms have been used to induce LTP and LTD. The most common method for inducing LTP has been to use extracellular stimulation together with a recording of extracellular field excitatory postsynaptic potentials (fEPSPs). The fEPSP, although recorded extracellularly, is believed to represent an average of the EPSPs of many synapses in the vicinity of the recording electrode. To induce LTP, first a baseline is established (Figure 1(a)). This means that a very low-frequency stimulus is applied (typically once every 30–60 s), the fEPSP is recorded, and over the baseline period, the magnitude or slope of the fEPSP is required to remain constant. After the baseline period, several bursts of a high-frequency stimulus are applied (theta burst stimulation (TBS), typically two to five bursts of four stimuli at 100–200 Hz, with interburst period of 200 ms). After the TBS, the magnitude and slope of the baseline are usually increased (Figures 1(a)–1(c)). Using this method of extracellular stimulation, LTD can also be induced using low-frequency stimulation (typically 1–5 Hz) with a large number of stimuli (≈1000).

Pairing is the name given to another commonly used induction protocol. In a pairing protocol, the postsynaptic cell is recorded and stimulated by means of a patch clamp electrode. After baseline, LTP is induced by pairing a low-frequency extracellular stimulus

Figure 1 Different protocols for inducing synaptic plasticity in slices. (a) In rate-based induction, extracellular stimulating and recording electrodes are used. (b) First a baseline field excitatory postsynaptic potential (fEPSP) is established using a very low-frequency stimulus. Next a low-frequency stimulation (hundreds of pulses at 1–10 Hz) is used to elicit long-term depression (LTD) or a high-frequency stimulus (30–200 Hz) is used to elicit long-term potentiation (LTP). (c) A schematic diagram of plasticity as a function of frequency. (d) In pairing-based plasticity, an extracellular stimulation is paired with an intracellular voltage clamp-controlled depolarization. (e) If the cell is slightly depolarized to −50 mV, LTD is induced, whereas strong depolarization to 0 mV produces LTP. (f) Plasticity curve as a function of postsynaptic depolarization. (g) In spike timing-dependent plasticity (STDP) induction protocols, one presynaptic and one postsynaptic cell are patch clamped. (h) If the presynaptic cell is induced to repetitively fire 10 ms before the postsynaptic cell, LTP is induced. If the firing order is reversed, LTD is induced. (i) A schematic plasticity curve as a function of Δt. (All diagrams are schematic illustrations.)

with a strong depolarization of the postsynaptic cell (Figures 1(d)–1(f)). A moderate depolarization of the postsynaptic cell, paired with a low-frequency stimulus, results in LTD (Figures 1(d)–1(f)).

A more recent induction protocol is spike timing-dependent plasticity (STDP). This form of plasticity is induced by a repeated delivery of pre- and postsynaptic spikes with a given time interval Δt between the pre- and postsynaptic spikes. In an STDP protocol, the precise value of Δt determines the size and magnitude of the resulting synaptic plasticity. Typically, if the presynaptic spike precedes the postsynaptic spike ($\Delta t > 0$), LTP is obtained (Figures 1(g)–1(i)), and if the postsynaptic spike comes before the presynaptic spike ($\Delta t < 0$), LTD is obtained. However, other parameters, such as frequency of stimulation, magnitude of presynaptic EPSP, and the location of the stimulated synapse along the dendritic tree also affect the induction of STDP.

Biophysical Models for the Induction of Synaptic Plasticity

A biophysical model is defined by a set of mathematical equations that represent the biochemical and physiological processes that lead to the induction and expression of synaptic plasticity. However, because it is not possible to implement precisely every portion of the physiological and biochemical networks leading to synaptic plasticity, these

biophysical models must rely on many simplifications and abstractions.

Calcium-Dependent Models of Bidirectional Synaptic Plasticity

Calcium transients in the spine determine the sign and magnitude of many forms of synaptic plasticity. The source of the major portion of postsynaptic calcium is influx through the *N*-methyl-D-aspartate (NMDA) receptors, and therefore blocking them pharmacologically can eliminate bidirectional synaptic plasticity. A partial block of NMDA receptors can convert LTP to LTD. Moreover, strong and brief postsynaptic calcium transient, in the absence of a presynaptic stimulus, can produce LTP, whereas prolonged calcium transients with moderate magnitudes result in LTD.

A key component of most biophysical models of synaptic plasticity is the NMDA receptor. Since the NMDA receptor depends both on binding of neurotransmitter and on postsynaptic voltage, it is a coincidence detector, thus providing Hebbian properties to NMDA receptor-dependent synaptic plasticity. Early models of LTP simulated calcium influx through NMDA receptors during LTP induction protocols. In these models, a large calcium transient is taken to be the correlate of LTP. These models simulated stimulation protocols that activate multiple synapses on the same dendritic branch at various frequencies and examined resulting calcium transients in a single spine. A common conclusion of these different studies was that to generate large calcium transients during LTP, the calcium buffers, which absorb free calcium, must be saturated, thus amplifying the small signal observed in the calcium currents. However, these early studies did not take into account back-propagating action potentials (BPAP) or active dendritic conductances.

The calcium control hypothesis, an influential concept in the field, postulates that a large calcium transient produces LTP whereas a moderate increase in calcium results in LTD. This hypothesis has subsequently received significant experimental support. Several different models for the induction of synaptic plasticity are based, either explicitly or implicitly, on this hypothesis.

To simulate calcium-dependent synaptic plasticity, it is necessary to define rules that translate calcium dynamics in postsynaptic spines to changes in synaptic strength. A simple choice is to assume that the peak of the calcium transients determines the sign and magnitude of the synaptic weight change. This simplified assumption might have some unrealistic consequences, such as that the width of calcium transients has no effect on the magnitude of plasticity. A simple dynamical system that implements the calcium control hypothesis has the following form:

$$\mathrm{d}W_i/\mathrm{d}t = \eta(\mathrm{Ca})[\Omega(\mathrm{Ca}) - \lambda W_i] \qquad [1]$$

Here W_i is the synaptic efficacy of synapse i, Ω (Figure 2(a)) determines the sign magnitude of synaptic plasticity as a function of Ca levels, η (Figure 2(b)) is a calcium-dependent learning rate, which is typically a monotonically increasing function of calcium, and λ is decay constant. If $\lambda = 1$, for sustained calcium elevation, the synaptic efficacy converges to the value of Ω, and the rate of convergence depends on η.

It is very easy to simulate pairing-induced plasticity (Figure 1(d)–(f)) on the basis of the calcium control hypothesis and mathematical models of NMDA receptors. Because of the voltage dependence of NMDA receptors, pairing a presynaptic stimulus with a moderate postsynaptic depolarization (Figure 3(a)) produces a significantly smaller calcium transient than if the presynaptic stimulus is paired with a strong depolarization. Consequently (Figure 3(b)), the change in the simulated synaptic weights, after 100 presynaptic stimuli, is a function of the level of the postsynaptic voltage during induction, in qualitative agreement with experimental results. In the simplest models, all calcium influx is assumed to originate from NMDA receptors. Models that take into account calcium influx through voltage-gated calcium channels (VGCC) as well produce results that are qualitatively similar.

Rate-dependent induction protocols have also been simulated using similar assumptions. Modeling such

Figure 2 Calcium-dependent functions that control synaptic plasticity. (a) The Ω function controls the sign and magnitude of synaptic plasticity. At low calcium concentrations corresponding to baseline activation, no change in synaptic weight occurs. At intermediate calcium concentration, long-term depression (LTD) is induced, and at high calcium, long-term potentiation (LTP) is induced. (b) The η function, which controls the rate of convergence to the steady state, is a monotonically increasing function of calcium.

Figure 3 Pairing-induced plasticity (schematic diagrams). (a) Calcium transients induced by a single presynaptic stimulation at resting membrane potential (black dashes), at slightly depolarized potential (−50 mV, red dashes), and for highly depolarized potential (0 mV, blue). (b) The plasticity curve shows the magnitude of plasticity as a function of postsynaptic voltage; V_m, membrane potential.

rate-dependent protocols, in which there is no direct experimental control over the postsynaptic neuron, requires a model of a spiking postsynaptic neuron.

In a calcium-based model of synaptic plasticity, the presynaptic spike naturally effects calcium influx because glutamate released due to the presynaptic spike binds postsyanaptic NMDA receptors and causes the receptors to open. The postsynaptic spike can alter calcium influx through NMDA receptors because the BPAP, which depolarizes the postsynaptic cell, causes an increased conductance through the NMDA receptors. Given the assumptions of the calcium control hypothesis, what is required for induction of STDP is that calcium transients during post–pre ($\Delta t < 0$) conditions be larger than transients due to unpaired presynaptic or postsynaptic stimulation but smaller than transients due to pre–post stimuli ($\Delta t > 0$). Typically, neuronal spikes in cortex are assumed to be of very short duration, ≈1 ms. Figure 4(d) shows calcium transients for different conditions: pre alone (blue), $\Delta t = -10$ ms (red), and $\Delta t = 10$ ms (black), while assuming a BPAP that decays within 2 ms. There is very little difference between pre alone and post–pre, and in the pre–post condition, calcium transients are only slightly larger. There is no difference between post–pre and pre only conditions because by the time of the presynaptic spike, the postsynaptic voltage generated by the BPAP entirely disappears, and the extra calcium influx in the pre–post condition is small because of the short duration of the BPAP. These two problems can be overcome if the BPAP, as commonly observed in dendrites, has a slow repolarization tail potential (Figure 4, bottom). This tail potential is still present when the presynaptic spike occurs during a post–pre protocol (Figures 4(f) and 4(h)), producing a difference between post–pre and baseline. The long tail of the BPAP also increases the total calcium influx during pre–post (Figures 4(g) and 4(h)) protocols. A consequence of this set of assumptions is STDP curves as presented in Figure 5(b). For $\Delta t < 0$ they produce LTD, as observed experimentally; for small values of $\Delta t > 0$, they result in LTP; but for larger values of Δt, they produce LTD again.

The pre–post form of LTD predicted by such models is different from the cartoon image of STDP presented in Figure 5(a). Does this pre–post form of LTD exist experimentally? In hippocampal slices, this form of LTD exists, is robust, and has a similar magnitude to the post–pre form of LTD. In contrast, in experiments performed in cortical slices or hippocampal cultures, this form of LTD is either absent or at least significantly smaller than the post–pre form of LTD. This raises the possibility that different mechanisms are at work in these different cortical regions or types of experimental preparation.

Another explanation for the absence of the second LTD window in some preparations is that calcium transients show a significant variability due to stochastic synaptic transmission. Much of this stochastic variability might arise from the stochastic opening and closing of the small number of postsynaptic NMDA receptors. If this variability is large enough, it might result in a very significant reduction in the magnitude of the second LTD window.

Two-Coincidence Models and Other Pathways for Induction

Most models of synaptic plasticity based on the calcium control hypothesis predict an STDP curve in

Figure 4 Calcium transients during induction of spike timing-dependent plasticity, with a narrow back-propagating action potential (BPAP; (a)–(d)) and a BPAP with a wide tail ((e)–(h)). Here all currents are assumed to arise from *N*-methyl-D-aspartate (NMDA) receptors, and these diagrams are schematic. The probability of NMDA receptors in the open state (P_{open}) due to glutamate binding (blue) and the postsynaptic voltage due to BPAP (green) (a) pre only; (b) pre before post; (c) post before pre. (d) Shows calcium transients, in arbitrary units (AU), for the three cases: pre only (blue), post–pre (red), pre–post (black). Post–pre does not differ from baseline, and pre–post increased only moderately. Calcium transients are now different for the three different cases (h).

Figure 5 Spike timing-dependent plasticity (STDP) curves (schematic diagrams). (a) Some experimental results indicate STDP curves with a single long-term depression (LTD) region at $\Delta t < 0$ and a single long-term potentiation (LTP) region at $\Delta t > 0$. (b) Other experiments find an additional LTD region at larger values of $\Delta t > 0$. Note that in all cases, results of single experiments (+) diverge significantly from the simple fit curves.

which there is a pre–post form of LTD in addition to the standard post–pre form of LTD. An alternative to the single-coincidence models described above are two-coincidence models, which postulate that LTP is triggered by calcium influx through NMDA receptors, whereas LTD is triggered by a second coincidence detector that is sensitive to post-before-pre activation. One option is that the second coincidence detector is implemented by calcium influx through VGCCs concurrent with the activity of metabotropic glutamate receptors. Experimental work has indeed shown that postsynaptic NMDA receptors might not be necessary for spike timing-dependent LTD, and that metabotropic glutamate receptors and VGCCs

are necessary for spike timing-dependent LTD. Some experiments have also found that the activation of cannabinoid receptors is necessary for this LTD. Although elements of the two-coincidence model have received support, the biophysical details of this second coincidence detector have yet to be elucidated.

Alternatives to the idea that the second coincidence detector leads to LTD have been proposed. One idea is that calcium influx through VGCC suppresses LTD or that specific calcium temporal profiles invoke a veto mechanism to suppress LTD, eliminating the pre–post form of LTD.

Modeling the Biochemical Pathways Leading from Calcium to Change in Synaptic Efficacy

The question of how the same molecule, calcium, can trigger both LTP and LTD was first addressed in a model proposed by John Lisman in 1989. Lisman's model postulates that moderate calcium preferentially activates phosphatases, which dephosphorylate calcium/calmodulin-dependent protein kinase II (CaMKII), whereas high calcium levels cause a net phosphorylation of CaMKII. The correlate of synaptic efficacy in this model is the phosphorylation level of CaMKII, and this mechanism could therefore account for bidirectional synaptic plasticity.

Recent experimental evidence has shown that a correlate of synaptic plasticity is the phosphorylation state of the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors: LTP is correlated with phosphorylation at s831, a CaMKII site, and LTD is correlated with dephosphorylation at s845, a protein kinase A (PKA) site. Models by Castellani and colleagues simulated some of the kinases and phosphatases involved in the signal transduction pathways leading from calcium transients to synaptic plasticity. This approach was that synaptic plasticity is first expressed in posttranslational changes in AMPA receptors. Therefore, they constructed a minimal biochemical induction pathway that links these specific changes in AMPA receptors with the original signal, the change in postsynaptic calcium levels.

Figure 6 shows the elements of this induction model, which is an extension of Lisman's work. Plasticity protocols cause calcium to enter the spine, which then binds to calmodulin (CaM) to form Ca-CaM. Ca-CaM can bind and activate, either directly or indirectly, different kinases and phosphatases. At low levels, Ca-CaM is assumed to primarily bind protein phosphatase 2b, which indirectly activates protein phosphatase 1 (PP1) (Figure 6(a)). PP1 then dephosphorylates AMPA receptors at both s831 and s845 sites (Figure 6(b)). A higher postsynaptic calcium concentration causes direct activation of CaMKII and an indirect activation of PKA through the cyclic adenosine monophosphate pathway. CaMKII phosphorylates AMPA receptors at s831 and PKA at s845. PKA also indirectly inactivates PP1, thus decreasing phosphorylation at both sites. The phosphorylation of both these sites increases the conductance of the AMPA receptors and controls receptor trafficking.

To construct this model, various forward and backward kinetic coefficients are needed. However, only a small portion of them are known. It is possible to choose constants, in a way that is consistent with experimental data, such that in this model, at moderate calcium, LTD is induced and at higher calcium, LTP is induced. However, different sets of kinetic coefficients can be extracted from the data. Although the different sets of coefficients produce results that are qualitatively

Figure 6 Schematic diagrams of biochemical pathways involved in the induction of bidirectional synaptic plasticity. (a) Kinases and phosphatases that are activated by calcium and that modify the conformational state of the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors (AMPARs). (b) Biochemical pathways for the phosphorylation and dephosphorylation of AMPA at two phosphorylation sites. I1 is the regulatory subunit of PP1 that binds to PP1, and inhibits its activity when in the phosphorylated state (I1p). AMP, adenosine monophosphate; ATP, adenosine triphosphate; CaM, calmodulin; CaMKII, calcium/calmodulin-dependent protein kinase II; cAMP, cyclic adenosine monophosphate; GluR1 and GluR2, metabotropic glutamate receptors; PKA, protein kinase A; PP, protein phosphatase; s831, a CaMKII site; s845, a PKA site.

similar to each other and to experiments, these different parameters produce results that are quantitatively significantly different. Under certain conditions, such enzymatic models can be approximated by the simpler calcium-dependent models described by eqn [1].

One problem with these enzymatic models is that they require many unmeasured kinetic coefficients. However, a far more difficult problem is that these models are based on a mass action approach, an approach that is valid for large, well-mixed systems. However, synapses are neither large nor well mixed, and therefore these mass action simulations might produce results with significant errors. An alternative approach is to simulate biochemical reactions using detailed stochastic simulations that are not based on the mass action approach. Such simulations must take into account both stochastic fluctuations due to the limited synaptic volume and the three-dimensional structure and organization in the spine. Consequently, such simulations are very difficult and computationally intensive; however, they might be necessary in modeling biochemical processes that occur in spines. It is also important to know which of the biochemical processes in the spine require this detailed form of modeling and which ones are suitable for the simpler mass action approach.

Models for Maintaining Synaptic Plasticity

Synaptic plasticity is expressed by changes to the synaptic transmission machinery. Such changes include receptor phosphorylation, change in receptor number, and presynaptic changes in probability of release. Changes in conformational states of receptors through phosphorylation are counteracted by dephosphorylation by phosphatases and by protein turnover and trafficking and therefore are likely to have a limited lifetime, much shorter than the lifetime of memory. Similarly, changes in number of receptors are likely to be transient due to trafficking and turnover of receptor proteins. Similarly, presynaptic changes, although their mechanism is less explored, are likely expressed in changes in proteins, changes that are also likely to be transient. However, although changes in protein function or number are transient, the memories they encode can last a lifetime.

The inherent transience of synaptic efficacies was noted in 1984 by Francis Crick, who suggested that cooperative interactions among proteins can overcome this problem. Crick suggested a specific but quite abstract model of such cooperativity. Some form of cooperativity underlies most models that address this problem.

In the absence of a correcting mechanism, protein turnover sets an upper limit to the stability of synaptic plasticity since it will erase both conformational changes to proteins and change in protein number. Similarly, protein trafficking also limits the lifetime of memories because proteins that are altered in one synapse move away, removing the synapse-specific trace laid down by plasticity. However, there is no agreed on estimate about the rates of protein turnover and trafficking. While recent estimates of protein turnover in slices are on the order of 2–20 h, previous studies produced much longer estimates. Similarly, different methods produce significantly differing estimates regarding the timescale of receptor trafficking. However, even longer estimates of receptor dwell time are much shorter than the lifetime of some memories.

Induction protocols of synaptic plasticity (see the section titled 'Different induction protocols for bidirectional synaptic plasticity' above) last between seconds and minutes. However, different types of induction protocols can produce either a transient change, one that returns to baseline within 2–4 h, or a long-lasting change. For example, LTP induced by a single theta burst produces a transient LTP (E-LTP), but four theta bursts produce a long-lasting LTP (L-LTP). Similarly, different induction protocols can produce short LTD (E-LTD) or long-lasting LTD (L-LTD). It is interesting that the induction of L-LTP and L-LTD depends on the synthesis of new proteins during the induction phase. The timescales of E-LTP and E-LTD are roughly consistent with temporal estimates for protein turnover and trafficking. The much longer lifetimes of L-LTP and L-LTD and their protein synthesis dependence can lead to the hypothesis that protein synthesis can somehow counteract protein turnover and trafficking.

A Molecular Switch

One possible mechanism that can stabilize synaptic efficacies is a bistable molecular switch. Such a switch can be generated by a kinase that is active when phosphorylated and that can phosphorylate itself. This type of a positive feedback loop often has two stable steady states: one is unphosphorylated, and another one is nearly totally phosphorylated. If the system is in the phosphorylated stable state, when a phosphorylated molecule is degraded and replaced by an unphosphorylated molecule, it will quickly be phosphorylated by its active neighbors. This autophosphorylating kinase can act directly on receptors to determine synaptic efficacy.

The most widely investigated mechanism proposed for such a bistable switch is the autophosphorylation of CaMKII molecules. CaMKII molecules are embedded as subunits in a holoenzyme composed of approximately ten other CaMKII molecules. CaMKII molecules are activated by a Ca-CaM signal and can move to a relatively stable active phosphorylated state

by interacting with other CaMKII subunits. This is a more complex model than the simple phosphorylation loop described above. It is apparent that a model of CaMKII requires some level of a Ca-CaM signal so that the phosphorylated state is stable in face of protein turnover. Different models of CaMKII autophosphorylation have been proposed; some exhibit bi-stability, while other models do not. However, similar to biophysical models of induction, many of the kinetic parameters of the system are unknown, and the exact details of the appropriate model are not yet fully agreed on. Therefore, it remains to be determined whether a realistic representation of CaMKII autophosphorylation allows bi-stability. Moreover, experimental studies have not found direct support for bi-stability of the autophosphorylating CaMKII system.

Although the importance of CaMKII for the induction of LTP is not disputed, there is less unequivocal evidence regarding its importance for the maintenance of L-LTP or long-term memory. Recent results have shown prolonged phosphorylation of CaMKII during the maintenance of L-LTP; however, the fraction of phosphorylated kinase after LTP in such experiments seems far from saturation, unlike the predictions of the computational models. It is interesting to note that the putative targets of CaMKII, such the AMPA receptors, seem to be only transiently phosphorylated after protocols that induce long-term memory. Blocking of CaMKII activity during the maintenance phase of L-LTP in most experiments, but not all, did not block the maintenance phase of LTP.

The Cluster Model

The cluster theory of synaptic stability offers an alternative to molecular switch approaches to synaptic stability. In this theory it is assumed that receptors in the postsynaptic density are typically clustered (Figure 7(a)) and that receptors within the cluster interact so that they influence the trafficking of receptors in and out of the cluster in such a way that the lifetime of the cluster exceeds by order of magnitude the dwell time of each receptor within the cluster. This model is based on several assumptions: (1) Synaptic efficacy is proportional to the number of postsynaptic receptors, such as AMPA receptors; (2) receptors in the postsynaptic density are clustered; (3) the insertion rate of a receptor in the vicinity of other receptors in the cluster is much higher than for an isolated receptor; and (4) the rate of receptor removal from the cluster is independent of interactions with other receptors in the cluster. Assumptions (1) through (3) are essential assumptions of this model, while assumption (4) could be altered while preserving the main features of the model.

Simulations of such networks (Figures 7(b) and 7(c)) show that although individual receptors within a cluster are rapidly trafficked in and out of the cluster, the cluster itself remains stable for long periods. Although the exact instantaneous number of receptors fluctuates, it fluctuates around a mean that remains stable for periods that are much longer than the dwell time of a single receptor. These receptor clusters are not stable fixed points; instead they are in a metastable state and will eventually decay.

Figure 7 The cluster theory of synaptic stability. (a) Receptors in the postsynaptic density (PSD) tend to cluster. When a receptor is removed because of turnover or trafficking out of the receptor, it is rapidly replaced by another receptor. (b) A simulation of a 7×7 cluster of receptors shown at time $T = 0$, 50, and 100, where 1 corresponds to the average dwell time of a receptor. Although receptors are rapidly removed and replaced, the cluster remains stable. (c) The number of receptors as a function of time in two independent simulations.

The lifetime of clusters depends linearly on the dwell time of receptors and increases steeply with the initial size of the cluster. For example, if we assume a receptor dwell time of 20 min, then the median lifetime for a 9×9 cluster of receptors can be more than 1 year.

Additional Mechanisms

Other possibilities have been raised to account for the stability of learning and memory in the face of molecular instability. One such idea is that synaptic efficacies themselves are not stable and that in the absence of neuronal activity, they decay. However, network activity might be able to stabilize efficacies. According to this idea, the interaction between synaptic plasticity and network activity acts to stabilize synaptic weights. If a pattern is embedded in a network by changing appropriate synaptic weights, such patterns are more likely to be spontaneously activated, and when they are activated, they are further potentiated, counteracting the synaptic decay. Such spontaneous activation could be manifest during periods of dreams or rest. However, a study by Wittenberg and colleagues has shown that although one embedded activity pattern can be stabilized with this mechanism, multiple patterns cannot since one of the embedded patterns takes over the network and eliminates the other patterns. It remains to be seen whether this is a general property of this proposed mechanism or whether it can be corrected with an appropriate choice of plasticity mechanism.

Another idea, motivated by experimental findings regarding long-term facilitation in *Aplysia*, is that memory can be preserved by a self-sustaining prionlike state. This theory assumes that a specific translation factor (cytoplasmic polyadenylation element binding protein (CPEB)), which is associated with the persistence of long-term facilitation in *Aplysia*, has prionlike properties. The prionlike behavior implies that this protein can be folded in different ways which have different functional properties and that this prionlike state is self-sustaining in the sense that new proteins that arrive to the vicinity of prions take on the prion form. The prionlike isoform of CPEB in *Aplysia* neurons is more active than the nonprion form. The concept of memories being encoded by a prion state therefore assumes that synaptic facilitation causes transformation of a key synaptic protein to its prionlike state, which is self-sustaining. It is not clear how such memory can be reversed or whether the prionlike state will not spread to nearby synapses. Although CPEB is also important for L-LTP in mammals, its structure in mammals is significantly different, it has phosphorylation sites that are absent in *Aplysia*, and prionlike properties have not been demonstrated in mammalian CPEB.

A detailed model for the protein synthesis-dependent induction of L-LTP was proposed by Smolen and colleagues. However, this model does not propose a mechanism for how L-LTP can persist beyond the characteristic timescales of the different molecules within the network. Observations regarding the importance of the synthesis of new proteins on L-LTP and L-LTD are confusing because the inhibition of protein synthesis has an impact on the induction, but not the maintenance, of L-LTP. However, an intriguing possibility that bi-stability at the level of protein synthesis can contribute to synaptic stability is yet to be examined in mathematical models.

Discussion

Various models for the induction and maintenance of synaptic plasticity have been proposed. Such biophysical models rely on known components of the physiology and biochemistry that lead to synaptic plasticity. These models are also required to account for known induction protocols of synaptic plasticity and for the impact of different pharmacological inhibitors. However, all models must at this point rely on approximations, as well as on not fully substantiated assumptions. In this sense all models are to a certain extent phenomenological. One problem with most existing models is that they rely on the mass action approach, which is valid only for well-mixed systems with a large number of molecules. Alternative approaches to simulations in structured, small-volume molecules are in their infancy. Therefore, current models of synaptic plasticity are not truly quantitative, but rather they are qualitative models that could be used as proof of concept. Like quantitative models, they can have robust consequences that can be tested experimentally, and we can use such models to test whether a specific mechanism can indeed accomplish what it was proposed to accomplish and whether it has additional unforeseen consequences. In the long run, and despite current limitations, computational models are the only systematic methodology that can connect the biophysical mechanisms of synaptic plasticity to experimental results observed on the cellular and system levels.

Neuroprotection: Endogenous Mechanisms

Introduction

This is an article on endogenous neuroprotective strategies found in nature against anoxic/ischemic insults. Cells require oxygen and glucose to produce the energy required for function. In vertebrates, blood flow confers these necessary components. Loss of blood flow is referred to as ischemia (the deprivation of oxygen and glucose). Ischemia commonly leads to a rapid loss of cell function and the potential for cell death. The phenomenon of endogenous protection against ischemia has been observed throughout the animal kingdom. Special attention has been placed on these protective adaptations for organs that are highly susceptible to energy deprivation, such as the heart and brain. The brain has the highest energy requirements of vertebrate organs and may be the most vulnerable to energy failure. In mammals, brain is approximately 3% of the body mass, yet it receives approximately 15% of the total cardiac output and consumes 20% of the body oxygen. In mammals, anoxia (lack of oxygen), ischemia, and hypoglycemia (low glucose) each lead to the cessation of electrical activity in the brain within minutes. If these insults are prolonged, the loss of electrical activity is followed by depletion of high-energy intermediates (i.e., adenosine triphosphate (ATP), phosphocreatine) and the loss of the calcium, potassium, sodium, and chloride ion gradients across cell membranes. The loss of these gradients results in membrane depolarization. As ionic depolarization occurs, as for example in ischemia, neurons release the excitatory neurotransmitter glutamate, which in turn may amplify or directly cause irreversible pathologies during energy failure. This glutamate-mediated toxicity is termed excitotoxicity and is a major contributor to neurodegeneration following ischemia.

The pathophysiological mechanisms leading to neuronal cell death after cerebral ischemia are highly complex. Neurons continue to die over days and months after a stroke (an ischemic event occurring in the brain). This phenomenon is referred to as delayed cell death. Although not clearly defined, neuronal cell death may result from apoptosis, necrosis, or a cell death mechanism that is a mixture of these processes.

Reperfusion refers to the restoration of normal blood flow after an ischemic event. It is now understood that the reperfusion phase following cerebral ischemia contributes substantially to ischemic injury and that mitochondrial dysfunction plays a central role in this type of injury.

Although mammalian brains and hearts are highly sensitive to the loss of energy supply, as during a stroke or heart attack, these organs have an intrinsic metabolic adaptation that can confer resistance to ischemia. This state is referred to as ischemic tolerance or ischemic preconditioning (IPC). Ischemic tolerance can be induced using a brief ('sublethal') ischemic episode. After a period of recovery, the organ is resistant to a subsequent stronger ischemic insult. This induction of tolerance against ischemia has gained attention as a powerful neuroprotective metabolic state against conditions of stress such as anoxia/ischemia in heart and brain. Because stroke remains the leading cause of disability and the third leading cause of death in the Western world, the intrinsic mechanisms of ischemic tolerance are important considerations for the development of therapeutics.

We consider that the induction of tolerance by ischemic preconditioning has three distinct phases: (1) the triggering phase, (2) the signal transduction phase, and (3) the genomic phase.

Triggering Phase

Multiple possible induction pathways (triggering phase) (Figure 1) have been implicated in the induction of ischemic preconditioning: neuroactive cytokines, activation of glutamate receptors, adenosine receptors, the ATP-sensitive potassium channels, nitric oxide, oxidative stress, and hypothermia.

Signal Transduction Phase

Studies of these putative triggering factors and putative links among them have centered on the roles of several signal transduction pathways (Figure 1). For example, increases in cytosolic Ca^{2+} may play a key role, since Ca^{2+} can activate several important enzymes, with subsequent initiation of downstream signal transduction pathways for IPC-induced tolerance. Research has identified some members of the signaling pathways: protein kinase C (PKC), inducible nitric oxide synthase, and mitogen-activated protein kinases (MAPKs). PKC activation might be a common signal transduction factor in heart and brain, since Ca^{2+} can directly or indirectly activate selective PKC isozymes. PKC is also the target of the adenosine A1 receptor, which promotes PKC activation via

Figure 1 Schematic representation of the different phases of ischemic preconditioning with a hypothetical timescale. production of diacylglycerol (DAG) and inositol trisphosphate (Figure 1).

Support for the possible role of different PKC isozymes during IPC emerged from recent studies showing that preconditioning could be simulated with anactivator of εPKC (ψε receptor of activated C kinase (ψεRACK)). This phenomenon is referred to as pharmacological preconditioning (PPC). Blockade of ischemic preconditioning with a specific antagonist of εPKC (εV1-2) provided further evidence for the role of εPKC in ischemic preconditioning. These results demonstrated that the preconditioning-induced neuroprotective effect requires activation of εPKC. εPKC also activates the extracellular signal-regulated kinase (ERK)1/2 pathways after ischemic preconditioning in brain, and adenosine A1 receptor initiated this signaling pathway (Figure 1).

An alternative signaling pathway for IPC is mediated by MAPKs. These are components of a common signaling cascade found in the brain. These enzymes can be activated by receptor tyrosine kinases, PKC, G-protein-coupled receptors, and diverse cellular stresses (note that the mild ischemic insult used for preconditioning is also a cellular stress). The three major MAPK pathways identified are the 42 and 44 kDa ERKs and the two stress-activated MAPK families – the 46 and 54 kDa c-Jun N-terminal kinases (JNKs) and the 38 kDa p38/reactivating kinases (Figure 1).

Another study reported that *in vitro* oxygen/glucose deprivation (OGD) preconditioning induces p21ras (Ras) activation in an *N*-methyl-D-aspartate receptor-dependent and NO-dependent manner. Ras activates the (MAP or ERK kinase) MEK1/2–ERK1/2 pathways, but can also activate other alternative signal transduction pathways. Ras activity is necessary and sufficient for OGD tolerance in neurons. Pharmacological inhibition of Ras, as well as a dominant negative mutation of Ras, blocked OGD preconditioning, whereas a constitutively active form of Ras promoted neuroprotection against lethal OGD insults.

Genomic Phase

A major emphasis in this field has been placed on the role of the expression of neuroprotective genes after IPC (Figure 1). It is plausible that the increase in expression of these stress-related, neurotrophic, and immediate early genes (IEGs) in response to a mild preconditioning insult may help mediate the protection of vulnerable neurons to subsequent lethal ischemic insults.

Growth and neurotrophic factors have been implicated in protection of vulnerable regions with IPC. Neurotrophins are best known as survival factors that are capable of sustaining neurons during critical periods. For example, preconditioning by cortical spreading depression (CSD) induced brain-derived neurotrophic factor (BDNF) expression.

IEGs were shown to be activated by preconditioning. IEGs are transcriptional regulators, and members of the fos and jun families have been found to bind to the activator protein-1 (AP-1) binding site of downstream genes. AP-1 binding activity was reported to increase in a rapid linear fashion in the CA1 and CA3 regions destined for neuronal survival.

Heat shock proteins (HSPs) were also induced by preconditioning. Two minutes of ischemia (i.e., IPC) caused inhibition of protein synthesis at 1 h of recirculation, but recovery of translation was present at 5–24 h later. Induction of HSP70 was found to enhance recovery of protein synthesis, which is normally blocked during heat shock and other metabolic stresses. HSP70 expression was induced by 2 min of ischemia in gerbils, and this protected vulnerable neurons in the CA1 hippocampus from a later 5 min ischemic insult. HSPs are thought to act as molecular chaperones, preventing proteins from aggregating or denaturing under conditions of physiological stress.

Cellular Targets of Protection

As described previously, it is believed that reperfusion following cerebral ischemia contributes to ischemic injury and that synaptic and mitochondrial dysfunction play a central role. The next two sections discuss the roles of synaptic and mitochondrial dysfunction.

Synaptic Dysfunction

The link between synaptic dysfunction and brain ischemia is evident by the fact that about 50% of long-term survivors of cardiac arrest or transient ischemic attack (TIA) exhibit impaired mental abilities, manifested as learning impairment, memory disturbance, lack of concrete thinking, impaired attention and concentration, and reduced capacity to plan, initiate, and carry out mental activities.

Experimental cortical infarcts in focal cerebral ischemia models lead to an enhanced mode of synaptic plasticity, long-term potentiation (LTP) in the area surrounding the infarct. In addition, previous studies demonstrated that γ-aminobutyric acid A ($GABA_A$) receptor-mediated decreases in electrophysiological activities precede the morphologic deterioration in post-ischemic CA1 hippocampal neurons. Seizures and altered synaptic plasticity (LTP) linked to cognitive deficits strongly suggest that alterations of synapses *per se* may be involved in these post-ischemic complications.

Anoxic insults can also directly induce a form of LTP. Anoxic LTP involves post-ischemic overactivation of *N*-methyl-D-aspartate (NMDA) receptor-mediated synaptic responses. Since it has been postulated that overactivation of NMDA receptors may promote cell death, it was proposed that this type of synaptic derangement was key in delayed neuronal death.

Many groups have demonstrated that IPC promotes tolerance by ameliorating different aspects of neuronal excitotoxicity. For example, glutamate release during ischemia was ameliorated by two forms of preconditioning: CSD and by hypoxia/hypoglycemia. Decreases in glutamate release were accompanied by increases in GABA release (GABA is the major inhibitory neurotransmitter in the brain), and were linked to downregulation of the glial glutamate transporter isoforms EAAT2 and EAAT1. IPC also promoted an increase in GABA release and upregulation of $GABA_A$ receptors in the hippocampus.

In a recent study, it was found that IPC promoted a robust increase in the release of GABA after lethal ischemia (Figure 2). It was also observed that the activity of glutamate decarboxylase (the predominant pathway of GABA synthesis in the brain) was higher in the IPC group compared with control and ischemic groups.

Figure 2 Chart flow depicting potential cellular targets for neuroprotection after ischemic preconditioning. GABA, γ-aminobutyric acid; εPKC, protein kinase C epsilon.

Mitochondrial Dysfunction

In the past 10 years a specific organelle, namely, the mitochondrion, has received special attention as a key player in cell death pathways. This is evidenced by numerous studies that support the hypothesis that mitochondrial dysfunction plays a central role in reperfusion injury after cerebral ischemia.

Mitochondria make ATP using oxidative phosphorylation via the mitochondrial respiratory chain. ATP is the primary source of energy for active cellular processes. Following cerebral ischemia, a prominent change in redox activity of mitochondrial respiratory chain components has been observed. Previous studies suggested that this hyperoxidation may result from loss of electron carriers from mitochondria following cerebral ischemia, such as cytochrome *c*. The loss of cytochrome *c* from mitochondria might affect respiratory chain activity and/or trigger the apoptotic cascade. The release of cytochrome *c* has been linked to apoptosis (programmed cell death).

Mitochondria respiratory deficits have also been observed after ischemia. Mitochondria isolated from ischemic brain exhibited decreases in 'state 3' respiratory rates of approximately 70% with nicotinamide adenine dinucleotide (NAD)-linked respiratory substrates. Nonsynaptosomal mitochondria were insensitive to ischemia itself; however, mitochondria became dysfunctional in the late reperfusion phase. Mitochondria from synaptic terminals were greatly affected by ischemia but partially recovered during reperfusion. The rate of oxygen consumption decreased in the CA1, CA3, and CA4 regions in the late reperfusion phase. Mitochondrial dysfunctions are reported in core and penumbra regions after focal cerebral ischemia. Isolated mitochondria exhibited decrease in adenosine diphosphate (ADP)-stimulated respiration during the early reperfusion period.

However, activity of mitochondrial electron transport chain (ETC) complex I, II–III, and IV was preserved in penumbra as well as in the core region during early reperfusion following middle cerebral artery occlusion (MCAO). During the late reperfusion phase following MCAO, the activity of mitochondrial ETC complex I is decreased. In summary, there are two phases of mitochondrial dysfunctions. In the first phase (early reperfusion), mitochondrial dysfunctions are mild (decreased activity of complex IV). However, in the second phase (late reperfusion), mitochondrial dysfunction is more pronounced.

IPC significantly protected against delayed cell death, and this protection was correlated with mitochondrial protection against the deficits in respiration affecting complexes I–IV (Figure 2). As described previously, many studies have demonstrated that reactive oxygen species (ROS) and the resulting oxidative stress play a pivotal role in neuronal cell death. There are two major regions in the ETC where ROS are produced. One is complex I and the other is complex III. Since oxidative stress is implicated in the pathophysiology that ensues after cerebral and cardiac ischemia, one can surmise that a key mechanism by which IPC protects hippocampus against delayed neuronal cell death is by protecting mitochondrial oxidative phosphorylation, diminishing ROS production, and limiting pro-apoptotic molecules to be released from mitochondria. In fact, all three mechanisms have been observed to occur in different models of IPC. In this model, the activity of the antioxidant enzymes glutathione peroxidase, glutathione reductase, and Mn superoxide dismutase was significantly increased. Furthermore, superoxide and hydrogen peroxide concentrations following OGD were significantly lower in the IPC group. Finally, cytochrome *c* release from mitochondria to the cytosol was suppressed in the ischemia tolerance-induced hippocampal CA1 region.

Cerebral Ischemic Preconditioning: Clinical Relevance

The clinical relevance of ischemic preconditioning was first described in heart. As in heart, TIA has been suggested to represent a clinical equivalent of ischemic preconditioning in brain. TIA is defined as a brief episode of neurologic dysfunction caused by focal brain or retinal ischemia, with clinical symptoms typically lasting less than 1 h, and without evidence of acute infarction. Weih et al. added support to the hypothesis that TIA may provide protection from a subsequent stroke when examining stroke outcome from 148 patients with and without a prior TIA. Furthermore, of 2490 screened stroke patients, 293 patients with ipsilateral TIA a few days before the main stroke had favorable outcomes.

Conclusions

The value of effective neuroprotective therapies for stroke patients as well as cerebrovascular surgery candidates is considerable. In the United States, stroke constitutes the third leading cause of death, and there are nearly 3 million people who have survived a stroke but live with disabilities. By limiting the extent of ischemic damage, neuroprotective therapies may reduce not only the number of deaths, but also the resulting degree of disability incurred with stroke and cerebrovascular surgery. The definition of ischemic preconditioning will definitely provide an important step toward such therapies.

Neuroprotection: Pharmacological Approaches

M Singh, University of North Texas Health Science Center, Fort Worth, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Neuroprotective strategies vary according to the particular aspect of disease pathology that they are intended to affect. Alzheimer's disease (AD) is an age-associated, progressive neurodegenerative disorder, the etiology of which is not completely understood but for which several mechanisms have been proposed. In the following sections, in an effort to review the different pharmacological approaches used to promote neuroprotection, the example of AD will be used, whereby a description of specific pathogenic mechanisms will be followed by a discussion of what pharmacological approaches have been developed or proposed.

The Amyloid Hypothesis

The amyloid hypothesis states that the excess production, aggregation, and/or accumulation of amyloid beta (Aβ) contributes to neurotoxicity, resulting in one of the histopathological hallmarks of AD, the amyloid plaque. Aβ, a protein first described in meningeal vasculature of Alzheimer's patients, is generated through two sequential proteolytic cleavages of its precursor, a large type I membrane protein called amyloid precursor protein (APP). The first cleavage step involves the protease, beta amyloid cleavage enzyme (β-secretase; BACE1), also known as Asp2 and memapsin 2. The second proteolytic complex, termed γ-secretase, consists of at least four integral membrane proteins, presenilin, nicastrin, APH1, and presenilin enhancer 2 (PEN2).

Based on the hypothesis that the generation and/or inappropriate accumulation of Aβ results in neurodegeneration, it is easy to see how pharmacological approaches that target the synthesis, aggregation, and clearance of this protein may be advantageous. BACE inhibitors (or inhibitors of their expression) represent one class of therapeutics that is currently being developed. As an example, the nonpeptidic BACE inhibitor, GSK188909, has been found to decrease the level of Aβ produced both *in vitro* and *in vivo* and thus may have promise in reducing the neurotoxic consequences of Aβ. Alternatively, neprilysin is an Aβ-degrading enzyme. Thus, identifying pharmacological agents that regulate neprilysin expression/activity may influence Aβ levels in the brain. Antioxidants can upregulate neprilysin activity, as can somatostatin. In fact, somatostatin reduces the 42-amino-acid form of Aβ in the culture medium of primary neurons. Cerebrolysin, currently in phase III clinical trials in the United States, may also be an effective agent in reducing amyloid burden, as it has been shown to improve cognition (assessed by the Alzheimer's Disease Assessment Scale – Cognitive) and global function in AD patients. One of the mechanisms underlying this effect is believed to be through its influence on the maturation and transport of APP.

Other agents that are being considered as neuroprotectants include activity-dependent neurotrophic factor (ADNF) and humanin, both of which have been shown to be capable of suppressing amyloid toxicity. However, these compounds are not without their limitations. For example, ADNF appears to lose its protective effects at higher concentration, and humanin has a relatively low bioavailability, given its vulnerability to degradation. However, a recently described 'hybrid peptide,' colivelin, appears to hold significant promise. Colivelin is a synthetic peptide resulting from the fusion of ADNF to a derivative of humanin; it has been found to exert extremely potent protective effects against amyloid toxicity (at concentrations as low as 100 fM), protects against memory deficits, and has the advantage of being able to readily cross the blood–brain barrier.

Another approach that has been considered for use to alleviate amyloid burden is administration of an anti-Aβ vaccine (AN1792). Though several animal models have suggested its likelihood for success, the initial trial to assess the efficacy of this strategy was terminated due to the incidence of meningeoencephalitis in approximately 6% of the patients. However, alternative approaches in vaccinating against Aβ involving modified immunogens and modes of administration are still being considered and could hold promise.

Cholinergic Deficits

Cholinergic neurons, particularly in the ventral forebrain, are severely compromised in AD. This observation, when coupled with the finding that reduced cholinergic function in the cerebral cortex and hippocampus correlates with dementia severity, serves as an important basis for the cholinergic hypothesis of AD and has prompted the development of anticholinesterases. Anticholinesterases serve to reduce the breakdown of the neurotransmitter, acetylcholine, and thus enhance cholinergic neurotransmission. Interestingly,

however, these compounds not only influence the sustainability of cholinergic neurotransmission, but also appear to have neuroprotective effects through other mechanisms. For example, the cholinesterase inhibitors donepazil and galanthamine protect neuronal cells from glutamate-induced neurotoxicity. This protective effect is mediated through α4- and α7-containing nicotinic receptors, and subsequent activation of the phosphatidylinositol 3-kinase pathway. Thus, the most common and Food and Drug Administration (FDA)-approved pharmacological treatment for AD appears to be protective by two complementary systems, one that involves the maintenance of neurotransmission and another that involves activation of neuroprotective signaling pathways initiated by nicotinic cholinergic receptors.

Oxidative Stress

There is increasing evidence that oxidative stress is a prevalent component of the pathobiology of AD. Accumulating free radicals and the resulting oxidized proteins, lipids, and nucleic acids are believed to contribute to the dysfunction and death of brain cells, consistent with the free radical theory of aging. As such, antioxidants have been proposed to have neuroprotective effects that may help reduce the progression of neurodegenerative disorders, including AD. Antioxidants with neuroprotective potential can be classified as those that directly scavenge free radicals, those that inhibit the generation of free radicals, or those that work indirectly by enhancing the cellular defense systems that serve to detoxify the free radicals produced.

Examples of antioxidants are numerous and include tocopherols (e.g., vitamin E) and certain estrogens (e.g., 17*β*-estradiol). These compounds, by virtue of their chemical composition (i.e., the presence of a phenolic group), can donate a proton to saturate the unpaired electron of highly reactive oxygen species such as the hydroxyl radical. With respect to its potential benefit in protecting against neurodegeneration in AD, vitamin E has been shown to reduce oxidative stress elicited by the pro-oxidant stressor, A*β*, and to supports its potential benefit as a pharmacological treatment of the disease. However, clinical studies that have addressed the efficacy of vitamin E have been equivocal. Some epidemiological studies suggest that vitamin E may delay the onset of AD while others fail to support the benefit of this pharmacological strategy.

Excitotoxicity

Glutamate, the most abundant excitatory neurotransmitter in the brain, can activate its *N*-methyl-D-aspartate (NMDA) receptor, resulting in long-term potentiation, which in turn, is thought to be an important cellular mechanism underlying learning and memory. However, persistent activation of the NMDA receptor results in a chronic influx and accumulation of calcium, leading to neuronal dysfunction and death, a phenomenon referred to as excitotoxicity. This excitotoxicity has been proposed to play a major role in the neurodegenerative changes seen in AD. As such, an obvious therapeutic approach to reduce the neurodegeneration in AD would be to reduce this overactivation of the NMDA receptor. In fact, the most recent FDA-approved drug for the treatment of AD is the NMDA receptor antagonist, memantine. An important feature of this compound is its ability to cause an 'open channel block,' whereby the ion channel is blocked principally under conditions when it is excessively open and thus spares normal, physiological function of the NMDA receptor.

The therapeutic potential for memantine has been demonstrated in clinical trials; however, it appears that memantine does not alter the disease progression, but rather provides symptomatic benefits. This may argue that glutamate receptor overactivation or dysregulation may be an important component of the pathological cascade of events, but, in and of itself, is not the pathogenic mechanism underlying AD. Nonetheless, the use of memantine together with other pharmacological approaches may yield the necessary, multitarget strategy of treating a complex syndrome such as AD.

Loss of Trophic Support

Neurotrophins are a family of growth factors that include nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF). These trophic factors have been found to protect against cell death induced by a variety of insults that mimic specific pathologic aspects of aging and AD. Coupled with the observation that neurotrophin expression is altered in AD brains, it is not surprising that efforts to promote the restoration of neurotrophin expression and/or function have been suggested as a means of reducing neuronal dysfunction and loss in AD.

Neurotrophins function through the activation of their cognate receptors, the Trk family of tyrosine kinases and the p75 neurotrophin receptor. Typically, NGF binds preferentially to TrkA, and BDNF to TrkB, while both bind with approximately equal affinity to the p75 neurotrophin receptor. The p75 receptor has historically been ascribed a supportive role in neurotrophin signaling, whereby it helps promote high-affinity binding and selectivity of the neurotrophin to its cognate Trk receptor. More recently, however, it has become apparent that the p75 receptor may play an active role in modulating

cell survival, although the precise function of the p75 receptor may depend heavily on cell context. In cells in which p75 is co-expressed with Trk receptors, p75 may serve to enhance responses to the neurotrophins (as stated previously). However, in cells that have diminished or low levels of Trk receptors, the p75 receptor may activate death-promoting signaling cascades in a ligand-dependent manner, resulting in apoptosis.

This 'death-inducing' influence of p75 receptors has attained further significance with the recent finding that the neurotrophins are synthesized as propeptides (proneurotrophins), which, in contrast to the mature neurotrophins that have higher affinities for their respective Trk receptors, have higher affinities for the p75 neurotrophin receptor instead. Thus, neuronal dysfunction or atrophy consequent to aging or age-associated diseases may result not only from decreases in mature neurotrophin expression or function, but also potentially from increased accumulation of the proneurotrophins. In fact, Fahnestock and colleagues have described that the proneurotrophin for NGF (pro-NGF) is increased in AD brains.

However, given that neurotrophins, such as NGF, do not readily cross the blood–brain barrier, achieving therapeutic concentrations of neurotrophins in the central nervous system (CNS) may be problematic, and would require rather invasive methods to deliver the neurotrophin. Coupled with the fact that neurotrophins have pleiotropic effects (some of which may be beneficial while some may be detrimental) and have potentially poor pharmacological profiles (e.g., stability issues), the alternative pharmacological strategies have been considered. One such alternative is the development of small-molecule mimetics, which not only have the advantage of crossing the blood–brain barrier readily, but are also being designed to exhibit functional selectivity based on preferential binding to either the Trk or p75 receptors. For example, some small-molecule mimetics are aimed at mimicking the protective effects of neurotrophins by eliciting activation of protective signaling pathways triggered by activation of the Trk receptors. Others are designed to bind to the p75 receptor and can prevent the damage-promoting effects associated with binding of Aβ to the p75 receptor.

Selective Pleiotropism as a Consideration in Developing Pharmacological Neuroprotectants

Given that AD is a complex disorder that may have multiple etiologies, it is possible that the lack of sustainable efficacy of currently approved pharmacological interventions for the disease is due to having targeted only one of multiple systems going awry. Thus, it is possible that the most effective neuroprotective treatment for a disorder such as AD is one that exerts pleiotropic effects – that is, the treatment aids in reducing oxidative stress, amyloid toxicity, and excitotoxicity, and helps restore trophic support. However, pleiotropy may also have unwanted consequences. For example, it has been suggested that the significant side effects (e.g., pain) associated with neurotrophin administration to human patients are a direct result of activation of both receptor mechanisms (p75 and Trk). Thus, by developing pharmacological agents that have 'selective pleiotropy,' we may be able to take advantage of the beneficial effects while limiting the negative consequences of a particular system. The neurotrophin system serves as a useful model to explain this concept. Through a better understanding of structure–function determinants, specific ligands have been developed that take advantage of the cell survival-promoting effects of Trk receptors, while minimizing (or even antagonizing) the cell death-promoting effects (i.e., preventing Aβ from promoting toxicity through the p75 receptor).

Closing Remarks

Although there are relatively few FDA-approved pharmacological interventions to reduce neuronal dysfunction and death in diseases such as AD, there are a variety of newly recognized and promising candidates. The themes by which they are being developed are based on our current understanding of the pathobiology by which neuronal dysfunction occurs, and emphasize the principle that safe and effective pharmacological approaches for such diseases can only be realized through a thorough understanding of both the normal biology and the pathobiology of the disease.

Introduction

The ultimate goal of studying proteomes is to achieve a comprehensive view of the characteristics and function of every protein present within a biological system. This has only recently become feasible since the completion of genome projects which have defined the basic set of genetic instructions which can code for a multitude of proteomes. The complexity of the genome is overshadowed by that of the transcriptome, which describes the full complement of mRNA transcripts transcribed from the genome of the cell. This, in turn, gives rise to yet another level of complexity seen in that of the cellular proteome. The complexity of proteomes is controlled by a variety of transcriptional, translational, and posttranslational regulatory points, each of which can modify the expression of genetic information in response to the dynamic cellular state (Figure 1). The covalent modification of mature proteins is one of the most important points of dynamic regulation of proteomes, and of the over 300 or more different protein modifications which have been reported, phosphorylation and glycosylation are prototypic.

Comprehensive proteome analysis also seeks to elucidate protein subcellular distribution and protein–protein interactions, which are crucial in determining the integration of large numbers of proteins into interaction networks, and functional molecular complexes that ultimately perform a myriad of cellular functions (Figure 2). The composition of such multiprotein complexes or organelles is variable among cell types, organs, regions of organs (such as different brain regions), and species. In addition, the proteome is highly dynamic and temporal and thus describes the complement of proteins expressed in a cell at a single time.

Understanding proteomes at many of these levels of complexity is undoubtedly necessary for dissecting the molecular basis for many complex neurological diseases. The starting point for neuroproteomics has been to define and map synaptic proteomes in model organisms as well as humans. The synapse is a subcellular specialization that transmits and converts patterns of electrical activity into cellular memory. This processing of electrical information is mediated by the protein components of the synapse and the phosphorylation of these components is an important part of the regulation of this process. This specialized proteome can be biochemically isolated and the protein components can be identified by mass spectrometry (MS). Establishment of such a molecular map permits insight into the organization and functioning of the synaptic proteome.

There are many approaches used to study large numbers of proteins in the brain, from the comparative analysis of protein expression to the mapping of molecular complexes. A number of examples of such approaches are reviewed here to highlight the diversity of proteomic applications in neuroscience. Herein, we review how these key proteomic methodologies are being applied to the study of neurobiology and describe the recent paradigm shifts in the understanding of synaptic biology.

Proteomic Mass Spectrometry

MS permits the identification of proteins by the determination of the exact mass of peptides and the fragmentation of these peptides to determine the sequence (and thus the identification) of the peptide and the parent protein. Protein samples, such as purified organelles or protein complexes are usually separated by their relative molecular weight on sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) gels. The protein bands are visualized by dyes such as Coomassie brilliant blue and then are excised from the gel. The protein-containing gel slices are washed and incubated with proteolytic enzymes such as trypsin, and the resultant peptides extracted from the gel slices (Figure 3).

A mass spectrometer consists of an ion source, a mass analyzer that measures the mass-to-charge ratio (m/z) of peptides, and a detector that counts the numbers of ions at each m/z value. Electrospray ionization (ESI) mass spectrometers use a heated capillary needle through which the peptide solution elutes and is subsequently ionized and introduced into the mass spectrometer. This type of ion source is readily compatible with liquid chromatographic (LC) separations, resulting in an LC-MS/MS (liquid chromatography-coupled mass spectrometry) setup in which thousands of peptides can be identified in a single experiment. In a typical LC-MS/MS experiment, a peptide mixture is separated by analytical reversed-phase chromatography in a high-performance liquid chromatography (HPLC) system and is introduced into the mass spectrometer via the ESI source. Multiply protonated peptides give rise to the first mass spectrum (MS1), and then the computer generates a prioritized list of the most intense precursor ions detected, which are

Figure 1 Generation of molecular complexity. There are at least six points at which the complexity of the information encoded in the genome is increased by transcriptional, translational, and posttranslational control. At the posttranslational level, more than 300 different types of modifications, including protein phosphorylation, exist. These processes can easily transform the 22 000 gene loci in the human genome into an estimated 1 million different polypeptide forms, greatly increasing genome-to-proteome complexity.

Figure 2 Complexity of proteomes. Once a polypeptide has undergone splicing, posttranslational modifications, and so forth, there are further levels of proteome complexity relating to how proteins exist in a cell. Proteomes from different species, tissues, or cell types differ not only in their composition but also in their protein interactions, protein complexes, and organelles. Complex diseases are usually caused by changes in more than one level in this complexity, and therefore disease proteomics should take this into account. An essential point about this complexity is the need for adequate bioinformatics approaches to integrate such proteome data.

subsequently subjected to fragmentation by energetic collision with gas (collision-induced dissociation (CID)) in the collision cell. This MS/MS spectrum contains data relating to the amino acid composition of the peptides and the pattern of fragmentation that occurred. This process of tandem MS provides *m/z* values of peptides and fragmentation data for each peptide. These data are then used by sequence database-searching programs such as MASCOT or SEQUEST to provide probability-based peptide matches and therefore protein identifications.

Subcellular Proteomics

The observation of cells under an electron microscope for the first time in the 1940s revealed a previously

Figure 3 Workflow of an LC-MS/MS experiment. A mixture of peptides from a protein sample digest is separated by reversed-phase chromatography on a nanoflow HPLC. The peptides elute from the RP column and are ionized by an electrospray source. In the first stage of mass spectrometry, *m/z* values and charge states for each precursor ion are determined and the most abundant precursor ions are selected for analysis in the second stage. The ions are then fragmented with by collision-induced dissociation (CID) with a gas to produce fragment ions which are detected. Using the mass (from MS-1) and sequence information (from MS-2), protein sequence databases are searched to provide peptide identifications and protein matches. The analysis of phosphopeptides is similar except that specific scanning approaches can be used in the mass spectrometer to detect the loss of phosphate during CID. Assignment of the exact position of phosphorylation is accomplished by manual interpretation of the mass spectra. HPLC, high-performance liquid chromatography; LC, liquid chromatography; *m/z,* mass-to-charge ratio; MS, mass spectrometry; RP, reversed-phase.

unexpected level of complexity. Extensive compartmentalization was observed and was found to be achieved by intracellular membranes. This realization prompted intensive investigation of subcellular organelles and in the following decades led to the development of a number of methodologies to physically isolate cellular organelles. The identification of the protein composition of subcellular organelles has been a significant challenge for many years and is only now becoming routine with sophisticated MS-based platforms (Table 1). Most subcellular organelles are isolated using density-gradient centrifugation, in which a gradient of sucrose solutions is used to partition different organelles according to their density. A limitation of this approach is the difficulty in the assessment of the degree of purity of the isolated fractions. Usually, the presence and absence of subcellular markers is used to indicate the level of contamination of cosendimenting cellular debris.

Recently, with the advent of quantitative MS-based approaches, it is possible to assess the relative amounts of each protein present in a fraction compared to the starting material of the isolation. This approach was successfully applied to the identification of proteins in the centrosome. In this study, researchers quantitatively profiled hundreds of proteins across several centrifugation fractions and identified proteins which were quantitatively enriched in centrosomes, thereby identifying bona fide centrosomal proteins.

Traditionally, the protein content of purified organelles are separated by either one-dimensional (1-D) or two-dimensional (2-D) SDS-PAGE, and protein-containing bands or spots are excised, digested, and subjected to analysis by MS. 1-D SDS-PAGE has the advantage of being particularly well suited for the separation of membrane proteins, whereas 2-D SDS-PAGE provides better separation of protein species. However, both of these approaches require band or spot excision, which is very labor intensive, is not very reproducible, and causes significant sample loss due to incomplete peptide extraction from the gel slices/spots. These difficulties have been overcome, in part, by gel-free separations of peptides such as multidimensional protein identification technology (MudPIT) pioneered by John Yates, in which the protein sample is denatured and digested in solution and the resultant peptides are separated in the first dimension by ion-exchange chromatography and in the second dimension by reverse-phase chromatography. The first application of this methodology was the profiling of the yeast proteome, and this facilitated identification of 1484 proteins, far exceeding the numbers of protein identifications from traditional methods.

Table 1 Summary of proteomic data from subcellular organelles studies[a]

Organelle	*Number of proteins*
Postsynaptic proteome	1124
Mitochondria	847
Phagosome	525
Nucleolus	489
Exosome	295
Spliceosome	292
Neutrophil granules	286
Lipid raft	241
Lysosome	215
Clathrin-coated vesicles	209
Nuclear pore	174
Golgi	136
Centrosome	64

[a]The large numbers of proteins in the postsynaptic proteome probably reflects the fact that this cellular specialization contains elements of other organelles, such as mitochondria and Golgi, as well as integral postsynaptic membrane proteins.

Profiling Synaptic Proteomes

The postsynaptic density (PSD) is a structural component of the synapse that can be observed under the electron microscope, beneath the postsynaptic membrane. Recent proteomic efforts have provided an insight into the complexity of the PSD and its subcomponents (Figure 4). The last 5 years have seen tremendous growth in our knowledge of the protein components of mammalian synapses. The first investigation of the synapse proteome appeared in the year 2000, with the identification of the components of the *N*-methyl-D-aspartate (NMDA) receptor complex (77 proteins) (Figure 4). The large number of proteins in this complex was at first controversial because it exceeded the total number of known PSD proteins. This report was soon followed by the first MS-based characterization of the PSD, which revealed just 31 proteins in the PSD, most of which were already known.

Since then, a number of proteomic analyses of isolated PSDs have been reported and the most common approach used was as follows. Synaptic fractions were first isolated from mouse forebrains by differential centrifugation on sucrose gradients. PSD fractions were isolated from the crude synaptic fraction by the relative insolubility of PSDs in Triton X-100. PSD proteins were separated by SDS–PAGE (Figure 5), and in one example, 37 gel slices were analyzed by LC–MS/MS. Some 7402 peptides were identified, corresponding to 620 nonredundant protein identifications, with an average of 34 proteins identified per gel slice (corresponding to an average of 16.7 unique proteins per gel slice).

Figure 4 Examples of brain proteomes. A number of different types of brain proteomes with different levels of complexity have been studied. These can be classified into many categories, ranging from subcellular organelles such as the postsynaptic density, to multiprotein complexes such as glutamate receptor complexes (NMDA, MAGUK, and AMPA) to subproteomes which comprise phosphorylated proteins. All these proteomes are very likely to be heterogeneous in different cell types and in different brain regions. AMPA, α-amino-3-hyroxy-5-methyklisoxazole-4-proprionic acid; MAGUK, membrane-associated guanylate kinase; NMDA, *N*-methyl-D-aspartate; PSD, postsynaptic density.

When data from seven of these PSD analyses (and data from glutamate receptor (GluR) complexes) are compiled into one postsynaptic data set, a nonredundant list of 1124 postsynaptic proteome (PSP) proteins is obtained. In order to define a set of higher confidence, proteins that were identified two or more times (466 proteins) can be placed in a group termed the consensus PSD (cPSD). The majority of these proteins are abundant and so are more likely to be detected in multiple analyses, and the set of proteins detected once is perhaps of lower abundance or may reflect differences in sample preparation. The data integration performed on these PSD data sets has resulted in a confidence-ranked database of postsynaptic proteins which totals 1124. This tenfold increase in known postsynaptic components since the year 2000 reflects the technological advances of MS-based protein identification compared to traditional methods.

The initial approach to characterize the organization of the PSP was to classify the proteins into categories that describe their known functional properties (Table 2). Within the overall PSP, representatives of many classes of proteins representing a broad range of cell biological functions were observed: membrane-bound receptors; adhesion proteins and channels; a plethora of signaling proteins and adaptors; and proteins involved with regulation of transport, RNA metabolism, translation, and transcription. The cPSD contains similar numbers of proteins in most classes compared to the total PSD data set, with the exception of channels and receptors, signaling proteins, and synaptic vesicle proteins. This is most probably due to the lower abundance of these proteins, resulting in a decreased likelihood of detection. This supports the idea that the cPSD represents a consensus of protein identifications which, on the one hand, decreases individual data set bias for contaminating proteins (nuclear or mitochondrial) and, on the other hand, has limited coverage of some protein classes because of abundance issues.

Synaptic Multiprotein Complexes

Proteomic approaches for the molecular dissection of multiprotein complexes usually involve purification of the entire complex by a variety of affinity methods, and protein identification by Western blotting or MS-based approaches. The first proteomic analysis of multiprotein complexes relevant to the brain was the purification and identification of the molecular constituents of the NMDA receptor–adhesion protein signaling complexes (NRC). The NMDA receptor has a low abundance in neurons compared with the overall protein content. Therefore, it is important to generate highly enriched samples containing the target molecule. This can be achieved using a variety

Figure 5 Identification of postsynaptic density (PSD) proteins by MS analysis of gel slices using a coomassie-stained SDS-PAGE gel lane containing purified mouse forebrain PSD proteins. The resulting numbers of peptides, proteins, and transmembrane (TM) proteins identified in each gel slice by LC-MS/MS analysis are shown. 1D SDS-PAGE separation offers effective protein separation of complex mixtures with an average of 34 proteins identified per gel slice and an average of 12 peptides characterized for each protein. The number of peptides detected per gel slice increases proportionally with molecular weight. 1D SDS-PAGE is very compatible with membrane samples, and the distribution of proteins with TM regions is shown. LC, liquid chromatography; MS, mass spectrometry; SDS-PAGE, sodium dodecyl sulfate polyacrylamide gel electrophoresis. Adapted from Collins MO, Husi H, Yu L, et al. (2006) Molecular characterization and comparison of the components and multiprotein complexes in the postsynaptic proteome. *Journal of Neurochemistry* 97(supplement 1): 16–23.

Table 2 Summary of PSD protein classifications[a]

	Total PDS	*cPSD*
Channels and receptors	80	39
MAGUKs/adaptors/scaffolders	54	33
Ser/Thr kinases	46	20
Tyr kinase	3	2
Protein phosphatases	18	11
G-proteins and modulators	77	34
Signaling molecules and enzymes	278	98
Transcription and translation	119	41
Cytoskeletal and cell adhesion molecules	153	97
Synaptic vesicles and protein transport	159	76
Novel	107	11
Other	30	4
Total	1124	466

[a]Classified to show protein class enrichment. cPSD, consensus PSD; MAGUKs, membrane-associated guanylate kinases; PSD, postsynaptic density.

of methods, generally involving affinity chromatography steps. These can range from ligand affinity (drugs, substrates, or co-factors) to the more widely used approach of immunoprecipitation, involving specific antibodies to the molecule of interest. A major drawback in using antibody-based approaches for proteomic analysis is the introduction of the IgG itself, which interferes with the analysis by overshadowing proteins of interest that co-migrate during the gel separation. All these ligands, groups, or proteins are then coupled to a resin either irreversibly (usually in the case of small molecules) or through a secondary affinity linkage specific for the bait molecule. Neuronal extracts are then incubated with the resins bearing the bait, and bound proteins separated from one another as well as from the matrix by conventional gel analysis.

Identification of isolated proteins can be readily achieved using Western blotting or MS analysis such as that described for the analysis of PSDs. Using an antibody-based approach targeting the NR1 subunit of the NMDA receptor, the NRC was shown to comprise 77 proteins organized into receptor, adaptor, signaling, cytoskeletal, and novel proteins, of which 30 are implicated in binding studies and another 19 participate in NMDA receptor signaling.

NMDA receptor and metabotropic glutamate receptor (mGluR) subtypes were linked to cadherins and L1 cell-adhesion molecules in complexes lacking α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors. These neurotransmitter–adhesion receptor complexes were bound to kinases, phosphatases, guanosine triphosphatase (GTPase)-activating proteins and Ras with effectors, including mitogen-activated protein kinase (MAPK) pathway components. A striking feature of the composition is that there appears to be modules or sets of signaling proteins that are known to make up key components of signal transduction pathways that can be distinctly regulated. For example, all the molecules necessary to induce the phosphorylation of MAPK following NMDA receptor stimulation are present in the NRC (including calmodulin-dependent protein kinase II (CaMKII), SynGAP, Ras, MAPK kinase (MEK), and extracellular signal-regulated kinase (ERK)). Their modules may allow the NMDA receptor and mGluR to integrate signals within the complex and then to couple downstream cellular effector mechanisms, such as trafficking of AMPA receptors and cytoskeletal changes that mediate structural and physiological plasticity. Furthermore, at least 18 NRC constituents are regulated by synaptic activity, indicating that the composition of the complex is dynamic. In the hippocampus, these activity-dependent genes are known to undergo specific temporal changes following the induction of plasticity.

This NRC data set was further expanded from 77 to 186 proteins using a combination of peptide-affinity chromatography and MS identification of new components of the complex. Purification of membrane-associated guanylate kinase (MAGUK)-associated signaling complexes (MASCs) was achieved by peptide-affinity chromatography using a hexapeptide corresponding to the C-terminus of the NMDA receptor NR2B subunit. This approach extended the NRC data set to comprise 186 proteins, which constitute the MASC. The importance of this complex is highlighted by the fact that mutations or polymorphisms in 47 MASC genes are associated with 183 human disorders, of which 54 are nervous system disorders. In addition, 43 MASC proteins have been reported to be important in synaptic plasticity, and 40 have been associated with rodent behavior.

AMPA receptor complexes have been purified using immunoaffinity chromatography, resulting in the identification of ten unique proteins. The mGluR5 receptor complex has been characterized in a similar fashion and was found to comprise 76 proteins, including the NMDA receptor subunit NR2A. The majority of proteins in all three GluR complexes have been independently identified as PSD proteins (Figure 6). These complexes also contain proteins which have not yet been detected in PSD analyses, presumably due to abundance issues in the analyses of PSD preparations compared to enriched protein complexes. It is important to note that the majority of the components of these complexes have been validated as PSD proteins and that the overlap between these complexes occurs in the cPSD (Figure 6), supporting the notion that the cPSD is an important subset of the total PSD data set. This is consistent with a postsynaptic organization in which the MASC signaling complex is connected to multiple cell biological effector mechan-

Figure 6 Multiprotein complexes in the postsynaptic proteome. Venn diagram illustrating the overlap of three glutamate receptor complexes (AMPA, MASC, and mGluR5) with the total and cPSD datasets. It can be seen that the majority of overlap between components of these complexes and the PSD occurs in the high-confidence cPSD dataset. Proteins detected in these multiprotein complexes, which were not found in any of the PSD datasets, are generally of low abundance and are enriched in immunopurifications of complexes compared to whole PSD analyses. AMPA, (α-amino-3-hyroxy-5-methyklisoxazole-4-proprionic acid; AMPA-R, AMPA receptor; cPSD, consensus PSD; MAGUK, membrane-associated guanylate kinase; MASC, MAGUK-associated signaling complex; mGluR5, metabotropic glutamate receptor 5; mGluR5-R, metabotropic mGluR5 receptor complex; PSD, postsynaptic density. Reproduced from Collins MO, Husi H, Yu L, et al. (2006) Molecular characterization and comparison of the components and multiprotein complexes in the postsynaptic proteome. *Journal of Neurochemistry* 97(supplement 1): 16–23, with permission from Blackwell Publishing.

isms organized into their respective complexes. In addition to MASC and AMPA complexes, components of other complexes such as cell adhesion, growth factor, cytoskeletal, transport, and ribosomal complexes were found in the PSP. These three receptor protein complex data sets, together with PSD data sets, provide for the first time a general composition of the PSP, and further mapping of other receptor protein complexes will undoubtedly refine our view of the molecular architecture of the synapse.

Synapse Phosphoproteomics

Approaches to Probe the Phosphoproteome

Traditional biochemical approaches to analyzing phosphorylation usually involve focused study of one phosphoprotein and often of one particular phosphorylation site. Antibodies that specifically recognize the phosphorylated epitope can be made and used to purify the phosphoprotein and to detect the phosphoprotein in Western blots or for imunohistochemical or immunocytochemical analyses. Generation and validation of such phospho-specific antibodies is a time-consuming process, taking up to 1 year to obtain an antibody that can be used confidently. The use of ^{32}P-labeled γ-adenosine triphosphate (ATP) for *in vitro* kinase reactions has been employed widely, and separation of labeled phosphorylated peptides by thin-layer chromatography (TLC) provides information about the number phosphopeptides and the intensity of phosphorylation. Analysis of these phosphopeptides from TLC plates has been performed using MS (matrix-associated laser desorption ionization time-of-flight (MALDI-TOF)) and Edman sequencing. However, this methodology is suitable for single-phosphoprotein studies, and the use of ^{32}P is hazardous.

Phosphoproteome enrichment strategies Development of MS and in particular LC-MS/MS in the late 1990s permitted the identification of large numbers of peptides in proteome-scale experiments. The use of MS for the characterization of phosphorylation on a proteome scale was hampered by the characteristics of phosphorylation itself. It has been estimated that one-third of any given proteome is phosphorylated and the stoichiometry of phosphorylation is often low; so to study phosphorylation on a global level, phospho-enrichment is a prerequisite.

Digestion of a proteome or even a portion of a proteome can result in the generation of tens of thousands of tryptic fragments. This number of peptides is overwhelming in an LC-MS/MS experiment, and because the mass spectrometer is usually operated in a mode which selects only the most intense ions for sequencing, only the most abundant portion of the proteome is sampled. Many signaling proteins are present at low abundance in cells, and the portion of these proteins that are phosphorylated at any one time may also be quite low. Therefore, in a standard LC-MS/MS experiment, the chance of detecting and sequencing a phosphopeptide is very low indeed. A number of strategies to overcome these problems were developed, involving either physically enriching for phosphorylated species or isolating phosphopeptide-specific signals in the mass spectrometer.

A number of chemical modification strategies have been developed in which the phosphate group has been replaced with a moiety that is chemically more stable than phosphate. One such method employs β-elimination of the phosphate from phospho-threonine or phospho-serine and results in the formation of dehydroaminobutyric acid or dehydroalanine, respectively. These products can be detected using tandem MS or in another method, Michael addition is used to add a reactive thiol group after β-elimination to provide a linker for the attachment of an affinity tag. This affinity tag is usually biotin, and it permits purification of the chemically modified (previously phosphorylated) peptides. This type of chemical modification of phosphate is not applicable to phosphotyrosine residues and suffers from side-chain reactions in which cysteine and methionine can be modified. Other chemical modification protocols, which are applicable to all phosphorylated residues, have been developed, but they involve many chemical reactions and have not been used successfully on real proteomic samples.

These chemical modification-based strategies were challenged in 2002 with the modification of the traditional immobilized metal-affinity chromatography (IMAC) methodology. IMAC purification of phosphopeptides is based on the attraction of negatively charged phosphate groups to positively charged immobilized (on a resin) metals. The main problem associated with this protocol is that acidic groups of aspartic and glutamic acid and electron donors (histidine) can bind to the positively charged metal, thereby contaminating the eluted sample. This nonspecific binding was addressed by chemical esterification of acidic residues before the IMAC enrichment. Application of this modified procedure to the yeast proteome permitted the characterization of 216 phosphopeptides.

Mass spectrometry-based strategies for phosphorylation analysis The use of MS for phosphorylation-site identification has increased greatly over the last decade, superseding traditional approaches of 2-D phosphopeptide mapping and Edman sequencing. In the period from 1992 to 2003, 1281 phosphorylation

sites were characterized by MS in 203 publications. In the latter years of this period, advances in sample preparation enabled hundreds of phosphorylation sites to be determined and reported in a single publication. In addition, the concomitant advances in technology of mass spectrometers have also facilitated the transition from single-phosphoprotein analysis to the analysis of phosphoproteomes. Identification of phosphopeptides and the characterization of phosphorylation sites by LC-MS/MS analysis is more difficult than standard protein identification experiments and can be achieved by special phosphoscanning functions in the mass spectrometer. Neutral loss scanning is a popular approach used to detect phosphopeptides, and it involves monitoring for the loss of ions characteristic of phosphorylated residues. When peptides containing phosphoserine or phosphothreonine are subjected to CID, they usually undergo gas-phase β-elimination, resulting in a neutral loss of phosphoric acid (-98 Da) or are dephosphorylated (-80 Da). The resulting mass spectrum indicates the position of the loss of phosphate by a spacing of 69 Da (dehydroalanine) or 83 Da (dehydroaminobutyric acid). This type of analysis requires prior knowledge of the charge state of the precursor ion before CID and thus is highly compatible with quadrupole time-of-flight (Q-TOF) mass spectrometers operated in data-dependent acquisition mode. This approach is not as efficient for detecting phosphotyrosine because phosphotyrosine is more resistant to neutral loss. However, another scanning approach is suitable for the detection of phosphotyrosine and is based on the production of reporter ions characteristic for the loss of phosphotyrosine. Immonium ions of phosphotyrosine have a mass-to-charge ratio (m/z) value of 216.043 and are generated by the double cleavage of the peptide backbone. These can be detected with good sensitivity, with detection possible using subpicomolar amounts of gel-separated protein. In addition, when phospho-Ser/Thr/Tyr-containing peptides are fragmented by CID in the negative ion mode, a characteristic PO^{3-} ion ($m/z = -79$) can be detected by precursor ion scanning. Once this ion is detected, the mass spectrometer can be set to automatically switch to positive ion mode to conduct MS/MS for sequencing.

Challenges of phosphoproteome analysis The main challenge for phosphoproteome analysis is the enrichment of phosphorylated proteins and peptides to sufficient quantities so that they can be characterized by MS. Preservation of phosphorylation during enrichment is essential because any loss of phosphorylation due to phosphatase activity or by chemical dephosphorylation significantly reduces the likelihood of detection of low levels of phosphorylation. Phosphoproteome-enrichment methods should also be as straightforward as possible to minimize sample losses and to enhance the reproducibility of the protocol. Another important challenge of proteomic or phosphoproteomic experiments is the analysis of the large volumes of data that can be produced. After identification of the phosphorylation sites, comprehensive bioinformatic analysis is necessary to annotate the phosphorylation sites. Extensive literature mining for functional information pertaining to phosphoproteins, phosphorylation sites, and also the sequence surrounding the phosphorylation sites should be performed. The use of prediction algorithms to annotate domains, amino acid sequence characteristics, and potential kinases and binding sites is necessary. Without this kind of postanalysis annotation, lists of phosphopeptides are of limited initial value. In a similar manner, the generation of long lists of protein identifications in proteome profiling experiments presents the problem of data analysis. It is necessary to systematically annotate such lists with as much relevant data as possible to extract the value and biological significance of the data.

Application to the Synapse Phosphoproteome

The complexity of the synapse in terms of its components and the processes it carries out necessitates a complex and robust regulatory system. Phosphorylation at the synapse has been studied for over 35 years, and the identification of phosphorylation sites has been an arduous process. The study of synaptic phosphorylation on a protein-by-protein level was inherently biased, with attention focused on channels and receptors, which were the earliest class of proteins characterized at the synapse by pharmacological methods. Undoubtedly, phosphorylation of this class of proteins is important, but the identification of phosphorylation sites in a global unbiased manner is necessary to expand our understanding of synaptic signaling beyond local regulation of channel function.

Recently, a number of studies have focused on the identification of synaptic phosphorylation sites by MS. One of the largest of these studies, which employed a sequential protein and peptide IMAC enrichment, resulted in the detection of over 650 phosphorylation events, corresponding to 331 sites (92% of which are novel) on 79 phosphoproteins (**Figure 7**). An additional 149 candidate phosphoproteins were identified by profiling the composition of the protein IMAC enrichment. This degree of novelty in terms of newly identified phosphoproteins as well as phosphorylation sites highlighted a previously unrecognized complexity in synaptic phosphorylation.

Figure 7 Schematic overview of methodology. The target proteome, in this case a subcellular fraction, is phase partitioned by its differential solubility in 6 M urea. The soluble fraction can be processed in two ways. Traditionally, this fraction is digested in solution, desalted, and applied to a peptide IMAC column (green arrows) with or without methyl esterification and analyzed by LC-MS/MS. In addition, we have developed top-down enrichment step in which the soluble proteins are applied to a protein IMAC column (blue arrows) and the eluted phosphoproteins are digested and also analyzed by LC-MS/MS. A novel combination of these two approaches (red arrow) in which a two-step enrichment of phosphoproteins and phosphopeptides and analysis by LC-MS/MS results in improved identification of phosphorylation sites. The urea-insoluble fraction, which represents tightly bound or integral membrane proteins, can be analyzed by direct digestion in 2 M urea to release peptides from cytoplasmic domains of these proteins, which can be applied to a peptide IMAC column to isolate phosphopeptides. These combined strategies, when applied to the synapse phosphoproteome, yielded the identification of over 650 phosphorylation events corresponding to 331 phosphorylation sites. This combined strategy of phase partitioning and sequential enrichment of phosphoresidues allows the comprehensive analysis of a complex sample. FPLC, fast-protein liquid chromatography; IMAC, immobilized metal-affinity chromatography; LC, liquid chromatography; MS, mass spectrometry.

To examine the significance of this complexity, the representation of phosphorylation data across synaptic proteins and important synaptic subcomponents and organelles was examined. This data set contained postsynaptic components including the PSD (134 proteins) and NMDA receptor-associated proteins (44 proteins) and presynaptic components, of which the most striking examples were Piccolo-Bassoon transport vesicles. A prominent feature of the synapse phosphoproteome was the appearance of many phosphorylated postsynaptic scaffold proteins. Major components of the NMDA receptor complex, such as PSD-95, Chapsyn-110, and SynGAP, were all phosphorylated, indicating that the scaffolding functions of these proteins may be regulated by phosphorylation. This suggested that the PSD scaffold, which provides a molecular matrix that supports and connects synaptic membrane receptors with intercellular signaling pathways, is itself subject to regulation.

A prominent theme which emerged from the study of the synapse phosphoproteome was that of kinase multiplicity. Data derived from *in silico* predictions of cognate kinases for identified phosphorylation sites and *in vitro* phosphorylation of peptide arrays suggested that a small number of kinases could phosphorylate many proteins and that each substrate is phosphorylated by many kinases. This phenomenon may represent signal integration (i.e., when signaling pathways converge and result in multisite phosphorylation of substrate). Another possibility that is not mutually exclusive is that kinase multiplicity represents robustness in signaling networks. The existence of a number of variant signaling pathways involving different kinases/phosphatases or substrates, which have the same downstream target (e.g., transcription

factor activation), would ensure signal transduction robustness. Finally, the complexity of synaptic signaling may require subtle fine-tuning, which may be mediated by combinations of different kinases working on the same substrates, resulting in slightly altered activity or localization of the substrate.

Neuroproteomics Perspective

The strength of MS-based proteomics lies in its ability to generate vast amounts of unbiased data that permit rapid characterization of proteomes and phosphoproteomes, which would not be possible using conventional techniques. The complete characterization of the protein inhabitants of every organelle in a cell type would provide valuable information on protein localization, provide annotation for the large numbers of proteins of unknown function, and provide a starting point for large-scale functional investigations of the biology of each organelle. Such data would be invaluable for neuroscience research, and the application of this approach to synapses would certainly provide an unprecedented parts list and platform for the study of synaptic biology.

The most important and striking point to come out of the research reviewed here is that the PSP is incredibly complex. The large number of proteins in the PSP presents a daunting challenge to systematically attribute synaptic function to each protein. However, for the first time we are in a position where we actually know the identity of the majority of proteins in the PSP and are able to ask questions concerning the entire PSP, as opposed to discrete subsets of proteins, as in the past.

Now that the field of proteomics is coming to the end of its developmental phase, the application of proteomic methodologies to biological problems should provide even more leaps of knowledge in the next 5 years. Analysis of the phosphoproteome is not currently routine; however, phosphoproteomic methodologies are maturing. It is anticipated that full phosphoproteome coverage is not achievable from analyses of basal states in tissue because some phosphorylation sites are of such low abundance in the absence of a specific stimulation. Therefore, the real challenge is to move from a discovery phase of phosphorylation-site identification to a profiling phase of phosphorylation in response to stimulation of cells or tissues with drugs and inhibitors. Similarly, the recent development of quantitative MS will facilitate the profiling of dynamic proteome states. The use of bioinformatics in the analysis of these data will be of the utmost importance, and this is an area that will need much attention if the value of such data is to be fully appreciated. We can envisage that the application of these new approaches using well-defined chemical (NMDA) or electrical stimulation paradigms (long-term potentiation (LTP)) in cultured neurons or tissue slices will undoubtedly reveal novel and interesting aspects of the complexity of synaptic plasticity.

Neuropsychological Testing

Introduction

The psychometric assessment of cognitive and motor functions has proved to have considerable utility in the diagnosis of neurological and psychiatric disorders. Many insidious disorders that evade early identification using the most advanced medical technologies (e.g., neuroimaging; electroencephalography, EEG) can often be effectively diagnosed using neuropsychological testing. Following are examples of neurological conditions that depend heavily on neuropsychological assessment for accurate diagnosis:

- Individuals with early Alzheimer's disease often have normal neurological examinations, magnetic resonance imaging (MRI) and computed tomography (CT) brain scans, and EEG findings. However, studies have found that neuropsychological testing has proved to be one of the most effective procedures for the earliest diagnosis of this pervasive disorder.
- Some elderly patients with severe depression present with memory complaints and low scores on mental status exams that are comparable to those of patients with early Alzheimer's disease, thereby making it difficult to distinguish between these two conditions. However, neuropsychological tests can differentiate between the qualitatively different memory profiles of depressed individuals versus those of early Alzheimer's patients with approximately 95% accuracy.
- Children with fetal alcohol syndrome (FAS), who often have significant deficits in cognitive development, are typically first identified by their facial dysmorphic features. However, many children who are exposed to alcohol *in utero* have normal facial features but go on to develop levels of cognitive impairment that are comparable to those of children with FAS. Neuropsychological testing is important for identifying children who were prenatally exposed to alcohol but who do not have the facial dysmorphic features in order to determine if they should receive early educational interventions for cognitive impairments.
- Some individuals who have had serious head traumas suffer brain damage and cognitive impairments and yet have normal findings on neuroimaging. Other individuals can have head trauma without brain damage, but exaggerate cognitive deficits for external incentive. Neuropsychologists have developed empirically based methods for distinguishing between head-injured individuals with bona fide cognitive deficits secondary to brain damage versus head-injured individuals without permanent brain damage who attempt to feign cognitive impairment on cognitive testing.

Historical Perspective

The field of clinical neuropsychology evolved in the 1940s through the 1960s primarily as a tool to aid in addressing the very broad question of whether a patient had organicity or brain damage. The need to address this general question was important at that time, because CT and MRI brain scans had not yet been developed. In addition, the primary focus of the neurological examination has always involved testing of reflexes and senses, both of which are mediated by the sensorimotor cortex and connecting pathways. This focus leaves vast regions of the brain that can be damaged but without altering sensorimotor functions. Instead, neuropathology in these other regions often affects cognitive skills. When brain damage is subtle to moderate, the decline in cognitive functions can also be mild to moderate. Neurologists and other physicians often conduct a 'mental status exam,' which is a cursory assessment of cognitive skills, such as asking the patient to remember three words. Such brief, nonstandardized exams usually are capable of identifying patients with severe brain damage, but they frequently fail to identify patients with mild to moderate neurocognitive dysfunction.

The need to identify individuals with mild to moderate brain damage outside the sensorimotor circuitry was one of the primary reasons why psychologists began studying neurological patients. Since the early 1900s, psychologists have been armed with powerful methodologies for rigorously measuring subtle differences in mental abilities. The fields of psychometrics and IQ testing, two of the most important contributions in the history of psychology, have long provided clinicians with the means for reliably measuring the development of intellectual and cognitive functions in children and adolescents. In the hands of the neuropsychologist, these methodologies offer the ideal procedures for gauging even subtle declines in intellectual and cognitive functions in individuals with brain dysfunction.

The pioneers in this area were a handful of psychologists during the 1940s through the 1960s; working at a time before there was a field of clinical neuropsychology, these psychologists had the vision to see the

tremendous utility of adapting psychometric tests to the assessment of cognitive decline in brain-damaged patients. These early leaders included, among others, Arthur Benton, Kurt Goldstein, Harold Goodglass, Ward Halstead, Donald Hebb, Edith Kaplan, Alexander Luria, Brenda Milner, Ralph Reitan, Andre Rey, Hans-Lukas Teuber, Elizabeth Warrington, and David Wechsler. In administering a wide variety of cognitive tests to patients with focal brain damage, psychologists soon discovered another vital contribution of their methodologies: more accurate characterizations of neuropsychological syndromes with different profiles of cognitive strengths and weaknesses. This work resurrected the importance of the early writings (late 1800s and early 1900s) of neurologists on the aphasias, agnosias, apraxias, and other syndromes, and brought a psychometric rigor to the descriptions of these syndromes. In addition, the emergence of cognitive science in the 1960s also brought more sophisticated experimental procedures for isolating and studying the integrity of specific cognitive processes in patients with focal brain lesions.

In modern times, the need for neuropsychologists to identify organicity or brain damage *per se* has decreased with the development of more sensitive structural and functional neuroimaging techniques. Although there continues to be some neurological disorders (e.g., Alzheimer's disease) that begin with such microscopic lesions that neuropsychological testing is still required for early detection, neuroimaging will likely soon be capable of detecting these insidious disorders as well. However, with advances in the detection of more subtle neurological conditions, and with such diverse individual differences in how similar levels of brain damage can affect cognitive functions, there continues to be growing need for clinical neuropsychologists to document each patient's profile of cognitive and motor strengths and weaknesses. In this context, clinical neuropsychology has become a flourishing field of practice.

The Basic Premise of Neuropsychological Testing

As a general rule, cognitive and motor functions tend to fall within the normal range of the bell curve in an individual with a healthy brain, with some relative strengths and weaknesses. However, when one or more regions of the brain have been damaged by injury or disease, the cognitive and motor functions that are mediated at least in part by those regions often will become significantly impaired. Accordingly, the clinical neuropsychologist will typically administer to a patient with known or suspected brain damage 20–30 different tests assessing attention, language skills, math abilities, visual–spatial functions, new learning and memory, problem solving, abstract thinking, and other cognitive and motor skills. In past research, these tests were administered to large numbers of neurologically intact individuals (the normative group) and to patients with different types of brain damage; the neuropsychologist uses these normative and clinical data to draw conclusions about whether a patient's raw scores on the tests fall within the expected or impaired ranges. This determination is not an exact science, since many neurologically normal individuals will have some test scores that fall in the impaired range, and some brain-damaged patients, especially if they have relatively high premorbid cognitive skills, may have few scores in the impaired range. Nevertheless, by examining the patient's profile of cognitive and motor strengths and weaknesses, the neuropsychologist can make inferences about the integrity of different brain regions and can begin to formulate hypotheses about the presence or absence of different neurological disorders.

What Comprises a Neuropsychological Evaluation?

The typical neuropsychological evaluation takes 6–8 h. For most teenagers and adults, the examination can be completed in a day, with ample breaks. For younger children, older adults, or patients whose endurance has been significantly compromised by a neurological, medical, or psychiatric condition, the examination can be conducted across two or three sessions.

In the morning and early afternoon hours of a 1-day exam, patients are typically administered the cognitive and motor tests when they are usually more alert. Some neuropsychologists administer the tests themselves, whereas others employ a trained psychological technician to administer the tests; both approaches are acceptable in the field, since the tests have standardized administration procedures. In the afternoon, patients who have adequate cognitive skills are often administered a psychological inventory designed to assess their self-reported emotional functioning. In addition, a comprehensive clinical interview is also typically conducted. In this era of managed care, many patients are first given neuropsychological screening exams, which usually vary from 30 min to 3 h in duration. If a patient exhibits some evidence of cognitive impairment on the screening exam, then more extensive neuropsychological testing may be conducted.

Selection of Tests

Neuropsychologists typically select tests that have empirically documented reliability and validity;

adequate, updated normative data; and empirically demonstrated utility in identifying neurocognitive deficits in brain-damaged patients. Modern neuropsychological tests often contain improvements over their predecessors by the incorporation of constructs from cognitive science, thereby making the tests more sensitive to the assessment of specific cognitive processes. Some neuropsychologists use a 'battery approach,' meaning that they will administer all tests or subtests that comprise a particular battery or scale (e.g., all subtests of the Wechsler Memory Scale-III). Other neuropsychologists use an 'eclectic approach,' meaning that they will pick and choose only certain tests or subtests from different batteries or scales (e.g., many psychologists administer only two subtests of the Wechsler Memory Scale-III: the Logical Memory subtest and the Visual Reproduction subtest). In addition, some neuropsychologists adopt a 'fixed approach,' meaning that they try to give the same tests to all patients, whereas other neuropsychologists use a 'flexible approach,' meaning that they will tailor the selection of tests administered to each patient based on the patient's presenting problems and referral question. These different approaches are all acceptable in the field, provided that the major domains of cognitive, motor, and behavioral functions are adequately covered by the tests selected. Table 1 lists a number of tests that are commonly used by neuropsychologists to assess cognitive and motor functions in children and adults.

The Clinical Interview

A critical part of the neuropsychological evaluation is the clinical interview. A comprehensive survey of possible risk factors for brain damage should be explored in the interview. In addition, many factors beyond brain damage *per se* can affect performance on rigorous psychometric tests of cognitive and motor skills, and these factors should also be covered in the interview. Important areas to explore in the interview include early developmental problems (e.g., pregnancy and delivery complications; prenatal exposure to alcohol, drugs, or other teratogenic agents; delays in achieving developmental milestones as an infant or toddler); cultural factors (e.g., English as a second language, being raised in another country); educational history (e.g., level and type of education obtained, history of learning disability or attention problems); occupational history (e.g., the degree to which an individual's work requires higher level thinking skills); history of medical illnesses that are risk factors for brain dysfunction (e.g., hypertension, diabetes); history of head injury or loss of consciousness; past and current psychiatric disorders; past and current alcohol and drug use; current medications (e.g., narcotic analgesics); current emotional state; current physical state (e.g., headaches and other pain symptoms, which can affect performance on psychometric tests); and family history of medical and psychiatric disorders (e.g., a family history of Alzheimer's disease is a risk factor for this disorder). Based on information gathered in the clinical interview, the neuropsychologist attempts to identify which risk factors may be present in an individual and how they may affect the person's performances on the cognitive and motor tests.

Another step in the clinical interview is to ask the patient, and family members if they are available, about their perceptions of the patient's cognitive complaints, the onset of the problems, and whether the problems have changed over time. Sometimes this information can be helpful in evaluating, for instance, whether a patient's cognitive difficulties started abruptly, as with a stroke, or gradually, as in Alzheimer's disease. However, the self-reported cognitive difficulties of patients and their family members often fail to correlate with objective test results. For example, depressed patients sometimes report severe memory difficulties when their actual scores on objective tests of memory may be normal or near normal.

Finally, the clinical interview allows the neuropsychologist to observe directly patients' emotional demeanor and behavioral functioning at a time when they are discussing their problems and symptoms. These observations can be valuable for identifying whether a psychiatric component is contributing to a patient's presentation.

Test-Taking Effort

Scores on difficult cognitive and motor tests are valid only if the examinee exerts adequate effort in taking them. An important part of the neuropsychological evaluation is the assessment of the individual's motivation to perform well on the tests. Some individuals exert minimal effort on neuropsychologist tests for secondary gain. For example, an inmate may intentionally perform poorly on memory tests to support his or her claim of amnesia for the accused crime. As another example, an individual involved in litigation related to a car accident may claim that he or she suffered a brain injury in the accident. When this individual undergoes a neuropsychological evaluation, he or she may fail to exert adequate effort on the tests, with the hope of looking 'brain damaged' and obtaining a large settlement. The frequency with which individuals have been found to exaggerate cognitive problems on neuropsychological tests has been reported to be as high as 30% of cases referred in the context of forensic evaluations.

Table 1 Examples of commonly used neuropsychological tests for adults and children

Domain	*Representative test*
Adults	
Intellectual functions	Wechsler Adult Intelligence Scale-III
Learning and memory	California Verbal Learning Test-II
	Rey Auditory Verbal Learning Test
	Rey Osterrieth Complex Figure Test
	Warrington Recognition Memory Test
	Wechsler Memory Scale-III
Visuospatial abilities	Block Design Subtest (WAIS-III)
	Hooper Visual Organizational Test
	Judgment of Line Orientation
	Rey Osterrieth Complex Figure Test
Language	Boston Diagnostic Aphasia Exam
	Boston Naming Test
	Controlled Oral Word Association Test
	Token Test
	Vocabulary Subtest (WAIS-III)
Executive functions	Category Test
Abstraction ability	Delis–Kaplan Executive Function System
	Similarities Subtest (WAIS-III)
	Trail Making Test
	Verbal Fluency Tests
	Wisconsin Card Sorting Test
Attention	Digit Span Subtest (WAIS-III)
	Digit Vigilance Test
	Spatial Span (WMS-III)
Motor Functions	Finger Tapping Test
	Grooved Pegboard Test
	Grip Strength (Hand Dynamometer)
Emotional/behavioral functions	Beck Depression Inventory
	Hamilton Depression Scale
	Millon Clinical Personality Inventory
	Minnesota Multiphasic Personality Inventory-II
Screening instruments	Kaplan Baycrest Neurocognitive Assessment
	Mattis Dementia Rating Scale
	MicroCog
	Repeatable Battery for the Assessment of Neuropsychological Status
Academic achievement	Wechsler Individual Achievement Test
	Wide Range Achievement Test-III
Children	
Intellectual functions	Cognitive Assessment System
	Wechsler Intelligence Scale for Children-IV
	Woodcock–Johnson Tests of Cognitive Ability
Specific neuropsychological domains	California Verbal Learning Test–Children's Version
	Children's Memory Scale
	Delis-Kaplan Executive Function System
	NEPSY Neuropsychological Battery
	Peabody Picture Vocabulary Test-III
	Wide Range Assessment of Memory and Learning
	WISC-III as a Neuropsychological Instrument
Emotional/behavioral functions	Child Behavior Checklist
	Personality Inventory for Children

Neuropsychologists have developed a number of tools for evaluating an individual's test-taking effort, including specific cognitive 'malingering' tests, analysis of typical and atypical profiles of neurocognitive dysfunction, consistency of test findings and profiles across repeat evaluations, and examination of whether a patient's low scores on neuropsychological tests are consistent with how he or she is functioning in everyday life. Even with these procedures, however, it is sometimes difficult to identify a clever patient who is feigning cognitive difficulties, especially if he or she does so to a mild degree (more

blatant forms of exaggeration are easier to detect). As reported in the literature, some individuals have admitted to having been 'coached' by their attorneys as to which tests are designed to detect malingering, prior to their neuropsychological evaluations. In addition, individuals can learn about malingering tests on the Internet. For these reasons, neuropsychologists strive to use different methods for the detection of inadequate effort and to stay one step ahead of public knowledge by developing new effort-testing techniques.

Premorbid Level of Cognitive Functioning

The most common reason that patients are referred for a neuropsychological evaluation is to determine whether they have acquired brain damage from some neurological insult, and, if so, whether they have experienced a decline in their level of cognitive functioning from a premorbid (preexisting) state. However, inferences about declines in cognitive functioning must include estimates of the individual's level of cognitive functioning before the onset of the insult. Neuropsychologists employ several techniques for estimating or correcting for premorbid level of cognitive functioning, including the following approaches:

- Testing overlearned cognitive skills that tend to be resilient to the effects of more diffuse brain damage and that correlate significantly with preexisting IQ (e.g., tests of individual word reading or vocabulary level are good predictors of premorbid verbal IQ).
- Developing normative test data that are corrected not only for age but also for education level, a strong predictor of premorbid IQ.
- Obtaining prior scholastic test scores from the individual's school records, since these scores correlate robustly with an individual's verbal IQ as an adult.
- Using regression analyses based on key demographic variables, such as education and occupation levels, to derive formulas for estimating premorbid IQ.

The estimation of premorbid level of cognitive functioning is a difficult task. Each method should be considered as a tool that may or may not be useful or even appropriate for a particular patient. For instance, the use of education-corrected norms can be invaluable for one patient and misleading for another. Following are three case examples that illustrate this point:

- A physician with 20 years of education and a premorbid IQ of 130 suffers a left hemisphere stroke. While her postinjury scores on language tests are within the average (normal) range for her normative age group, these scores fall in the impaired range for her education group (i.e., compared to age-matched individuals with approximately 20 years of education). In this case, the education-corrected norms are warranted because they provide an empirically based method for documenting evidence of acquired cognitive decline in this individual.
- A self-made businessman has a premorbid IQ of 130 but left high school after his sophomore year because his father was killed in a car accident and he had to begin working to help support his family. As an adult, this individual suffers a left hemisphere stroke and obtains scores on language tests that fall in the average (normal) range using both age- and education-corrected norms (i.e., compared to age-matched individuals with approximately 10 years of education). However, these standardized scores are likely misleading, because they are obtained from a normative reference group that likely has a lower mean premorbid verbal IQ than that of the patient. For this individual, it would have been more appropriate to use one or more of the other methods to estimate the patient's premorbid level of cognitive functioning (e.g., obtain school records to see if scholastic test scores are available for this individual; administer a single-word reading test).
- At birth, an individual suffers a brain insult secondary to delivery complications. In school, he is found to have an IQ that falls in the borderline mentally retarded range. He completes only 8 years of education. As an adult, he is evaluated by a neuropsychologist who scores the test findings using education-corrected norms (i.e., his raw scores are compared to age-matched individuals with approximately 8 years of education). The patient's standardized scores using these norms fall in the low-average range and the neuropsychologist claims that the patient does not have brain damage. However, the use of education-corrected norms is inappropriate for this case. The patient's relatively low education level was likely one of the 'effects' of his early brain insult (not the cause), and to correct his scores for a low level of education essentially negates one of the main effects of his brain damage. For this individual, age-corrected norms would be more appropriate to document that the patient shows evidence of cognitive impairment (i.e., borderline mental retardation) relative to his age-matched peers.

As a general rule, prior scholastic or IQ test scores that are obtained from a patient's school records when he or she was around 10 years of age or older are often the best method for estimating premorbid level of intellectual functioning, because achievement and IQ scores tend to be relatively stable across the life span. In addition, each person's premorbid

functioning should be estimated individually, given that there are significant individual differences in IQ level among people with similar levels of education. Other factors that contribute to discrepancies in IQ among people with similar levels of education include motivation to achieve in school (e.g., a person with average IQ and high motivation may achieve a high level of education, whereas a person with superior IQ and low motivation may drop out of school early); differences in the quality of the education (e.g., university-based graduate school versus private professional graduate school); and English as a second language (e.g., a highly educated person may have learned English as a second language and, as a result, obtain only average scores on English-based verbal tests, despite achieving a relatively high level of education). Unfortunately, for the majority of patients evaluated, school test results are not accessible, necessitating the use of one of the other methods for estimating premorbid functioning. Finally, it is important to note that the different methods for estimating premorbid mental abilities may apply to certain domains of cognitive functioning but not to others. For example, the ability to read individual words of varying difficulty has been found to be a significant predictor of verbal IQ. However, verbal IQ tends to have relatively low correlations with executive functions and memory skills (accounting for 0–16% of the variance). Thus, while current reading ability can be a useful predictor of premorbid verbal IQ, it tends to be less effective in predicting premorbid level of executive functions and memory skills.

Analysis of Test Performance

After the neuropsychological tests have been administered, raw scores are summed for each test and converted to standardized scores. In addition to these quantitative scores, many neuropsychologists also examine test performance for qualitative features that may be pathognomonic of brain dysfunction. For instance, a patient may speak primarily in content words and omit the little grammatical words of language (e.g., the patient says, "Hospital . . . Monday" when trying to say that he came into the hospital on Monday). This qualitative feature of the patient's language, when seen consistently, is pathognomonic of a type of language disorder called Broca's aphasia, and likely reflects a brain injury in the posterior region of the left frontal lobe. As another example, a patient may omit most details and features from the left side of his drawings (see Figure 1); this neurobehavioral syndrome, known as left hemi-inattention, typically occurs following brain damage to posterior regions of the right hemisphere.

Figure 1 An individual who suffered a cerebral vascular accident in the right parietal lobe was asked to copy a model drawing of a daisy (top). The patient's drawing (bottom) illustrates left hemi-inattention.

Emotional, Behavioral, and Personality Testing

The neuropsychological evaluation typically goes beyond the assessment of cognitive and motor skills, and also includes psychometric testing of emotional, behavioral, and personality functioning. Many neuropsychologists administer tests such as the Minnesota Mutiphasic Personality Inventory-2 (MMPI-2) or the Beck Depression Inventory as part of their standard evaluation, given that the patient has the cognitive capacity to take them. These tests assist the neuropsychologist in determining whether a patient has a psychiatric disturbance, which, in turn, may be affecting his or her performance on the neuropsychological tests. Most practicing neuropsychologists obtain their doctoral degrees in clinical psychology before receiving specialized training in neuropsychology, and this training enables them to conduct general psychodiagnostic assessments as part of their neuropsychological evaluations.

Final Interpretations and Recommendations

The heart of the neuropsychological evaluation, and the most difficult part, is drawing final conclusions

about the presence, nature, extent, and causes of a patient's cognitive, motor, and behavioral difficulties and, if necessary, formulating recommendations for helping the patient. Just because a patient obtains test scores that fall in the impaired range does not mean that he or she has brain damage.

The first step in the interpretation process is to determine whether a patient's test scores are valid (using techniques discussed earlier) and internally consistent (e.g., if a patient has a word-finding deficit, then he or she should exhibit difficulty on any task that places extensive demands on precise naming ability). If the test scores appear valid and consistent, the neuropsychologist then attempts to characterize the patient's profile of cognitive–motor strengths and weaknesses. Based on an estimate of the patient's premorbid level of cognitive functioning, the neuropsychologist opines whether the patient's weaknesses represent acquired deficits. Next, the neuropsychologist, drawing upon his or her knowledge of brain–behavior relationships, tries to decide whether the patient's profile of cognitive–motor strengths and weaknesses is typical of particular types and locations of brain dysfunction. The neuropsychologist then must weigh all of the patient's risk factors for acquired brain damage, such as a recent head trauma or stroke, history of medical illnesses that may compromise brain functioning, history of serious psychiatric disorder, past alcohol or drug abuse, or a family history of a genetically based neurological disorder (e.g., Alzheimer's disease). In considering these different risk factors, the neuropsychologist tries to determine whether the patient's cognitive–motor profile is more likely to be associated with one risk factor than another, or with multiple risk factors.

Before a final conclusion can be reached about the presence of neurocognitive dysfunction, the neuropsychologist must rule out all possible explanations for the patient's low test scores, going beyond brain damage *per se*, such as educational and cultural factors, current medications, current emotional and physical state, and level of motivation to perform well on the tests. In addition, the neuropsychologist must conduct a psychodiagnostic evaluation to determine whether the patient has a psychiatric disorder and, if so, whether this disorder is contributing to the patient's cognitive difficulties. After integrating, analyzing, and synthesizing this extensive and varied body of information, the neuropsychologist is then in a position to proffer his final impressions about the presence or absence of brain dysfunction and its sequelae. If the neuropsychological data strongly implicate a neurological disorder, such as Alzheimer's disease, then it falls within the neuropsychologist's purview to make those diagnoses.

At the end of the report, the neuropsychologist will typically offer recommendations for the patient. Common areas of recommendations include the following approaches:

- Additional neurological, medical, or psychiatric examinations, consultations, or procedures (e.g., MRI brain scan; psychotropic medication consultation).
- Speech therapy or cognitive rehabilitation.
- Individual or family psychotherapy or other behavioral interventions.
- Educational interventions and programs (especially for children and young adults).
- Vocational testing and counseling.
- Social work consultation to address the patient's living situation and the need for various levels of assistance and supervision with activities of daily living.
- Repeat neuropsychological evaluation in the future to determine the status of the patient's cognitive functioning over time.

When feasible, the neuropsychologist often will meet with the patient and his or her family to discuss the findings of the evaluation and the need for the various recommended interventions.

Repeat Neuropsychological Testing

The readministration of the same or similar neuropsychological tests to a patient at a later time can serve several clinically useful purposes. As an example, for patients suspected of having a progressive dementia such as Alzheimer's disease, the first neuropsychological testing provides baseline data. The repeat testing, which usually is done 9–12 months later, affords an objective measure of whether the patient exhibits a decline in cognitive functions typical of a progressive disease. Some neuropsychological tests may show practice effects on repeat testing, which is an improvement in performance from having taken the same or similar tasks at an earlier time. However, the inexorable progression of a disorder such as Alzheimer's disease typically overrides any improvement in scores related to practice effects.

Repeat testing also is helpful for charting the recovery of neurocognitive functions over time following a brain insult, such as a stroke or brain injury. Recovery of brain functions tends to occur relatively slowly, with a 1-year time period often used as the benchmark for the vast majority of the recovery to have occurred. By comparing a patient's test scores obtained a few months after an injury with those obtained a year or more postinjury, the neuropsychologist, after factoring in practice effects, can provide objective data about the

patient's recovery process. Other important reasons for conducting repeat testing include monitoring improvement in cognitive functions following various interventions, such as cognitive rehabilitation and pharmacological treatment, and determining the validity of an individual's test scores by examining the consistency of his or her profile of cognitive and motor strengths and weaknesses over time.

Common Referral Questions for Adults

Adult patients typically are referred for a neuropsychological evaluation by neurologists, neurosurgeons, clinical psychologists, psychiatrists, primary care physicians, speech pathologists, other health professionals, and attorneys. The following examples of consult questions illustrate some of the reasons why adult patients undergo neuropsychological testing:

- To assist in evaluating whether a patient with increasing cognitive difficulties, as reported by the patient, family members, or health professionals, has an insidious neurological disorder. Examples of these disorders include multiple sclerosis, brain tumor, idiopathic hydrocephalus, white-matter ischemic changes, and Alzheimer's disease.
- To evaluate whether a patient who has had a risk factor for brain damage does, in fact, exhibit cognitive–motor deficits or emotional–behavioral changes consistent with brain dysfunction. Examples of these risk factors include head trauma, chronic alcohol or drug abuse, certain medical illnesses (e.g., hypertension, diabetes, kidney failure, HIV infection), certain psychiatric disorders (e.g., schizophrenia), and exposure to neurotoxic agents.
- To assess the presence, nature, and extent of cognitive–motor deficits and emotional–behavioral changes in patients with known brain pathology. These patients are referred after it has been determined, usually from the neurological examination and neuroimaging, that they have had, for instance, a cerebral vascular accident or have a brain tumor, Parkinson's disease, probable Alzheimer's disease, or MRI- or CT scan-confirmed brain damage following a head trauma. The question for these patients is not whether they have brain damage, but rather the presence, nature, and extent of cognitive, motor, and behavioral sequelae of their brain dysfunction.
- To assist neurosurgeons in several ways, such as in evaluating whether a patient with intractable seizures and in need of resection of the epileptogenic focus has language skills localized in this general brain region (this testing usually involves a Wada procedure, where one cerebral hemisphere at a time is anesthetized during cognitive screening); in conducting pre- and postsurgery evaluations to determine whether a neurosurgical procedure (e.g., insertion of a shunt tube to relieve hydrocephalus; resection of a brain tumor) alters cognitive–motor functions for better or worse; and in reevaluating cognitive functions over a period of several years in a hydrocephalus patient who has received a shunt in order determine if the shunt has continued to function normally.
- To evaluate the cognitive functions of individuals with more serious psychiatric disorders that often have a neurological component (e.g., schizophrenia).
- To provide recommendations regarding the patient's capacity to return to work or to receive vocational retraining in a new occupation that would be best suited for the patient, given his or her profile of cognitive strengths and weaknesses.
- To offer recommendations for cognitive rehabilitation (e.g., teaching the patient memory compensatory strategies).
- To assist in determining whether a patient with brain dysfunction has the cognitive, motor, and behavioral capacity to perform important activities of daily living (e.g., ability to drive a car, handle finances, prepare meals, live independently, comply with medication regimens, care for self).
- To make recommendations regarding the best living situation for the patient in light of his or her cognitive, motor, and behavioral deficits (e.g., independent, assisted-living, or nursing-home placement).

Common Referral Questions for Children

Neuropsychological evaluations are generally more difficult to conduct for children than for adults. Just as children differ in their physical growth rates, they also differ in the development of their cognitive and motor functions. It is sometimes difficult to determine whether a 'cognitive deficit' in a child represents a permanent impairment or simply a lag or delay in the development of that ability. In addition, the classic brain–behavior relationships that have been documented in adults do not always apply to children, making it difficult to localize cognitive deficits to particular brain regions. For example, a lesion in the left superior temporal gyrus can result in a Wernicke's (fluent) aphasia in an adult and in a nonfluent aphasia in a child. Finally, some children present with pronounced attention problems, hyperactivity, or other behavioral disturbances that make it difficult for the child to focus on the psychometric tests and provide valid test responses.

Despite the challenges inherent in child neuropsychology, this area of practice has become one of the fastest growing disciplines within the field. Referrals for child neuropsychological evaluations usually are made by pediatricians, pediatric neurologists, clinical

psychologists, school psychologists, speech therapists, educators, and sometimes parents. Many of the referral questions for children are similar to those for adults, such as assessing whether the apparent onset of new cognitive difficulties reflects an insidious neurological disorder (e.g., brain tumor); evaluating whether a known risk factor for brain damage (e.g., birth complications, head trauma, lead exposure) has, in fact, resulted in cognitive, motor, or behavioral dysfunction; and assessing the presence, nature, and extent of cognitive, motor, and behavioral changes in patients with known brain pathology (e.g., childhood seizure disorder). Following are examples of other specific reasons why children are referred for neuropsychological testing:

- To determine whether a child who is struggling academically in school has a learning disability. Neuropsychological research has documented different types of learning disabilities (e.g., verbal vs. nonverbal) that may reflect neurodevelopmental abnormalities in distinct brain regions.
- To assess whether a child whose mother abused alcohol or drugs or consumed other teratogenic agents during her pregnancy (e.g., certain medications) exhibits cognitive, motor, or behavioral deficits suggestive of prenatal brain damage (e.g., FAS).
- To assist educators in developing the best educational program for a child based on the child's profile of cognitive and behavioral strengths and weaknesses.
- To assess recovery of function in a child who has suffered a documented traumatic brain injury and to provide recommendations for cognitive remediation and educational assistance.

Conclusions

Clinical neuropsychology has become one of the fastest growing disciplines in psychology. Neuropsychological testing not only provides an empirically rigorous method for assisting in the diagnosis of neurological, medical, and psychiatric patients, it also enhances our scientific understanding of one of the great mysteries of life, namely, the generation of mental processes from brain structures.

Neuropsychology of Primate Reward Processes

E A Murray, National Institute of Mental Health, Bethesda, MD, USA

Published by Elsevier Ltd.

What Is Reward and Where Is It Processed?

Reward is operationally defined as anything an animal will work to obtain or will systematically approach. This article uses the term reward interchangeably with positive reinforcement, notwithstanding their somewhat different origins and meanings.

A key problem in understanding reward processing in primates (or in any other group of animals) is that reward is a surprisingly complex and nuanced concept. Rewards have both hedonic and incentive value, which correspond to the concepts of liking and either wanting or seeking, respectively. In addition, rewards may vary in terms of probability, timing, quantity, quality, context, and effort required to obtain them. Context alone has many facets. A reward could be available all the time (i.e., it could be context independent). More often, however, reward is available conditionally. For example, a reward might usually be available but not as much recently (i.e., it could be dependent on temporal context); it might be available in one location but not another (i.e., it could be dependent on spatial context); and, in human primates, at least, it could be both wanted and not wanted to be wanted (i.e., it could be dependent on first-order and second-order intentionality). The complexity of reward does not end there. Rewards have both a general aspect and have a wide diversity of specific aspects (e.g., olfactory, gustatory, tactile, visceral, and visual features of multiple dimensions). Naturally occurring rewards include food, in general, and specific kinds of food, in particular. They also include water, salt, warmth (and sometimes cold), and sex. In addition, initially neutral stimuli or places associated with these types of reward become reinforcing under certain circumstances.

Many parts of the brain allow animals to learn about rewards. Indeed, we might argue that every part of the brain plays a role in reward processing; each part is either directly or indirectly involved in acquiring information about the stimuli, places, events, and actions associated with reward. Dopaminergic neurons, which detect rewards and deviations from predicted rewards to promote learning, play an especially crucial role in reward processing in primates, as they also do in other animals. This article explores, however, a more narrow topic. It deals with those neural structures known to play both an essential and a general role in processing rewards in primates, namely the amygdala, orbital and medial prefrontal cortices, and basal ganglia.

What Is Special about Reward Processing in Primates?

In primates, the advent of the granular prefrontal cortex, which interacts with the amygdala, the basal ganglia, and other structures involved in reward processing, makes the primate way of dealing with rewards different than that of other animals, including other mammals. The nature of this difference is not yet well understood. Nevertheless, I assume in this article that the granular prefrontal cortex underlies a knowledge of the physical world, the self, and social groups that is unique to primates. This view of primate neuropsychology does not disparage other animals. Many other clades have evolved unique ways of knowing about the world and thereby producing advantageous outcomes. But we are primates and so have an intensified interest in our way of doing things.

Several areas that are called prefrontal cortex in rodents and other nonprimate mammals, such as the orbital and medial prefrontal areas, have clear homologs in primate brains. The common mammalian areas include the infralimbic and prelimbic cortices, the anterior cingulate cortex, and the agranular insular cortex, among others. However, according to the comparative neuroanatomical evidence, rodents lack a homolog of the granular prefrontal areas of primates. These areas include the dorsolateral prefrontal cortex (approximately area 46), the dorsal prefrontal cortex (area 9), the ventral (or ventrolateral) prefrontal cortex (area 12 or 47/12, and areas 44 and 45), the frontal pole cortex (area 10), and the rostral portion of the orbital prefrontal cortex (parts of areas 11 and 13). In addition, the most rostral parts of other areas, such as the prelimbic, infralimbic and cingulate cortices, might also be unique to primates, depending on how they are defined.

Collectively, neuroanatomists often refer to these uniquely primate areas as the granular prefrontal cortex, despite the fact that they do not have a granular cytoarchitecture. As applied to the remainder of the neocortex, the term granular refers to the hypertrophied layer 4 found in primary sensory areas. Instead, the so-called granular prefrontal areas have a homotypical or dysgranular architecture, a kind of cortex absent in the frontal cortex of other mammals.

Clearly, if these granular prefrontal areas appeared during the course of primate evolution, the interaction of cortex as a whole with the other brain areas involved in reward processing must have changed accordingly. This idea applies to both frontal cortex–amygdala interactions and those between the frontal cortex and basal ganglia. Accordingly, the next two sections take up the role in reward processing of the amygdala and amygdala–frontal interaction, respectively. Subsequently, the role of the orbital and medial prefrontal cortices in reward processing is addressed; the final section discusses the basal ganglia.

Amygdala

Reward versus Punishment

A role for the amygdala in negative reinforcement – punishment, as opposed to reward – has dominated work on the amygdala. The amygdala plays a central role in conditioned fear, including fear-potentiated startle, by linking initially neutral stimuli to the innately programmed triggers of defensive responses such as freezing, reflex potentiation, and many aspects of autonomic arousal. This fact has led to the mistaken idea that the amygdala serves primarily to process negative reinforcement, as opposed to rewards. Following this line of thought, some experts have referred to the primate amygdala as a protection device.

Recent neuropsychological studies demonstrated, however, that the amygdala's role in reward processes is as important as its role in punishment and fear. For instance, when sensory inputs occur in close temporal proximity to reward, the amygdala appears to link those sensory inputs with the neural circuits mediating instinctive behaviors, such as autonomic reflexes and orienting responses. This kind of learning promotes the processing of stimuli that predict biologically significant events. In other instances, the amygdala acts to enhance the processing of unexpected (surprising) sensory events. And in yet other instances, the amygdala acts to assign positive value to neural representations of sensory inputs. Thus, the amygdala plays a key role in connecting reward-linked sensory information to the instinctive processes that underlie some of the most fundamental aspects of vertebrate behavior.

The basolateral group of nuclei (including the lateral nucleus, the basal nucleus, and the accessory basal nucleus) and the central nucleus of the amygdala contribute differently and in parallel. The basolateral amygdala links neutral stimuli with the specifics of reinforcement (e.g., the tastes, smells, sights and visceral sensory signals associated with rewards), whereas the central nucleus links stimuli to more general aspects of reward, such as its affective significance.

Neuropsychology in Nonhuman Primates

Unlike correlative techniques, such as those used in neuroimaging and neurophysiology, neuropsychological methods enable a rigorous assessment of whether a particular structure makes an essential contribution to a given cognitive capacity. There are several ways to measure reward-processing capabilities in nonhuman primates, and two commonly used approaches have contributed to understanding the amygdala's function in reward processes: In one, monkeys learn to link objects with food value; in the other, monkeys learn to link the presentation of a picture with food.

The first approach is carried out in two stages. First, monkeys are familiarized with a large number of objects, half of which are associated with one kind of food, designated Food 1, and half of which are associated with a different food, designated Food 2. Second, the value of one food is decreased by feeding it to the monkey, and the effect of this selective satiety on choices between Food 1- and Food 2-associated objects is compared with a baseline condition in which there was no prefeeding.

Intact monkeys avoid choosing objects associated with a devalued food, as indicated by the high devaluation score for the unoperated control group (Figure 1, (**1**)). In these experiments, sated monkeys shift their choices away from objects associated with the devalued food by about half, yielding a score of ~17 out of a possible 30. In contrast, monkeys with selective, bilateral amygdala lesions continue to choose much as they did before any food had been devalued. This deficit is reflected in the low devaluation score after bilateral amygdala removal (Figure 1, (**4**)), in which the monkeys make, on average, only approximately four fewer choices of objects associated with a devalued food. Control procedures have shown that changes in visual perceptual abilities, food preferences, or satiety mechanisms cannot account for the impairment. Thus, monkeys with amygdala lesions cannot efficiently link objects with the current value of a food reward.

Precisely how objects are linked to food value and how this information translates to shifts in response selection remain largely unknown. The test outlined here comprises several components: forming object representations, linking those representations with the incentive value of the associated food, registering and encoding a change in the reward value due to selective satiation, linking object representations with those updated values, and using these changed representations to choose between objects.

Figure 1 Contribution of the amygdala (Am) and orbital prefrontal cortex (PFo) to object–food value associations. The top row shows ventral views of the macaque brain showing the lesion for the five groups (rostral is up). The black line and bar for the crossed lesion group (3) represents the transection of the corpus callosum and anterior commissure. All operated monkeys underwent two stages of surgery, involving lesion of either the Am (pink shading) or PFo (blue shading). The graph shows the devaluation scores. Higher devaluation scores indicate a greater ability to avoid choosing objects after decreases in the value of their associated food reward. The highest possible score is 30 choices, which would indicate complete avoidance of objects associated with devalued food. When tested after the second-stage surgery, each of the operated groups was significantly impaired relative to controls.

Transient inactivation of the amygdala by focal infusion of the GABA agonist muscimol has clarified the mechanisms of stimulus valuation in primates. In these experiments, monkeys received infusions of either saline or muscimol, bilaterally, via cannulae lowered to the basolateral amygdala, either before or after satiation. As expected, saline infusions had no effect. Nearly identical results were obtained when the basolateral amygdala was inactivated after the selective satiation procedure. By contrast, inactivation of the basolateral amygdala immediately before and during the satiation procedure prevented the shift in object choices that normally occurs with selective satiation. Thus, the basolateral amygdala needs to be functionally intact for registration of a change in the incentive value of the food reward and for the subsequent adjustment in the monkey's choices. Apparently, once the value of the food reward has been updated, no further contribution of the basolateral amygdala is required for these functions.

The contribution of the primate amygdala to processing rewards has also been shown in another way. This second approach relies on the fact that animals will work to obtain the presentation of a picture that has been linked with food, called a conditioned reinforcer. (In general terms, any stimulus that has been linked to reward, and for which animals will work, is called a secondary, or conditioned, reinforcer.) Once a conditioned reinforcer has been established, intact monkeys will put forth a great deal of effort to earn the presentation of the conditioned reinforcer, even if the food reward is available only infrequently. Marmoset monkeys with bilateral amygdala damage fail to put forth this effort. In addition, they fail to show the autonomic responses, such as increases in heart rate and blood pressure, that usually accompany the sight of reinforcers. Presumably the amygdala damage disrupts the same process as previously described for the selective satiation test – linking stimuli with current value – in addition to disrupting the activation of autonomic centers. However, conditioned reinforcers probably act through at least one additional mechanism independently of incentive value, as evidenced by the ability of a conditioned reinforcer to support new learning even after the devaluation of the food with which it was originally paired.

The neuropsychological findings presented here show that the primate amygdala performs a key aspect of reward processing; it is necessary for linking initially neutral stimulus representations with current, updated biological values. Furthermore, different parts of the amygdala contribute to reward processes in different ways. The basolateral amygdala plays a crucial role in updating the representations of value for specific aspects of each reinforcer or reinforcer type (e.g., visual features, taste, and smell),

whereas the central nucleus of the amygdala performs a comparable function for general aspects of reinforcement (e.g., food reward, in general, rather than a particular kind of food).

What Is Different about Primates?

What about this is specific to primates? The answer is that the amygdala is likely to provide the same function – linking neutral representations with updated value – for the highest aspects of cognition.

The amygdala has a long evolutionary history, stretching back to the earliest land animals and perhaps beyond, to the earliest vertebrates. It has relatively direct connections with the hypothalamus, as well as reciprocal anatomical relations with high-order cortical areas such as those that compose the granular prefrontal cortex. Amygdala relations with the granular orbital and medial prefrontal regions may hold the key to the amygdala's contribution to the primate way of processing rewards; in addition to assigning value to objects, the amygdala may also assign value to the kinds of information stored in and processed by the granular prefrontal cortex.

In nonhuman primates, this information includes rules, strategies, categories, and aspects of social knowledge, among other cognitive functions, processed via the extensive and reciprocal connections of the amygdala with the frontal cortex. In humans, likewise, the amygdala assigns values that guide social interactions, and this capacity is also likely to involve interactions with the frontal cortex. Amygdala damage reveals deficits in recognizing facial expressions of fear and in judging from facial expressions whether others are trustworthy. Indeed, the amygdala is thought to be important for acquiring social (moral) conventions, such as learning to avoid actions that will harm others. Other evidence mirrors the findings already described regarding valuation in nonhuman primates. Studies in humans have shown that the amygdala plays a role in assigning positive values to pictures associated with food reward. Significantly, the value assignments mediated by the amygdala may be inaccessible to conscious awareness, at least in any direct way. For example, in experimental settings, when people view pictures and at the same time receive reward, they acquire picture preferences, although they remain unaware of the relationship between the picture presentation and the probability of reward. Patients with amygdala damage, however, do not display such preferences; that is, they do not acquire the unconscious bias, or preference, for particular objects.

The findings described indicate that the amygdala is necessary for linking updated biological value with the representations of objects. There is evidence that this is the case in all mammals and probably in other animals, as well. In nonhuman primates, however, this function probably extends to other representations, such as those for members of a social group, abstract behavior-guiding rules and problem-solving strategies, and knowledge about how to achieve goals during long and highly variable event sequences. Primates may not be unique in all of these capabilities, but we are uniquely good at all of them. In humans, this function probably extends even further, to representations of ideas, abstract concepts and beliefs, and aesthetic values, including self-worth.

Prefrontal–Amygdala Interactions

Although interactions between the amygdala and the primate prefrontal cortex lie at the heart of attaching value to abstractions such as ideas, rules, strategies, and concepts, little is known about the mechanisms of amygdala–frontal cortex interactions in primates. Fortunately, research on rodents may shed light on how value-to-representation linkages are forged in mammals generally, including primates.

Neuronal activity in the orbital frontal cortex of rodents, in areas that are probably homologous with the more posterior parts of orbital frontal cortex in primates, reflects the value of expected outcomes. Significantly, this activity is evident during the presentation of a stimulus that predicts the reward before the reward is given, and the emergence of this activity depends on the integrity of the amygdala. Consequently, stimulus–value associations mediated by the basolateral amygdala appear to be established in the orbital frontal cortex of rodents, and these representations are thought to serve as the basis of reward expectancy. Extending this finding to the granular prefrontal cortex of primates, its more abstract representations of the world are probably linked to current value through similar mechanisms.

The findings from the selective satiation procedures described earlier accord with this general view. According to one model, the sight of an object elicits activity in the orbital prefrontal cortex that reflects the current value of the expected outcome and may therefore underlie the ability of monkeys to choose objects appropriately in the face of changes in the value of the goal. Strong support for this model comes from the effects of crossed surgical disconnection of the amygdala from the orbital prefrontal cortex, which disrupts adaptive response selection after selective satiation (Figure 1, (3)).

Orbital and Medial Prefrontal Cortex

The selective satiation and conditioned reinforcer tests of reward processing have also been applied to the study of orbital prefrontal cortex in primates. This research has revealed that the orbital prefrontal cortex, like the amygdala, is essential for linking objects with current food value (Figure 1, (5)). In addition, this region of the cortex is essential for learning a new response when that learning is supported only by presentation of a conditioned reinforcer. Thus, damage to the orbital prefrontal cortex produces some of the same effects on reward processing as does damage to the amygdala, although these regions probably make selective contributions to reward processing as well.

How do the amygdala and orbital prefrontal contributions to reward processing differ? Some evidence suggests that, whereas the amygdala is primarily important for linking sensory inputs to value, the orbital and medial prefrontal cortical regions are preferentially involved in using that information to guide choices and actions. It has been suggested that the orbital prefrontal cortex, in particular, provides a common currency for the valuation of competing goals, a function critical to adaptive response selection.

The medial and orbital prefrontal cortex both function in reward processes – both have been identified as regions linking motivation, cognition, and action – but they contribute differently. For example, damage to the medial prefrontal cortex, unlike damage to the orbital cortex, spares the acquisition of a new response for conditioned reinforcement. One possibility is that the orbital prefrontal cortex links objects with current reward value to guide choices among objects, whereas the medial prefrontal cortex links actions with current reward value to guide choices among actions. Recent evidence supports that idea for the medial prefrontal areas. Removal of part of the anterior cingulate cortex disrupts monkeys' abilities to link particular actions with reward (see Figure 2) and to choose optimally under conditions in which different actions take on different values, based on the probability of reward delivery. Medial prefrontal cortex damage also disrupts monkeys' valuations of social stimuli. Finally, the medial prefrontal cortex is anatomically linked to visceromotor structures and may therefore be important for adaptive autonomic and affective responses.

Basal Ganglia

If the amygdala, through its interactions with the uniquely primate granular prefrontal cortex, provides the linkage between initially neutral representations and their updated biological value, what then of the basal ganglia's role? The basal ganglia receives a signal from dopaminergic neurons in the midbrain that convey information about reward. At a minimum, dopaminergic neurons signal the occurrence of unexpected rewards and deviations from predicted rewards. Like amygdala–frontal cortex interactions, basal ganglia–frontal cortex interactions are affected by the existence of the uniquely primate parts of the frontal lobe – the granular prefrontal cortex.

In rodents, the dorsal basal ganglia is essential for at least two different types of learning, both involving reward processing: stimulus–response learning and action–outcome learning. In stimulus–response learning, the ingestion of food or fluid reward in the past has acted to enhance the association between a particular stimulus and a particular response. The reward itself does not enter into the stimulus–response association, at least not at the time of the behavior; given the appearance of the stimulus, the animal performs the associated response. Because the animal performs the response without respect to the value of the predicted outcome, stimulus–response behavior is often called a habit. Action–outcome associations, unlike stimulus–response associations, are sensitive to the value of the outcome. For that reason, this latter kind of learning is thought to play a major role in goal-directed behavior. Although some researchers maintain that the basal ganglia functions only in stimulus–response learning, recent work has overturned this idea. Instead, according to research in rodents, different portions of the dorsal basal ganglia are essential for stimulus–response and action–outcome learning.

Although neuropsychological data from non-human primates remain scarce, damage to the dorsal basal ganglia (but not damage to the amygdala or orbital prefrontal cortex) produces deficits in visual discrimination learning. In these tasks, monkeys must learn and remember which of two objects to choose in order to produce a reward. Monkeys with damage to the portions of the basal ganglia that receive highly processed sensory input from visual cortex (such as the head and tail of the caudate nucleus and the posterior ventral putamen) solve visual discrimination problems more slowly than do intact monkeys. Because other already-learned visual tasks can be performed efficiently, this impairment does not depend on alterations in visual perceptual processing. Instead, although discrimination deficits are notoriously difficult to interpret, it seems likely that problems with stimulus–response and action–outcome learning account for the discrimination deficits that follow lesions of the dorsal basal ganglia.

Figure 2 Contribution of the anterior cingulate cortex in monkeys to action–reward associations: (a) presurgery performance; (b) postsurgery performance of controls and lesion group. Monkeys were trained to perform two different actions on a joystick and to switch between them as needed to obtain a food reward. Only one action was rewarded at a time. After monkeys had obtained 25 rewards for performing one action, only the other action was rewarded for a series of trials. Curves show the mean percentage of correct responses for trials before and after a switch trial (trial 0, dashed vertical line), averaged over several such switches. Although both groups performed comparably before surgery (a), monkeys with lesions of the anterior cingulate cortex were impaired after surgery (b). Note that the lesion group detected errors, as indicated by the rapid change in the action performed immediately after the switch (blue arrow). Thus, monkeys with anterior cingulate cortex lesions had a specific difficulty linking actions to reward. Also in (b) is a medial view of the macaque brain (rostral to the left, dorsal up) showing the location of lesion (blue shading), with the dashed lines indicating the banks of the cingulate sulcus. Copyright 2006.

In addition to the dorsal basal ganglia, parts of the ventral basal ganglia play a crucial role in reward processing. The ventral basal ganglia, in concert with the amygdala, link stimuli with reward outcome, a type of learning termed stimulus–outcome learning. One study in monkeys showed that bilateral damage to the nucleus accumbens, a part of the ventral striatum, caused impairments during a food hoarding task in which subjects had to remove peanuts from their shells and store them for future consumption. The same monkeys efficiently hoarded peanuts without shells, suggesting that their difficulty might lie in recognizing the incentive value of the shell-covered peanut. A deficit in stimulus–outcome learning might account for this finding.

A theoretical account of basal ganglia function posits that the basal ganglia recognizes contexts for action. According to this view, the cortex and thalamus provide the basal ganglia with a vast array of inputs, some of which predict biologically significant events. When a particular pattern of inputs produces reward delivery, the basal ganglia encodes that context, retaining the relevant inputs and discarding the irrelevant ones. In this way, the basal ganglia could extract the dimensions of input that have the most relevance for either stimulus–outcome or action–outcome learning and for various combinations of these kinds of learning.

Another role for the basal ganglia may be in acquiring performance rules involving reward. In some neuropsychological tests, a reward can be used much like any other sensory signal to trigger a performance rule. According to this idea, the occurrence (or nonoccurrence) of food, for example, guides the

selection of a rule, and the role of food depends on its informational value, as opposed to its reward or reinforcement value. Support for this idea is provided by the finding that intact monkeys can learn to reject their most recent reward history as well and as fast as they can learn to follow it. For example, in one test, monkeys learned a performance rule of the win-stay/lose-shift type, in which they must choose a previously rewarded object to gain an additional reward. Conversely, other monkeys learned the opposite performance rule, one of the win-shift/lose-stay type, in which they must reject a previously rewarded object and choose an unrewarded one instead. Despite the fact that one group of monkeys learned to reject its most recent reward history, both groups learned at the same rate. Some tasks commonly used to assess reward learning in primates, such as object reversal learning, may also depend on this rule-based type of learning, at least in experienced monkeys. Evidence for a role of basal ganglia in this informational (value-independent) aspect of reward processes comes from the finding that damage to the basal ganglia severely disrupts object reversal learning. So does damage to the orbital prefrontal cortex and to areas such as perirhinal cortex and entorhinal cortex, which are anatomically connected to it; however, damage to the amygdala has no effect. These deficits thus involve frontal cortex–basal ganglia interactions more than frontal cortex–amygdala ones.

Summary

Through its role in linking representations in the granular prefrontal cortex with updated valuations, the primate amygdala provides the neural basis not only for choosing among objects based on their current biological value but also for esthetics and the valuation of abstract goals, knowledge, and ideas; for attaching value to a particular course of action; and for social and self-referential valuations. Some evidence suggests that the amygdala is primarily involved in linking sensory inputs to value, whereas the orbital and medial prefrontal cortical regions use that information to guide choices and actions. Like amygdala–frontal interactions, aspects of basal ganglia–frontal interactions in primates reflect the contributions of the granular prefrontal cortex. The cortex and basal ganglia together subserve the kinds of reward-mediated behaviors that depend on performance rules, as well as on stimulus–response and action–outcome associations and, in conjunction with the amygdala and frontal cortex, stimulus–outcome associations.

Birth of Neuropsychology

Broadly conceived as an attempt to understand the relationships between brain, mind, and behavior, neuropsychology has a long history, but it was only in the 1960s that an autonomous field of scientific inquiry with that name was formally established. Although there is some evidence for occasional appearances of the term 'neuropsychology' and its derivatives in medical writings of the nineteenth century and perhaps even earlier, the term began to acquire some visibility in the 1940s and 1950s because the influential North American psychologists Lashley, Hebb, and Teuber used it in their efforts to advocate the interaction, if not the coalescence, of neurology and psychology. (Hebb gave the subtitle *A Neuropsychological Theory* to his celebrated book, *The Organization of Behavior*, and Lashley and Teuber mentioned neuropsychology as part of the classical field of physiological psychology.)

The official birth of neuropsychology as an independent scientific discipline can be dated to 1963, when an international specialty journal titled *Neuropsychologia* started its publication on the initiative of a small group of neurologists, psychologists, and psychiatrists partaking in an informal discussion forum called the International Neuropsychology Symposium. The scope and aims of neuropsychology were spelled out in the first issue of the journal in an unsigned manifesto attributable to the Editor-in-Chief, the French neurologist Henry Hécaen. According to the manifesto, the foundation of a new journal and a new distinctive discipline, neuropsychology, was intended to meet the needs of a number of investigators in a number of more traditional fields who had more in common with one another than with the members of their original specialties. More specifically, the term 'neuropsychology' was understood to mean a particular area of neurology of common concern to neurologists, psychiatrists, psychologists, and neurophysiologists, with an interest focused mainly, but not exclusively, on the cerebral cortex, and on disorders of language, perception, and action. It was recognized that although certain of these disorders could be studied only in adult humans, information of great value to the understanding of basic cerebral mechanisms and to human pathology was expected to come as well from experiments on animals, from ethological studies of learning and conditioning, and from analyses of normal development in children.

That the field was ripe for more than one specialized publication was very soon made clear by the appearance, in the following year, of another journal devoted to the study of the nervous system and behavior; this journal was entitled *Cortex*, and its frank neuropsychological character was attested by an opening article by Aleksandr Luria on the role of neuropsychology in the diagnosis of local brain damage. The same year, 1964, saw the publication of a reader, edited by R L Isaacson; this publication, entitled *Basic Readings in Neuropsychology*, collected 16 papers from scientific journals, 14 of which reported animal experiments, in confirmation of the perceived importance of this approach for the new field of neuropsychology.

The Anatomo-Clinical Approach as a Main Root of Neuropsychology

The concept of neuropsychology explicitly or implicitly set forth in the aforementioned publications extended the boundaries of the discipline well beyond those of the outgrowth of one of its main roots, the anatomo-clinical approach applied in the nineteenth and early twentieth centuries to the study of psychological dysfunctions in brain-injured patients. On the inspiration of phrenology, but with a much greater scientific respectability, the anatomo-clinical approach had worked on the belief that mental functions are localizable in the brain and that cerebral organization is based on an orderly system of functionally specialized centers linked by discrete and selective anatomical connections. Functional localization in the brain was assumed to be demonstrated when an autoptically ascertained lesion in a particular cerebral region could be shown to stand in a systematic relation with a particular psychological ability, insofar as that ability was lost, and others were preserved, in patients carrying that lesion. Based on that approach Broca, Wernicke, Liepmann, Lichtheim, Bianchi, Dejerine, and others had been able to localize some specific psychological functions, particularly in the domains of language and voluntary motor control, in specific regions of the cerebral cortex, strengthening the view that the brain is made up by a set of centers, akin in a sense to the cerebral organs of phrenology, each with its own functional specialization.

The physiological connectionism of the anatomo-clinical approach assumed that interactions between functionally allied centers occurred through the discrete

fiber pathways linking the appropriate cortical regions, hence clinical symptoms and syndromes were divided into those resulting from lesions directly encroaching upon putative specialized centers, and those caused by the interruption of fiber pathways and the attendant disconnection of allied centers. This localization–connectionist view received support not only from existing knowledge of brain anatomy and human neuropathology, but also from the study of the effects of circumscribed brain lesions and electrical stimulations in experimental animals, although such effects were of course restricted to basic sensory and motor functions.

Decline of the Anatomo-Clinical Approach in the First Half of the Twentieth Century

In spite of a number of undisputable achievements, in the first decades of the twentieth century the localizationist–connectionist approach came under severe criticism from different angles, and especially as a result of detailed clinical examinations of young soldiers who had suffered from missile wounds of the brain in World War I. Influential clinical neurologists such as Monakow, Head, Marie, and Goldstein, dissatisfied with the rather crude anatomical and behavioral analyses of their predecessors (caricatured as brain cartographers and diagram-makers), shared Hughlings Jackson's aversion to the attribution of normal psychological functions to cortical areas based on behavioral effects of their lesions. They saw any attempt to localize language and other higher nervous functions in the brain as a futile exercise, and convinced themselves that disorders of higher nervous functions had better be imputed to diffuse alterations of brain organization, in contrast with elementary motor and sensory defects which could instead be precisely related to specific sites of brain damage, as in the case of discrete, topographically organized visual field losses resulting from different bullet trajectories within the occipital lobes. At the same time, general theories of cerebral organization entertained by holistically oriented schools of psychology seemed largely incompatible with the localization of psychological functions in brain centers connected by select fiber paths. Radical learning theorists tended to depict the developing nervous system as a random, unstructured, and essentially equipotential network to be molded and shaped into a functionally adaptive system by use, practice, and conditioning.

Based on his lesion experiments in rats, Lashley, perhaps the most important physiological psychologist of the time, contrived a general theory of the brain based on mass action and functional equipotentiality of the cortex, whereby the severity of functional deficits correlated with the amount of cortex removed, independent of lesion site, and most perceptual and learning functions could be subserved by virtually any part of the cortex. In a different vein, but again in sharp contrast with localization–connectionist views, the Gestalt doctrine of psychoneural isomorphism equated brain activities underlying psychological functions with diffuse electrical fields spreading throughout the cortex as a volume conductor rather than with distinct patterns of nervous impulses traveling along orthodox neuronal circuits. Finally, interest in brain–behavior relationships was discouraged by behavioristic extremists who advocated the restriction of behavior analysis to directly observable input–output relationships of the whole organism, with total disregard for any independent neurophysiological evidence.

Return of Localization and Connectionism

These viewpoints against localization and connectionism were neither completely illogical nor totally devoid of some factual evidence. It is true, for example, that during development there is an excessive production of neurons and neuronal connections, many of which are functionally inappropriate and must be eliminated by the action of natural environmental influences at later stages of maturation. It is also true that the brain is not a mosaic of centers and that functionally specialized populations of neurons tend to be distributed in the brain rather than being concentrated in circumscribed centers. But developments in the neurosciences beginning around the middle of the twentieth century proved beyond doubt that anatomical and physiological specificity and selectivity are the hallmarks of a cerebral organization in which there is no room for either mass action or functional equipotentiality. Work in neuroembryology and neurophysiology showed that well before birth the genes and developmental processes determine highly specific neural connections, which are then maintained and perfected by environmental influences.

Cytoarchitectural and myeloarchitectural subdivisions of the cortex, as described by the early neuroanatomists, were given specific functional meaning by the demonstration that most of these subdivisions contain orderly maps of the sensory or motor peripheries, as well as populations of neurons with quite distinctive physiological properties. An important distinction surfaced between neuronal systems conveying specific sensory or motor information, and deep-brain systems with diffuse projections to the thalamus and cortex which can modulate the activity of the entire nervous system in the sleep–wake cycle

as well as in attentional and motivational regulations. The identification of different synaptic transmitters subsequently furnished evidence for the existence of several of these diffusely projecting systems, each marked by a single transmitter specific for that system and for its action on its cortical and subcortical targets. Better controlled lesion experiments in animals and more accurate and systematic analyses of neurological patients made it clear that, depending on its locus, focal brain damage can bring about unique combinations of impairments and spared psychological capabilities, allowing reasonable inferences about the cerebral localization and organization of normal psychological processes. On the basis of such a renewed localizationist approach, it became feasible both to use the pattern of losses and preservations of functional high-order capabilities for inferring the site of the causative brain lesion, and in turn to employ theories about normal psychological functioning in order to predict the psychological outcome of a particular cerebral injury. The logic of the interpretation of the psychological effects of brain lesions benefited considerably from the distinction between a simple dissociation (lesion X produces impairment of performance on task A but not on task B), which may at least in part depend on task difficulty rather than functional specialization, and the more revealing double dissociation (lesion X produces impairment of performance on task A but not on task B, while lesion Y produces impairment of performance on task B but not on task A), an effective methodological weapon for strengthening the reliability of inferences about functional localization.

Technological Progress in the Aid of Neuropsychology

Starting from the 1960s and 1970s, the advances of the newly born discipline of neuropsychology were helped considerably by technological progress. In the old times neuropsychologists had to wait for postmortem examinations or to rely on entry and exit sites of bullets or other objects in the skull in order to obtain direct anatomical evidence for the locus of brain damage. In the case of closed head brain injuries, it was often the neuropsychologist who inferred the locus of damage on the basis of a specific pattern of psychological deficits. This situation changed drastically when the invention of X-ray computed tomography (CT) scanning in the 1970s allowed one to see the injured structures of the living brain in a noninvasive manner, making it possible to obtain independent parallel evidence on psychological deficits and brain pathology, and to follow their evolution over time. In the following decades, further spectacular advances in the noninvasive imaging of the normal working human brain have been obtained with positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), both of which monitor changes in local blood flow related to metabolism and chemical and electrical activities of neurons and glia. These techniques have shown that diverse cognitive operations are associated with rather distinctive combinations of activated cortical regions interspersed among other cortical regions with unchanged activity. It has therefore become feasible to match the deficits in specific cognitive operations resulting from a localized cortical lesion against the activation of the same cortical region in the normal brain during the execution of the same cognitive operations.

Complementary information to the preceding evidence can now be obtained with transcranial magnetic simulation (TMS), which allows temporary functional inactivation of select cortical areas in normal observers during the execution of cognitive tasks. Further, the perfection of the classical electroencephalographic and evoked-potentials techniques and the introduction of magnetoencephalography have furnished the possibility to obtain global or local brain correlates of behavioral and mental states with a temporal resolution far superior to that of the X-ray or PET or fMRI imaging techniques. Digital computers have enormously facilitated the collection and analysis of behavioral and brain data, and computer science and artificial intelligence have contributed to neuropsychological progress both practically and theoretically. In these sciences, a movement called connectionism attempts to explain human cognition using artificial neural networks, composed of large numbers of units linked by connections with variable strength. The units are the analogs of neurons, and the variable connections mimic synaptic connections. Although artificial neural networks have been proved capable to learn typical neuropsychological tasks (e.g., reading or face recognition) with stimulation-induced changes in the strength of connections between the units, the resemblance between the artificial intelligence connectionism and the anatomophysiological connectionism of neuropsychology is vague. The genes and the forces of development predispose a prenatal, extremely selective pattern of connections between the brain neurons, which artificial neural networks, with their initially random connections, cannot simulate in a veridical manner. Finally, thanks to techniques for recording from single neurons in experimental animals, particularly in freely behaving monkeys, an enormous amount of information has been obtained on the organization of the material substrates of the higher nervous functions in those animals. In many cases this information has provided a decisive

guidance for probing the corresponding substrates of cognition in man.

Some Major Achievements of Neuropsychology

As implied in its original program, neuropsychology has mostly succeeded when progress was made in a convergent fashion on the two fronts – the brain on one front and the mind or, to use a more fashionable term, cognition on the other. Since its start in the early 1960s, neuropsychology experienced profound changes in the understanding of cerebral organization, especially as regards the role of long corticocortical connections in the transfer of sensory, motor, and higher order information. In support of the validity of the concept of anatomo-functional connectionism, Geschwind and others reestablished the reality of aphasic disconnection syndromes contingent on lesions of the long association connections within the cortex of the left hemisphere, and the split-brain studies of Sperry and co-workers demolished one of the alleged cornerstones of Lashley's view of the long corticocortical connections as mere 'skeletal structures,' devoid of any demonstrable mental or behavioral function.

Far from being a mere mechanical link between the two hemispheres, the most developed of these connections, the corpus callosum, was shown to be the essential route for the interhemispheric exchange of information underlying mentation and behavior control. In addition, the independent cognitive abilities of the two separate hemispheres proved to be considerably different, in general keeping with much new evidence from the analysis of the deficits caused by right and left hemispheric lesions. The adoption of appropriate statistical tests in studies of large cohorts of patients with brain lesions in approximately corresponding hemispheric locations led to a definitive rejection of the classical concept of an overall left cerebral dominance in favor of the notion of a complementary functional specializations of the two hemispheres.

The unique specialization of the left hemisphere for all language functions was confirmed not only in right-handers but also in most left-handers, and the right hemisphere was in turn found to be predominant in various cognitive tasks that cannot be aided by verbal mediation, such as the exploration and cognition of space, the discrimination and recognition of unfamiliar and familiar faces, and the perception and memory of colors and complex visual shapes. Lesions of the right hemisphere were attributed a special role in the unilateral hemineglect syndrome as well as in emotional and affective disorders such as anosognosia (e.g., the denial of illness) and the flattening of affect. Discoveries on hemispheric asymmetry of functions in brain-injured patients stimulated a multitude of studies on normal observers tested with different sensory inputs channeled into single hemispheres while responses were measured as simple or choice reaction times, in order to assess various aspects of transfer of cognitive information between the hemispheres. The time-honored methodology of mental chronometry was also applied to the analysis of attentional modulation of cognitive processes, allowing important distinctions between automatic and voluntary orienting mechanisms, as well as between the allocation of attention to spatial locations and that to objects.

The field of memory was revolutionized by the work of Brenda Milner on the famous patient H.M., who had been submitted to a bilateral medial temporal removal for epilepsy control, with a resulting extremely severe anterograde amnesia but normal short-term memory and fair-to-good long-term memory for preoperatory facts and events. The demonstration that this patient could learn at a normal rate and retain skills of which he was totally unaware made a definitive case for a fractionation of memory into components, a case which had been postulated mainly on theoretical grounds but never revealed with such compelling evidence. This groundbreaking discovery started many very successful lines of investigation which led to a fractionation of both short-term and long-term memory into multiple components. The subdivision of long-term memory into the declarative and nondeclarative categories, in their turn subdivided into different subcategories, has been greatly fruitful for neuropsychology because convincing evidence is now available that forms of memory distinguishable at the cognitive level are also associated with distinct neural substrates at cortical and subcortical sites. The discovery of strikingly selective agnosic disorders which affect the information processing of some categories of objects or living beings or their parts, while sparing the handling of information from other categories, has strongly suggested that different knowledge categories are represented in different regions of the cortex, a suggestion strongly supported by data from fMRI and TMS studies in normal observers. Finally, possible approaches to the neurology of consciousness have been furnished by the discovery of dissociations between conscious and unconscious forms of vision, as occur in blindsight and other situations in both brain-damaged patients and normal observers, and the proposed distinction of an occipitotemporal brain system for conscious visual perception, and an occipitoparietal brain system for visually guided action not necessarily accompanied by awareness.

Cognitive Neuropsychology: A New Neuropsychology?

The strong development of neuropsychology in the last decades of the twentieth century is attested by a strong increase in the number of publications specializing in various aspects of the field. In the year 2006 there were about 20 international scientific journals dealing specifically with neuropsychology, 12 of which included in their titles the term 'neuropsychology' or related terms (Table 1). In most cases the adjectives which accompany the noun 'neuropsychology' in the titles of these journals, as well as in those of neuropsychological textbooks and other related publications, are merely indicative of obvious disciplinary subfields and specializations: experimental, clinical, human, animal, comparative, developmental, applied, rehabilitative, and so forth. Unlike these self-explanatory qualifications, the adjective 'cognitive' deserves special attention, because in the past two decades the phrase 'cognitive neuropsychology' has come to denote a new conception of neuropsychology and a more restricted agenda for neuropsychological research. These have been clearly explicated in 1984 in an editorial (unsigned, but attributable to the Editor-in-Chief Max Coltheart) in the first issue of the journal *Cognitive Neuropsychology*, and reiterated in an editorial by Coltheart and Alfonso Caramazza in the same journal 22 years later. Since its inception, neuropsychology had indisputably been cognitive, insofar as it had amply concerned itself with cognition and the brain, where the emphasis is on the 'and,' and the word 'cognition' applies broadly to all aspects of mentation and action control. But in the newly proposed scenario it is argued that cognitive neuropsychology, as a branch of cognitive psychology, should primarily aim at understanding how the human mind works, while considering the question of how the brain works as a secondary if not irrelevant problem. Cognitive processes are seen as computational programs instantiated on a special computer, the human brain, the physical structure of which belongs to a level of reality different from that of the mind and does not necessarily provide insights into the mind computational programs. The mission assigned to the newly conceived cognitive neuropsychology is that of testing on brain-damaged patients theories which assume that cognitive tasks are normally carried out by sets of discrete, separable, and relatively autonomous information-processing components (sometimes called modules, not to be confused with the cortical neuronal modules known to neurophysiology). In particularly informative single cases, the cognitive effects of a local brain lesion are such as to suggest that a postulated single processing component of a cognitive system has been selectively removed, while the remaining parts of the system have remained largely or totally functional. What is important in these data is not the location or nature of the brain lesion, but rather the demonstration that a multicomponent cognitive system, *a priori* represented as a box-and-arrow diagram, has been selectively deprived of one of its elements, either a box or an arrow. While the modularity assumption and the reliance on single cases are common to the classical anatomo-clinical approach, the distinguishing features of cognitive neuropsychology are the priority of the theoretical framework in which the cognitive effects of brain lesions are interpreted, and the conviction that explanation of human cognition must take place at a level of analysis totally separate from the brain level. Understanding of brain functioning is neither a foundation nor a goal of the new cognitive neuropsychology, although psychological theories about normal cognition which are tested against the losses of

These include, for example, *Cortex*, *Behavioral Neuroscience*, *Brain and Cognition*, *Brain and Language*, and *Cognitive Brain Research*.

cognitive capabilities following focal brain injuries may in some cases be inspired and constrained by existing neurological knowledge. As a result of these developments, there exists today a wide range of scientists working in neuropsychology, all of whom call themselves cognitive neuropsychologists, but who entertain quite different views of their study subject and its specific methodologies. At one extreme, closer to the pristine neuropsychological tradition, there are those who address such questions as "what are the cognitive functions of the prefrontal cortex?" "what is the role of the hippocampus in memory?" etc., and use a variety of techniques in animals and humans to obtain proper answers. At the other extreme, radical cognitive neuropsychologists, dubbed 'ultracognitive,' seem to pride themselves on an intentional policy of eschewing any attempt to correlate the pattern of cognitive deficits under examination with the causative changes in cerebral organization. For the latter group, traditional anatomo-clinical studies of cognitive defects from brain lesions, along with all other studies of brain–cognition relationships based on more modern technologies, should be regarded as belonging to cognitive neuroscience rather than to cognitive neuropsychology. There is at present some justified resistance to this rather arbitrary distinction and to the restriction of the usage of the phrase 'cognitive neuropsychology' to research conditions in which the prefix neuro-is justified solely by the presence of a *per se* insignificant brain lesion. Perhaps the increasingly fashionable term 'cognitive neuroscience' will eventually prevail and drive out the term 'neuropsychology' for good.

The Future of Neuropsychology

The term 'neuropsychology' may well be destined to disappear from the neuroscientific vocabulary, but the pristine target of neuropsychology – to understand the relationships between the mind and behavior on one hand, and the brain on the other – will still remain the ultimate goal of the neurosciences of the future. Studies of cognitive alterations from brain damage will perhaps continue to occupy a central place on the scene, but progress will inevitably depend on many other experimental and theoretical approaches and on combined contributions from all biological sciences, from molecular biology to paleoanthropology, as well as from psychology, from cognitive and computer science, and from philosophy. The as yet poorly understood neuropsychology of complex cognitive and emotional derangements as occur in major psychoses (e.g., bipolar disorder, schizophrenia, clinical depression, obsessive–compulsive disorder) will progress to a point where the already blurred border toward neuropsychiatry will eventually vanish. There is still a long, effortful way to go, but the endeavor is worth the effort. To know how the human brain furnishes the medium through which all members of our species cognize, emote, and act would be tantamount to solve the perennial mind–brain problem, an achievement which, in William James' words, would make all previous achievements pale.

Published by Elsevier Ltd.

Introduction

Formulation of the Basic Concept

The concept of neurosecretion originated in the 1930s when Ernst Scharrer reported neurons with secretory cell characteristics in certain nuclei in the hypothalamus of mammals, birds, reptiles, fish, and invertebrates. At the time it was known that the posterior pituitary secreted vasopressin and oxytocin. However, Scharrer's concept of neurosecretion was initially derided because it was widely believed that secretion from the posterior pituitary (neurohypophysis) originated from the glia-like pituicytes characterized by large lipid droplets and that the release was stimulated by axons derived from the hypothalamus and running in the neural lobe stalk. It was only after Wolfgang Bargmann and others performed key experiments involving histochemically staining the neurosecretory material throughout the neurons and then separating the neurohypophysis from the hypothalamus that the hypothalamic origin of posterior pituitary hormones and the concept of neurosecretion were established. Later, Harris, Guilleman, Schally, and others demonstrated that the secretion of anterior pituitary (adenohypophysis) hormones is controlled by peptides and amines released from neurons ending on hypothalamo-pituitary portal capillaries and carried by them to the anterior pituitary. This extended the neurosecretion concept to the parvocellular neurosecretory neurons.

As in most other systems secreting peptides and amines, the secretory products of neurosecretory neurons are present in dense core neurosecretory vesicles (NSVs). Release of the products by neurosecretion from the axonal terminals is therefore the result of exocytosis of the NSVs into the extracellular space and then into the bloodstream and distant targets (neuroendocrine secretion). However, it is clear that neurosecretory neurons also release their products into the brain extracellular space to exert widespread effects on brain structural and functional organization.

The terminals of neurosecretory axons in the neural lobe, median eminence, and other neuroendocrine sites resemble synaptic boutons, and it is clear that the basic mechanism of exocytosis of vesicular contents is similar in both. The classical synapse therefore probably evolved from peptidergic neurosecretory terminals because networks of peptidergic signaling cells are present in primitive organisms which evolved long before the first synapse-containing nervous system.

Model Systems

For many years, the mammalian magnocellular neurosecretory system, the neurons of which release oxytocin or vasopressin (antidiuretic hormone) into the systemic circulation to act, respectively, on uterus and breast or kidney and blood vessels, has remained the model system of choice for generic experiments on neurosecretion (Figure 1). The parvocellular system, which releases growth hormone-releasing hormone, somatostatin, gonadotrophin-releasing hormone (GnRH), thyrotrophin-releasing hormone (TRH), corticotrophin-releasing hormone (CRH), and dopamine, is essential for the control of the anterior pituitary, but the magnocellular system has a number of advantages for experimental purposes: more peptide is produced, the neurohypophysis is easily separated from the rest of the brain, and many of the magnocellular neurons are gathered together into the supraoptic (SON) and paraventricular (PVN) nuclei, one of which (SON) is readily accessible from the ventral surface of the brain for recording and peptide collection. Because many of the basic cellular processes are similar, much of the study of vesicular exocytosis in neurosecretion has also been based on studies on chromaffin or PC12 cells and on brain synaptosomes.

Extension of the Basic Concept: Secretion from All Parts of Neurosecretory Neurons

For many years, it was accepted that the secretory products were released only from axonal terminals. Indeed, it was even suggested that the secretory material known to be present in both the axonal dilations (Herring bodies) and dendrites of the neurons was 'parked' there for storage or destruction because it was not required by the axon terminals (destruction of NSV by smooth endoplasmic reticulum (ER)/lysosome systems does occur in both compartments). Studies using tannic acid capture of exocytosis first showed clearly that any part of the axon within the neurohypophysis, and not just the terminals, is capable of exocytosis of the dense core vesicles. Experiments also showed that peptide could be released in the hypothalamus, but this was assumed to come from axon collaterals. However, in 1989, tannic acid capture of exocytosis visualized by electron microscopy showed unequivocally that the dendrites of magnocellular

neurons can release oxytocin and vasopressin by exocytosis. This has since been extended by sophisticated assay studies to many other peptidergic neurons.

Compartments of Neurosecretory Neurons

Perikarya

The perikarya of magnocellular neurosecretory neurons are large, with the following organelles: extensive rough endoplasmic reticulum, smooth endoplasmic reticulum including Golgi apparatus, variable numbers of NSVs, lysosomes, and mitochondria. Numerous synaptic boutons abut the surface, which is otherwise covered with astrocyte lamellae. Perikarya of parvocellular neurosecretory neurons are smaller but contain the same complement of organelles, although usually many fewer NSVs.

Axons and Their Specializations

Neurosecretory axons leave either the perikarya or the initial segments of the dendrites. As they pass toward the neural lobe, they have dilatations which are not dependent on the presence of clusters of NSVs. As the axons enter the neural lobe, each has many large axonal 'swellings' (the largest of which are called Herring bodies), which do not contact the perivascular basal lamina, and many nerve 'endings' (terminals), which abut the basal lamina. Both contain substantial numbers of NSVs and mitochondria, but the nerve endings in both the neurohypophysis and the median eminence are characterized by the presence of clusters of electron-lucent microvesicles (ELMVs), with a few larger electron-lucent vacuoles which are the recaptured membrane of exocytosed NSVs. Occasional clusters of ELMVs are also found in the axonal swellings, oriented against membrane contacting pituicyte cytoplasm (Figure 2). The ELMVs are known to contain calcium and to be able to accumulate it with high affinity. In neurosecretory terminals in the neurohypophysis, median eminence, and organum vasculosum of the lamina terminalis, ELMVs have been shown to contain significant amounts of the vGLUT2 glutamate transporter and glutamate, but their function is unclear. NSVs are transported down the axons, maturing as they proceed. In the neurohypophysis, they preferentially pass first into the nerve endings and then accumulate in the swellings if not released from the nerve endings or if there is no space for them in the nerve endings. This preferential release of newly

Figure 1 Low-magnification electron micrograph of part of a vasopressin-secreting magnocellular neuron in the supraoptic nucleus of a mouse adjacent to a capillary (Cap). In the cytoplasm, there are many round dense core neurosecretory vesicles (NSV) approximately 160 nm in diameter in addition to larger irregular dense lysosomes (L), mitochondria, and endoplasmic reticulum. Cores of neurosecretory vesicles can be seen being packaged in the numerous Golgi stacks (G). The nucleus (N) contains a prominent nucleolus (Nu). Reproduced from Morris JF and Gainer H (2004) Neurosecretory vesicles. In: Adelman G and Smith BH (eds.) *Encyclopedia of Neuroscience*, 3rd edn. Amsterdam: Elsevier.

Figure 2 Low-magnification electron micrograph showing the specializations of neurosecretory axons in the posterior pituitary. Undilated parts of the axons give rise to numerous large 'swellings' (S) and 'endings' (E). Only the endings contact the perivascular basal lamina and contain substantial populations of electron-lucent microvesicles. Pituicyte cytoplasm (P) is interspersed between the neurosecretory processes. Cap, capillary.

Figure 3 High-power electron micrograph showing part of a neurosecretory nerve ending abutting the basement membrane and perivascular space in the posterior pituitary of a rat. Two neurosecretory vesicle cores (arrows) have been captured in the process of exocytosis by the tannic acid method (which has made their cores more electron-dense). Other neurosecretory vesicles lie at varying distances from the plasmalemma. The nerve ending also contains numerous electron-lucent microvesicles (ELMV) which contain glutamate and can accumulate calcium. Reproduced from Morris JF and Gainer H (2004) Neurosecretory vesicles. In: Adelman G and Smith BH (eds.) *Encyclopedia of Neuroscience*, 3rd edn. Amsterdam: Elsevier.

Figure 4 Low-magnification electron micrograph showing a dendrite of a magnocellular neuron filled with many neurosecretory vesicles and abutted by two synaptic boutons (arrowheads). Reproduced from Kawata M and Leng G (eds.) (2004) Neurohypophysial hormones. *Journal of Neuroendocrinology* 16, p. 404, by permission of Blackwell Publishing.

mature vesicles is similar to that demonstrated for bovine adrenal chromaffin cells. The largest axonal dilatations retain the most aged NSVs and degrade them.

Magnocellular axons appear to have the ability to continue to grow. If the neural lobe is removed or the pituitary stalk damaged, some magnocellular neurons die, but the surviving axons form a mini-neural lobe and function is restored. In part, the restoration of function is due to axons sprouting and making contact with capillaries in the median eminence. In the neurohypophysis, some axons grow through the basement membrane and into the perivascular space (Figure 3). When this happens, perivascular microglia engulf and digest the aberrant axonal processes.

Dendrites

Magnocellular neurosecretory neurons, like most peptidergic neurosecretory neurons, have long but relatively simple dendritic trees, largely devoid of dendritic spines but contacted by many different synaptic boutons (Figure 4). The dendrites emerge from the perikarya with no sharp junction, emphasizing the functional similarity of the two compartments. Dendrites of SON neurons form a dense network beneath the pia just lateral to the nucleus; those of the PVN pass medially toward the third ventricle. Like the axons, many dendrites have large dilatations often filled with NSVs. Substantial amounts of rough ER are present in the dendrites, particularly in the region of synaptic contacts, but there are no recognizable Golgi stacks. However, there are some clusters of smooth ER membranes and small vesicles close to synapses. There is no evidence that the dendrites can package NSVs. This occurs in the perikarya, and the NSVs are transported into the dendrites along the substantial bundles of microtubules in their cores (Figure 5). Dendrites do not, however, contain the clusters of ELMVs which characterize the nerve endings. How NSVs are directed into either the axon or the dendrites is uncertain. The kinesin motor transports NSVs into axons and dendrites, and the glutamate receptor interacting protein (GRIP1) steers kinesin into dendrites. In some invertebrate systems, NSVs are distributed differently according to their contents.

Neurosecretory Vesicles

Neurosecretory vesicles are produced in the cell body of neurosecretory neurons. Their proteins are synthesized in the rough ER, modified and packaged in the Golgi apparatus usually as a larger precursor, and then mature as they pass into the axons or dendrites.

Figure 5 Electron micrograph showing the exocytosis of three neurosecretory vesicle cores (arrows) from a magnocellular dendrite (D) containing many secretory vesicles and a prominent core of neurotubules and surrounded by glial processes (G). Reproduced from Kawata M and Leng G (eds.) (2004) Neurohypophysial hormones. *Journal of Neuroendocrinology* 16, p. 404, by permission of Blackwell Publishing.

Figure 6 High-power electron micrograph showings the exocytosis of a vasopressin-containing vesicle (immunogold labeled for vasopressin neurophysin) from a dendrite (D). The secretory vesicle core is exocytosed immediately beneath a synaptic bouton (S) contacting the dendrite.

Neurosecretory vesicles vary in size, shape (generally spherical), and the number that are present in the neurons; their peptide/protein or amine content renders them dense core by electron microscopy. They usually contain one major secretory product (e.g., vasopressin or oxytocin) and numerous other compounds. Some of these (e.g., the chromogranins and prohormone convertases) have a role in the formation of the vesicles and their contents, but many others are bioactive signaling molecules present in much smaller amounts than the main hormone. For example, vasopressin vesicles also contain dynorphin, enkephalin, galanin, TRH, PHI, and cholecystokinin; oxytocin vesicles also contain these, but they contain CRH rather than PHI. It has also been shown that salusins, TOR-related peptides thought to be involved in blood pressure regulation, are co-packaged only with vasopressin, and transforming growth factor-β_1 has been added to the ever expanding list of bioactive molecules packaged in magnocellular NSVs. The amounts of the co-stored products vary with physiological status. They are released with the major product and usually have local modulatory actions either on the compartment from which they are released (autocrine) or on surrounding structures (neurons, synaptic boutons, and glia). In certain circumstances, a proportion of magnocellular vesicles contain more than one of the major products (e.g., lactation – vasopressin and oxytocin). The number of neurosecretory vesicles in any system has evolved to match the need. Where there are large fluctuations in demand (e.g., for stress hormones and vasopressin), stores are large; where fluctuations are small (e.g., TRH), stores are much smaller. The size of the vesicles varies in a way that is not obviously related to their content, although presumably the quantal size has evolved to an optimum for that system. Vasopressin vesicles in magnocellular dense core vesicles which secrete into the systemic circulation are approximately 160 nm in diameter, but they are approximately 110 nm in suprachiasmatic neurons which release into the local extracellular space; similarly, the parvocellular peptidergic neurons which release into the very small portal circulation have smaller (~100 nm) dense core vesicles.

In addition to their core contents, vasopressin-containing NSVs (at least) carry vasopressin V_{1a} and V_{1b} receptors in their membranes so that, upon exocytosis, the receptors can be incorporated into the surface membrane and act as autoreceptors (Figure 6). This incorporation is clearly important in the dendrites, but its role in the axonal terminals is unclear. By contrast, the membrane of pituicytes surrounding the axonal terminals is richly supplied with vasopressin receptors. Oxytocin neurons also express oxytocin receptors, but their transport to the membrane via oxytocin-containing NSVs remains to be demonstrated.

Neurosecretion from Axons in the Posterior Pituitary and Median Eminence

Electrical Activation of Release

Release by exocytosis of neurosecretory vesicles from the neurohypophysis is stimulated by the electrical activity of the neurons. Basal release is poorly understood, but it is increased by taurine from the pituicytes acting via $GABA_A$ and glycine receptors. Many neurosecretory neurons fire in burst patterns. Moderately activated vasopressin cells fire phasically, interspersing bursts of action potentials with quiescent periods; these are not coordinated among the numerous vasopressin cells. By contrast, although oxytocin neurons have a variable frequency but steady firing pattern in virgin animals, during lactation they fire in high-frequency bursts 1 or 2 s long and recurring every 5–10 min during the suckling stimulus. These firing bursts are coordinated to approximately 0.5 s not only within a nucleus but also between the oxytocin neurons of the supraoptic and paraventricular nuclei. Action potentials in bursts release proportionally more hormone than do action potentials that are not in bursts. The need for bursting may reflect the electrical properties of the very highly branched and dilated axons within the neural lobe and is known to affect the calcium transients within the nerve terminals.

The Role of Calcium Transients in Neurosecretory Axons

An increase in intraterminal calcium is an essential prerequisite for the exocytosis of NSVs. Spikes invading the terminal arborization can open voltage-dependent calcium channels. Neurosecretory terminals contain a number of these: L- and N-type are present in both oxytocin and vasopressin terminals; Q-type preferentially control vasopressin terminals, whereas R-type control oxytocin terminals. These channels are sensitive not only to voltage but also to opioids which are co-packaged in the NSVs and therefore act as autocrine inhibitors. Release of calcium from intracellular stores of calcium is also involved in stimulated release, but its precise role is uncertain because removal of extracellular calcium blocks depolarization-induced release. Calcium is accumulated and stored in mitochondria, NSVs, and ELMVs, which are a prominent feature of the nerve endings. The bursts of action potentials which characterize neurosecretory neurons are essential not only for generating the increases in intracellular calcium and secretion but also for terminating the activity. High-frequency stimulation causes changes in calcium influx which directly decrease the population spike amplitude via calcium-activated potassium conductances, causing a cumulative increase in spike latency. The calcium extrusion pump plays a major role in decreasing intraterminal calcium; neither sodium–calcium exchange nor calcium storage appears to be involved, despite the observation that a potassium-dependent sodium–calcium exchanger is localized in the neurohypophysial terminals. Caldendrin, a protein associated with the soma–dendritic compartment of brain neurons, is present in variant form in neurohypophysial axons. Its association with Q-type calcium channels suggests a function in triggering calcium transients in vasopressin terminals.

Interestingly, it has been shown that CD38, a transmembrane ADP-ribosyl cyclase which catalyzes the formation of a number of calcium signaling molecules (cyclic ADP-ribose and nicotinic acid adenine dinucleotide phosphate) is important in the control of oxytocin (but not vasopressin release). Lack of it is associated with changes in social behavior reminiscent of autism – a condition for which defects in oxytocin-induced pair bonding are strongly implicated.

Mechanism of Exocytosis in Neurosecretory Axons

Studies on the mechanism of exocytosis in a number of systems, primarily brain synaptosomes and chromaffin cells, have increased our understanding of the mechanisms and molecules involved in vesicle docking, activation, and fusion (exocytosis). Many of the molecules are common to both constitutive and regulated secretory pathways in yeast, invertebrate, and vertebrate systems. The vesicles in 'classical' synapses and in neurosecretory systems have many proteins in common. However, classical synapses contain higher levels of the proteins presumably because of their much faster release. Molecules shared by the two systems include the vesicle membrane proteins synaptotagmin (p65) and synaptobrevin (VAMP), vesicle-associated proteins, rab-3, and munc18; the plasma membrane proteins syntaxin, neurexins, and SNAP-25 (synaptosome-associated protein); and soluble proteins such as NSF (*N*-ethylmaleimide-sensitive factor) and α-, β-, and γ-SNAP (soluble NSF-attachment protein). Some proteins known to be involved in exocytosis appear to be restricted to synaptic vesicles (e.g., synapsin 1 and synaptophysin), whereas others are specific for NSVs (e.g., cytochrome b_{561}). Knockout experiments using chromaffin cells indicate that rabphilin brings together the membrane SNAP-25 and the vesicle protein Rab3A and, in so doing, controls the number of releasable vesicles docked to the plasma membrane. Vesicles docked to the plasma membrane still need 'priming' to make them ready for release. Priming involves the assembly of a SNARE complex in which the vesicular SNARE protein synaptobrevin interacts with SNAP25 and

syntaxin; calcium regulation is provided by the vesicle membrane calcium-sensor protein synaptotagmin. Coupling of synaptotagmin to the SNARE complex involves the vesicle membrane protein snapin, which stabilizes the release-ready vesicles. Calcium-dependent exocytosis in chromaffin cells is significantly reduced in snapin−/− mice.

Readily Releasable Pool of Neurosecretory Material

In all neurosecretory organs, endocrine cells, and probably most secretory cells, even a maximum electrical or depolarization stimulus releases only a small portion of the total hormone or other secretory product available. This protects large stores from being needlessly depleted by a supramaximal stimulus, which is an important mechanism due to the time required to replenish stores by protein synthesis, vesicle packaging, prohormone breakdown, and axonal transport. By contrast, some cell types, such as mast cells, appear to have evolved to be able to secrete all their product upon stimulation. In neurosecretory systems, some vesicles are probably already docked to the membrane and primed for release, whereas others have to be transported to the membrane. In some secretory systems (e.g., chromaffin cells), it appears that partial exocytosis ('kiss-and-run') occurs, but there is no evidence for this in mammalian classical neurosecretory systems. Control of intracellular calcium levels is clearly important in determining what is released, but the precise mechanisms controlling the readily releasable pool are poorly understood. In synapses the RAL_A-GTPases have been shown to be involved in protein kinase C-stimulated release of transmitter from neurons; protein kinase C increases the readily releasable pool of synaptic vesicles docked to the membrane. Certainly, the readily releasable pool of neurosecretory product is not a fixed fraction of the total but, rather, varies with the strength of the stimulus. This is to be expected because there must be a lag between release and the action of the released neurohormone. Secretion of an amount of product determined by the strength of the stimulus allows the feedback control systems fine control without excessive variation about the desired endpoint.

Modulation of Secretion from Neurosecretory Axons

Role of Pituicytes: Neuronal–Glial Plasticity

Pituicytes and their processes surround the neurosecretory axons in the neurohypophysis and occupy part of the perivascular basal lamina on which the nerve endings abut. Pituicytes share some characteristics with astrocytes, and they are probably important in taking up potassium and glutamate released during secretory activity. However, in distinction to astrocytes, they are also characterized by large cytoplasmic lipid droplets, the function of which is unclear. The extent to which the pituicytes envelop the axons varies with the functional state and is reduced when secretion is increased either by osmotic stimulation or in parturition and lactation. Noradrenaline released from nonneurosecretory axons stimulates this pituicyte plasticity. Pituicytes contain significant amounts of taurine; its release is controlled by osmotic conditions, being decreased in hyperosmolar and increased in hypo-osmolar conditions. Taurine acts via strychnine-sensitive glycine receptors to inhibit the depolarization-induced rise in intracellular calcium and subsequent release of vasopressin from the terminals. In this way, the osmotic status controls vasopressin release not only via central osmoreceptors which stimulate synthetic and electrical activity in vasopressin neurons but also locally in the neurohypophysis.

Role of Locally Secreted Factors

Numerous local factors modulate secretion from neurohypophysial terminals. The opioid peptides dynorphin and enkephalin, co-packaged in the NSV, inhibit secretion; the μ-opioid receptor preferentially inhibits oxytocin secretion acting in part via the R-type calcium channels. Similarly, galanin, co-packaged with both oxytocin and vasopressin, inhibits their osmotically stimulated secretion. By contrast, transforming growth factor-β, which coexists in some vasopressin neurons, has not been shown to modulate oxytocin or vasopressin secretion but exerts its effects in the anterior pituitary. Other molecules, not co-packaged, also influence neurosecretion. ATP, which accumulates extracellularly in the stimulated neurohypophysis, stimulates the secretion of vasopressin via a P2X receptor on the terminals, but the metabolism of ATP to adenosine changes the effect because adenosine inhibits terminal calcium and releases via inhibitory adenosine A1 receptors. The ATP/adenosine mechanism therefore strengthens spike/calcium mechanisms to ensure at first an increase in release, but as cellular metabolism generates adenosine, activity in that terminal is switched off and another can take over.

The neural lobe contains scattered noradrenaline terminals, and noradrenaline, via α_1 receptors, stimulates the secretion of vasopressin. It also causes changes in pituicytes such that they occupy less of the perivascular basal lamina, and the neurosecretory terminals can occupy more. Similarly, histamine released from scattered terminals in the neural lobe

increases secretion of both vasopressin and oxytocin via H1 and H2 receptors. α-Melanocyte-stimulating hormone (α-MSH) inhibits release of oxytocin from nerve terminals but has the opposite effect on dendrites. Similarly, the endothelins ET1 and ET3, acting via ETA receptors, stimulate the release of vasopressin in the isolated neurohypophysis but inhibit it in the hypothalamus.

Neurosecretion from Soma and Dendrites

The dendrites of all neurosecretory neurons contain substantial amounts of the secretory product, packaged in NSVs. The amount varies physiologically, as demonstrated by the reduction in dendritic vasopressin during osmotic stimulation and changes in dendritic GnRH during the breeding cycle of starlings. Dendritic secretion of neuropeptides and amines is an important element in the control of neurosecretory neuronal activity. In most systems, release from dendrites is inferred from the release of secretory product into the extracellular space in the region of dendrites and far from the axon terminals. The proximity of the supraoptic nucleus dendrites to the ventral surface of the brain and the large amounts of vasopressin or oxytocin contained in those dendrites have made this a prime experimental model system for the study of dendritic release, which appears to be a universal phenomenon at least among peptidergic and aminergic neurons.

Oxytocin neurons have dendritic oxytocin receptors and vasopressin neurons vasopressin receptors, and both have receptors for opioid peptides in their NSVs. Dendritically released neuropeptide can therefore act in an autocrine and paracrine manner. Oxytocin is also known to act at presynaptic receptors to inhibit transmitter release. This effect is caused by the dendritic secretion of endocannabinoids, aided by an action of oxytocin on local autoreceptors to stimulate the secretion of sufficient endocannabinoid to inhibit the release of glutamate from presynaptic terminals.

There are many more peptides than classical synaptic transmitters, many of which are co-packaged in dense core vesicles. All – whether neuroendocrine or not – are released centrally and act on specific receptors, of which there are many subtypes for each peptide. In many cases, these receptors are abundant in areas where there are few axons containing their peptide ligand. Ludwig and Leng argued that dendritic peptide release has a function strikingly distinct from that of conventional neurotransmitters. Dendrites provide a major source of bioactive peptides with relatively long half-lives which are able not only to act in an autocrine and juxta/paracrine manner on local neurons or glia but also to diffuse to different and distant targets where they can functionally reorganize complex behaviors. Moreover, dendritic-released peptides achieve a much higher concentration (100- to 1000-fold) in the small extracellular space of the brain compared to that of the rest of the body. This allows considerable diffusion from the release site while providing the nanomolar concentrations needed to activate their receptors.

Dissociation of Axonal from Soma–dendritic Release

Given their different functions, it is not surprising that axonal and dendritic release do not occur in parallel and therefore can be differentially regulated. Vasopressin and oxytocin release from axons occurs almost immediately after hyperosmotic stimulation, but their release from dendrites occurs approximately 1 h later and lasts longer. In lactation, oxytocin release in the hypothalamus increases before there is any detectable secretion into the bloodstream. α-MSH, which inhibits the firing of oxytocin neurons and systemic release of oxytocin, acts via MC4 receptors to release intracellular calcium in oxytocin dendrites and stimulate dendritic release.

Mechanism of Soma–Dendritic Release: Role of Calcium and Priming of Dendritic Release

As in the neurohypophysis, an increase in intracellular calcium is essential to stimulate the exocytosis of the dendritic peptide-containing vesicles. That increase in calcium can be stimulated by electrical activity via voltage-gated calcium channels, but release of oxytocin and vasopressin from magnocellular dendrites is stimulated, in the absence of electrical activity, by oxytocin and vasopressin, respectively, via their receptors on the dendrites. The critical source of the intracellular calcium differs in the two systems. In oxytocin cells, an autocrine action of oxytocin mobilizes calcium from thapsigargin-sensitive intracellular stores. By contrast, vasopressin-induced release of vasopressin depends on the entry of calcium from voltage-gated calcium channels and some intracellular release. Because the vasopressin-containing vesicles will not only release vasopressin but also carry vasopressin receptors to the membrane, vasopressin release from the dendrites can be long-lasting. The proteins involved in the exocytosis of dendritic NSVs have not been much studied. It appears that dendrites contain many proteins involved in exocytosis from the nerve terminals, but some, such as synaptobrevin, appear to differ somewhat.

The effect of sex steroids on secretion from magnocellular neurons has long been controversial. Whereas estradiol is known to facilitate oxytocin release, estrogen receptor-β appears to be preferentially

localized to vasopressin neurons. There is morphological evidence that estradiol can induce dendritic exocytosis, apparently acting via NMDA receptors. By contrast, assay or slice preparations indicate that estradiol, progesterone, and the neurosteroid allopregnanolone all induce release of oxytocin and vasopressin from the supraoptic nuclei of young rats by a mechanism that involves $GABA_A$ receptors, and that the effect is much reduced in older animals.

In addition, although spike activity in magnocellular neurons often by itself causes negligible release of peptide, the increase in calcium released from intracellular stores and stimulated by the action of the peptide (or by experimental application of thapsigargin) can 'prime' the dendrites such that subsequent spike activity can, for a long period after the priming, induce substantial dendritic release of peptide.

Role of Soma–Dendritic Release on Neural Glial Plasticity

One of the most striking transitions in adult hypothalamic, if not brain, activity is the change that occurs in oxytocin neurons at the time of parturition in preparation for lactation. Prior to parturition, oxytocin perikarya and dendrites contact one another only at limited, isolated points; the remainder of their surface is separated by lamellae of astrocytic glia. However, during parturition and throughout lactation, the oxytocin cells enlarge, and there are substantial areas of contact between adjacent somata, adjacent dendrites, and between somata and dendrites. The dendrites become grouped as opposed bundles surrounded by astrocyte cytoplasm. Furthermore, whereas in preparturient animals synaptic boutons contact a single postsynaptic cell body or dendrite, double synapses form which contact elements of more than one cell. Associated with these morphological changes is a profound change in electrical activity. Prior to parturition, oxytocin neurons fire with no obvious pattern and no correlation between adjacent cells. During suckling, they fire in coordinated bursts every 5–10 min to generate the bolus of oxytocin secretion required to cause milk ejection from the mammary glands. These profound changes are brought about by the local action of oxytocin in the presence of an appropriate sex steroid milieu.

Introduction

Approximately 25 years ago, the observation that some steroids persist in the brain long after removal of the steroidogenic endocrine glands led to the formulation of the neurosteroid concept. This term designates those steroids which are locally synthesized from cholesterol within the nervous system. The study of the biosynthesis, mechanisms of action, and functions of neurosteroids has become a very active field of research. Novel therapeutic perspectives for the diseased, lesioned, and aged brain are offered by the possibility to stimulate the synthesis of neurosteroids with neurotrophic or neuroprotective actions.

Terminology

According to their chemical definition, steroids are small lipids characterized by the cyclopentanoperhydrophenanthrene (sterane) skeleton of four fused rings. This class of molecules includes cholesterol, its precursors starting from lanosterol, the oxysterols, the vitamin D family, the ecdysteroids in insects, the brassinosteroids in plants, and the steroids resulting from cholesterol side chain cleavage (scc) by cytochrome P450scc, which include those commonly referred to as steroid hormones.

The term 'neurosteroid' does not designate a particular class of steroids but, rather, refers to their site of synthesis, the nervous system. Initially, the term was applied to those steroids which are synthesized within the nervous system *de novo* from cholesterol after cleavage of its side chain between carbons 20 and 22. According to this definition, two conditions are mandatory for a steroid to qualify as a neurosteroid: (1) its persistence in nervous tissues after removal of the steroidogenic endocrine glands and (2) the expression and activity within the nervous system of the enzymes involved in its synthesis. The original definition has sometimes been extended to include steroid metabolites formed within the nervous system from circulating precursors. However, their synthesis depends on the presence of peripheral endocrine glands. Estradiol, which is formed in the brain from testis-derived testosterone, is an example. The term neurosteroids is also frequently used to simply designate steroids present and active within the brain. This is very unfortunate because such a broadening of the definition bypasses the original concept: the local synthesis of steroids by neural cells. Steroids with biological effects in the nervous system could be qualified as neuroactive, an extension of the term initially proposed to designate only those steroids which rapidly alter the excitability of neurons by modulating neurotransmitter receptors.

It is well established that almost all the cholesterol present in brain and peripheral nerves is locally synthesized by glial cells and, to a much smaller extent, by neurons. Moreover, cholesterol is not just a structural component of the cell membranes and of the myelin sheaths; rather, it is also an important signaling molecule. One of the oxysterols, 24S-hydroxycholesterol, is almost exclusively formed in the brain, and for this reason it was named cerebrosterol. Thus, cholesterol and oxysterols may qualify as neurosterols.

Historical Background

In the late 1970s, the concept of neuropeptide evolved from the observation that specific peptides are common products of the endocrine glands and of the nervous system. Synthesized from large precursor molecules by nerve cells, neuropeptides were shown to act as neuromodulators or neurotransmitters. In 1981, Etienne-Emile Baulieu and collaborators reported the first evidence that some steroids are locally produced within the brain and designated them as neurosteroids. They were first detected by radioimmunological assays in the rodent brain, where they continue to be present after removal of the steroidogenic endocrine glands by castration and adrenalectomy. The next important step was the demonstration that neurosteroids are indeed synthesized by glial cells and neurons – that is, that functional enzymes involved in their synthesis and metabolism are present, particularly cytochrome P450scc, which catalyzes the first step in steroid hormone synthesis and is only present in steroidogenic mitochondria. From an evolutionary standpoint, the synthesis of neurosteroids has been shown to take place in the brain of all vertebrate phylae, including fish, amphibians, birds, and mammals. Enzymes involved in neurosteroid synthesis are also expressed in the human brain, and the activity of some of them has been demonstrated in biopsies from patients with epilepsy.

Neurosteroid Synthesis and Metabolism

The biosynthesis and metabolism of neurosteroids has been extensively studied in rats and mice. Which steroids can be locally synthesized within the rodent

nervous system? The question needs to be answered cautiously, and results of related studies should be interpreted within their precise context. In fact, the expression and activity of steroidogenic enzymes are subject to complex regulations, and they may be expressed and functional in a defined compartment of the nervous system only under particular conditions, depending on environmental influences, cellular interactions, the presence of neurotransmitters or neuropeptides, the developmental stage, or the integrity of the nervous tissue. It is also important to be aware of some technical constraints. Thus, the relevance of studies on the formation of neurosteroids by cultured neural cells isolated from embryonic or newborn animals needs to be examined *in vivo* because of the phenotypic plasticity these cells exhibit *in vitro*. Also, studies of the expression of steroidogenic enzymes by *in situ* hybridization, reverse transcriptase-polymerase chain reaction, or immunocytochemistry, although they provide very important information, do not demonstrate their functionality.

The synthesis of pregnenolone, progesterone, and its reduced metabolites has been demonstrated within the central and peripheral nervous systems. The conversion of cholesterol to pregnenolone by cytochrome P450scc takes place in the mitochondria, where the enzyme forms a ternary complex with adrenodoxin reductase and adrenodoxin (the cholesterol desmolase complex). The presence of cytochrome P450scc was first detected in the rat and human brain by immunocytochemistry, and then its activity was demonstrated in cultured glial cells. Studies from different laboratories have shown that the enzyme is expressed at low levels throughout the rodent brain and in both glial cells and neurons. Studies have demonstrated the presence and activity of cytochrome P450scc in dorsal root ganglia, the dorsal horns of the spinal cord, and the somatosensory cortex, suggesting an important role of neurosteroid synthesis in the regulation of pain.

Pregnenolone is converted to progesterone by the 3β-hydroxysteroid dehydrogenases (3β-HSDs), present in mitochondria and cytoplasm. 3β-HSD isoenzymes have been cloned from several species: two in human, four in rat, and six in mouse. Unfortunately, the different 3β-HSD isoforms have been numbered according to the chronology of their discovery; consequently, the isoforms of different species do not correspond by number. Most studies do not distinguish isoforms; however, human type 2 and rat type 1 3β-HSDs seem to be the major isoforms expressed in brain. Detailed *in situ* hybridization studies revealed widespread 3β-HSD expression in rat brain and spinal cord during both development and adulthood. Expression and activity of 3β-HSD occur in both neurons and glial cells. After administration of the 3β-HSD inhibitor trilostane, pregnenolone concentrations were markedly increased in the brain of castrated and adrenalectomized rats, thus showing that the conversion of pregnenolone to progesterone is a very active metabolic pathway in the rat brain.

Progesterone is further converted to 5α-dihydroprogesterone (5α-pregnane-3,20-dione) by steroid 5α-reductases. These NADPH-dependent enzymes convert a number of Δ4–3-ketosteroids, including progestagens, glucocorticoids, mineralocorticoids, and androgens, into their 5α-reduced metabolites. Two 5α-reductase isozymes are encoded by distinct genes and designated as type 1 and type 2. The type 1 isoform is expressed throughout the rat brain at all stages of development, whereas the type 2 isoform shows a more restricted distribution and is mainly present in the gray matter of the spinal cord. 5α-Dihydroprogesterone is further converted into allopregnanolone (3α-hydroxy-5α-pregnan-20-one or 3α,5α-tetrahydroprogesterone) by 3α-hydroxysteroid oxidoreductase (3α-HSOR). Only one 3α-HSOR isoform has been identified in rat and mouse, whereas four human isoforms have been cloned. These enzymes are also frequently referred to as 3α-hydroxysteroid dehydrogenases (3α-HSDs), but we prefer the 3α-HSOR nomenclature since they catalyze bidirectional reactions.

A key question regards the presence and activity of cytochrome P450c17 (17α-hydroxylase/17,20-lyase) in the nervous system, since it ensures the formation of androgen and estrogen precursors by catalyzing the conversion of pregnenolone into dehydroepiandrosterone and that of progesterone into androstenedione. Indeed, the other enzymes involved in the formation of androgens and estrogens are expressed in the brain, namely the 17β-hydroxysteroid oxidoreductase, which converts androstenedione into testosterone, and the aromatase, which converts either testosterone into estradiol or androstenedione into estrone. Hence, whether androgens and estrogens are synthesized *de novo* from cholesterol within the brain, or whether they are only formed from circulating precursor steroids, depends on the presence of cytochrome P450c17 in brain. Whereas it is the case for the brain of lower vertebrates, particularly frogs, in which cytochrome P450c17 expression and activity have been unequivocally demonstrated, its presence in mammalian brain long remained controversial until neurons and astrocytes were shown to convert pregnenolone into dehydroepiandrosterone under precise conditions of culture. Cytochrome P450c17 has been detected in the principal neurons of the hippocampal formation, and its expression and activity were demonstrated in the rat spinal cord by a combination of molecular, anatomical, and neurochemical approaches. Local

de novo synthesis of estrogens and glucocorticoids was also evidenced in the rat brain, at least within specific regions. The significance of these observations needs clarification.

Mass spectrometry is a valuable technique for the analysis of steroids and has provided new opportunities for the study of neurosteroid synthesis, metabolism, and role in nervous tissues. The identification and assay of neurosteroids by gas chromatography/mass spectrometry or by liquid chromatography/mass spectrometry has provided reference data for neurosteroid presence and fluctuations within specific brain regions under defined physiopathological conditions. As a consequence, these specific technologies have challenged some well-established concepts, such as the sulfoconjugation of 3β-OH steroids, particularly of pregnenolone and dehydroepiandrosterone, in the rodent brain.

Neural Cells Involved in Neurosteroid Synthesis

According to current knowledge, neurosteroids are synthesized throughout the central and peripheral nervous systems by both glial cells and neurons. It is important to determine in which part of the nervous system and in which cell type a particular neurosteroid is synthesized. However, regarding the question of which steroids can be synthesized within the nervous system, it is necessary to be careful of making excessive generalizations because of the regulated expression of steroidogenic enzymes. Some examples illustrate the complexity of the problem. First, in the adult rat brain, aromatase is exclusively expressed in neurons. However, in response to an excitotoxic or traumatic injury, the enzyme becomes strongly expressed in astrocytes. Second, when cultured at low density, astrocytes preferentially convert pregnenolone into progesterone, whereas pregnenolone is nearly exclusively metabolized to 7α-OH-pregnenolone at confluency. Third, cell culture experiments have provided evidence that the neuroactive progesterone metabolite allopregnanolone is mainly synthesized by glial cells and acts on $GABA_A$ receptors of nearby neurons by a paracrine mechanism. This finding is supported by *in vivo* experiments showing that 3α-HSOR activity in the rat olfactory bulbs is unchanged after the infusion of kainic acid, which destroys neurons but lets glia intact. Conversely, other results have shown that 3α-HSOR is present in the principal glutamatergic neurons of the cerebral cortex, the hippocampus, and the olfactory bulbs and is co-localized with 5α-reductase type 1. Fourth, in peripheral nerves, Schwann cells only express 3β-HSD and synthesize progesterone when in contact with axons. Therefore, these examples indicate that the description of neurosteroid biosynthetic pathways needs to be interpreted according to the experimental context (Figure 1).

Regulation of Neurosteroid Synthesis

The synthesis of steroids in the endocrine glands is regulated by trophic hormones and growth factors. Steroidogenesis involves a basic transcription of the genes encoding steroidogenic enzymes, on which an acute regulation is superimposed, governing the movement of cholesterol into the mitochondria and the modulation of enzyme activities. Very little is known about the regulation of neurosteroid synthesis and metabolism in the nervous system.

The regulatory mechanisms of steroid synthesis in neural cells involve at least in part factors distinct from those operating in the gonads and adrenal glands. Indeed, complex interactions between neural cells obviously play an important role in the regulation of neurosteroid synthesis: specific neurotransmitters and neuropeptides exert strong influences on the expression and activity of steroidogenic enzymes. The role of neuropeptides has been explored mainly in the amphibian brain, and the relevance of these findings to mammalian species needs further investigation. Steroids are also involved in the regulation of neurosteroid biosynthetic pathways. Namely, the *de novo* synthesis of neuroprogesterone is induced by estradiol in the hypothalamus and in cortical astrocytes of ovariectomized and adrenalectomized female rats.

The transport of cholesterol inside the mitochondria, where cytochrome P450scc is located, is a rate-limiting step in the biosynthesis of steroids, and its stimulation results in increased synthesis of neuroactive steroids. Both *in vitro* and *in vivo* studies have demonstrated that the peripheral benzodiazepine receptor (PBR) (also called mitochondrial benzodiazepine receptor or translocator protein) transports cholesterol from the outer to the inner mitochondrial membrane. Hence, PBR agonists stimulate the synthesis of neurosteroids, as shown in cultured glial cells and in the brain of castrated and adrenalectomized rats. Interestingly, strong upregulation of PBR expression is observed in response to injury and during neurodegenerative and demyelinating diseases. These observations suggest that PBR ligands may ensure neuroprotection and myelin repair.

Drugs other than those interfering with the intramitochondrial cholesterol transport also directly affect the biosynthesis and metabolism of neurosteroids. For example, the selective serotonin reuptake inhibitors, used as antidepressants and including fluoxetine, sertraline, and paroxetine, stimulate the formation of

Figure 1 Major biosynthetic pathways of unconjugated neurosteroids and steroid hormones. allopregnanolone by increasing the affinity of human 3α-HSD type III for 5α-dihydroprogesterone. Sertraline and fluoxetine also block the reverse oxidative reaction – that is, the conversion of allopregnanolone into 5α-dihydroprogesterone.

Mechanisms of Neurosteroid Actions

Contrary to steroid hormones provided by the endocrine glands, locally synthesized neurosteroids likely act in an autocrine/paracrine manner in the nervous system. It is often claimed that most neurosteroid actions are mediated by the modulation of neurotransmitter receptor activities. However, there is no evidence that the molecular targets of neurosteroids differ from those of steroid hormones reaching the brain via the circulation. Whatever their origin, steroids may influence both gene expression by binding to intracellular receptors and neuronal excitability by directly acting on the cell membrane. The idea of a preferential action of locally synthesized neurosteroids on the neuronal membrane stems from the observations

that the activities of some neurotransmitter receptors, such as *N*-methyl-D-aspartate and nicotinic acetylcholine receptors, are only influenced by high micromolar concentrations of steroids, which are supposedly not reached by the accumulation of circulating hormones. This is mere speculation since it is not technologically feasible to measure the local concentration of a steroid at the level of a few cells or synapses.

During the past few years, there has been tremendous progress in our understanding of the multiple mechanisms of steroid actions in the nervous system. They comprise the regulation of gene transcription, the modulation of neurotransmitter receptors, and the activation of signaling cascades via specific membrane receptors. The recognition of the significance of nuclear coregulator proteins in determining the transcriptional activities of steroid receptors, as well as the cloning of new membrane steroid receptors, is expected to completely change our understanding of steroid action in the near future. Pregnenolone, previously considered as a precursor for other biologically active steroids, has been shown to bind in a selective and saturable manner to microtubule-associated protein (MAP-2), which belongs to a group of proteins involved in the assembly and stabilization of microtubules. By binding to MAP-2, pregnenolone stimulates the polymerization of microtubules and enhances neurite outgrowth of PC12 cells. Based on these findings, it is hoped that new synthetic pregnenolone derivatives with neuroprotective and neurotrophic actions can be developed.

Among the multiple neurotransmitter receptors identified as potential targets for the actions of steroids, the most well studied are the $GABA_A$ receptors. At physiological nanomolar concentrations, the progesterone metabolite allopregnanolone is a potent positive modulator of these receptors. The enantioselectivity of the effects of allopregnanolone on $GABA_A$ receptors and the development of a selective inhibitor of the GABA modulatory effects of 5α-pregnane steroids support the existence of specific binding sites. However, recombinant $GABA_A$ receptor subunit expression coupled with site-directed mutagenesis has not allowed the identification of a steroid-binding pocket on the $GABA_A$ receptor complex, although structural motifs involved in steroid modulation have been described. Thus, the precise mechanisms by which pregnane steroids interact with $GABA_A$ receptors remain undefined. It is important to note that allopregnanolone does not indiscriminately enhance neuronal inhibition via $GABA_A$ receptors throughout the nervous system. Indeed, accumulating evidence indicates that steroid–$GABA_A$ receptor interactions are specific to individual brain regions and different neuronal populations. More important, local neurosteroid metabolism has been demonstrated to influence $GABA_A$ receptor activity.

Biological Significance

The biomolecules have been classified into functional groups. This is also the case for the steroids, which have been grouped into various categories, such as prohormones, sex hormones, and stress hormones. Once such restrictive labels are attributed, it is difficult to get rid of them. However, research during the past few years has revealed the pleiotropic effects of steroids in the nervous system. Indeed, pregnenolone and dehydroepiandrosterone, previously considered as mere precursor molecules, have been shown to exert neurotrophic and neuroprotective effects, respectively, by directly acting on microtubules or on the neuronal membrane. Progesterone and estradiol, usually referred to as female sex hormones, are important regulators of vital neuron and glial functions in the male and female nervous system. Namely, progesterone has been shown to play an important role in the viability and plasticity of neurons and in the formation of myelin sheaths, which insulate and protect the axons. As previously mentioned, the progesterone metabolite allopregnanolone is a potent stimulator of $GABA_A$ receptors, an activity which explains some of its psychopharmacological actions, particularly its anesthetic, analgesic, and anxiolytic effects, as well as its role in stress, depression, memory, seizure susceptibility, and alcohol dependence. Significantly, the modulation of $GABA_A$ receptors by allopregnanolone also plays an important role in neuroprotection and myelin formation, although neuroprotective effects of allopregnanolone may also involve its binding to the pregnane X receptor.

It is within the frame of this conceptual evolution that the search for the biological significance of neurosteroid synthesis has to be placed. In fact, we still know very little concerning their specific functions. A major difficulty is due to the fact that the steroids present in nervous tissues are either locally produced or derived from the endocrine glands. Indeed, most steroids, except the conjugated ones, easily cross the blood–brain and blood–nerve barriers. One strategy to study the specific functions of locally synthesized neurosteroids is to get rid of the peripheral sources of steroid hormones by castration and adrenalectomy. This approach has, for example, allowed the demonstration of an inhibitory influence of neuroprogesterone on $\sigma 1$ receptor function and on memory processes *in vivo*.

The disturbance of vital functions by the removal of the steroidogenic endocrine glands, particularly the

adrenal gland, is a serious drawback, making the study of the physiopathological significance of neurosteroids in long-term processes such as development, regeneration, and aging difficult. For this reason, a number of studies have been limited to the local administration of steroids, receptor antagonists, or enzyme inhibitors in animals with intact gonads and adrenal glands. For example, the local application of the 3β-HSD inhibitor trilostane to the lesioned mouse sciatic nerve has provided evidence for a role of locally synthesized progesterone in peripheral nerve regeneration and myelination. The stereotaxic infusion of neurosteroids into specific brain regions has provided evidence for their involvement in memory processes.

Other studies have established correlations between changes in tissue levels of steroids and particular functions or phenotypic characteristics. Expression of 3β-HSD and levels of progesterone were found to be strongly upregulated in the brains of dysmyelinated mouse mutants and in the spinal cord of streptozotocin-treated diabetic rats. Neuropathic pain was also shown to increase the synthesis of pregnenolone and allopregnanolone in the rat spinal cord. Levels of pregnenolone and progesterone were also significantly increased within the spinal cord of castrated and adrenalectomized rats after injury. All these observations provide strong evidence for the concept that an increase in the synthesis of neurosteroids is involved in the mechanisms by which nerve cells cope with neurodegeneration.

On the contrary, in the brain of the NP-C mouse, an animal model of Niemann–Pick type C disease characterized by neurological deficits and Purkinje cell loss, levels of 5α-dihydroprogesterone and allopregnanolone are decreased, as is the expression of 5α-reductase and 3α-HSOR, especially in the cerebellum. Most important, the systemic administration of allopregnanolone significantly delays the onset of neurological symptoms and prolongs Purkinje cell survival.

With the synthesis of neurosteroids well established, the study of their regulation and their biological functions remains an important challenge. The discovery of neurosteroids has offered new perspectives for neurobiology and therapeutic applications. It is certainly not an easy field of investigation, but the difficulties are similar to those encountered for the neuropeptides.

Introduction

Neurotensin (NT) is a tridecapeptide (Figure 1) that was isolated in 1973 from bovine hypothalamus and shortly after from bovine small intestine. In the brain, NT is predominantly expressed in neurons within discrete brain areas and nuclei, where it acts as a neuromodulator. The effects of centrally administered NT include the well-documented interaction of the peptide with dopaminergic (DA) systems, the ability to induce opioid-independent analgesia, inhibition of food intake, and modulation of pituitary hormone release. In the periphery, NT is primarily produced in endocrine N cells scattered throughout the jejuno-ileal mucosa. The peptide is released on food ingestion and regulates a number of digestive processes, including gastrointestinal motility and pancreatic and biliary secretion. In addition, NT exerts growth-promoting effects on normal gastrointestinal tissues and on cancer cells derived from a variety of organs. Other organs that produce NT include the heart and adrenals.

Like all neuropeptides, NT is synthesized as part of a larger precursor that also contains neuromedin N (NN), a six-amino-acid, NT-like peptide. Pro-NT/NN is differentially processed in the tissues, where it is expressed to give rise to different combinations of active peptides. NT and NN are released from neuroendocrine cells in a Ca^{2+}-dependent manner and exert their effect by interacting with NT receptors located on target cells, of which three have been cloned to date. Two, the NTS1 and NTS2, belong to the family of G-protein-coupled receptors with seven transmembrane domains. The third one, NTS3, is identical to sortilin, a protein that belongs to a family of receptors with one transmembrane domain and is involved in the sorting of proteins to various cell compartments. NT and NN actions are terminated by desensitization of the receptors they activate and by degradation mechanisms that take place in the extracellular space.

This article will review data pertaining mostly to the brain functions of NT.

Biosynthesis, Processing, and Degradation of NT

Biosynthesis

Cloning of canine and bovine pro-NT/NN complementary DNA revealed that NT and NN are part of the same precursor protein. Subsequently, cloning of the rat precursor gene showed it to comprise four exons and three introns, with NT and NN both being encoded in the fourth exon. Studies of pro-NT/NN gene induction in PC12 cells, a neuroendocrine cell line that synthesizes high amounts of pro-NT/NN in response to hormonal stimuli, showed that induction was under the coordinated control of several regulatory sequences, including activating protein-1, cyclic adenosine monophosphate (cAMP), and glucocorticoid response elements.

Rat pre-pro-NT/NN is a protein of 169–170 amino acids that starts with a signal peptide that is quickly removed on translocation into the endoplasmic reticulum to yield pro-NT/NN, whose organization is depicted in Figure 1. The precursor then travels through the regulated secretory pathway, where it undergoes several posttranslational transformations that end with the storage of the final maturation products in secretory vesicles of neuroendocrine cells. Rat pro-NT/NN contains four Lys-Arg dibasic sites (numbered 1 to 4 from N- to C-terminus in Figure 1). Site 1 is located in the middle of the precursor whereas sites 2, 3, and 4 flank and separate NT and NN in the C-terminal portion of the precursor. In tissues that express pro-NT/NN, site 1 is generally unprocessed whereas sites 2, 3, and 4 are differentially cleaved, leading to the production of different combinations of bioactive products represented in Figure 1. Thus, in the brain, pro-NT/NN gives rise to NT and NN. In the gut, precursor cleavage leads mainly to the formation of NT and a large peptide ending with the NN sequence at its C-terminus (large NN). In the adrenals, NT, large NN, and a large peptide ending with the NT sequence (large NT) are the major products.

Processing

Dibasics are the consensus sites recognized and cleaved by processing endoproteases that belong to the recently identified family of proprotein convertases (PCs). PC1 and PC2 are exclusively expressed in the regulated secretory pathway of neurons and endocrine cells whereas PC5-A is expressed in both

Figure 1 Amino-acid sequence of NT and NN, organization of pro-NT/NN, and major bioactive products generated in tissues by pro-NT/NN processing. The dibasic sites are represented by thick vertical bars and numbered from 1 to 4 from N- to C-terminal.

endocrine and nonendocrine cells. The cleavage specificity of the three PCs toward pro-NT/NN was studied in the neuroendocrine PC12 cell line that lacks PC1 and PC2 expression and presents very little PC5-A. As expected, wild-type PC12 cells poorly processed pro-NT/NN. In contrast, when stably transfected with either of the three PCs, each resulting transfectant readily processed the precursor, albeit with different patterns. Thus, in PC1–PC12 cells, cleavages at sites 3 and 4 proceeded almost to the same extent and were more efficient than cleavage at site 2. This predominantly generated NT and large NN and produced only small amounts of NN (Figure 2). In PC2–PC12 cells, pro-NT/NN was cleaved equally at sites 2, 3, and 4, thereby producing equivalent amounts of NT and NN (Figure 2). In PC5-A–PC12 cells, site 4 was cleaved to a greater extent than site 3 whereas site 2 was very poorly processed, thus resulting in the production of NT, large NT and large NN in comparable amounts and of virtually no NN (Figure 2). It thus appears that PC1, PC2, and PC5-A process pro-NT/NN with patterns that are similar to those observed in the gut, brain, and adrenals, respectively.

Several pieces of evidence indicate that PC2 is indeed the major brain pro-NT/NN convertase. Thus, PC2 is the most abundant prohormone convertase in the brain and therefore, not unexpectedly, co-localizes extensively with immunoreactive NT in neuronal populations that express pro-NT/NN. It is interesting that subsets of NT/PC2-immunopositive neurons are also positive for PC1 and PC5-A, but in general, those neurons expressing PC1 do not contain PC5-A and vice versa. That PC2 plays a major role in processing brain pro-NT/NN is further demonstrated in PC2$^{-/-}$ mice in which brain levels of NN are decreased by more than 50% with a compensatory

Figure 2 Cleavage specificity of pro-NT/NN and major products generated by proprotein convertase (PC) 1, PC2, and PC5-A. The same representation as in Figure 1 is used. Arrow sizes are indicative of the extent to which each dibasic is cleaved by the PCs.

increase in the levels of large NN, indicating that processing at site 2 is impaired, as would be expected from the cleavage specificity of PC2. There is also a 20% reduction in NT levels in PC2$^{-/-}$ mice, which is less than would be expected, had PC2 been the sole pro-NT/NN convertase in brain, supporting the idea that PC1 and PC5-A are also active in processing brain pro-NT/NN.

Degradation

Whereas classical neurotransmitter action in the synapse is often ended through specific reuptake of the transmitter into nerve terminals, the favored mechanism for terminating neuropeptide action entails proteolytic degradation. NT degradation was initially studied *in vitro* with brain membranes, which identified primary cleavage sites in the NT

sequence: Arg8–Arg8, Pro10–Tyr11, and Tyr11–Ile12 peptide bonds. The use of general and specific peptidase inhibitors showed that the Arg8–Arg9 cleavage was due to endopeptidase EC 3.4.24.15 (also known as thimet oligopeptidase) and that EC 3.4.24.11 (also referred to as enkephalinase, neutral endopeptidase, neprilysin, CD10, or CALLA) was entirely responsible for the Tyr11–Ile12 cleavage and only partly responsible for that at the Pro10–Tyr11 bond. Finally, an unidentified metallopeptidase was shown to account for the remainder of the Pro10–Tyr11 bond-cleaving activity. This enzyme, endopeptidase EC 3.4.24.16 (also designated neurolysin), was later purified and cloned. These data are summarized in Figure 3. All three peptidases belong to the class of Zn-metalloendopeptidases and are specialized in cleaving small bioactive peptides in the extracellular space. They have a wide distribution in the brain and peripheral tissues, and it was indeed demonstrated in all the tissues examined that NT was degraded by a combination of the three metallopeptidases. Their action on NT effectively leads to complete biological inactivation of the peptide as its ability to activate its receptors is entirely borne by the C-terminal hexapeptide sequence which is precisely the target of the metalloendopeptidases. Other peptidases are involved in further degradation of the NT breakdown products generated by the three metallopeptidases (Figure 3). They do not act as primary inactivating enzymes and are therefore less relevant to NT inactivation.

Figure 3 Scheme of NT degradation in brain. Primary inactivating cleavages are indicated by solid arrows, and further degradation of breakdown products by dashed arrows. The primary inactivating metallopeptidases, EC 3.4.24.11, 15, and 16, are highlighted in green, blue, and red, respectively. The secondary cleaving enzymes are boxed in light violet.

Brain Distribution of NT

Originally isolated from bovine hypothalamus, the neuropeptide NT was further localized throughout the central nervous system of several mammalian species, such as rat, calf, monkey, and human. Initial radioimmunoassay, carried out on rat brain extracts, revealed that the highest concentrations of NT immunoreactivity are detected in the hypothalamus, amygdala, spinal cord, and brain stem structures such as periaqueductal gray, dorsal raphe nucleus, substantia nigra, and ventral tegmental area (VTA). Subsequently, high densities of NT-immunoreactive nerve cell bodies and processes were detected throughout the brain and spinal cord by immunohistochemistry (Figure 4). In particular, NT-containing axonal fibers and/or NT-positive cell bodies are abundant in the

Figure 4 Topographic distribution of NT-containing neurons in the rat central nervous system. Schematic midsagittal section of the rat brain provides an overview of the distribution of NT immunoreactivity throughout the neuraxis. Acb, accumbens nucleus; Am, amygdaloid nucleus; ARC, arcuate hypothalamic nucleus; BST, bed nucleus of the stria terminalis; CA1, field CA1 of Ammon's horn; CPu, caudate-putamen; F, frontal cortex; GP, globus pallidus; NTS, nucleus of the solitary tract; PAG, periaqueductal gray; Pir, piriform cortex; RMg, raphe magnus; SNc, substantia nigra, compacta part; SNr, substantia nigra, reticulata part; Sub, subiculum; VMH, ventromedial hypothalamic nucleus; VTA, ventral tegmental area.

nucleus accumbens; bed nucleus of the stria terminalis; medial and lateral septal nuclei; central, basolateral, and medial amygdaloid nuclei; subparafascicular and gustatory nuclei of the thalamus; paraventricular, and arcuate hypothalamic nuclei; lateral hypothalamus; substantia nigra; VTA; periaqueductal gray; raphe nuclei; locus coeruleus; nucleus of the solitary tract; and substantia gelatinosa of the spinal trigeminal nucleus and dorsal horn of the spinal cord. The topographic distribution of NT immunoreactivity overlapped extensively with that of NT-expressing cells as determined by *in situ* hybridization histochemistry. There were a few regions, however, in which NT immunolabeling appeared more restricted than from *in situ* hybridization data. For instance, the subiculum and CA1 region of the hippocampal formation, which were reported to contain high levels of NT messenger RNA (mRNA), were barely immunoreactive. These discrepancies could be due to selective targeting of NT peptides to neuronal processes.

In the developing rat brain, NT was found, by radioimmunoassay, immunohistochemistry, and *in situ* hybridization, to be expressed very abundantly during the first two postnatal weeks, after which its concentration rapidly decreased to adult levels. This overexpression is regionally selective, affecting predominantly cells located in the retrosplenial and cingulated cortices, the pyramidal cell layer of the subiculum and hippocampal CA1, and the mitral cell layer of the olfactory bulb. The transient overexpression of NT during brain development suggests that this neuropeptide may be involved in the establishment of neuronal circuitry.

NT Receptors and Signaling

Central effects of NT and its analogs are mediated by the activation of at least three different receptor subtypes, identified as NTS1, NTS2, and NTS3 (also called gp95/sortilin). A summary of the biochemical, biological, and pharmacological properties of these receptors is provided in Table 1.

NTS1 and NTS2 belong to the G-protein-coupled receptor family and were initially distinguished pharmacologically on the basis of their affinities for NT and their differential sensitivity to the antihistamine-1 drug levocabastine. Referred to as the high-affinity ($K_{dv} = 0.1$–$0.3\,\text{nmol}\,\text{l}^{-1}$) levocabastine-insensitive binding site, NTS1 has been linked, through Gi/o, Gq, and Gs protein coupling, to a variety of signaling cascades, including formation of cyclic guanosine monophosphate and cAMP, phospholipase C, and inositol phosphate signaling cascades; arachidonic acid production; and activation/inhibition of mitogen-activated protein kinases (ERK1/2 and JNK) and serine/threonine protein kinase Akt. Association of NT to NTS1 induces internalization of receptor–ligand complexes into NTS1-expressing cells via clathrin-coated pits. The endocytic process is dependent on the integrity of the C-terminal extremity and requires the recruitment of dynamin, intersectin, and both isoforms of β-arrestin 1 and 2. NTS1 internalization is accompanied by NT endocytosis. However, the intracellular trafficking patterns of NTS1 and of NT may be distinct, depending on the time period of agonist exposure. Biochemical and cell imaging studies revealed that under acute agonist exposure, internalized NTS1 receptors are targeted to lysosomes for degradation whereas under prolonged agonist exposure, NTS1 is routed toward the perinuclear *trans*-Golgi recycling compartment. NTS1 gene activation and *de novo* receptor synthesis therefore contribute to cell resensitization.

The levocabastine-sensitive, low-affinity NT receptor (NTS2) was cloned from mouse, rat, and human brain by a strategy based on sequence homology with the known NTS1 receptor. NTS2 shares approximately 60% amino-acid homology with NTS1 and binds NT and levocabastine with similar affinity ($K_{dv} = 2$–$10\,\text{nmol}\,\text{l}^{-1}$). In contrast to NTS1, the signaling properties of NTS2 are still controversial, exhibiting cell-type expression- and species-dependent pharmacological properties (Table 1). For instance, depending on the heterologous expression cell system (oocytes, CHO, COS-7, and HEK293 cells) used to characterize the signal transduction mechanisms of the NTS2, levocabastine and NT analogs were reported to act as agonists, inverse agonists, or competitive antagonists at NTS2 sites. The most convincing data supporting an agonist role for endogenous NT on NTS2 receptors are, however, the ability of NT to induce a sustained mitogen-activated protein kinase (MAPK) p42/p44 activation in rat cerebellar granule cells expressing endogenous NTS2. Different results have also been reported on the constitutive activity of the human NTS2 (hNTS2) transfected in COS and CHO cells.

Although the agonistic properties of NT on the NTS2 receptor remain a debate, NTS2 receptors were found to efficiently internalize on NT binding via a clathrin-coated pit and dynamin-dependent mechanism, a property usually associated with an activation by agonists. Note that ligand–receptor complexes were found to form clusters at the cell surface but not to internalize in cultured astrocytes following NT stimulation, suggesting that NTS2 internalization capacities are likely cell type dependent. In contrast to NTS1, sequestrated mouse NTS2 (mNTS2) receptors are efficiently recycled to the plasma membrane. The third intracellular loop and

in particular the tyrosine-237 residue are crucial for mNTS2 receptor internalization and recycling, respectively. Recently, the neuron-enriched endosomal protein of 21 kDa (NEEP21) was shown to be involved in mNTS2 recycling. However, species discrepancies are here again detected. In opposition to mNTS2, the hNTS2, in which a cysteine residue naturally replaces the tyrosine in position 237, does not undergo recycling following endocytosis. The underlying mechanisms responsible for NTS2 receptor preservation at the cell surface seem to be different depending on the length of agonist exposure. Indeed, whereas under acute agonist exposure, maintenance of cell surface receptors seems to be related to NTS2 recycling, under persistent exposure to NT, this preservation of cell plasma membrane NTS2 receptor densities appears to involve recruitment of spare receptors from internal stores, thereby preventing functional desensitization.

Originally identified as the intracellular sorting protein sortilin, the NTS3 receptor is unique among neuropeptide receptors in that it is a single transmembrane domain protein. NTS3 exhibits striking sequence similarities with proteins involved in intracellular transport and trafficking. Accordingly, several studies have demonstrated a predominant association of NTS3 with intracellular sorting organelles such as the Golgi apparatus, endosomes, and Glut4 vesicles. Although only 5–10% of this receptor is expressed at the cell surface, NTS3 efficiently internalizes NT. NTS3 has the ability to bind several ligands in addition to NT, such as the lipoprotein lipase, the endoplasmic reticulum resident receptor-associated protein, and its own propeptide released after maturation of the precursor form by furin, suggesting that its role probably exceeds that of an NT signaling receptor. Binding of NT to NTS3 was reported to elicit proliferative responses in a variety of cancer cell lines and to alter agonist-induced cellular trafficking and signaling of NTS1 in HT29 human colon cancer cells. However, the strongest evidence that NTS3 participates in NT signaling comes from the demonstration that NTS3 mediates the NT-induced migration of human microglial cells by a mechanism dependent on the stimulation of both MAPK and phosphoinositide-3 kinase pathways. Recently, sortilin has also been shown to interact with the p75 neurotrophin receptor (p75NTR) in the induction of apoptosis on binding unprocessed nerve growth factor (NGF) proNGF. However, the occupancy of NTS3 by NT prevents the proNGF-induced formation of the sortilin–p75NTR receptor complex and thereby counteracts the p75NTR-induced neuronal cell death. Taken together, these studies suggest that NT binding to NTS3/sortilin may play an important role in inflammation and neurotoxicity.

Localization of NT Receptor Subtypes

Initial evidence for the existence of NT receptors was derived from radioligand-binding experiments on membranes prepared from brain and gastrointestinal tissues. However, it is only with the application of autoradiographic-binding techniques, using [^{3}H]NT or [^{125}I]NT as radioligand, that a comprehensive picture of brain NT receptor distribution began to emerge. Subsequently, the cloning of NT receptors allowed the generation of mRNA probes and antibodies to investigate their distribution by Northern blotting, *in situ* hybridization, and immunohistochemistry at light and electron microscopic levels.

NTS1 Receptors

Autoradiographic studies using [^{125}I]NT in the presence of blocking concentrations of levocabastine (to prevent labeling of the low-affinity site) have revealed a selective association of NTS1-binding sites with selective neuronal populations throughout the hypothalamus, basal forebrain, and limbic system (Figure 5). High concentrations of NTS1-binding sites were distributed in the perikarya and dendrites of subsets of chemospecific neurons in a variety of brain regions, including DA neurons in the ventral midbrain, cholinergic neurons in the basal forebrain, and vasoactive intestinal peptidergic neurons in the suprachiasmatic nucleus of the hypothalamus. This distribution is consistent with reported NTS1-mediated NT effects on locomotion, memory, cognition, circadian rhythms, and sleep–waking cycle, as well as on the regulation of hypothalamopituitary functions. Accordingly, all these regions were later found to contain numerous nerve cell bodies expressing NTS1 mRNA and/or NTS1 receptor proteins by *in situ* hybridization and immunohistochemistry, respectively. The highest levels of staining were observed in the islands of Calleja, diagonal band of Broca, magnocellular preoptic nucleus, pre- and parasubiculum, suprachiasmatic nucleus, anterodorsal nucleus of the thalamus, substantia nigra, and VTA.

At the cellular level, NTS1 receptors were predominantly associated with perikarya and dendrites in some regions (e.g., in the basal forebrain, ventral midbrain, pons, and rostral medulla) and with axons and axon terminals in others (e.g., in the lateral septum, bed nucleus of the stria terminalis, neostriatum, paraventricular nucleus of the thalamus, and nucleus of the solitary tract). These labeling patterns

Figure 5 Comparative distribution of [125I]NT-binding sites (dark-field, left) and NTS1 immunoreactivity (bright-field, right) in the substantia nigra (SN; (a), (a′)), the supraschiasmatic nucleus (SCH; (b), (b′)), III: third ventricle; OX: opticchiasm and the anterodorsal thalamic nucleus (AD; (c), (c′)), sm: stria medullaris; AV: anteroventral thalamic nucleus). In all regions, the labeling patterns are strikingly similar. In the substantia nigra, compacta part (SNC) and the ventral tegmental area (VTA), NTS1 immunoreactivity is detected within both perikarya and processes, whereas in the substantia nigra, compacta reticulata (SNR), the labeling is mainly observed over dendritic arbors. Within the SCH and AD, the immunoreactivity is also apparent within perikarya and dendrites in the ventral tier of the nucleus. Scale bars = 300 μm (a, a′); 200 μm (b, b′, c, c′). Reprinted Boudin H, Pélaprat D, Rosténe W, and Beaudet A (1996) Cellular distribution of neurotensin receptors in rat brain: Immunohistochemical study using an antipeptide antibody against the cloned high affinity receptor. *Journal of Compartive Neurology* 373(1): 76–89, with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Ltd.

suggest that neurons expressing NTS1 receptors target these receptors to both their somatodendritic and axonal elements, providing evidence for pre- and postsynaptic effects of NT in different brain regions. At the subcellular level, in all areas examined, a significant proportion of both immunoreactive and radiolabeled NTS1 was found in association with neuronal plasma membranes. In brief, in the nucleus accumbens, NTS1 receptors were mainly associated with the plasma membrane of axon terminals, whereas they were mostly observed over the membrane of DA neurons in the substantia nigra and VTA. By contrast,

Figure 6 Immunolabeled NTS1 receptor proteins associated with dendrites (D) in rat substantia nigra. One of the labeled dendrites (D1) shows only intracellular immunogold particles whereas the other (D2) is predominantly labeled on its plasma membrane (white arrowheads). Inset: Note the presence of NTS1 proteins in association with the outer membrane of an endosomal vesicle (white arrowheads) and of an endocytic profile (black arrowheads). ma; myelinated axon. Scale bars = 0.5 ìm and 0.2 ìm (inset). Copyright (1998) by the Society for Neuroscience.

dendrites showed a higher concentration of intracellular receptors, suggesting that neurons expressing NTS1 receptors maintain large receptor reserves (Figure 6). An important fraction of these intracellular receptors are associated with the Golgi apparatus and endoplasmic reticulum, indicating that newly synthesized receptor proteins are in the process of synthesis and posttranslational modifications. Electron microscopy immunocytochemistry also revealed NTS1 receptors in endosomal vesicles, suggesting that NTS1 receptors internalize on ligand stimulation.

NTS2 Receptors

Early autoradiographic-binding studies, based on the displacement of specific [^{3}H]NT, [^{125}I]NT, or [^{3}H] SR142948A (a nonpeptidic NT antagonist) binding by levocabastine or on the direct labeling of NTS2 receptors using [^{3}H]-levocabastine as radioligand, reported a widespread distribution of levocabastine-sensitive NTS2 receptor sites in adult rat brain. In conformity with the results obtained by autoradiographic approaches, *in situ* hybridization histochemistry revealed that mRNA encoding NTS2 was diffusely distributed throughout the brain. High NTS2 expression levels were detected in the olfactory system, cerebral and cerebellar cortices, hippocampal formation, and selective hypothalamic nuclei. A striking feature of NTS2 distribution was its association with every single sensory system in the brain. Moderate to dense hybridization signal and NTS2 immunoreactivity were observed in a variety of olfactory (e.g., olfactory bulb, anterior olfactory nucleus, and piriform cortex), visual (e.g., suprachiasmatic nucleus, superior colliculi, lateral geniculate body), auditory (e.g., superior olivary nuclei, cochlear nuclei, and temporal cortex), and gustatory cerebral structures (e.g., nucleus of the solitary tract), suggesting that the NTS2 might be involved in the modulation of primary afferent pathways (Figure 7). Of particular interest from a functional perspective is the intense labeling of brain stem structures involved in pain control. Indeed, NTS2 mRNA and receptor proteins were highly expressed in brain stem structures implicated in the descending control of nociceptive input, such as the periaqueductal gray, dorsal raphe nucleus, raphe magnus and pallidus, gigantocellular reticular nucleus, pars alpha, and lateral paragigantocellular nucleus. The strong NTS2 immunolabeling also found in the dorsal root ganglia and in the superficial layers of the dorsal horn of the spinal cord suggests that NTS2 receptors are ideally poised to regulate NT's spinal antinociceptive actions (Figure 8).

Biochemical, *in situ* hybridization, receptor autoradiographic, and immunohistochemical studies all concur in demonstrating that in the rodent brain, the developmental pattern of NTS2 receptors is markedly different from that reported for the NTS1s. Indeed, NTS2 receptors are absent at birth, appear late during development, and do not reach their maximal levels until adulthood. In contrast to NTS2, NTS1 is expressed before birth, peaks at

Figure 7 NTS2 receptor mRNA (a, b) and proteins (c, d), as detected by immunohistochemistry and *in situ* hybridization, respectively, in the olfactory (a, b), auditory (c), and visual (d) sensory systems. Dark-field views of sections of the olfactory bulb (a) and piriform cortex (b). Within the olfactory bulb, intense hybridization is apparent over mitral and granular cells whereas only weak labeling is visible over plexiform and glomeruli layers. In the piriform cortex, silver grains were almost exclusively confined to layer II. Distribution of NTS2 immunoreactivity in the superior olivary complex (c) and lateral geniculate nucleus (d). In the rostral pons, the superior olivary complex exhibits a mix of labeled somata and processes. Intense labeling is observed over the dorsal and ventral tiers of the lateral geniculate nucleus as well as in the adjoining zona incerta. As shown in the inset, the NTS2 staining accounts for dendritic processes. (c, d) Reprinted from Sarret P, Perron A, Stroh T, and Beaudet A (2003) Immunohistochemical distribution of NTS2 neurotensin receptors in the rat central nervous. *Journal of Comparative Neurology*. 461(4): 520–538. with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Ltd.

around postnatal day 10, and progressively decreases thereafter, reaching adult levels between 30 and 40 days. On the basis of their ubiquitous distribution, as well as their pattern of ontogenic development, NTS2 receptors were originally surmised to be mainly associated with glial cells. Accordingly, NTS2 binding and/or mRNA were detected in association with astrocytes both *in vitro* and *in vivo*. This NTS2 glial expression was low under basal conditions but was massively upregulated in reactive astrocytes surrounding a cortical stab wound, suggesting that NTS2 receptors may play a role in the regulation of inflammatory responses and neuronal regeneration. Despite its expression in glial cells, the cellular localization of NTS2 is predominantly neuronal. However, unlike NTS1 receptors, which were reportedly distributed over perikarya, dendrites, and axons of neurons, NTS2 receptors were predominantly, although not exclusively, associated with dendritic processes.

NTS3 Receptors

Both NTS3/sortilin mRNA and immunoreactive proteins displayed a broad distribution throughout the brain. High levels of NTS3/sortilin expression and immunoreactivity were found in neuronal cell bodies and dendrites of cortical areas such as the piriform cortex and hippocampus, the islands of Calleja, medial and lateral septal nuclei, amygdaloid nuclei, thalamic nuclei, the substantia nigra, and the Purkinje cell layer of the cerebellar cortex

Figure 8 Distribution of levocabastine-sensitive NTS2 receptor immunoreactivity in spinal and supraspinal cerebral structures. (a) The ventral periaqueductal gray (PAG) and dorsal raphe nucleus (DR) both exhibit a dense network of immunopositive processes. (b) The gigantocellular reticular nucleus (GiA), pars alpha, exhibits numerous labeled perikarya as well as processes. Medially, the nucleus raphe magnus (RMg) is strongly stained, and the raphe pallidus (RPa) displays moderate immunoreactivity. (c) Localization of NTS2 receptors in lumbar spinal cord. Immunoperoxidase staining reveals the presence of intense NTS2 immunoreactivity within the superficial layers of the dorsal horn. A dense plexus of NTS2-immunoreactive neuronal processes is observed in laminae I and II. (d) Cellular distribution of NTS2 receptors in primary afferent neurons. Strong NTS2 labeling is evident in subpopulations of small and large dorsal root ganglion cells. Aq, aqueduct; 3n, oculomotor nucleus; py, pyramidal tract; ml, medial lemniscus. Scale bars = 500 μm (a), 350 μm (b), 600 μm (c), 200 μm (d). (a, b) Reprinted from Sarret P, Perron A, Stroh T, and Beaudet A (2003) Immunohistochemical distribution NTS2 neurotension receptors in the rat central nervous system. *Journal of Comparative Neurology* 461(4): 520–536, with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Ltd. (c,d) Reprinted from Sarret P, Esdaile MJ, Perron A, Martinez J, Stroh T, and Beaudet A (2005) Potent spinal analgesia elicited through stimulation of NTS2 neurotensin receptors. *Journal of Neuroscience* 25(36): 8188–8196.

(Figure 9). Furthermore, in the brain stem, all cranial nerve motor nuclei were strongly labeled. However, even if NTS3 mRNA and immunoreactivity patterns were mainly associated with neuronal elements, NTS3 receptors were also found in association with glial cells, corresponding, in morphology, to oligodendrocytes.

Many of the regions enriched in NTS3 mRNA and immunoreactive neurons had previously been documented as highly innervated by neurotensinergic axon terminals, thereby supporting the concept that NTS3 may act as a *bona fide* NT receptor. As observed for the NTS2 receptor, the distribution of NTS3/sortilin did, however, largely exceed that of NT terminal fields. Several regions previously described as NT-negative, such as the hippocampal CA fields, the cerebral cortex, and the cerebellum, displayed very high levels of NTS2 and NTS3 mRNA and protein, suggesting that NT may not be the exclusive endogenous ligand to act on NTS2 and NTS3 receptors. Moreover, the superimposition of NTS3/sortilin with NTS1 and NTS2 receptor subtypes suggests that it might interact with these receptors to mediate central NT effects. At the electron microscopic level,

Figure 9 NTS3/sortilin *in situ* hybridization (a–c) and immunoreactivity (a′–c′) in the parietal cortex (a, a′), amygdaloid complex (b, b′), and hippocampal formation (c, c′). In the parietal cortex, dark-field micrograph of NTS3/sortilin antisense probe-hybridized section and immunocytochemical analysis reveal a large number of cell bodies in layers II/III and V. In the amygdaloid complex, sortilin immunoreactivity displays a distribution identical to the pattern of mRNA expression in both nuclei (PMCO, posteromedial cortical amydaloid nucleus; PLCo, posterolateral cortical amydaloid nucleus). At higher magnification (inset), the labeling is clearly over large neuronal cell bodies in the PMCo. In the hippocampal formation, NTS3 mRNA expression and immunoreactivity are both very high and selective. All subfields of Ammon's horn (CA1-3) display extremely high levels of hybridization signal. Some labeled cells are also evident in the hilus of the dentate gyrus (DG, arrowheads), whereas the DG granule cell layer itself is only faintly labeled. Scale bars = 200 μm (a, a′), 150 μm (b, b′), 60 μm (c, c′), 12 μm (inset to b), 40 μm (inset to b′). Reprinted from Sarret P, Krzywkowski P, Segal L, Nielsen MS, Petersen CM, and Mazella J (2003) Distribution of NTS3 receptor/sortilin mRNA and protein in the rat central nervous system. *Journal of Comparative Neurology* 461(4): 483–505, with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Ltd.

NTS3 was predominantly concentrated over intracytoplasmic membrane-bound organelles, such as the Golgi apparatus, saccules of endoplasmic reticulum, and vesicles. This subcellular distribution conforms to the purported role of this protein in the sorting and trafficking of intracellular ligands.

NT/Dopamine Interactions

It has long been recognized that centrally administered NT exerts a number of effects similar to those of neuroleptic drugs. This observation led to a considerable number of studies aimed at defining

the interactions that might exist between NT and DA systems in the brain. There is at present unquestionable neuroanatomical, electrophysiological, neurochemical, and behavioral evidence that NT modulates DA transmission in the nigrostriatal and mesocorticolimbic pathways. Actually, NT behaves either as a psychostimulant or as a neuroleptic, depending on what part of the mesocorticolimbic DA circuitry is targeted by the peptide. *In vitro* and *in vivo* application of NT to DA neurons of the VTA stimulates DA neuronal activity. In contrast, administration of NT in the nucleus accumbens, a projection area of the VTA, inhibits DA transmission. The stimulatory, psychostimulant-like effects are mediated through NTS1 receptors that are abundantly expressed by VTA DA neuronal cell bodies and dendrites. The inhibitory, neuroleptic-like effects are also mediated via NTS1 receptors located postsynaptically to DA nerve terminals in the VTA. In addition, both antipsychotic and psychoactive drugs modify NT expression and transmission in these circuits, suggesting that the peptide mediates the effects of both types of drugs. Recent studies with either the NTS1 antagonist SR 48692 or with NT and NTS1 knockout mice further support the notion that NT participates, via the NTS1, in the response to psychostimulants as well as to that of both typical and atypical neuroleptic drugs.

Since clinical and postmortem data indicate that central NT systems are altered in schizophrenic patients, there is an ongoing debate to know whether an NTS1 agonist or antagonist would be accurate as an antipsychotic drug in the treatment of schizophrenia. Recent evidence points to NT agonists as offering promising leads for developing an active neuroleptic-like drug. Thus, SR48692 failed in clinical trials to reveal antipsychotic properties whereas NT agonist mimetics, crossing the blood–brain barrier, proved to exert neuroleptic-like effects in the rat following peripheral administration. On the other hand, there are reasons to believe that an NT antagonist might find useful application in treating drug addicts since amphetamine and cocaine sensitization are attenuated by SR48692 and SR142948A in the rat.

NT and Pain Modulation

Considerable breakthroughs have been made in the past 5 years in understanding the role of NT in pain responses. Originally, intrathecal and intracerebroventricular administrations of NT were shown to produce a profound analgesia in a variety of pain paradigms, including hotplate, tail-flick, and writhing tests. It is important to note that NT's antinociceptive effects were also reported to be naloxone insensitive, implying that they were not exerted through endogenous opioid systems. However, site-specific microinjection experiments have provided evidence that NT may actually induce hyperalgesia instead of analgesia following administration in the periaqueductal gray and rostroventral medulla (RVM) and brain regions projecting to these structures. Indeed, studies performed using lower, close-to-physiological doses suggest that NT produces facilitatory effects on nociception. The biphasic effect of NT may be explained by a dose-dependent activation of distinct populations of pain modulatory neurons or by the recruitment of different receptor subtypes. Nevertheless, the recent demonstration that NT knockout mice display defects in stress-induced analgesia may also suggest that the transition from pain facilitation to analgesia involves stress-induced increases in NT signaling in pain modulatory regions.

Both NTS1 and NTS2 appear to be required for different aspects of NT-induced analgesia. Knockdown of the NTS1 receptor, using either knockout mice or peptidic nucleic acids, as an antisense strategy, revealed that NT fails to increase response latencies in the hotplate test. Furthermore, intrathecal or intra-RVM administration of the relatively selective NTS1 antagonist SR48692 also partly abolished NT-induced analgesia in the tail-flick assay. Although a number of studies have implicated NTS1 in NT modulation of pain responses, several lines of evidence point to the levocabastine-sensitive low-affinity NTS2 subtype as a major antinociceptor. Indeed, the NT antagonist SR142948A, which recognizes both high- and low-affinity NT receptors, blocked NT-induced analgesia, whereas the NTS1 antagonist SR48692 did not. Accordingly, NTS2-preferring NT analogs were considerably more potent in eliciting antinociception than were NTS1-preferring analogs. The most convincing evidence comes from antisense inhibition experiments and NTS2-deficient mice, in which NT-induced analgesia was markedly inhibited. The future development of tissue-specific knockdown of both NTS1 and NTS2 will help determine their respective role in NT pain modulation. Further research to design NTS1- and NTS2-selective novel analogs that cross the blood–brain barrier may also offer new avenues for the treatment of pain without the side effects associated with the use of opioids.

Feeding Behavior and Obesity

It is well documented that food intake and body weight are regulated by a number of hypothalamic orexigenic and anorexigenic neuropeptides. These peptides are thought to coordinately regulate body weight through a complex, partially elucidated

mechanism orchestrated in part by leptin, an adipose tissue-released hormone that acts centrally in the hypothalamus to control body weight and energy expenditure. The anorexigenic effect of centrally administered NT has been known for 20 years. Further support for a role of NT in food intake came from the observation that hypothalamic expression levels of NT are decreased in genetic models of obese rats and mice including the Zucker fa/fa rat and the ob/ob mouse that are deficient in leptin receptor and leptin, respectively. More recently, a number of reports pointed to NT as a possible mediator of leptin-induced reduction in food intake. It has been shown that leptin receptors are present on and activate NT-expressing neurons in the arcuate nucleus and the dorsomedial area of the rat hypothalamus. Furthermore, central administration of leptin for 3 days increases NT gene expression whereas chronic intraperitoneal administration for 7 days decreases NT levels in the lateral hypothalamus. Leptin and NT reciprocally potentiate each other's inhibitory effect on food intake. Immunoneutralization of central NT with an NT antiserum or administration of the NT antagonist SR48692 completely blocks the inhibitory effect of leptin on food intake in food-deprived rats. Finally, in contrast to NT knockout mice that did not differ in their body weight from their wild-type littermates, NTS1 knockout mice exhibited increased food consumption, body weight, and white adipose tissue mass compared with wild-type littermates. Together, these data strongly suggest that NT is a major link in the complex neuropeptide network that controls body weight and that the peptide effects on feeding are exerted through the NTS1 receptor. NT agonists could therefore be useful in the treatment of obesity. In this context, it is of interest that an NT analog that crosses the blood–brain barrier was found to reduce food intake and body weight following intraperitoneal administration in normal and genetically obese Zucker fa/fa rats.

Neurotoxins

Introduction

The noted physiologist, Walter B Canon, promoted the precept that the function of a nerve could be determined by cataloging the absence-deficits when that nerve was removed. In the first half of the twentieth century that removal entailed either axonal transection or chemical or electrolytic ablation of the nucleus of origin (perikaryon). This experimental approach was common at the time, and it proved valuable in uncovering the functions subserved by particular nerve tracts. Nevertheless, there were obvious limitations to that experimental approach:

1. Not all nerve tracts are amenable to surgical transection or ablation, because of their physical location or axonal length (which might be measured in micrometers). In the brain there were only a small number of defined nerve tracts in that era, so the approach was impractical in the central nervous system (NS) (i.e., one must recognize the presence of a tract in order to be able to transect it.).
2. Particularly in spinal cord and brain, defined transection of a single tract was virtually impossible, because of the multiplicity of coordinate and crossing nerve bundles and other tracts. Inadvertently, many tracts would be transected.
3. A nerve tract often includes several different neuronal phenotypes, so that even a defined transection routinely would equate with the ablation of many different kinds of nerves within that tract.
4. Finally, as is obvious from the above-noted items, surgical and electrolytic lesions cannot specifically remove a single neuronal phenotype (i.e., cholinergic nerves only).

Selective neurotoxins provide a means to circumvent all of the above-noted limitations of a surgical approach. There are many examples of selective neurotoxins capably destroying a specific neuronal phenotype deep in the brain (or elsewhere), while leaving the surrounding neuropil virtually intact. This article is intended to (1) review the nature of selective neurotoxins, (2) describe the multiple mechanisms by which they might act, (3) discuss the practicality of using neurotoxins and the possible outcomes, (4) briefly touch on the breadth and scope of neurotoxins, and (5) assign limitations to neurotoxins in experimental investigations.

Historical Background

Selective neurotoxins were first discovered in the last half of the twentieth century. In the 1950s, Rita Levi-Montalcini, in her work with Victor Hamburger and Stanley Cohen, initiated the experiments that defined, explored, and uncovered the nature of neurotrophins – showing that the substance nerve growth factor (NGF), in particular, was necessary for development, growth, and sustenance of sympathetic and sensory ganglia. In an elegant series of studies this group ultimately developed an antibody to NGF and demonstrated that sympathetic nerves in whole animals could be destroyed by anti-NGF, leaving an animal 'immunosympathectomized.' This represented the first highly selective neurotoxin. Botulinum neurotoxin (BoNT) was long known as a neurotoxin, but its mechanism of action was realized only in the past 50–60 years, and its usage in medicine and in experimental physiology took hold only recently. BoNT is now regarded as a selective neurotoxin, but it was categorized as a poison (nonselective) in history. New selective neurotoxins were discovered in the late 1960s, and even more afterwards – with known neurotoxins still growing in number.

Criterion for Definition as a Selective Neurotoxin

The definition of 'selective neurotoxin' is a moving target. Anti-NGF was selective for sensory and sympathetic nerves, which represent different neuronal phenotypes. Anti-NGF is still regarded as a selective neurotoxin. However, for virtually all other neurotoxins there is a loose requirement that they have phenotypic or receptor selectivity. For example, 6-hydroxydopamine (6-OHDA) destroys catecholaminergic nerves (i.e., dopaminergic, noradrenergic, and potential for adrenergic) with relative selectivity. 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and its metabolite 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridinium ion (MPP^+) are selective for dopaminergic nerves (see Figure 1). Substituted amphetamines (AMPHs) are relatively selective for monoaminergic nerves (i.e., dopaminergic and serotoninergic). Excitatory amino acids have selectivity for subtypes of glutamate receptors, while there is no phenotypic selectivity.

Therefore, the term 'selective neurotoxin' is reserved for a chemical that has relative but not necessarily absolute selectivity for either a specific neuronal phenotype, or for a population of phenotypically diverse nerves with a particular type of receptor. Although

Figure 1 9w?>Structures of neurotransmitters/neurotoxins. 6-OHDA, 6-hydroxydopamine; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; MPP^+, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridinium ion; DSP-4, *N*-2-chloroethyl-*N*-ethyl-2-bromobenzylamine; 5-HT (serotonin), 5-hydroxytryptamine; 5,6- and 5,7-DHT, 5,6- and 5,7-dihydroxytryptamine; MDA, methylenedioxyamphetamine; MDMA, 3,4-methylenedioxymethamphetamine (ecstasy); 6-OHDOPA, 6-hydroxydopa; HPP^+, haloperidol metabolite; NMDA, *N*-methyl-D-aspartate; AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; BOAA, β-*N*-oxalylamino-L-alanine; BMAA, β-*N*-methylamino-L-alanine; TIQ, 1,2,3,4-tetrahydroisoquinoline.

there are cytoplasmic poisons (cyanide, carbon monoxide), heavy metals, and noxious substances that will destroy nerves and other cells in general, by virtue of their nonspecificity they generally are not classified as selective neurotoxins, although rotenone (discussed later) is an exception.

Nature of Neurotoxin Selectivity

Only by examples can one perceive the nature of a selective neurotoxin, and only with this background can generalizations be made. Several neurotoxins are selectivity because of their affinity to the transporter for the neurotransmitter in question. For example, 6-OHDA has high affinity to the dopamine transporter (DAT) and norepinephrine transporter (NET) of dopaminergic and noradrenergic nerves, respectively. As such, 6-OHDA is accumulated in high amount only within dopaminergic and noradrenergic nerves, attaining high cytoplasmic concentration, sufficient to inactivate vital enzymes or cytochromes and thus able to initiate necrotic or apoptotic processes. Several other neurotoxins act in much the same manner as 6-OHDA: MPP^+ has high affinity for the DAT; 5,6- and 5,7-dihydroxytryptamine (5,6-DHT; 5,7-DHT) have high affinity for the serotonin (5-HT) transporter (SERT); and substituted AMPHs have high affinity for DAT, NET and SERT. These respective neurotoxins act primarily in the nerves so associated.

Receptor-selective neurotoxins include glutamate *per se* and aspartate *per se*, which act at multiple glutamate receptors, but nonetheless produce overexcitation (i.e., excitotoxicity) of the postsynaptic nerves on which the receptors reside. *N*-Methyl-D-aspartate (NMDA), quinolinate, and ibotenate produce excitotoxicity via NMDA receptors; kainate and domoic acid are excitotoxins acting at the kainate subtype of glutamate receptor; α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), as well as the unnatural amino acid *β-N*-oxalylamino-L-alanine (BOAA), act at the AMPA receptor; the unnatural amino acid *β-N*-methylamino-L-alanine (BMAA) acts at metabotropic group I receptors. Notably, many of the glutamate receptor agonists, while being neurotoxic because of their action at one particular receptor subtype, act at multiple glutamate receptor subtypes. In this instance, usage defines a 'selective neurotoxin.' In other words, there is an experimental application whereby an excitotoxin fulfilled the criterion needed to obtain the experimental goal.

Clostridial neurotoxins (e.g., botulinum neurotoxin and tetanus toxin) are so-called Trojan horse toxins. The C-terminal end of the heavy chain of BoNT binds to a specific protein on cholinergic nerves; next, BoNT is translocated inside the cholinergic nerve via the N-terminal domain; and inside the nerve ending, the light chain of BoNT catalytically cleaves proteins involved in transmitter exocytosis (i.e., V-SNARE and T-SNARE proteins). Cholinergic nerves thus become functionally inactive for a long period (weeks to months) – but the nerves are not overtly destroyed. This usage thus expands the definition of a neurotoxin to extend to long-term inactivation, not limiting 'neurotoxicity' to an ability to necessarily destroy a nerve.

Mechanisms of Neurotoxin Action

Neurotoxins tend to impede vital cytoplasmic processes, and this can be accomplished by an action at one of many different sites. Identified neurotoxins are known to (1) disrupt energy production, (2) dysregulate ionic gradients, (3) impair neurotransmitter synthesis/storage/release, (4) interfere with transcription, translation, and formation of requisite cytochromes, enzymes, and other proteins, (5) promote formation of abnormal proteins or other products, or (6) eliminate the necessary neurotrophic stimulation (e.g., anti-NGF). Other sites can also be affected. A number of these points highlighted here are outlined and discussed, in part, in the following sections.

Oxidative Inactivation of Vital Cellular Elements

Some neurotoxins act through the inactivation of a vital cellular element or series of elements, which include enzymes, proteins, lipids, cytochromes, and DNA. For example, 6-OHDA and MPP^+ act on mitochondrial cytochromes and ultimately impair energy (ATP) production. In the process, the mitochondrial transition pore is opened, and apoptosis is activated. However, if the damage is sufficiently severe, necrosis can occur before apoptosis or necroptosis runs its course.

In the preceding scenario, the neurotoxin action may be direct or indirect. For example, MPP^+ *per se* potently inhibits mitochondrial cytochrome I. By contrast, 6-OHDA autooxidizes to quinones and semiquinones, each of which can mediate the 6-OHDA effect via their actions at sites on the mitochondria and other cellular elements. Additionally, the quinones and semiquinones promote the formation of peroxides, superoxide radical, and hydroxyl radical, each of which can act at multiple cytoplasmic sites to inactivate vital cellular elements.

The neurotoxins 5,6- and 5,7-DHT act in much the same manner as 6-OHDA, except that 5,6- and 5,7-DHT act primarily in serotoninergic nerves (owing to their high affinity to SERT), while 6-OHDA acts primarily in catecholaminergic nerves (owing to its high affinity to DAT and NET).

Alkylation of Vital Cellular Elements

The 2-chloroethylamine neurotoxins *N*-2-chloroethyl-*N*-ethyl-2-bromobenzylamine (DSP-4) and xylamine have high affinity to the NET, and are thus accumulated in high amount in NE nerve terminals. Inside the nerve ending, DSP-4 randomly alkylates reactive sites, the most notable being unsaturated lipids, sulfur moieties on proteins, including mitochondrial cytochromes. Consequently, the nerve is functionally inactivated for a long duration (months to years), as reflected by long-term reduction of the neurotransmitter NE (also by long-term reduction in the NET-synthesizing enzyme, dopamine β-hydroxylase). Many other undefined sites would also be alkylated and inactivated inside the nerve.

Ethylcholine aziridinium ion (AF64A), having high affinity for the choline transporter, is thus accumulated by cholinergic nerves. In addition to covalently bonding to the choline transporter, once inside the nerve AF64A interacts with reactive molecular sites, like DSP-4, and produces functional inactivation and neurotoxicity to the cholinergic nerve. AF64A binds to and inactivates choline acetyltransferase, choline kinase, choline dehydrogenase, and acetylcholine esterase (AChE). AF64A-generated reactive oxygen species produce oxidative stress; and alkylation by AF64A disrupts the integrity of DNA, gene transcription, and RNA transcription. Initiation of apoptosis leads to cell death.

Trojan Horse Neurotoxins

As indicated earlier, BoNT and tetanus toxin are translocated into the nerves, at which time the toxins are bound. Inside the nerve, these Trojan horse neurotoxins catalytically cleave those proteins essential for exocytosis and thereby produce long-term inactivation of the nerve. In one sense, other neurotoxins that are carried into nerves can be classified as Trojan horse neurotoxins. For example, it can be said that 6-OHDA masquerades as DA and is carried into the DA terminal via the DAT; once in the nerve, 6-OHDA disrupts cellular function and destroys the cell. MPTP/MPP^+, substituted AMPHs, 5,6- and 5,7-DHT, and a number of other neurotoxins would act similarly. However, 6-OHDA is distinctly different molecularly from DA, while BoNT carries its own translocation device (protein), making its own 'door' into the cell. So, a Trojan horse neurotoxin can take different forms, having different categorizations.

Potential for Trojan horse neurotoxins By re-engineering the BoNT molecule, it becomes possible to target proteins on specific types of nerves. A re-engineered BoNT could target only sensory neurons, for example, and produce long-term analgesia in people with chronic pain. Alternatively, even nonneuronal cells (e.g., epithelial cells) can be targeted, and the endopeptidase portion of the molecule can be replaced with a recombinant protein (e.g., epidermal growth factor) to alter release of cellular products (e.g., mucin). A BoNT molecule reformulated with epidermal growth factor (or analog) might impair the exocytosis of mucin. Re-engineered BoNT molecules could be a useful means, and a new drug approach, for the treatment of human disorders such as cystic fibrosis, asthma, and chronic obstructive pulmonary disease. Alternatively, a noxious drug could be substituted for the catalytic domain of BoNT, coupled with an altered binding domain that might target a site on a cancerous cell, to derive an anticancer drug with high potency and little adverse effect. Many other permutations for the BoNT or tetanus toxin molecule are possible.

Neurotoxicity Produced by Excitotoxicity

Agonists at ionotropic glutamate receptors potentially are capable of overstimulation of a postsynaptic neuron. The neurotransmitters glutamate and aspartate are imbued with this potential, as are agonists with preferential activity at kainate receptors (kainate, domoic acid), AMPA receptors (AMPA, kainate, quisqualate, BOAA), or NMDA receptors (endogenous quinolinate, NMDA, ibotenate, BMAA). Excitotoxicity is accompanied by increased Na^+ ion fluxes at each of these receptor subtypes as well as increased Ca^{2+} ion flux at the NMDA receptor. In low amount, the amino acid BMAA additionally potentiates neuronal injury produced by other insults.

Interference with Neurotrophin Stimulation or Ontogenetic Nerve Activity

Anti-NGF, discussed earlier, is a targeted antibody that inactivates NGF, a neurotrophin required for ontogenetic development of sympathetic ganglia. In mice treated with NGF, sympathetic nerves, deriving from sympathetic paraganglia, fail to develop and remain absent throughout life.

During development redundant and unsuccessful neurons undergo apoptosis when lacking adequate physiologic contact and excitation from neuronal cross-talk. Thus, during ontogeny and particularly during the brain growth spurt, substances that interfere with or block neuronal cross-talk are apt to produce neuronal apoptosis. Normally cytoprotective NMDA receptor blockers (in adulthood) become neurotoxins when administered during ontogeny, by blocking neuronal cross-talk and thereby signaling that the soon-to-be apoptotic nerve is quiescent and

therefore 'redundant.' In ontogeny, NMDA blockers are neurotoxins, as are γ-aminobutyric acid (GABA) mimetics, including alcohol. Thus, all anesthetics, being either NMDA blockers or GABA mimetics, are neurotoxic when administered in ontogeny (including in humans). The CNS deficits in fetal alcohol syndrome are attributable to the apoptosis induced in the manner described here.

Targeted Antibody – Production of Neurotoxicity

An immunotoxin, 192 IgG–SAP – immunoglobulin G (IgG) conjugated to a ribosome-inactivating protein (i.e., saporin; SAP) – binds to a membrane-bound p75 neurotrophin receptor on cholinergic nerve terminals; after its internalization from receptor endocytosis it is transported to the cell body, where it irreversibly impairs protein synthesis and causes ultimate neuronal cell death.

Nonselective Neurotoxin(s) with Specialized Use to Model a Disease State

When the mitochondrial complex I inhibitor rotenone is administered to rats over a period of months, a partial loss of pars compacta substantia nigra dopaminergic neurons occurs along with a hypolocomotor syndrome that in some ways models Parkinson's disease (PD). There are pros and cons to the model, including the fact that the extent of complex I inhibition with rotenone is more widespread and more homogeneous in brain than is seen in PD, the extent of nigral degeneration is much less with rotenone than in PD, and the hypolocomotor effect with rotenone is not correlated with DA cell loss, as it is in PD; also, the rotenone effects are not consistent (in replication) among investigators. Rotenone, long used as a rat poison, is a lipophilic substance that enters virtually all cells and has notable nonselectivity. Nevertheless, because rotenone is now commonly used to model PD, it might be considered in the realm of a 'selective' neurotoxin.

Neurotoxins for the Future

Ideal Properties of a Neurotoxin

One can envision an ideal neurotoxin as having a high degree of selectivity coupled with high potency for a specific neuronal target. These properties enable a neurotoxin to destroy one specific set of neurons (possibly a single phenotypic group, or possibly even a particular neuronal nucleus in brain) without damaging adjacent neurons or glia. It thus becomes more reasonable to ascribe particular functions to the missing set of neurons.

Alternatively, one can envision an ideal neurotoxin as one that mimics most or all of the histological/pathological details of a neurodegenerative or neuropsychiatric disorder as it presents in humans – possibly with deficits in many neuronal nuclei. For example, the multidimensional Parkinson syndrome in humans cannot be attributed solely to loss of pars compacta dopaminergic neurons. Rotenone, described earlier as a means for producing an animal model of PD is one attempt at this latter type of selectivity.

Validation of a Neurotoxin

For a neurotoxin that produces overt necrosis, apoptosis, or necroptosis of a single neuronal phenotype, one can validate neurotoxicity by assessing one or more of a host of neuronal functions or viability: (1) loss of neuronal perikarya and terminal innervation, (2) loss of activity of the rate-limiting neurotransmitter synthesizing enzyme, (3) loss of neurotransmitter stores, (4) loss of membranous transporter sites or activity, or (5) altered behavioral expression. For example, for a neurotoxin that destroys dopaminergic neurons in substantia nigra pars compacta, one would see a relative absence of nigral cells and relative absence of dopaminergic innervation in basal ganglia sites, loss of tyrosine hydroxylase activity, DA depletion from tissues and a decrease in microdialysate levels of DA, loss of DAT in striatal homogenates, and a relative absence of spontaneous motor activity. Biochemical, histological, immunocytochemical, physiological, and behavioral techniques might be engaged, according to the expertise of a laboratory and the degree of confirmation (of neurotoxicity) desired or required.

For a neurotoxin that produces long-term functional impairment without induction of necrosis or apoptosis, one would focus on the nature of the impairment, whether it be loss of neurotransmitter stores or loss of response to nerve stimulation, or other parameter relating to function.

Neurotoxins as Experimental Tools, and Limitations

As neuroscience ever evolves to a greater degree of sophistication in methodology, one can envision that neurotoxins will be uniquely synthesized for individualized experiments. For example, identification of a protein or protein fraction will provide a means to develop a unique binding site or antibody to the neuron under study, so that unique neuronal lesioning is produced with a high degree of selectivity. A limitation to this approach is that the clinical presentation of a neurodegenerative disorder often relates to the involvement of many different tissues or even brain sites. A targeted neurotoxin cannot

replicate all elements of a disorder. Nevertheless, the desired lesion will provide a better means of characterizing the functional role of the targeted set of neurons.

Usual limitations of a neurotoxin relate to nonselectivity of action. When there is collateral damage to nontargeted neurons (and/or glia), it becomes problematic in concluding that a particular action or function was attributable to the nerve in question. Also, if potency is low it is not possible to effectively lesion a large proportion of the target neurons or the nerve terminal tree.

Neurotoxins as Therapeutic Agents

Re-engineered clostridial neurotoxins represent a promising therapeutic strategy for targeted treatment of a variety of clinical disorders, including cancer chemotherapy. Already, this project has been initiated. A reconfigured or substituted binding domain provides selectivity of the molecule for the desired cell group; a reconfigured or substituted catalytic domain (which could feasibly be a drug or cell poison) provides the desired cellular effect. Ideally, both are accomplished with minimal collateral undesired effects.

Vanilloid receptor agonists such as capsaicin are already in use for long-term elimination of pain – initially producing excitation, eventually producing receptor desensitization, and ultimately producing toxicity to sensory neurons conducting pain impulses.

Despite these examples of clinical utility for neurotoxins, in nearly all instances preservation of cellular activity is the norm – not destruction of a cell. Accordingly, most classical neurotoxins find greatest utility as experimental research tools to model disease states and to better elucidate mechanisms involved in cell death.

Endogenous Neurotoxins and Neuroprotectants

Quinolinate, another excitatory amino acid at the NMDA receptor, is a putative endogenous neurotoxin. Perhaps as a balance, kynurenic acid is produced endogenously by glia, acting as a broad-spectrum antagonist for all ionotropic glutamate receptors, and as an antagonist with high affinity for the glycine site of the NMDA receptor complex. As such, kynurenic acid is regarded as an endogenous neuroprotectant.

Endogenously produced β-carbolines (e.g., 2,9-dimethyl-β-norharmanium), formed from tryptophan or derived indolealkylamines, and particularly when dimethylated, are neurotoxic species with the potential to damage nerves and give rise to neurodegenerative disorders. Another chemical class, tetrahydroisoquinolines, are metabolites of dopamine (e.g., *N*-methyl(*R*) salsolinol) that have been proposed as a neurotoxic species also giving rise to neurodegenerative disorders. In the case of 1-methyl-1,2,3,4-tetrahydroisoquinoline and certain β-carbolines, a neuroprotective effect is found.

More investigation is needed into purported endogenous neurotoxicants and neuroprotectants, in regard to sites of production, sites of action, threshold amounts for physiological effects, and relative susceptibility of targets.

Selective Neurotoxins in the Twenty-First Century

Discovered only in the past 40 years, selective neurotoxins are now an integral component of neuroscience research. Exogenous neurotoxins, such as MPTP and rotenone, are regularly used in PD research studies. MPTP, as a detrimental xenobiotic, was uncovered consequent to its producing Parkinson syndrome in humans. As such, MPTP has re-enlivened the debate as to whether such substances in the environment are producing nonevident nerve damage and the so-called diseases of aging. This view is further reinforced by the discovery of unnatural amino acids that similarly produce neurotoxicity and neurodegenerative disorders in humans (e.g., BOAA, BMAA). Glutamate is implicated in Alzheimer's disease, in stroke, and in ischemic injury. Glutamate receptor antagonists are under development by pharmaceutical companies, as prophylaxis against Alzheimer's disease. Huntington's disease is now viewed as a neurodegenerative disorder arising from glutamate excitotoxic neuronal damage. Glutamate antagonists and substituted AMPHs produce behaviors and lesions associated with psychosis and schizophrenia. Haloperidol and other 'typical' antipsychotics produce tardive dyskinesia, possibly via neurotoxic metabolites resembling MPP^+. It is evident that there are numerous clinical and behavioral entities which neurotoxins replicate. Many neurotoxins are yet to be discovered, and we see only the tip of the iceberg now, in terms of experimental potential and in reference to clinical applicability of neurotoxins.

Neurotoxic substituted AMPHs (e.g., methylenedioxyamphetamine, methylenedioxymethamphetamine (ecstasy)) are drugs of abuse, commonly used at all-night dance parties (i.e., 'raves'). Users take the risk of serotoninergic neuronal degeneration in brain, along with the sometimes fatal hyperthermia that occurs as an acute effect of the drug. Cocaine, another widely abused drug, is fatal because of its propensity to produce arrhythmia and convulsions. Cocaine neurotoxicity in animals is associated with chronic treatments.

The concept of endogenous neurotoxins and identifiable neurotransmitter-related neuroprotectants is a new one. Studies to date have opened the door

into what is becoming a vast arena for scientific exploration.

Neurotoxins and their Neurotoxicology

M I Sabri and P S Spencer, Oregon Health and Science University, Portland, OR, USA

Introduction

Neurotoxicity of drugs and other chemicals is an important and challenging public health problem. Substances that produce a primary toxic effect on the nervous system are referred to as neurotoxins or neurotoxicants. Agents such as carbon monoxide and cyanide that secondarily render damaging effects on the nervous system are also considered to be neurotoxic agents. Chemicals with neurotoxic potential occur naturally as the products of bacteria (e.g., diphtheria toxin), plants (*β*-*N*-oxalylamino-L-alanine [L-BOAA]), and animals (palytoxin); these agents often have high specificity and discrete biological actions resulting in neurotoxicity. Certain purified natural agents, such as the compounds of arsenic, lead, and manganese, have widespread toxic potential but predominantly affect the nervous system. Naturally occurring and synthetic chemicals used as therapeutic drugs (nitrofurantoin), vitamins (pyridoxine), recreational substances (ethanol, cocaine), domestic products (zinc pyridinethione), pesticides (chlorpyrifos), occupational chemicals (acrylamide, hydrocarbon solvents), and food contaminants (domoic acid) can also induce human neurological diseases. Serious efforts are therefore required to identify, eliminate, and develop a public policy for neurotoxic substances, similar to that for carcinogens. Neurotoxic agents can be divided into various categories (Table 1).

Neurotoxicology is an area of neuroscience that deals with chemicals that produce adverse or undesired effects on the nervous system and behavior of humans and animals. Although the subject of neurotoxicology is solidly based on principles of neuroscience and toxicology, the discipline also encompasses relevant aspects of many other specialized fields, including behavioral toxicology, biochemical toxicology, cancer chemotherapy and other areas of clinical pharmacology (notably the side effects of therapeutic drugs), forensic toxicology, defense medicine (predominantly chemical warfare agents), mycotoxicology, neurology, nutritional toxicology, occupational and environmental medicine, ophthalmology and otorhinolaryngology, pesticide toxicology, psychopharmacology, psychiatry, clinical psychology, teratology, toxicology, tropical medicine, veterinary medicine, and zoology (notably entomology and marine biology). Many experimental neuroscientists employ selected neurotoxic agents as discrete tools to probe the nervous system or to model human neurological or psychiatric disorders. Although the actions of exogenous chemical substances represent the primary focus of neurotoxicology, the metabolic disorders associated with elevated levels of endogenous agents (e.g., copper in Wilson's disease) are also relevant to the discipline.

Each year millions of people are occupationally or otherwise exposed to neurotoxicants. Indeed, many epidemics of neurotoxic diseases have occurred throughout the world (Table 2). Ataxia and blindness, caused by organic mercury compounds in fish in Japan and in fungicide-treated grain in Iraq; spinal cord degeneration and peripheral neuropathy caused by tri-*o*-cresylphosphate (TOCP) in cooking oil in Morocco; toxic oil syndrome in Spain; and tremors, motor disturbances, and anxiety caused by the pesticide Kepone (chlordecone) in the United States are some of the examples of human neurotoxic exposure (Table 2).

Factors Governing Neurotoxicity

Factors that determine vulnerability of the nervous system to chemical agents may be different during development, at maturity, and in late life. The developing nervous system is by far the most sensitive to the actions of neurotoxic agents. One of the most important factors that pose a threat to the nervous system is the immaturity of the blood–brain barrier (BBB) during development. The large majority of the nervous system is protected from chemical exposure by the mature BBB that separates the microenvironment of the brain parenchyma from circulating toxic substances. Regulation of the BBB is a key function of capillaries coursing through nervous tissue. Structural specializations of capillary walls in the form of tight junctions between adjacent endothelial cells constitute a diffusion barrier and allow the endothelium to regulate the selective transport of substances from blood to brain and vice versa. However, gases (oxygen, carbon monoxide, nitrous oxide), cross capillary walls with ease. The structure of chemicals is of critical importance in determining the neurotoxic response. While access to nervous tissue may dictate a direct neurotoxic effect, neurotoxicity ultimately depends on the ability of the agent to bind to the neural target and interfere with functional or structural integrity. Structure–activity relationships are therefore of cardinal importance for the expression of neurotoxicity. Recent studies have shown that 1,2-diacetylbenzene (1,2-DAB) but

Table 1 Types of neurotoxic agents

Category	*Example*
Chemical warfare agents	Sarin, soman, tabun
Drugs of abuse	Ethanol, heroin, ecstasy, nitrous oxide
Environmental pollutants	Carbon monoxide, lead, mercury
Experimental probes	Dinitrophenol, iodoacetate, pyrithiamine
Food additives/fragrances	Acetyl ethyl tetramethyltetralin, dinitro-methoxybutyltoluene
Industrial/occupational	*n*-Hexane, 1,2-diethylbenzene, acrylamide, manganese
Natural toxins	Gossypol, saxitoxin, tetanospasmin, BOAA, BMAA, cyanide, cycasin
Drugs	Cisplatin, taxol, vincristine

Table 2 Selected major neurotoxicity incidents

Year(s)	*Location*	*Agent*	*Comments*
400 BC	Rome	Lead	Hippocrates recognizes lead toxicity in mining industry
1930s	United States	TOCP	Compound often added to lubricating oil, contaminates Ginger-Jake, an alcoholic beverage; ~5000 paralyzed and ~100 000 affected
1930s	Europe	Apiol	Abortion-inducing drug containing TOCP causes neuropathy, 60 cases
1932	United States	Thallium	Barley laced with thallium used as a rodenticide used to make tortillas; 13 hospitalized with neurological symptoms, 6 die
1937	South Africa	TOCP	60 South Africans develop paralysis after using contaminated cooking oil
1946		Lead	More than 25 individuals suffer neurological effects after cleaning gasoline tanks
1950s	Japan	Mercury	Hundreds ingest fish and shellfish contaminated with mercury,121 poisoned, 46 deaths. Many infants with birth defects
1950s	France	Organotin	Contamination with triethyltin results in more than 100 deaths
1950s	Morocco	Manganese	150 miners suffer chronic manganese intoxication involving severe neurobehavioral problems
1950s–70s	United States	AETT	Neurotoxic component of fragrances; withdrawn in 1978
1956		Endrin	49 persons become ill after eating foods prepared from flour contaminated with the insecticide endrin; results in convulsions
1956	Turkey	HCB	Hexachlorobenzene, a seed grain fungicide, leads to poisoning of ~4000; 10% mortality rate
1956/1977	Japan	Clioquinol	Used to treat diarrhea found to cause neuropathy; ~10 000 affected over two decades
1959	Morocco	TOCP	Cooking oil contaminated with lubricating oil affects ~10 000 individuals
1960	Iraq	Mercury	Mercury used as fungicide to treat grain used in bread; affects more than 1000 people
1964	Japan	Mercury	Methyl mercury affects 646 individuals
1968	Japan	PCBs	Polychlorinated biphenyls leak into ice oil; affects 1665 people
1969	Japan	*n*-Hexane	93 cases of neuropathy following exposure to *n*-hexane, used to make vinyl sandals
1971	United States	Hexachlorophene	After years of bathing infants in 3% hexachlorophene, the disinfectant is found to be toxic to the nervous system
1971	Iraq	Mercury	Mercury used as fungicide to treat seed grain is used in bread; more than 5000 severe poisonings, 450 hospital deaths
1973	United States	MnBK	Fabric production plant employees exposed to solvent; more than 80 suffer polyneuropathy
1974–75	United States	Chlordecone	Chemical plant employees exposed to insecticide (Kepone); more than 20 suffer severe neurological problems
1976	United States	Leptophos	At least nine employees suffer serious neurological problems following exposure to insecticide (Phosvel)
1977	United States	Dichloropropene	24 individuals hospitalized after exposure to pesticide Telone
1979–80	United States	BHMH	Seven employees at plastic bathtub manufacturing (Lucel-7) plant experience serious neurological problems following exposure to BHMH
1980s	United States	MPTP	Impurity in synthesis of illicit drug found to cause symptoms identical to those of Parkinson disease
1981	Spain	Toxic oil	20 000 persons poisoned by toxic substance in oil, resulting in more 500 deaths; many suffer from neuropathy

Continued

Table 2 Continued

Year(s)	*Location*	*Agent*	*Comments*
1985	United States	Aldicarb	More than 1000 individuals in California, other western states, and Canada experience neuromuscular and cardiac problems following ingestion of melons contaminated with the pesticide (Aldicarb)
1987	Canada	Domoic acid	Ingestion of mussels contaminated with domoic acid causes 129 illnesses and two deaths. Symptoms include memory loss, disorientation, and seizures
1989–91	United States	L-Tryptophan dimer	1543 cases of eosinophilia-myalgia syndrome, with 28 deaths
1995	Japan	Sarin	4000 sickened and ten deaths from terrorist attack on Tokyo subway
2002	Worldwide	Acrylamide	Identification of acrylamide in fried food (French fries)

TOCP, tri-*o*-cresylphosphate; AETT, acetyl ethyl tetramethyl tetralin; MnBK, methyl-*n*-butyl ketone; BHMH, 2-*t*-butylazo-2-hydroxy-5-methylhexane; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

not 1,3-DAB induces peripheral neuropathy because only 1,2-DAB forms adducts with neuroproteins. Similarly 2,5-hexanedione but not 2,4-hexanedione induces hindlimb weakness and causes distal axonal degeneration because only the former reacts with epsilon amino group of lysine moiety and cross-links neural proteins.

The complexity of the nervous system also greatly contributes to its vulnerability to toxic agents. The nervous system is composed of a number of cell types (e.g., neurons and glia) that mature at different times during development. Neurons are classified and identified on the basis of their anatomical locations (hippocampal, striatal), neurotransmitters (cholinergic, dopaminergic), cellular structures (granular, pyramidal), or functions (motor, sensory). Oligodendrocytes, astrocytes, microglia, and Schwann cells are classes of neuroglia that are responsible for a broad range of functions, including neuronal support, maintenance, phagocytosis, and myelin production in the central and peripheral nervous system. Preservation of the normal relationship between neurons and glia is very important for the maintenance of nervous system function. Neurotoxins can easily disrupt this relationship by selectively damaging either cell type. Neurotoxicity is therefore one of the most complex toxic responses in humans and animals. The range of human neurotoxic disorders associated with overexposure to exogenous substances is given in Table 3. Some individuals may be more susceptible to certain neurotoxic agents because of age, malnutrition, genetic type, or disease (Table 4).

The major factors that govern the effect of circulating neurotoxic agents include the ability to gain access to neural tissue, the specific target within the nervous system, the concentration of the proximate toxin at the target site, and the chemical reactivity of the agent and its duration of exposure to the target site. All these factors are heavily influenced by circumstances surrounding exposure to the chemical, its port of entry into the body, its distribution within tissues, the rate of metabolism, the toxicity of its metabolic products, and the efficacy of their excretion. Dose of the chemical substance and duration of exposure are pivotal factors in determining whether an agent will produce a neurotoxic effect. Substances that are harmless at low levels may become neurotoxic as the dose and duration of exposure increase. Others, such as pyridoxine (vitamin B6), may be required in small amounts for normal nervous system function but become neurotoxic when the dose exceeds a certain level. Different types of neurotoxic responses often appear as a function of dose and duration of exposure. For example, ethanol in large quantities over a short period of time induces a reversible state of inebriation; prolonged consumption of ethanol in large quantities not only elicits the acute response, but also causes the development of chronic degenerative disease of brain and peripheral nerves.

Targets of Neurotoxic Chemicals

Neurotoxic substances act directly or indirectly to interfere with the structure and/or function of neural elements. Indirect mechanisms of action include chemical induction of hypoxia (carbon monoxide), hypokalemia (barium), or a vitamin deficiency state (ethanol). During neural development, chemicals that perturb mitosis or cell migration are especially likely to induce malformations (e.g., spinal bifida). Other compounds, such as ethanol, can induce behavioral abnormalities in offspring unassociated with major structural deficits. Although most chemical substances have unknown mechanisms of action, target sites for

Table 3 Illustrative manifestations of adult human neurotoxicity

Function affected	*Manifestation*	*Example*
Sensorium	Irritability	Carbon disulfide
	apathy/lethargy	carbon monoxide
	attention difficulty	anticholinesterases
	illusions, delusions	ergot
	depression, euphoria	dicyclopentadiene
	stupor, coma	3-nitropropionic acid

Table 4 Recognized susceptibility factors for human neurotoxic disorders

1. Age
2. Genetic abnormality (slow acetylators and hydroxylators)
3. Malnutrition (vitamin deficiency)
4. Preexisting hepatic disorders (impaired metabolism/ inactivation of neurotoxic factors)
5. Preexisting neurological and psychiatric disorders (epilepsy, schizophrenia)
6. Preexisting renal disorders (impaired excretion of neurotoxic agents and their metabolites)

some substances have been determined at the molecular and cellular level (Figures 1 and 2). Because many agents produce different effects as a function of dose and duration of exposure, their classification is problematic. Many agents inhibit axonal transport system and thereby induce axonal degeneration. Some neurotoxic substances disrupt the anterograde transport of materials from sites of synthesis (perikarya) to sites of utilization (e.g., β,β'-iminodipropionitrile). Certain neurotoxic agents interfere with retrograde transport (e.g., acrylamide). Some chemicals (e.g., vinca alkaloids) bind to tubulin and thereby inhibit microtubule-based bidirectional transport of axonal materials and elicit neurotoxicity. Presently, the most satisfactory approach is to group neurotoxins by their apparent target, recognizing that more than one site may be involved (Table 5). This provides a rational approach to understanding the clinical consequences of exposure and the starting point of an inquiry directed at mechanisms of toxicity. This approach also demonstrates that chemical substances of diverse origins may have remarkably similar cellular and functional effects. For example, chemicals that interfere with the opening or closing of sodium channels all produce symptoms of circumoral and distal-extremity dysesthesias in overexposed humans. Such agents can be found in algae (ciguatoxin), higher plants (veratrum alkaloids), invertebrates (tetrodotoxin), vertebrates (batrachotoxin), or manufactured chemicals (pyrethroids, dichloro diphenyl tetrachloroethane (DDT).

Figure 1 Diagram of a motor neuron showing cytological landmarks (right) and sites of action of certain neurotoxins (left). Tetanus toxin is taken up at nerve terminals and carried by retrograde transport to the neuronal perikaryon from which it passes transsynaptically to bind to, and block, axosomatic inhibitory inputs. 1,2-Diacetylbenzene (1,2-DAB), β,β'-iminodipropionitrile (IDPN), and 2,5-hexanedione block axonal transport of slow- and fast-moving materials synthesized in the cell body. β-*N*-Oxalylamino-L-alanine (L-BOAA) activates non-*N*-methyl-D-aspartate (non-NMDA) receptors. Diphtheria toxin binds to Schwann cells and arrests protein synthesis. Tetrodotoxin and pyrethroids interfere with nerve conduction by disrupting the function of sodium channels at nodes of Ranvier. Black widow spider venom causes massive release of neurotransmitter by promoting fusion of synaptic vesicles at sites outside the active zones. Botulinum toxin impairs release of acetylcholine by interfering with exocytosis at active zones. α-Bungarotoxin blocks neurotransmission by binding to the acetylcholine receptor. Sarin promotes excessive synaptic activity by inhibiting acetylcholinesterase, the enzyme responsible for terminating the action of the neurotransmitter, acetylcholine. Adapted from Adelman G and Smith BH (eds.) (2004) *Encyclopedia of Neuroscience,* 3rd rev. edn. New York: Elsevier, with permission from Elsevier.

Occurrence of Neurotoxic Disorders

Neurobehavioral dysfunction caused by toxic substances is widely recognized in humans. Veterinary neurotoxic disorders are common in animals grazing on poisonous plants (e.g., cycad) and in domestic animals exposed to pesticides. Many human neurotoxic syndromes are associated with the side effects of prolonged treatment with therapeutic drugs, notably anticonvulsants, anticholinergics, neuroleptics, and antiparkinsonian and antineoplastic drugs. Chinese traditional medicine may incorporate the products of dangerous plants (podophyllin) or contaminants (thallium). Neurological and psychiatric dysfunction also commonly occur with abuse of ethanol, narcotics, hallucinogens, central stimulants, solvents, and nitrous oxide. In the occupational setting, the acute cholinergic crisis associated with pesticide poisoning is commonplace and responsible for numerous deaths. Many other substances found in the workplace have been noted to induce short-term or long-lasting disorders of the nervous system. Environmental pollutants with neurotoxic potential (carbon monoxide, lead, mercury) are pervasive. Numerous animals secrete or harbor potent neurotoxins (conotoxin) that sometimes affect humans. Neurotoxic agents present as intrinsic components of foodstuffs (*Manihot esculenta, Lathyrus sativus*) or as contaminants (ergot in *Claviceps* spp.) are also responsible for outbreaks of neurological disease, especially in certain undeveloped regions of the world. Other biological neurotoxins in these regions are those associated with botulism, tetanus, and diphtheria. Finally, chemicals with experimentally proven neurotoxic potential also exist as food additives (monosodium glutamate, aspartate), flavors and fragrances (2,6-dinitro-3-methoxy-4-*t*-butyltoluene), and certain over-the-counter antiseborrheic agents (zinc pyridinethione). Substances with neurotoxic properties are therefore encountered in food, air, water, the general environment, and domestic and occupational settings.

Figure 2 Diagram of a neuron showing suspected and/or established intracellular sites of action of selected neurotoxins that induce peripheral neuropathy and other neurodegenerative diseases. Although certain agents form adducts with nuclear DNA and interfere with transcription or translation in the cell body, some neurotoxins disrupt intracellular mechanisms that are indicated by the numbered arrows: (1) routing of synthesized proteins via the Golgi apparatus; (2) proteins that bypass the Golgi apparatus; (3) microtubule-based fast anterograde transport (kinesin-driven); (4) turnaround; (5) retrograde transport (dynein-driven); or (6) lysosomal digestion. Some neurotoxins disrupt mitochondrial phosphorylation, glucose metabolism, or interact with neurofilaments. NF, neurofilament; SER, smooth endoplasmic reticulum; MITO, mitochondria; ATP, adenosine triphosphate; Pyr, pyruvate; Gluc, glucose; Ves, vesicle (synaptic); MVB, multivesicular body; MAM, methylazoxymethanol; NMU, N-methylnitrosourea; IDPN, β,β'-iminodipropionitrile; 1,2-DAB, 1,2-diacetylbenzene; BPAU, *p*-bromophenylacetylurea; MPP^+, 1-methyl-4-phenylpyridinium; 3-NPA, 3-nitropropionic acid; 2,5-HD, 2,5-hexanedione; CS_2, carbon disulfide; ZPT, zinc pyridinethione; L-BOAA, β-*N*-oxalylamino-L-alanine; L-BMAA, β-*N*-methylamino-L-alanine; STZ, strepto zotocin. Neurotoxins as Experimental Tools

Certain chemical neurotoxins have proven to be powerful probes to investigate the normal functioning of the nervous system. Many of these are highly specialized biological toxins with discrete sites of action. For example, sodium channel agents, such as tetrodotoxin and saxitoxin, have played a major role in elucidating molecular mechanisms underlying the electrical properties of the neuronal membrane. Snake and spider venoms have proved useful for studying the action of acetylcholine at the neuromuscular junction. Kainic acid has been extensively employed to explore excitatory mechanisms involving glutamate receptors. Mechanisms underlying axonal transport have been dissected with agents such as the spindle inhibitors (colchicine, vincristine), β,β'-iminodipropionitrile, and other neurotoxins (Table 2). Many other substances have been employed to create and explore animal models of human neuromuscular disease. Repeated exposure to acrylamide, 2,5-hexanedione, cisplatin, taxol, or TOCP produces models of peripheral neuropathy. Experimental parkinsonism has been induced in primates by 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and corticospinal dysfunction by L-BOAA. Paraquat, a herbicide, and rotenone, a pesticide, exert their toxic effects by inhibiting mitochondrial functions, causing oxidative stress and neurodegeneration. The pathogenesis of myasthenia gravis as a disorder of acetylcholine receptors was worked out with the aid of α-bungarotoxin and other elapid toxins. Mechanisms underlying certain types of demyelinating disease have been illuminated with agents such as hexachlorophene, lysolecithin, and acetyl ethyl tetramethyl tetralin (AETT). 1,2-DAB, the putative diketo metabolite of the neurotoxic aromatic solvent 1,2-diethylbenzene, damages motor neurons in rat spinal cord and induces giant proximal axonal swellings filled with 10-nm neurofilament, a prominent early feature of neuron degeneration in amyotrophic lateral sclerosis.

Neurotransmitter and Hormone Receptors on Oligodendrocytes and Schwann Cells

Oligodendrocytes

Neurotransmitter Receptors and Development

Oligodendrocytes (OLs) originate from oligodendrocyte progenitor cells (OPCs) that can be identified both *in vivo* and in culture based on the expression of specific cellular markers, including the platelet-derived growth factor receptor-α (PDGFR-α), the NG2 proteoglycan, and the transcription factor Olig2. OPC lineage progression to fully differentiated, myelinating oligodendrocytes can also be monitored by the expression of developmentally regulated antigens (O4 and O1) and myelin components, including myelin basic protein (MBP), 2′,3′-cyclic nucleotide 3′-phosphohydrolase (CNPase), proteolipid protein (PLP), and myelin-associated glycoprotein (MAG). One of the crucial series of events that occur in OPC development is arrest in cell proliferation, permanent cell cycle withdrawal, and terminal differentiation. It is therefore of critical importance to fully understand how OPC proliferation and cell cycle arrest are regulated both intrinsically and by extracellular signals.

OPCs proliferate in the postnatal subventricular zone (SVZ), and migrate out of the SVZ to developing white-matter regions, where they differentiate to mature OLs and myelinate axons. OPCs develop postnatally, after embryonic neurogenesis and formation of synaptic contacts are largely completed. Therefore neuronally released signals are likely to affect OPC development in the postnatal brain. Neurotransmitters are now recognized as developmental signals that regulate many aspects of neural cell development, including OPC maturation and myelination. For example, glutamate affects gene expression in OPCs through a Ca^{2+}-dependent process. OPCs express all neurotransmitter receptors that have also been found in neurons, although with some molecular and functional differences. Table 1 provides a complete list of these receptors.

Cell proliferation The control of OPC proliferation is one of the mechanisms that determine the final number of oligodendrocytes in the brain. Neurotransmitter amino acids, including γ-aminobutyric acid (GABA), glutamate, and glycine, exert different effects on OPC proliferation by acting on selective receptors that are expressed at different stages of the OL lineage.

Electrophysiological patch clamp studies in cultured brain OPCs demonstrate that these cells display GABA-elicited current responses. The pharmacological properties of these GABA-activated channels were similar to their neuronal counterparts, in terms of sensitivity to different receptor agonists and antagonists. However, differently from neurons, the benzodiazepine agonists and inverse agonists did not modulate the GABA responses in OPCs. Also in contrast to neurons, the rate of deactivation produced by brief agonist pulses in OPCs was voltage independent.

In the subventricular zone (SVZ), GABA inhibits cell proliferation of neural progenitors, including OPCs, acting through $GABA_A$ receptors. $GABA_A$ receptor agonists also inhibit proliferation of perinatal OPCs in cerebellar slice cultures. These inhibitory effects are most likely due to a depolarizing effect of GABA in immature cells. Interestingly, these effects of GABA persist in the adult brain, as demonstrated by the finding that progenitors of the SVZ/rostral migratory stream (RMS)/olfactory bulb (OB) pathway, including cells that generate oligodendrocytes in the OB, are depolarized by activation of extrasynaptic $GABA_A$ receptors to inhibit their proliferation.

OPCs co-express ionotropic glutamate receptors of the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and kainate subtypes. Electrophysiological analysis shows rapidly desensitizing responses to kainate and to AMPA. Analysis in single cells shows that two receptor populations are co-expressed and can be distinguished based on affinity for kainate, and on differential sensitivity for potentiation by concanavalin A and for block of desensitization by cylothiazide. Glutamate regulates OPC proliferation through the activation of AMPA receptors. Glutamate inhibits OPC proliferation in purified cultures and in cerebellar tissue slices. Furthermore, glutamate inhibits SVZ progenitor cell proliferation in cortical slices. The antiproliferative effects of glutamate are Ca^{2+} independent and arise from an increase in intracellular Na^+ and subsequent block of outward K^+ currents. AMPA/kainate receptor agonists cause a reversible G1 cell cycle arrest in OPCs, which is associated with accumulation of the cyclin kinase inhibitors $p27^{Kip1}$ and $p21^{CIP1}$, and a selective decrease in cdk2 activity and cdk2/cyclin E complex formation.

Table 1 Neurotransmitter receptors in oligodendrocytes and Schwann cells

Receptor	*Effects in oligodendrocytes*	*Effects in Schwann cells*
Acetylcholine		
Muscarinic M1–M4	Activation of the PI3K/Akt pathway	Increase in IP3
	Stimulation of cell proliferation	Decrease in $[cAMP]_i$
	Stimulation of cell survival	Block GFAP induction
Nicotinic	Increase in $[Ca^{2+}]_i$	
α3, α4, α5, α7; β2, β4		
Dopamine		
D3 receptor	Inhibition of cell differentiation	
GABA		
$GABA_A$ receptors	Depolarizing chloride currents	Mediation of neurosteroid (THP) action
	Increase in $[Ca^{2+}]_i$	Stimulation of PMP22 expression
	Lack of sensitivity to benzodiazepines	
	Inhibition of cell proliferation	
	Stimulation of MBP expression through THP	
$GABA_B$ receptors		Decrease in $[cAMP]_i$
		Inhibition of cell proliferation
		Inhibition of P_0, PMP_{22}, MAG expression
Glycine		
α2- and β-subunits	Depolarizing chloride currents	
	Increase in $[Ca^{2+}]_i$	
Glutamate		
AMPA and kainate: GluR2, 3, 4, 6, 7; KA1, 2	Rapidly desensitizing glutamate, kainate and AMPA currents	Stimulation of ATP release
	Increase in $[Ca^{2+}]_i$	
	Ca^{2+}-dependent induction of gene expression	
	Blockage of K^+ channels	
	Inhibition of cell proliferation	
	Inhibition of cell differentiation	
	Stimulation of integrin-mediated cell migration	
	Involvement in excitotoxic damage in hypoxia/ischemia and periventricular leukomalacia	
NMDA: NR1, NR2A–C, and NR3A	Depolarizing currents in immature and mature oligodendrocytes	
	Involvement in oligodendrocyte damage in hypoxia/ischemia	
Norepinephrine		
α,β-Adrenergic	Increase in $[cAMP]_i$ through β receptors	Increase in $[cAMP]_i$
	Inhibition of cell proliferation through β receptors	
	Stimulation of cell differentiation through β receptors	
Purinergic	Increase in $[Ca^{2+}]_i$	Increase in $[Ca^{2+}]_i$
P2X and P2Y receptors	Inhibition of cell proliferation	Inhibition of cell proliferation
		Inhibition of differentiation
P2X7 receptor		Regulation of IL-1β release
		Stimulation of inward current
Adenosine A2	Inhibition of cell proliferation	Increase in $[cAMP]_i$
Serotonin		
5HT1B, 2A, 2C		Increase in $[Ca^{2+}]_i$
Neuropeptides		
Calcitonin gene-related peptide		Stimulation of cell proliferation
Vasoactive intestinal peptide		Increase in $[cAMP]_i$

Studies in developing white matter have demonstrated that OPCs receive direct synaptic contacts from callaterals of unmyelinated axons in corpus callosum glutamate release from these axons on to NG2+ progenitors is actively dependent and causes activation of AMPA receptors in OPCs. The functional consequences of this phenomenon are unknown, but glutamate regulate OPC proliferation and differentiation through these synapses. It is also unknown whether release of other neurotransmitters also occurs through direct synaptic contacts on OPCs in white matter regions.

Purinergic receptors of the P2X and P2Y subtypes are expressed in OPCs in culture and *in vivo*. Adenosine

increases intracellular Ca^{2+} in OPCs and inhibits their proliferation. Similar effects are also observed by stimulating dorsal root ganglia (DRG) neurons in neuronal–glial co-cultures and in cerebellar slice cultures. The effects of adenosine are reproduced by ATP and ADP, which increase intracellular Ca^{2+} and inhibit OPC proliferation by activating metabotropic P2 receptors. P2Y receptors are localized in white-matter $NG2^+$ OPCs *in vivo* during postnatal development, suggesting that receptor signaling might also regulate proliferation *in vivo*. Inhibition of OPC proliferation is also observed with the β-adrenergic receptor agonist isoproterenol, which increases cyclic adenosine monophosphate (cAMP) levels in OPCs.

Opposite effects on OPC proliferation are detected with muscarinic receptor agonists. Carbachol stimulates OPC proliferation in culture through phosphatidylinositol (PI)-coupled muscarinic receptors in the absence of other mitogenic factors.

Cell migration OPC migration is a highly regulated process that is critical for proper white-matter development. Glutamate acting at G-protein-coupled AMPA receptors stimulates α-v integrin-mediated OPC migration by increasing the frequency of Ca^{2+} transients and by promoting cell motility. Interestingly, AMPA receptor subunits were found to be associated with the proteolipid protein (PLP)/α-v integrin complex, indicating that interactions among several membrane proteins regulate OPC migration. ATP and ADP also stimulate OPC migration, but the mechanism is still undefined.

Cell differentiation and survival OPC differentiation can be monitored by using specific antibodies that bind to developmentally regulated antigens. The possibility of monitoring OPC lineage progression has provided unique opportunities to investigate the effects of neurotransmitters on oligodendrocyte development and myelination. Glutamate prevents OPC lineage progression to the $O4^+$ and $O1^+$ stage by maintaining OPCs in cell cycle arrest, whereas isoproterenol exerts opposite effects and promotes cell differentiation, as determined by a large increase in the percentage of $O4^+$ preoligodendrocytes and $O1^+$ oligodendrocytes. Adenosine is a potent stimulator of OPC differentiation and myelination in DRG–OPC cultures, and ATP and ADP also promote OPC differentiation.

Dopamine D3 receptor expression was detected in OPC cultures and in the corpus callosum at the peak of myelination, but was not found in mature oligodendrocytes. Receptor activation with the agonist quinpirole led to reduced numbers of $O1^+$ cells, along with an increase in the number of precursors, indicating that dopamine binding delays or inhibits OPC differentiation.

OL programmed cell death is one of the crucial mechanisms that regulate the final OL number in the mature brain. The phosphatidylinositol 3-kinase (PI3K)/Akt pathway plays a central role in OPC survival, as demonstrated by effects of both muscarinic and cannabinoid receptor agonists, which promote cell survival through direct activation of this pathway.

Hormone Receptors and Development

Expression of hormone receptors in OL lineage cells is summarized in Table 2. Similar to neurotransmitter receptors, hormone receptors are also expressed through different stages of OL development, suggesting that distinct aspects of OL maturation are under hormonal influence.

Cell proliferation Insulin is a potent stimulator of oligodendrocyte generation and maturation. Insulin-like growth factor 1 (IGF-1) receptors are highly expressed in OPCs and in more mature OLs. Exposure of OPCs to IGF-1 increases cell proliferation through IGF-1 receptors, and IGF-1 synergizes with fibroblast growth factor 2 (FGF-2) to promote OPC entry into the cell cycle. This effect is due to enhanced cyclin D1 in G1 phase.

OLs express mu opioid receptor immunoreactivity early during development, and treatment with receptor agonists causes a large increase in $O4^+$ cell proliferation. Opioid receptors are also highly expressed in neural progenitors of the SVZ, although physiological effects different from those observed *in vitro* were associated with these receptors *in vivo*. In fact, proliferation of glial fibrillary acidic protein (GFAP)-negative cells in the SVZ, which presumably include OPCs, was decreased by morphine treatment.

Retinoic acid (RA) exerts profound effects on brain development, and RA nuclear α receptors (RAR-α) are expressed in OPCs. Interestingly, RAR-α expression is transiently stimulated by RA in the presence or in the absence of basic fibroblast growth factor (bFGF). Activation of these receptors inhibits OPC proliferation, indicating that retinoids participate, in concert with growth factors, in the control of oligodendrocyte development. Similar to RA, other hydrophobic signals, including thyroid hormone and glucocorticoids, also cause cell cycle arrest in OPCs.

Cell differentiation and survival OPCs express thyroid hormone receptors (TRs), and thyroid hormone is considered a major positive regulator of OPC differentiation. Oligodendrocyte subpopulations co-express the TRα and TRβ1 epitopes at specific developmental

Table 2 Hormone receptors in oligodendrocytes and Schwann cells

Receptor	*Effects in oligodendrocytes*	*Effects in Schwann cells*
IGF-1	Promotion of cell cycle entry Promotion of cell proliferation Increase in cellular myelin content	Stimulation of PI3K Promotion of cell survival Stimulation of cell proliferation Stimulation of differentiation Stimulation of focal adhesion kinase Stimulation of cell motility
Thyroid hormone (α1, β1)	Regulation of cell cycle exit Regulation of initiation of differentiation Stimulation of MBP expression	Stimulation of immediate early genes Stimulation of P_0 expression Stimulation of MBP expression
Retinoic acid	Regulation of cell proliferation Regulation of cell differentiation	Decrease in ciliary neurotrophic factor
Estrogen	Delay of cell cycle exit Promotion of membrane sheet formation	Stimulation of cell proliferation with cAMP Induction of progesterone receptor
Progesterone	Enhancement of cell branching Promotion of myelination Stimulation of MBP expression	Stimulation of P_0 and PMP22 expression Regulation of $GABA_B$ receptor expression
Glucocorticoid	Inhibition of cell proliferation	Stimulation of P_0 and PMP22 expression
Opioids (mu and kappa)	Regulation of cell survival Promotion of cell differentiation	
Parathyroid hormone-related protein		Promotion of cell proliferation Promotion of cell migration along axons
Erythropoietin		Promotion of cell proliferation

stages. Both TRα and TRβ1 isoforms are co-localized in oligodendrocytes during early development, before CNPase is expressed. Expression of TRβ1 varies during maturation, whereas TRα decreases during terminal differentiation. Thyroid hormone promotes OPC maturation in culture by (1) timing cell cycle exit and initiation of the differentiation process and (2) by enhancing MBP gene expression and myelination. Consistent with these findings, MBP mRNAs were significantly downregulated in the brain of hypothyroid rats.

IGF-1 strongly promotes OL generation and differentiation *in vitro*, and transgenic mice that overexpress IGF-1 display a higher content of myelin per single OL than do wild-type littermates, although the total OL number in the brain was unchanged. These findings demonstrate that endogenous IGF receptor activation promotes myelin synthesis *in vivo*.

RA has been reported to display opposite effects on OPC differentiation in different cellular systems. In cultured optic nerve OPCs, RA promotes cell differentiation, whereas in brain OPCs, RA inhibits cell differentiation. The opposite effects might be due to regional differences, or to distinct culture conditions used.

OLs possess a considerable 3α-hydroxysteroid dehydrogenase activity, the enzyme involved in progesterone and testosterone metabolism in the brain. The neurosteroid progesterone increases the expression of myelin proteins (MBP and CNPase) in rat OLs in primary culture. Consistent with these findings, this neurosteroid also enhances myelination in cerebellar organotypic slice cultures, as determined by MBP expression. The effect of progesterone on MBP expression is mediated by the classical intracellular progesterone (PROG) receptor (PR), as demonstrated by studies with specific receptor agonists and antagonists. Furthermore, consistent with these findings, no PROG effects on myelination are observed in organotypic cultures obtained from a PR knockout mouse. Progesterone is metabolized in the cerebellar cultures to 5α-dihydroprogesterone (5α-DHP) and to the $GABA_A$ receptor-active metabolite 3α,5α-tetrahydroprogesterone (3α,5α-THP; allopregnanolone). The 5α-reductase inhibitor L685-273 partially inhibits the effect of PROG, whereas 3α,5α-THP significantly stimulates MBP expression. This increase in MBP expression by 3α,5α-THP involves $GABA_A$ receptors, as demonstrated by inhibition with the selective $GABA_A$ receptor antagonist bicuculline. These results indicate enhanced MBP expression and myelination through two signaling systems, the intracellular PR and membrane $GABA_A$ receptors, and they indicate a new role for $GABA_A$ receptors in myelination. Gonadal steroids also elicit differential responses in OPCs: 17β-estradiol, but not PROG or testosterone, delays the exit of OPCs from the cell cycle and enhances membrane sheet formation, whereas PROG promotes cellular branching. Cytoplasmic estrogen receptor β (ERβ) is believed to mediate the increase in membrane formation induced by estradiol, suggesting that sex steroids could contribute to differences in repair.

OLs express proenkephalin and prodynorphin peptides, as well as both mu and kappa opioid receptors. A kappa receptor antagonist inhibits OL differentiation, indicating that endogenous opioids synthesized by OLs modulate cell survival via autocrine and/or paracrine mechanisms.

Oligodendrocyte Receptor Signaling in Injury and Disease

OLs are the major target of a variety of diseases and neurological disorders. For some of these disorders a neurotransmitter or hormone receptor-mediated mechanism is implicated. In other cases, enhanced OL survival under pathological conditions depends on selective hormone receptor activation.

It is well established that AMPA receptor antagonists attenuate excitotoxic injury in the developing white matter that occurs in hypoxia/ischemia. In particular, Ca^{2+}-permeable AMPA receptors are involved in glutamate-mediated death of immature and mature OLs. Interestingly, activation of metabotropic glutamate receptors (mGluRs) in oligodendrocyte lineage cells attenuates AMPA receptor-induced excitotoxicity. A similar effect is also observed with IGF-1, which protects pre-OLs from glutamate-mediated toxicity. Oligodendroccyte degeneration occurs in a variety of white-matter disorders, and glutamate-mediated excitotoxicity is thought to play an important role in many of these, including periventricular leukomalacia and multiple sclerosis.

OL *N*-methyl-D-aspartate (NMDA) receptor (NR) channels are formed by the NR1, NR2A–NR2C, and NR3A subunits, although based on their pharmacological and electrophysiological properties, channels that include the NR1, NR2C, and NR3A subunits are likely to be the most abundantly expressed. Importantly, differently from AMPA and kainate receptors, which are predominantly found on the cell somata, NMDA receptor channels in oligodendrocytes are mostly clustered on the cellular processes. NMDA receptors are found in OLs from different brain regions, indicating that their expression in this class of cells occurs regardless of their origin. NMDA receptors in OLs are less sensitive to Mg^{2+} block than are neuronal NMDA receptors, therefore, differently from neurons, activation of these channels by glutamate can occur at resting membrane potential and independently of simultaneous AMPA receptor activation.

The physiological function of OL NMDA receptors in the normal brain is still unknown, but their localization on distal domains of cellular processes and in myelin sheets suggests that they might be involved in OL differentiation and/or myelin formation and maintenance. Conversely, NMDA receptors have been associated with glutamate-induced damage in OLs. Ischemia induces NMDA-mediated inward currents in OPCs and in mature OLs, and causes Ca^{2+}-dependent damage to myelinating oligodendrocytes. Interestingly, AMPA and kainate receptor antagonists prevent damage of OL cell bodies, but do not influence deterioration of cellular processes, whereas NMDA receptor antagonists prevent their damage. These findings are also reproduced in chemically induced ischemia in the optic nerve, where a Ca^{2+} overload is observed in myelin. This is partially inhibited by NMDA receptor antagonists, which also attenuate structural changes in the myelin sheets.

Schwann Cells

Based on their morphology, biochemical composition, and specific axonal association, Schwann cells in the mature nervous system can be classified into four groups: myelinating Schwann cells (MSCs), nonmyelinating Schwann cells (NMSCs), perisynaptic Schwann cells (PSCs, or terminal Schwann cells), and satellite cells of peripheral ganglia. These diverse cell types are nonetheless generated from a single neural crest cell. Schwann cell formation involves two transient cell populations, Schwann cell precursors (SCPs) and immature Schwann cells. SCPs are distinguished from migrating neural crest cells by the presence of brain fatty-acid-binding protein (BFABP) and protein zero (P_0), and can be distinguished from immature SCs by the lack of glial fibrillary acidic protein, by cytoplasmic S-100 protein, and by the very distinct feature of axon dependence for their survival. Postnatally, GFAP is suppressed in myelin-forming cells but is retained in NMSCs. Mature MSCs maintain the potential to express GFAP, which can be derepressed once axonal contact is lost. Galactocerebroside (GC), the glycosphingolipid of the myelin sheath, is not only expressed in mature oligodendrocytes and MSCs, but is also found in adult NMSCs *in situ*, although its expression is eventually lost from SCs in culture due to lack of axonal signaling.

Axonal signaling determines fates of immature SCs developing into myelinating, nonmyelinating, and perisynaptic cells. Association with large-diameter axons derives cues to generate myelinating Schwann cells, whereas nonmyelinating SCs ensheathe small-diameter axons. The best characterized SCs remain the MSCs; these can be distinguished from MSCs by lower levels of GFAP, although specific markers are not known for PSCs. Survival and migration of Schwann cells are regulated by axon-derived neuregulin through SC ErbB receptor tyrosine kinases, whereas other factors, such as endothelins, regulate the timing of precursor maturation and Schwann cell generation. Unlike SCPs, SCs can survive in the absence of axons, indicating that

survival regulation changes with the development of autocrine loops in SCs that are absent from SCPs. These signals include factors such as IGF, neurotrophins, and platelet derived growth factor-BB.

Neurotransmitter Receptors and Development

Extracellular ATP is an activity-dependent axonal signal that inhibits the proliferation and differentiation of premyelinating SCs. ATP can activate a number of receptors, broadly divided into two families: the ligand-gated ionotropic (P2X) receptors and the G-protein-coupled metabotropic (P2Y) receptors. ATP released from sensory axons (DRGs) elicits in SCs increased intracellular calcium levels ($[Ca^{2+}]_i$), cAMP response element-binding protein (CREB) phosphorylation, and c-fos and Krox24 induction, but reduces mitogen-stimulated cell proliferation and expression of galactocerebroside and the O4 antigen. ATP hydrolysis ultimately generates adenosine, which also inhibits cell proliferation and which can activate several subtypes of metabotropic adenosine (P1) receptors – A1, A2, and A3. The A1 subgroup of adenosine receptors inhibits adenylyl cyclase while A2 receptors facilitate it. Calcium-linked A1 adenosine receptors are present in PSCs that surround the neuromuscular junction, but PSCs are distinct from SCs associated with axons. Surprisingly, in premyelinating SCs, ATP fails to regulate the extracellular signal-regulated kinase/mitogen-activated protein kinase (ERK/MAPK) cascade, which is involved in regulating cell proliferation and differentiation through changes in either calcium or cAMP. ERK activation is instead specifically mediated by adenosine through $A2_A$ receptors which signal through cAMP, although $A2_B$ is also detectable in premyelinating SCs. Thus, adenosine and ATP inhibit SC proliferation through A2 and P2Y1 receptors, respectively, but only ATP arrests SC differentiation. In contrast, adenosine promotes the differentiation of progenitor cells into myelinating oligodendrocytes in the central nervous system.

Both $GABA_A$ and $GABA_B$ receptors have been found in sciatic nerve SCs. Activation of $GABA_B$ receptors which are negatively coupled to adenylyl cyclase inhibits SC proliferation and reduces RNA and protein levels of myelin proteins P_0, myelin-associated glycoprotein (MAG), and peripheral myelin protein 22 (PMP22). $GABA_A$ receptors can also mediate modulatory activities of neurosteroids (see later, 'Hormone receptors and development'), which can in turn modulate $GABA_B$ receptor expression, with important consequences on SC development.

Immature Schwann cells express M1–M4 muscarinic receptor subtypes, inducing inositol 1,4,5-trisphosphate (IP_3) levels and decreasing cyclic AMP, without evoking calcium release. The same subtypes continue to be expressed in MSCs and NMSCs, although their developmental regulation suggests function during proliferation and differentiation. Furthermore, only quiescent, P_0^+-myelinating SCs responded to 5-hydroxytryptamine (5HT; serotonin) with calcium transients, indicating that postmitotic SCs express serotonin receptors, in particular the $5\text{-}HT_{2A}$ receptor, during differentiation, but their function in development remains uncharacterized.

Neurotransmitter Receptors and SC Signaling

Expression of neurotransmitter receptors in the SC lineage is summarized in Table 1. In response to cAMP analogs, SCs from the sciatic nerve express P2Y receptors which modulate intracellular calcium levels. At the neuromuscular junction (NMJ), PSCs express both ATP and adenosine receptors, and signaling via calcium occurs through P2X, P2Y, and A_1 receptors. However, despite excitatory corelease of ATP with acetylcholine (ACh) in the peripheral nervous system, a role for purinergic receptors in neuromuscular PSCs has not been established. Instead, PSCs are known to respond to acetylcholine with release of calcium from intracellular stores. PSCs in turn secrete neuroactive substances to modulate neurotransmitter release at the NMJ. Because muscarine blocks the induction of GFAP expression in PSCs upon blockade of synaptic activity, whereas ATP is ineffective, it is believed that muscarinic ACh receptors, rather than purinergic receptors, control PSC functions of growth, remodeling, and synapse modulation.

Although glutamate receptors of the NMDA, AMPA, and kainate subtypes have been found in adult guinea pig SCs *in vitro*, other studies describing the application of glutamate agonists in rat sciatic nerve report only partial or inconsistent calcium responses. Interestingly, SCs are one of several sources of purine nucleotides besides synapses and axons: ATP release from neonatal Schwann cell cultures occurs in response to glutamate and AMPA, and is specifically blocked by the AMPA receptor antagonist GYKI 52466 and competitive non-NMDA antagonist 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX).

In addition to glutamate receptors, α1-, α2-, and β-adrenergic receptors are also expressed in guinea pig SC. Isoproterenol, norepinephrine, and epinephrine increase intracellular cAMP levels, which can be synergistically enhanced by vasoactive intestinal peptide (VIP) or secretin. At the neuromuscular junction, substance P induces calcium release from internal SC stores, but when applied as a pretreatment, can also block or reduce muscarine- or ATP-induced calcium responses, indicating an involvement of

endogenous SP in PSC regulation and calcium signaling. The neuropeptides VIP, substance P, and somatostatin also hyperpolarize the SC membrane potential through mechanisms believed to be independent of cAMP.

The role of cAMP elevation in SC development remains controversial. The use of forskolin or cAMP analogs has been found to induce GC, O4 sulfatide, and P_0 expression, accompanied by the downregulation of GFAP and nerve growth factor (NGF) receptor in sciatic nerve preparations. In contrast to GC and P_0, the expression of which is inversely correlated with cell proliferation, cAMP induces O4 expression equally in dividing and nondividing SCs. However, in other studies, forskolin and calcitonin gene-related peptide (CGRP), a potent stimulator of adenylate cyclase in SCs, instead were found to promote SC proliferation in the presence of PDGF. These findings nonetheless led to important applications for cAMP-inducing neuropeptides in injury.

Neurotransmitter Receptors and Immune Function

In addition to its myelinating function, SCs also produce proinflammatory cytokines such as interleukin-1β (IL-1β). While ATP alone has no effect on the synthesis of pro-IL-1β, the posttranslational processing and secretion of IL-1β in stimulated SCs are dependent on the P2X7 receptor and its associated chloride conductance, implicating a function for purinergic receptors in neuroinflammatory disorders.

Hormone Receptors and Development

Insulin-like growth factor-1 promotes the proliferation of SCs through IGF-1 receptors. IGF-1 also induces morphological changes and enhances SC differentiation by inducing P_0 protein levels, even in the absence of cAMP. In co-cultures with DRG, SCs treated with IGF-1 show substantial myelination whereas those deprived of IGF-1 still survive, but fail to myelinate. IGF-1 appears multifaceted; not only does it regulate the proliferation and survival of developing SCs, it also promotes SC motility via the phosphatidylinositol 3-kinase pathway.

Thyroid hormones, which are important in oligodendrocytes, are also required for SC development. Triiodothyronine(T3) increases the incorporation of [^{3}H]thymidine in cultured rat SCs. Nuclear T3 receptor (TR) and T3 binding are found in peripheral glia only during the perinatal period, but adult Schwann cells can also exhibit TR immunoreactivity after nerve injury when they are deprived of axonal contact. TRα1 is the predominant isoform in SCs during sciatic nerve development. The subtypes TRα1 and TRβ1 have been localized in the proximal, peripheral part of the cochlear nerve, where reduced P_0 RNA levels are associated with a hypothyroid state. In addition to its genomic effect on the MBP promoter, T3 also produces rapid effects on immediate-early genes such as *Krox-20/Egr-2*, and this is crucial for peripheral myelin formation, Jun B, and c-fos. Thus, T3 regulates SC function and differentiation through the activation of specific transcription factors.

Neonatal SC cultured from sciatic nerves express intracellular receptors for estrogen and progestins, and the induction of progesterone receptors by estrogens is dependent on neuronal signals. The classical progesterone receptor is expressed in SCs. In primary SC culture, estrogen promotes proliferation only in the presence of elevated intracellular cAMP, while progesterone has no effect on proliferation but does enhance myelin formation. However, when SCs are kept in the integrated environment of the nerve, such as in nerve segments, both estrogen and PROG stimulate SC proliferation without forskolin.

SCs are not only targets for circulating steroids such as estrogens, but they can also synthesize neurosteroids, including pregnenolone, PROG, and their reduced metabolites. The enzymatic complex that converts families of steroid hormones into their 5α- and 3α,5α-reduced metabolites is present in nerves and SCs of the peripheral nervous system (PNS). The concentration of PROG in rodent sciatic nerves is 10 times higher than in plasma. SCs in co-culture with DRG produce significant amounts of PROG and its metabolites, some of which may regulate SC functions through autocrine actions.

Both *in vivo* and *in vitro*, the synthesis of the peripheral myelin proteins P_0 and PMP22 is increased by the treatment with PROG and its derivatives. The testosterone metabolite, dihydrotestosterone (DHT) is also capable of increasing P_0 mRNA levels, as are classical glucocorticoids. Since the androgen receptor (AR) is not found in SCs, studies have shown that DHT could exert a transcriptional activity through the PR instead, and also suggest that effects could additionally be mediated indirectly through neuronal AR. PROG, 5α-DHP, and 3α,5α-THP increase mRNA levels of P_0, whereas only THP can affect PMP22. The regulation of P_0 by THP is due to PR activation, because it is abolished by the PR antagonist mifepristone (RU486), but the stimulation of PMP22 expression by THP can be modulated only by agonists and antagonists of the $GABA_A$ receptor. This indicates the existence of distinct mechanisms for myelin synthesis. Interestingly, PROG, DHP, and THP have also been found to influence the expression of $GABA_B$ subunits in SCs, revealing complex cross-reaction

between the GABAergic receptor system with neuroactive steroids. The expression of hormone receptors is summarized in Table 2.

Schwann Cell Receptors in Disease and Repair

Peripheral nerves possess remarkable regenerative capacity. Following injury, axons and their myelin sheaths distal to the lesion deteriorate by a process known as Wallerian degeneration, leaving behind dividing Schwann cells, which produce, and respond to, a large number of factors crucial for regeneration of nerve fibers. IGF-1 from infiltrating macrophages interacts with the SC IGF-1 receptor, resulting in increased SC mitogenesis, which is important for regrowth following nerve transection. Erythropoietin (Epo) and its receptor are upregulated in nerves and SCs, respectively, during Wallerian degeneration, and recombinant Epo has been found to promote SC proliferation. VIP, CGRP, and peptide histidine isoleucine (PHI) are upregulated in many sensory neurons after injury; CGRP stimulates SC proliferation, while local administration of VIP after nerve transection accelerates early myelination and regrowth of axons, a process which may involve VIP-induced laminin synthesis in SCs. Parathyroid hormone-related peptide (PTHrP) upregulated in DRG and injured sciatic nerve stimulates SC proliferation and migration along the axonal membrane, suggesting that PTHrP promotes SC dedifferentiation, an important requirement for successful nerve regeneration.

PROG and pregnenolone increase remyelination of lesioned peripheral nerves, a process that is inhibited by trilostane (which blocks the conversion of pregnenolone to PROG) or by RU486 (which blocks the PR). Transected nerves reexpress TRα1 in the degenerating part of the nerve. Thyroid hormone is likely to act both on axotomized neurons and SCs during regeneration: local treatment with T3 following sciatic nerve transection results in increased numbers of myelinated axons of larger diameters and which possess thicker myelin sheaths.

Although inflammatory responses are important for SC dedifferentiation and removal of myelin debris, evidence also suggests that prolonged inflammation can inhibit SC proliferation and repair. Delivery of antiinflammatory proopiomelanocortin (POMC) peptides *in vivo* improves nerve regeneration after PNS injury. Stimulation of melanocortin-1 receptors with α-melanocyte-stimulating hormone (α-MSH) inhibits cytokine-induced nuclear factor-kappa B (NF-κB) activity in SCs, and may improve healing after injury. In addition, focal inflammatory reactions alone can cause neuropathic pain despite minor structural damage to axons or glia. The G-protein-coupled receptor GPR7, a member of the somatostatin-3 receptor family resembling the mu, delta, and kappa opioid receptors, is restricted to MSCs that contribute to fibers conveying mechanical perceptions and pain. GPR7 is significantly upregulated in SCs in immune-mediated neuropathies, and may be directly involved in modulating pain. GPR7 thus represents one of many potential targets in the development of therapeutic strategies for inflammatory PNS disorders.

Summary

Oligodendrocytes and Schwann cells are well-characterized glial lineages expressing numerous receptors for neurotransmitters and hormones; these receptors enable oligodendrocytes and Schwann cells to respond to developmental, pathological, and regenerative cues from neuronal synapses, axons, circulating immune cells, and even glial cells. The majority of signals which regulate lineage progression and myelin gene expression during development are also important modulators of disease and repair. An understanding of signal transduction mechanisms utilized by these receptors, and others yet uncharacterized, on these cells remains central to the design of effective therapeutic strategies in injury and myelin-associated disorders.

Astrocyte Excitation Leads to Release of Gliotransmitters

Astrocytes are 'excitable' in the sense that, when activated by internal or external signals, they deliver specific messages to neighboring cells – an activity that has been dubbed 'gliotransmission.' However, astrocytes cannot generate action potentials. Their excitation, which is chemically encoded, can be revealed not by electrophysiology, as in neurons, but by assays of $[Ca^{2+}]i$ transients and oscillations. Two main forms of astrocyte excitation are well documented: one that is generated by chemical signals in neuronal circuits (neuron-dependent excitation) and one that occurs independently of neuronal input (spontaneous excitation). Neuron-dependent excitation of astrocytes has been reported in many brain circuits following nerve fiber stimulation and the release of various transmitters and factors such as glutamate, γ-aminobutyric acid (GABA), acetylcholine, noradrenalin, dopamine, adenosine 5′-triphosphate (ATP), nitric oxide, and brain-derived neurotrophic factor (BDNF). The transfer of information from neurons to glia occurs through the spill-over of synaptically released transmitters, and probably also by direct synaptic-like communication in which astrocytes represent atypical postsynaptic cells. The binding of neurotransmitters to specific receptors in astrocytes generates $[Ca^{2+}]i$ elevations whose properties, including amplitude, frequency, and propagation, are governed by the intrinsic properties of both neuronal inputs and astrocytes. Spontaneous excitation is an unexpected property of astrocytes that has been observed both in acute brain slices and *in vivo*. It occurs in most astrocytes during development and decreases considerably during the first two postnatal weeks, when synaptic circuit formation occurs. However, spontaneous astrocytic $[Ca^{2+}]i$ oscillations seem not to fully disappear with adulthood. They are generated by Ca^{2+} release from internal stores when inositol 1,4,5-trisphosphate (Ins(1,4,5)P3) receptors are activated, with additional influx of extracellular Ca^{2+}.

An important response of astrocytes to their excitation, both by neuronal input and by self-generated stimuli, is the release of gliotransmitters – chemicals that act on adjacent neurons, glial cells, and blood vessels (Figure 1).

What Is a Gliotransmitter?

Gliotransmission was first revealed in 1994 when increases in $[Ca^{2+}]i$ in cultured astrocytes were shown to induce glutamate release followed by neuronal activation. However, a precise definition of gliotransmitters is missing. Here, we propose the following criteria for molecules released by astrocytes: (1) synthesis by and/or storage in the astrocytes; (2) regulated release triggered by physiological stimuli; (3) activation of rapid (milliseconds to seconds) responses in neighboring cells; and (4) a role in physiological processes. Over the years, the number of proposed gliotransmitters meeting these criteria has increased, and their properties have, in part, been unraveled (Table 1). In the following we focus on the mechanisms of their release.

Regulated Gliotransmitter Exocytosis

Exocytosis – the rapid form of transmitter release that is typical of neurons and neurosecretory cells – consists of the fusion of specific, membrane-bound vesicles with the plasma membrane, followed by the quantal discharge of their content. Whether a process of this type also occurs in astrocytes and accounts, at least in part, for gliotransmission has long been debated. Over the years, three main lines of indirect evidence have accumulated in support of exocytotic release:

1. The identification in astrocytes of crucial molecular components of the exocytotic machinery of secretory cells, in particular of the three proteins forming the core complex for membrane fusion, the soluble NSF-associated protein receptor (SNARE) proteins.

In neurons these are (a) the vesicle-associated membrane protein 2 (VAMP2; also called synaptobrevin II), exposed at the vesicle surface and defined as a v-SNARE, (b) the synaptosome-associated protein of 25 kDa (SNAP25), and (c) syntaxin1, with the latter two protruding from the plasmalemma into the cytoplasm and defined as t-(target-)SNAREs.

2. The observation that Ca^{2+}-dependent transmitter release in astrocytes – notably glutamate release – is sensitive to blockers of neuronal exocytosis. Such blockers include (a) the clostridial toxins, tetanus, and botulinum neurotoxin, which are Zn^{2+}-dependent endopeptidases that inactivate specifically the SNARE proteins and (b) the macrolide antibiotic Bafilomycin A1, a selective inhibitor of the vesicular proton pump (v-ATPase), which provides the driving

Figure 1 Chemical gliotransmission. Schematic representation of an astrocyte sending chemical signals to various types of cell sitting in its local territory of influence (gliotransmission). As depicted, astrocytes can release a variety of chemical gliotransmitters, some of which act preferentially on a specific cell type. Moreover, astrocytes can release gliotransmitters via several different mechanisms (see text) that probably represent distinct modes of action. Some such modes have been proposed to occur only in pathological conditions, whereas others would underlie physiological regulatory functions of astrocytes, for example, the control of synaptic transmission and of local blood flow.

force for uptake and accumulation of transmitters into synaptic vesicles.

3. The observation that a stimulant of exocytosis from synapses and neurosecretory cells such as PC12, the black widow spider toxin, α-latrotoxin, stimulates glutamate release from the astrocytes.

For a long time the preceding indirect evidence was counterbalanced by the lack of direct evidence for a specific vesicular population competent for regulated exocytosis. Recently, however, a clear synaptic-like microvesicle (SLMV) compartment, which is equipped for the uptake, storage, and release of glutamate, has been identified in adult hippocampal astrocytes by immuno-electron microscopy, and Ca^{2+}-dependent exocytotic fusion events have been documented in astrocyte cultures by several independent approaches, including total internal reflection and confocal fluorescence imaging, membrane capacitance, and electron carbon fiber measurements. Morphologically, astrocytic SLMVs *in situ* appear as clear vesicles resembling in size (30–50 nm) and rounded shape the synaptic vesicles present in glutamatergic nerve terminals. However, astrocytic SLMVs have a much less dense and orderly arrangement. In perisynaptic cell expansions, small, loosely arranged SLMV groups are often distributed just beneath the plasma membrane, opposite neuronal terminals or dendrites, and sometimes within synaptic distance of neuronal *N*-methyl-D-aspartate (NMDA) receptors (NMDARs). These astrocytic SLMVs express proteins that govern glutamate exocytosis – that is, the v-SNARE vesicle-associated membrane protein 3 (VAMP3, also known as cellubrevin), an analog of VAMP2/synaptobrevin II, together with vesicular glutamate transporters (VGLUTs). The three known VGLUT isoforms (VGLUT1–3) are all expressed by astrocytes, although not by all astrocytes. This indicates either that there are VGLUT-positive and VGLUT-negative astrocytes or that various VGLUT isoforms are distributed over distinct subpopulations of astrocytes, as has been observed in neurons. VGLUT-bearing SLMVs have also been identified at the electron microscopic level in cultured astrocytes, where they present a more heterogeneous size distribution (between 30 and 80 nm) and express VAMP2/synaptobrevin II together with VAMP3/cellubrevin.

Functionally, astrocytic exocytosis has peculiar properties when compared to exocytosis at neuronal synapses. Although an accurate analysis has not been yet performed, the stimulus-secretion coupling

Table 1 The repertoire of gliotransmitters

Gliotransmitter	*Cellular storage site*	*Regulated release mechanism*	*Release stimulants and modulators*	*Site of action (receptors)*	*Cell targets and effects*
Glutamate	SLMV	Ca^{2+}-dependent exocytosis	Glutamate, GABA, ATP, PG, TNFα SDF-1α, spontaneous astrocytic excitation	mGluR AMPAR KainateR NMDAR	Astrocytes, neurons (mostly stimulation)
	Cytosol	(activation of channels and/or transporters)			
ATP	DCG?	Ca^{2+}-dependent exocytosis?	ATP, glutamate, dopamine, LPA, thrombin	P2Y; P2X	Astrocytes, microglia, neurons, blood vessel cells? (mostly stimulation)
	Cytosol	(activation of channels and/or transporters)			
Adenosine		Ectonuclotidase-mediated ATP dephosphorylation	ATP, glutamate, dopamine, LPA, thrombin	A1, A2	Neurons (mostly inhibition)
	Cytosol	(activation of channels and/or transporters?)			
D-serine	SLMV?	Ca^{2+}-dependent exocytosis	Glutamate	NMDAR (glycine site)	Neurons (stimulation)
Eicosanoids (PG; HETE)	Not known to be stored	Ca^{2+}-dependent synthesis followed by rapid release	Glutamate, ATP, TNFα, SDF-1α, noradrenaline	Eicosanoid receptors	Astrocytes, blood vessel cells (stimulation, vasodilation/contraction)
Cytokines (TNFα)	Cell surface	Ca^{2+}-dependent, TACE-mediated surface proteolysis	ATP, SDF-1α	TNFα receptors	Astrocytes, neurons (stimulation)
Proteins and peptides (AchBP; ANP; others?)	DCG	Ca^{2+}-dependent exocytosis	Ach (for AchBP)	Ach binding; ANP and other peptide receptors	Neurons (AchBP: inhibition)

Only the agents responding to the four criteria discussed in the text have been included in this table. Several other agents, including taurine and homocysteic acid, are also considered to be gliotransmitters; however, for them the evidence is less complete.
PG, prostaglandin; HETE, 20-hydroxyeicosatetraenoic acid; TNFα, tumor necrosis factor α; AchBP, acetylcholine-binding protein; ANP, atrial natriuretic peptide; SLMV, synaptic-like microvesicle; DCG, dense-core granule; TACE, TNFα-converting enzyme; mGlu-R, metabotropic glutamate receptor; AMPA-R, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid glutamate receptor; NMDA-R, *N*-methyl-D-aspartate glutamate receptor; P2X, P2Y, purinergic 2X and 2Y receptors; SDF-1α, stromal-derived factor 1α, a chemokine; LPA, lysophosphatidic acid.

mechanism in astrocytes seems to be significantly slower (tens of milliseconds) and the Ca^{2+} affinity of the release machinery higher (in the nM range). Gliotransmitter release is triggered not by the action potential-induced opening of specific presynaptic Ca^{2+} channels, but by the activation of G-protein-coupled receptors (GPCRs), with ensuing Ins(1,4,5) P3-induced Ca^{2+} release from the stores of the endoplasmic reticulum. Among GPCR-evoked processes in various cell types, exocytosis of SLMVs in astrocytes appears to be the fastest, which suggests that endoplasmic reticulum cisternae are close to the vesicular release sites. Differences between gliotransmitter and neurotransmitter release might also arise from differences in the molecular components of the exocytotic machinery expressed by neurons and astrocytes, including different isoforms of SNARE proteins. Single-cell polymerase chain reaction after reverse transcription (RT-PCR) studies, performed *in situ* and in freshly isolated astrocytes, and high-resolution immunocytochemistry have documented the expression of four exocytotic proteins: SNAP23, a synaptic t-SNARE, complexin 2, Munc18a, and synaptotagmin IV. By contrast, SNAP25 and the synaptic vesicle proteins synaptotagmin I, synaptophysin, and synaptic vesicle glycoprotein 2 (SV2) were not found. Functionally, VAMP3 can be a substitute for VAMP2, whose expression in tissue astrocytes remains controversial. SNAP23, instead of SNAP25, could enhance the Ca^{2+} sensitivity of

exocytosis. The role of synaptotagmin IV instead of synaptotagmin I, the Ca^{2+} sensor for exocytosis of synaptic vesicles in nerve terminals, cannot be easily deciphered. The contribution of synaptotagmin IV to the Ca^{2+}-sensing mechanism has been recently questioned, but it has been reported that this protein favors a kiss-and-run mechanism – that is, the incomplete exocytotic fusion associated with fast vesicle recycling. Indeed, electron carbon fiber measurements of dopamine-loaded astrocytes suggest that kiss-and-run rather than full fusion could be the main mechanism of astrocytic vesicle fusion in response to physiological stimuli. Each kiss-and-run event would release only a small fraction of the total vesicle content, permitting multiple rounds of evoked releases without vesicle refilling.

Together with SLMVs, larger (100–700 nM), heterogeneous organelles are present in cultured astrocytes, some of which contain secretogranin II, a typical marker of neuronal dense-core secretory granules (DCGs). They also contain ATP. Interestingly, genetic manipulations aimed at preventing formation of the SNARE fusion complex in astrocytes *in vivo* led to reduced extracellular levels of adenosine, a metabolic product of ATP, consistent with the possibility that ATP is released from astrocytes via exocytosis of DCGs and then is rapidly transformed into adenosine by the action of specific extracellular enzymes, the ectonucleotidases. Lysosomes would be a further source of ATP release. Not only nucleotides but also peptides, such as the atrial natriuretic peptide (ANP), could be released from organelles that are distinct and regulated differentially from glutamatergic SLMVs. By contrast, D-serine, a potent co-agonist of glutamate at the NMDAR glycine-binding sites thought to be produced selectively in astrocytes, was recently reported to co-localize with markers of SLMVs, and could, therefore, be co-released from the vesicle population that is responsible for glutamate release. Functionally, this combination could be highly effective in activating NMDARs. These observations, although potentially important in view of the coordinate or antagonistic functional roles of the different gliotransmitters, should be interpreted at the present stage with caution because most of the observations have been made in cell cultures *in vitro* that only partially reproduce the specific gliotransmission properties of astrocytes in their native tissue environment. For example, VGLUT heterogeneity disappears *in vitro*, and all cultured astrocytes express multiple isoforms of the transporter together with various secretion-related proteins that are absent from tissue astrocytes. In addition, the levels of some of these proteins change with time in culture. More studies utilizing preparations *in situ* will therefore be necessary to confirm and clarify the heterogeneity and specific properties of the regulated exocytotic pathways in astrocytes.

Modulation of Gliotransmitter Exocytosis

Exocytotic gliotransmission is probably not a simple consequence of increases in $[Ca^{2+}]i$. Indeed, several distinct stimuli that all induce large $[Ca^{2+}]i$ responses evoke different transmitter release responses. Important regulatory mechanisms seem to exist, and, in some cases, GPCR-induced glutamate release was found to be strongly attenuated by blocking the synthesis of prostaglandins, tumor necrosis factor-α (TNFα), or both.

The role of these mediators is unclear. They could contribute to one or several of the following processes: (1) Ca^{2+} release from the internal stores triggering vesicle fusion; (2) priming of the secretory process itself; and (3) amplification of the whole cascade by autocrine/paracrine loops. Astrocytes lacking TNFα signaling display alterations of GPCR-evoked $[Ca^{2+}]i$ elevations, including reduced and slower Ca^{2+} peaks, suggesting that TNFα contributes to the shaping of GPCR-dependent $[Ca^{2+}]i$ elevations, although it is not strictly indispensable for their generation. It remains to be defined whether the release of prostaglandins and TNFα is part of the stimulus-secretion coupling mechanism triggered by GPCR stimulation or whether these agents are released tonically and set the appropriate basal conditions for efficient $[Ca^{2+}]i$ elevations and glutamate release. Evidence for both modes exists.

Interestingly, gliotransmitter release can be modified by concomitant activation of distinct receptors, with ensuing positive or negative cooperativity. For example, activation of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors, which does not stimulate glutamate release *per se*, was found to potentiate metabotropic glutamate receptor (mGluR)-evoked release and strengthen mGluR-dependent prostaglandin E2 (PGE2) production, possibly through transactivation of epidermal growth factor receptors (ErbB receptors). By contrast, the interaction between mGluRs and α1-noradrenergic receptors is an example of negative cooperativity. The $[Ca^{2+}]i$ elevations induced by the latter fail to stimulate glutamate release, but instead suppress a coincident mGluR-evoked release.

Nonexocytotic Gliotransmitter Release

Molecular transport across the plasma membrane through specialized proteins such as channels and transporters represents a second modality by which hydrophilic agents can be released from cells. Three types of large plasma membrane channel have been

claimed to participate in the nonexocytotic release of gliotransmitters from astrocytes, in particular of ATP and glutamate: (1) volume-regulated anion channels (VRACs), (2) gap junction hemichannels, and (3) purinergic P2X7 receptors.

1. The existence of specific VRACs was deduced from the observation that anionic amino acids, such as glutamate, aspartate, and taurine, are released in a nonvesicular, Ca^{2+}-independent fashion when astrocytes swell, notably in hypotonic media. Recent work raises the possibility that GPCR-evoked $[Ca^{2+}]i$ elevations may also trigger release of anionic amino acids including glutamate through VRACs. One important caveat concerning this release pathway is the fact that the molecular identity of VRACs is still unknown and the existence of such channels is generally inferred via pharmacological studies. However, drugs used as VRAC antagonists are not specific; for instance, they inhibit gap-junction hemichannels (see next listed item). In addition, these drugs affect anion channels in synaptic vesicles and prevent loading of transmitter into the vesicles. Therefore, identification of VRACs based on pure pharmacological criteria is inadequate. An additional, more solid criterion consists of the direct electrophysiological recording of the ion current generated by the passage of anionic gliotransmitters such as glutamate through the plasma membrane channels. Such currents have been recorded, however, only when high glutamate concentrations were added to the patch pipette. Therefore, it remains to be established whether the channels would drive significant glutamate release at the physiological cytosolic concentrations of the amino acid, about 50-fold lower than those used so far.

2. Gap-junction hemichannels, also known as connexons, are large (1–1.2 kDa), nonselective ion channels formed by hexamers of connexin 43 (CX43) that assemble in astrocytes and might function as autonomous permeation pathways instead of being coupled with a hemichannel of an adjacent cell to form a gap junction. The opening probability of the hemichannels, which is very low in astrocytes bathed in physiological media, increases significantly by reducing the concentrations of divalent cations, notably of Ca^{2+}, and was reported to be accompanied by the release of both ATP and glutamate. The involvement of hemichannels is consistent with the suppression of the release of these gliotransmitters by gap junction channel blockers (but see the following) and, in the case of ATP, by the absence of release in a glial cell line that lacks CX43, with restoration after transfection of the connexin.

3. The purinergic P2X7 receptor, which has been proposed to be an additional source of glutamate and ATP release, shares several properties with hemichannels, including an increased open probability at low extracellular Ca^{2+} concentrations. Moreover, recent work has shown that P2X7 receptors (900 Da) are blocked by the so-called gap-junction channel blockers, indicating that use of such agents cannot discriminate between gliotransmitter release via hemichannels and that via P2X7 receptors. This observation calls for a reconsideration of the interpretation of several previous studies. However, the pharmacology of P2X7 receptors has some additional and distinctive features with respect to those of connexin hemichannels: P2X7 is activated by ATP at high concentrations (EC50 $= 300\,\mu M$) and by 3′-*O*-(4-benzoylbenzoyl) ATP (BzATP) at lower concentrations and can be blocked by oxidized ATP but not by suramin. It is not clear whether the high ATP concentrations needed for P2X7 gating can be reached extracellularly in the healthy brain. Alternatively, prolonged activation of P2X7 channels in pathological conditions could lead to the release of cytosolic proteins and cell death.

Plasma membrane transporters may represent additional sources of gliotransmitter release. Among them are: (1) the ATP-binding cassettes (otherwise known as multidrug resistance transporters); (2) the high-affinity plasma membrane glutamate carriers, working in reverse mode; (3) the cystine/glutamate exchanger; and (4) the equilibrative nucleoside transporters (ENTs).

1. The ATP-binding cassettes have been proposed to account for the swelling-induced release of ATP; however, the evidence is still preliminary.

2. Reversal of high-affinity plasma membrane glutamate carriers is unlikely to occur during normal brain function, but probably is a main source of excitotoxic extracellular glutamate accumulation under ischemic conditions. Although most of the glutamate carriers are expressed in astrocytes, the neuronal carriers seem to strongly contribute to ischemic glutamate release: glutamate levels are higher in the neuronal than in the astrocytic cytosol, and this condition favors functioning in reverse mode.

3. Another source of glutamate release could be by the cystine/glutamate exchanger, a candidate for the cytosolic accumulation of cystine that is necessary for the synthesis of glutathione, one of the main endogenous antioxidants. Whether the extracellular concentrations of endogenous cystine are high enough to trigger the exchanger activity and whether its glutamate release occurs from astrocytes are unclear.

4. ENTs passively transport adenosine through cell membranes in either direction depending on the intra- and extracellular adenosine concentration through facilitated diffusion. Isoforms of these transporters

are expressed in astrocytes. Although under physiological conditions adenosine is mainly formed extracellularly, upon release of ATP from the astrocytes followed by ecto-nucleotidase-dependent catabolism, and ENTs mainly act as reuptake system for the nucleoside, under hypoxic conditions adenosine is formed inside the astrocytes, probably via the action of cytosolic nucleotidases, and released via a nonexocytotic process that is inversely controlled by $[Ca^{2+}]i$, that is, is suppressed by $[Ca^{2+}]i$ elevation. ENTs might play a role in such a release, although no direct evidence exists at present.

In conclusion, current evidence indicates that some gliotransmission might occur through channels and transporters; however, many aspects of these processes need to be clarified. Most importantly, it should be determined whether these processes occur under physiological conditions and, in this case, how relevant they are, especially because no mechanisms that account for their specificity and regulation have been identified.

Alternatively, several of these mechanisms could play roles in a variety of pathological conditions. At present, the results of numerous studies in the field are still inconclusive because of poor pharmacology and/or because the available information about the participating transport proteins is insufficient, preventing accurate molecular analysis of localization and function *in situ*.

Neurotransmitter Release: Synchronous and Asynchronous

R Grantyn and S Kirischuk, Humboldt University Medical School (Charité), Berlin, Germany

© 2009 Published by Elsevier Ltd.

Introduction

More than 50 years ago, Fatt and Katz showed that an action potential (AP) arriving at the frog neuromuscular junction releases the chemical neurotransmitter ACh in multimolecular packages which they called quanta. By that time, the quantum was detected on the basis of the conductance change induced in the follower cell – that is, the postsynaptic response which either occurred as an AP evoked response or as miniature postsynaptic activity ('mini'). Minis were recorded when AP generation was prevented by blocking voltage-activated sodium channels with tetrodotoxin (TTX). Fluctuating evoked responses were observed when lowering the ratio of extracellular Ca^{2+}/Mg^{2+} concentration. In this way, the AP-induced multiquantal end plate potential could gradually be decomposed to postsynaptic potentials containing increasingly fewer quanta, down to one quantum which equaled the mini.

Based on these observations, del Castillo and Katz assumed that the spontaneous asynchronous mini activity is the product of the same release machinery as the quantum in the AP-induced evoked postsynaptic response. In other words, evoked transmitter release was attributed to the synchronous occurrence of the same quanta that constitute mini activity. Thus, the evoked release would merely reflect a massive acceleration of spontaneous release. Whether or not this assumption is correct is the main topic of this article.

Definitions

In the central nervous system, one presynaptic nerve cell typically forms hundreds or thousands of synapses with multiple follower cells. The structural definition of a synapse commonly refers to one specialized contact comprising, on the presynaptic side, between one (some hippocampal inhibitory neurons) and hundreds (calyx of Held) of active zones and, on the postsynaptic side, a corresponding number of postsynaptic specializations that contain the transmitter receptors at high density. The set of synapses formed between two neurons is commonly referred to as a synaptic connection. The number of vesicles released at one synaptic connection varies, similar to the neuromuscular junction, in a quantal manner, with the variance of the release process being smaller the larger the number of active zones contained in the connection between two cells. The total number of quanta released by one presynaptic cell to one follower cell is called the quantum content of a synaptic response, and the total amount of transmitter released is given by the product of the quantum content and the number of transmitter molecules per quantum. Thus, the quantal content can be viewed as the presynaptic indicator of synaptic strength. When it is not possible to record unitary postsynaptic responses (i.e., the response to activation of just one synaptic connection), the frequency of minis is often taken as an indirect estimate of synaptic strength. This again rises the question to what extent observations made with minis are attributable to mechanisms of evoked release.

However, before going into greater detail, it is necessary to agree on a stricter use of the respective terminology because terms such as 'asynchronous release,' 'mini activity,' 'tonic release,' and 'spontaneous release' are often used interchangeably. Furthermore, it is not always clear whether the terms 'asynchronous' or 'spontaneous' refer to what is to be regarded as constitutively active quantal release (i.e., a form of release that can be distinguished by being Ca^{2+} independent).

Because Ca^{2+} concentration in presynaptic terminals and Ca^{2+} sensitivity of the exocytotic machinery are the two most critical determinants of the speed of fusion, Ca^{2+} sensitivity of postsynaptic activity may serve to distinguish between four different modes of the underlying release process: the highly synchronous AP-evoked response (with a K_D of $\sim 10\,\mu M$; data from calyx of Held); the asynchronous delayed response, as induced by high-frequency AP generation (or prolonged presynaptic depolarization) ($K_D \sim 1.5\,\mu M$; data from GABAergic synapses in culture); mini activity ($K_D < 1\,\mu M$); and constitutively active release (no Ca sensitivity). The release underlying the first three modes can, in a broad sense, be referred to as 'regulated,' whereas the constitutively active release is 'unregulated.'

The capacity for constitutively active release in the form of quanta might be a property of many, if not all, cells and is to be expected if the cytosolic concentration of a molecule reaches a critical level. For instance, by using appropriate cellular sensors, Poo and colleagues demonstrated that muscle cells loaded with the neurotransmitter acetylcholine soon start secreting this foreign transmitter in a pulsatile manner reminiscent of minis.

Minis are still to be defined as synaptic responses to transmitter release in the absence of AP generation. As in the original experiments on the frog neuromuscular junction, they are recorded in the presence of TTX. The term 'spontaneous synaptic activity' is commonly reserved for postsynaptic events recorded in the absence of TTX. This activity may therefore reflect all four forms of release.

An interesting question is whether or not minis always reflect a completely stochastic release process. By applying nonlinear methods to quantify any detected determinism in spontaneous release, Walmsley and colleagues presented evidence for the nonrandom nature of spontaneous inhibitory postsynaptic currents in mouse auditory neurons, which suggests that minis might not be very 'spontaneous' in their origin.

In any case, minis should not be equaled with basal constitutively active transmitter release, because in most neurons their frequency displays clear sensitivity to changes in extra- and intracellular Ca^{2+} concentration and to activation of presynaptic membrane receptors with access to intracellular Ca^{2+} signaling pathways at 'resting' conditions. However, mini activity recorded from single synapses under physiological Ca^{2+} concentration may include a fraction of exocytotic events that are Ca^{2+} independent and therefore fall into the category of constitutively active secretion. To isolate this type of mini activity, it might be necessary to inactivate some of the molecular elements that provide Ca^{2+} sensitivity to the fusion process. Also, as an approximation, one may acquire the minis which persist in Ca^{2+}-free extracellular salt solutions. In cortical cultures, only a very small percentage of synapses (~1% according to Murphy and colleagues) are able to sustain spontaneous release in the absence of Ca^{2+}. The very scarce Ca^{2+}-independent spontaneous activity can, however, be enhanced by manipulations such as application of hyperosmolar solutions or α-latrotoxin.

Possible Function of Asynchronous Mini Activity

The prevailing viewpoint is that synchronous evoked and asynchronous mini activity serve distinct functions and have a different origin. It is obvious that the synchronous evoked release is the major means to transmit a precise temporal pattern of presynaptic activity to the follower cell. Therefore, the underlying fusion activity is the most tightly controlled form of release. This tight control generally results in a rather low probability of vesicle release (~0.1–0.3), so that upregulation and also some downregulation can occur. In the course of synapse development, this form of release is achieved with some delay after an initial period during which release is more asynchronous.

Concerning minis, data are accumulating in favor of the idea that this form of asynchronous synaptic activity has its specific function in the maintenance of synapses. The group of Gähwiler and Thompson compared the effect of TTX and clostridial toxins on developing hippocampal neurons in slice cultures from the rodent brain. Because TTX prevented evoked release, whereas treatment with BoNT prohibited any form of release, they were able to examine the relative impact of synchronous evoked versus asynchronous mini release on synapse formation and maintenance. They concluded that maintenance of dendritic spines critically depends on the generation of mini activity, whereas evoked release is not required. Other studies supported the idea that mini activity may have a 'trophic' function, even though in intact brain preparations the mini frequency is typically rather low (typically 1–5 s^{-1}). Considering that one hippocampal neuron carries approximately 50 000 synapses, one has to conclude that only one quantum every 3 h can keep a synapse in place. On the other hand, it might suffice that a dendritic branch or an entire dendrite 'sees' an active presynaptic terminal. Schuman and colleagues showed that NMDA receptor-mediated minis stabilize synaptic function through active suppression of dendritic protein synthesis.

The notion that mini activity represents a specific form of synaptic communication is further supported by the observation that appropriate activation of presynaptic nicotic acetylcholine receptors, metabotropic glutamate receptors, or TrkB receptors (the receptors for the brain-derived neurotrophic factor), among others, can influence the activity of the follower neuron. Of course, the conductance change associated with the release of a single vesicle is quite small (105–180 pS for the AMPA receptor response to a glutamate-containing vesicle and 105–135 pS for a GABA-containing vesicle), but there are synaptic connections in the central nervous system that solely operate by releasing at the most one quantum per AP. Also, experiments have shown that this may be enough to modify the activity of the target cell, especially if the latter has a high input resistance. Regehr and colleagues showed that in cerebellar stellate cells single inhibitory quanta suppressed firing, whereas coincident excitatory quanta reliably and rapidly triggered firing. However, even in the relatively low resistance neurons of the cerebral cortex, nicotinic input (smoking) was shown to influence mini activity to a degree that cortical networks could be affected.

Together, these data justify a closer examination of the origin of minis as opposed to evoked transmitter release.

Different Vesicle Pools for Synchronous and Asynchronous Release?

Since the times of Katz, enormous effort has been focused on the characterization of distinct vesicle pools since it has become obvious that the individual vesicles vary with regard to their distance to the active zones, the site of presynaptic Ca^{2+} channel clusters, the release kinetics of directly monitored individual fusion events, and the incidence of labeling of endocytosed vesicles with styryl dyes. Most important, some vesicles are more readily released than others. The question arose of whether or not minis are preferentially generated by a distinct, more 'reluctant' vesicle pool. This pool would be replenished at rest and release vesicles more slowly than the readily releasable pool of vesicles. However, when vesicles were labeled with different styryl dyes during rest and activity, it became clear that there is a significant amount of cross-depletion of both vesicle pools, which supports the idea that synchronous AP-mediated and asynchronous mini release draw upon the same vesicle pool.

Differential Molecular Control of Synchronous versus Asynchronous Release?

In 1971, Quastel et al. suggested the existence of a final step in exocytosis that is not dependent on Ca^{2+}. Today, the experimental means exist to uncover the basal constitutively active spontaneous release by molecular manipulations. As a rule, evoked release is prohibited by deletion of individual components of the SNARE complex, such as VAMP2, syntaxin 1, or SNAP-25. All this spares some fraction of mini activity. Typically, the remaining mini activity exhibits low Ca^{2+} sensitivity. For instance, experiments with cultured hippocampal neurons revealed that in SNAP-25 knockouts the residual spontaneous release is Ca^{2+} independent, but it can be stimulated by hypertonic solution. It is also known that the key regulator of the SNARE complex, synaptotagmin, is required for Ca^{2+}-dependent synchronous release but not for mini activity. Of particular interest are experiments by Maximov and Südhof showing that synaptotagmin is also essential for the asynchronous delayed release after a stimulus train. This clearly indicates that asynchronous release activity is associated with the synchronous evoked release (Figure 1).

Figure 1 Synchronous and asynchronous forms of synaptic responses to activation of a single FM1-43-labeled synaptic terminal in culture. (a) Experimental scheme. One of two synaptic varicosities formed *en passant* by an axon crossing a dendrite is selected for direct electrical depolarization via a closely apposed patch pipette. The postsynaptic responses are recorded in the whole cell configuration from the nearby soma. (b) Phase contrast and FM1-43 fluorescence images of the respective view field ($10 \times 13.5\,\mu m$). (c) (Top) Presynaptic Ca^{2+} transient as acquired from the respective FM1-43 areas of the stimulated (B1) and nonstimulated (B2) boutons. In this case, Fura-2/AM was loaded for subsequent recording of the bulk Ca^{2+} signal as a measure of presynaptic activation. (Bottom) Corresponding single bouton-activated evoked inhibitory postsynaptic current (IPSC) in response to a very short (0.3 s) depolarizing pulse. (d, e) Superimposed traces of synchronous and asynchronous synaptic activity. The synchronous evoked IPSCs (eIPSCs) and asynchronous delayed IPSCs (dIPSCs), as well as the mini IPSCs (mIPSCs), were recorded in TTX. To elicit both eIPSCs and dIPSCs, the duration of the depolarizing pulse was prolonged to 3 ms.

However, all these data must not necessarily be interpreted as evidence for a totally distinct population of vesicles exclusively dedicated to asynchronous release as opposed to synchronous release. Whether a given vesicle is primed for evoked release or allowed to contribute to miniature activity may depend on the actual state of the fusion switch impacting this vesicle. Results obtained by the groups of Südhof and Rothman suggest that Ca^{2+} elevation enables synaptotagmin to remove a potent fusion-suppressive action of complexin on the SNARE complex. Complexins together with synaptotagmin 1 can be regarded as a fusion clamp that arrests vesicle secretion at rest but promotes synchronous fusion upon activity. According to this model, removal of the synaptotagmin/complexin break should increase the rate of constitutive exocytosis and, vice versa, overexpression of complexins should decrease Ca^{2+}-independent mini activity. The available experimental data are in accord with this proposal. Thus, the actual intracellular Ca^{2+} concentration remains the decisive determinant of the probability of release of any given vesicle. To what extent variable endowment/access of individual vesicles with various isoforms of the SNARE protein VAMP2 or regulatory proteins such as Rab3, RIM-1, and Munc-13 determines whether or not a vesicle is prone to contribute to mini activity remains to be elucidated.

Asynchronous Delayed Release as a Special Form of Evoked Release

After focusing on asynchronous mini release as opposed to synchronous evoked release, we may now regard an 'intermediate' form of release, namely the asynchronous delayed liberation of presynaptic vesicles in response to prolonged or repetitive presynaptic depolarization. Under physiological test conditions, asynchronous delayed release occurs during (or soon after) a burst of presynaptic APs. It is driven by an AP-induced presynaptic Ca^{2+} elevation that usually lasts much longer than an AP. Provided that the level of this Ca^{2+} increase is still high enough to initiate exocytosis (residual Ca^{2+} hypothesis), individual vesicles will be liberated even in the absence of a preceding presynaptic AP. Thus, similar to synchronous evoked release, asynchronous delayed release requires presynaptic activity. However, in contrast to evoked release, the latencies between the arriving APs and vesicle release are (1) in general much longer than a typical synaptic delay and (2) highly variable. The latter means that asynchronous delayed events display a rather stochastic behavior (i.e., they show similarity with mini activity). Indeed, the distribution of inter-event intervals in both cases is well fitted by a single exponential function (an approximate sign of the stochastic nature of the release process). Because the frequency of spontaneous postsynaptic responses is usually quite low, asynchronous delayed instead of truly spontaneous mini responses have often been used to estimate the quantal amplitude of a given postsynaptic response.

Typically, a train of APs is activated/applied to induce asynchronous delayed release. This stimulation protocol depletes the readily releasable pool of presynaptic vesicles and induces large and long-lasting presynaptic Ca^{2+} elevations. Consequently, only newly recruited vesicles mediate asynchronous delayed release. Because vesicle recruitment is a random process, asynchronous delayed activity is composed of monoquantal responses due to the release of single vesicles. Therefore, they are often called 'miniature-like' responses. However, and despite the fact that this approach can considerably speed up the estimation of quantal size, one has to consider and, if possible, avoid stimulation-induced modifications of presynaptic as well as postsynaptic characteristics of transmission (i.e., various expressions of long-term plasticity or postsynaptic receptor desensitization).

The physiological role of asynchronous delayed release is not fully understood. The observation that asynchronous delayed release at immature synapses is usually much stronger than in their mature counterparts led to the suggestion that this form of vesicle fusion may reflect immaturity of the presynaptic release machinery. For instance, the duration of asynchronous delayed currents elicited by 50 Hz trains at GABAergic synapses decreased in the superior colliculus from 2.5 s on postnatal day 0 to 1 s on postnatal day 22. Sensory deprivation in congenitally deaf mice also resulted in much higher asynchronous delayed release than in normally developing counterparts. However, in disagreement with the 'immaturity hypothesis,' many mature synapses display asynchronous delayed release as well, even after a single presynaptic AP. For instance, cerebellar granule cell synapses on Purkinje cells or stellate cells generate after a single spike asynchronous delayed release lasting hundreds of milliseconds. Synaptic terminals in hippocampal cultures release after a single AP vesicle with a time constant of decay of 200 ms.

It should also be considered that the physiological discharge pattern of many mature neurons is not a series of solitary APs, but it often comprises bursts of APs – a condition both necessary and sufficient to initiate asynchronous delayed release. At an interneuron-to-pyramidal cell synapse of the hippocampus, a single AP produces an asynchronous delayed response with a time constant of decay of 59 ms, whereas a train of 10 APs delivered at 50 Hz prolongs

the time constant of asynchronous delayed release to 230 ms. Auditory synapses in the chick brain stem display almost no asynchronous release at frequencies lower than 100 Hz, but at higher frequencies synaptic transmission during AP trains is mainly mediated by asynchronous release. Thus, one may conclude that, independent of the experimental preparation, high-frequency trains of 2–5 presynaptic APs have a good chance to induce an asynchronous delayed response.

Together, all these observations argue against the simple suggestion that asynchronous delayed release results from the imperfectness of release machinery. Instead, it is a complex, functionally relevant phenomenon that depends on a variety of presynaptic factors, including the availability of synaptic vesicles, Ca^{2+} sensitivity of the release machinery, and presynaptic Ca^{2+} signaling. Therefore, an individual presynaptic bouton appears not to function as a single compartment that probabilistically converts individual presynaptic APs into postsynaptic responses but instead as an integrator of many environmental and retrograde signals. This integration would affect the probability of not only evoked release but also all forms of asynchronous release. In addition, asynchronous delayed release provides a mechanism to influence follower cells for a prolonged period, after the presynaptic AP activity has subsided, and the strength of this influence would be determined both by the previous activity period and by newly arriving (retrograde or paracrine) signals.

Basics of Neurotransmitters

Neurological research interests over the past 50 years have shifted from the action potential activity of neurons to neuropharmacology. The study of neurotransmitters has been critical in understanding the molecular aspects of neuronal communication and disease. As the chemical messengers of the nervous system, neurotransmitters relay information across synapses via excitation or inhibition of the next neuron or effector tissue. Neurotransmitters can be classified into two broad categories, small-molecule neurotransmitters and neuropeptides. Small-molecule neurotransmitters, such as acetylcholine and the monoamines, are synthesized in the axon terminal of the neuron, and larger neuropeptides, such as somatostatin and vasopressin, are synthesized in the neuron's cell body. Following synthesis, neurotransmitters are transported to the axon terminal, where they are packaged into synaptic vesicles and stored.

An action potential is an electrical signal that is triggered by a stimulus and propagates along an axon. On the arrival of an action potential at the axon terminal, voltage-gated Ca^{2+} channels open to permit an influx of calcium ions. This depolarization of the axon terminal causes the synaptic vesicles to fuse with the presynaptic membrane. The density of voltage-gated Ca^{2+} channels increases with age; the neurotoxicity of the resulting excessive influx of calcium ions has been implicated in the loss of hippocampal neuron viability.

The neurotransmitters are released from the synaptic vesicles by exocytosis and diffuse across the synapse. Some are removed from the synapse by enzyme degradation or transported back to the presynaptic axon terminal, but others reach their specific neurotransmitter receptors on the postsynaptic membrane.

Types and Functions of Major Neurotransmitters with Respect to Aging and Disease

Catecholaminergic System

Dopamine Since Carlsson's research in the 1950s demonstrated that dopamine was a neurotransmitter, this catecholamine has been associated with multiple emotional and age-related behaviors, as well as neurodegenerative diseases. Neurotransmitters of the catecholaminergic system, which are synthesized through a common pathway starting with the amino acid tyrosine, belong to a wider class of substances called biogenic amines. After tyrosine is transported from the liver to catecholaminergic neurons and adrenal medullary cells, it is converted to L-dihydroxyphenylalanine (L-DOPA) by the enzyme tyrosine hydroxylase. Decarboxylation of L-DOPA produces dopamine, a neurotransmitter whose critical roles in movement are impaired in aging and neurodegenerative diseases.

Dopamine employs four major pathways distributed throughout the central and peripheral nervous systems. The nigrostriatal pathway originates in the substantia nigra in the midbrain and regulates the region of the basal ganglia responsible for controlling voluntary movement. The aging brain exhibits decreasing levels of dopamine, with the most reduction found in the putamen of the striatum in brains of patients with Parkinson's disease (PD). Damage to the substantia nigra also occurs in diseased brains, inhibiting the neurons of the thalamocortical circuit and producing motor symptoms such as tremors, bradykinesia, and rigidity. Because PD is a disease of aging, more cases are likely to arise in the future as the older population increases.

Dopamine also has implications in Alzheimer's disease (AD), though its exact roles have not been clearly established. About a third of AD patients eventually develop parkinsonian symptoms and exhibit a reduction in D_2, one of the two G-protein-coupled dopamine receptors, in the caudate and putamen. This is not observed in AD or PD alone, suggesting the existence of different regulatory mechanisms for dopamine receptors in these three conditions. Thus, although the functions of dopamine and the loss of dopaminergic receptors in PD have been well characterized, the implications of dopamine in other age-related diseases remain to be investigated.

Norepinephrine and epinephrine Another neurotransmitter of the catecholaminergic system is produced in synaptic vesicles when dopamine is converted to norepinephrine by dopamine β-hydroxylase. Noradrenergic cells in the central nervous system are most concentrated in the locus ceruleus of the brain stem. However, norepinephrine is more widely used in the sympathetic autonomic nervous system, where its release by postganglionic neurons is mediated by stress. In the adrenal medulla, epinephrine is derived from norepinephrine via phenylethanolamine *N*-methyltransferase. Though epinephrine is primarily released

into the blood as a stress hormone, it can also be used as a neurotransmitter. Norepinephrine and epinephrine's excitatory and inhibitory effects result in increased heart rate, dilation of the bronchi and pupils, and contraction of blood vessels in the skin.

PD often results in failure of the sympathetic nervous system, making patients vulnerable to falls. A common symptom is orthostatic hypotension, caused by impaired constriction of blood vessels due to sympathetic denervation in one or several regions of the heart. Sympathetic denervation occurs in most PD patients with or without accompaniment of orthostatic hypotension. Recent studies show that patients also experience sympathetic denervation in the kidneys and thyroid. Because norepinephrine and epinephrine are derived from dopamine, research on the origins of sympathetic denervation in PD may help in understanding the causes of dopaminergic neuron death.

The adrenergic systems of the central nervous system also have implications in AD pathophysiology. Degeneration of adrenergic neurons in the locus ceruleus expressing C1 adrenergic receptors causes the adrenergic system to compensate for the loss by increasing production of epinephrine in the cerebrospinal fluid (CSF). Such increases in CSF epinephrine levels reportedly correlate with severity of dementia in AD patients. In addition, increased density of α- and β-adrenergic receptors found in postmortem brain tissues of AD patients with symptoms of aggression indicates that aggressive behaviors in AD can be attributed to increased activity of the central adrenergic system.

Aging increases sympathetic activity and reduces norepinephrine uptake due to changes in the morphology of adrenergic receptors. Furthermore, stress causes activation of β1-adrenergic receptors that mediate endothelial cell injury, leading to atherosclerosis. Such chronic events in which stress responses are enhanced make age a risk factor for cardiovascular conditions such as hypertension, ventricular arrhythmias, and heart failure.

Serotonergic System

Loss of serotonin has profound implications in the emotional changes that accompany aging. Serotonin, or 5-hydroxytryptamine (5-HT), is synthesized from the amino acid tryptophan by the enzymes tryptophan hydroxylase and 5-hydroxytryptophan decarboxylase. In the central nervous system, serotonergic neurons are found in the raphe nuclei of the brain stem and project to regions of the hypothalamus and spinal cord; they are also located in the enterochromaffin cells of the gastrointestinal tract. Serotonin monitors a wide range of functions, such as sleep, anxiety, digestion, memory, learning, sexual function, and depression.

Aging is associated with decreases in levels of serotonin type 2A receptor (5-HT_{2A}) binding sites in the hippocampus and frontal and occipital lobes. In postmortem brains, serotonin type 1A receptor (5-HT_{1A}) binding sites were also reduced in the hippocampus and frontal and temporal lobes. A decrease in receptor density is correlated with a higher incidence of depression in older people. Depression is an early symptom of neurodegenerative diseases such as AD and also exacerbates cognitive impairment. Since serotonin transporters remove serotonin from the synapse by facilitating uptake into the presynaptic neuron, many antidepressants block these transporters to maintain endogenous serotonin activity.

Reduction in serotonin levels in the central nervous system and CSF is observed in postmortem AD brains. In addition, neurofibrillary tangles commonly form, and neuronal death occurs in the raphe nuclei. There is also a decrease in the density of cortical 5-HT receptors, which associate with cholinergic nerve terminals in the hippocampus and cerebral cortex, as well as denervation of 5-HT receptors in the neocortex. These factors suggest impairment of the serotonergic system in this disorder, which occurs later than defects of the cholinergic system.

Almost half of all PD patients exhibit mild symptoms of depression, which in turn exacerbates anxiety and contributes to cognitive decline in patients without dementia. Depression possibly also occurs as a result of dopaminergic neuronal death and association of serotonergic circuits with dopaminergic circuits. A product of serotonin catabolism, 5-hydroxyindoleacetic acid, is not only depleted in PD patients' CSF but is also more greatly reduced in PD patients exhibiting symptoms of depression, indicating that serotonin loss causes depression in PD.

Cholinergic System

Acetylcholine is the main neurotransmitter implicated in age-associated memory impairment and AD, the most common neurodegenerative disorder, with both familial and sporadic cases. Synthesis of acetylcholine, the primary neurotransmitter of the cholinergic system, occurs by the action of choline acetyltransferase on choline and acetyl coenzyme A. At the synapse, acetylcholinesterase catabolizes acetylcholine to its metabolites, choline and acetate. Acetylcholine is a major neurotransmitter in the central nervous system, where it is crucial in synaptic plasticity and cognitive functions such as memory and learning; in the peripheral nervous system, it produces excitatory effects in the neuromuscular junction and inhibitory effects in cardiac muscle.

Acetylcholine receptors are divided into two major classes, nicotinic and muscarinic. The ionotropic nicotinic receptors are commonly found in the

neuromuscular junction, where they mediate sodium entry and regulate voluntary muscle contraction. Nicotinic receptors are also active in postganglionic neurons of autonomic ganglia. The metabotropic muscarinic receptors have their activity concentrated in the parasympathetic autonomic nervous system and cardiac muscle, regulating physiological functions such as heart rate, blood pressure, and pupil dilation.

Reduced cholinergic function and long-term potentiation (LTP), caused by decreased acetylcholine production or the impairment of both nicotinic and muscarinic M2 receptors, occur with aging and to a greater degree in dementia. The cholinergic hypothesis of AD states that these defects contribute to cognitive decline and neuronal death in the early stages of the disease; however, it is still undetermined whether reduced cholinergic activity contributes to neuronal death or merely reflects the neurodegenerative processes of dementia.

There is evidence that smoking, during which the cholinergic agonist nicotine stimulates nicotinic receptors in the brain, is neuroprotective against AD. The neuroprotective properties of nicotinic receptors are most associated with those containing the α7-subunit, which protect the spinal cord and hippocampus, and the high-affinity receptors containing α4/β2-subunits, which protect the cortex and striatum. Activation of nicotinic receptors also increases levels of fibroblast growth factor in the striatum, substantia nigra, and hippocampus; brain-derived neurotrophic factor (BDNF) in the striatum; and nerve growth factor (NGF) in the hippocampus. Postmortem studies in older people without AD indicate that smokers have a lower density of senile plaques in hippocampal and cortical regions than do nonsmokers. Senile plaques are aggregates of the 39–43-amino-acid protein β-amyloid (Aβ); it is produced via abnormal processing of the transmembrane amyloid precursor protein (APP), which is normally processed to produce the nonamyloidogenic soluble APP (Figure 1). This connection between cholinergic function and misregulation of APP metabolism has been verified by a reduction in Aβ production on activation of muscarinic M1 and M3 receptors.

PD also leads to impaired cholinergic function in the basal forebrain and cortex and reduced nicotine binding in the substantia nigra. Nicotinic acetylcholine receptor stimulation has been consistently shown

Figure 1 A diagram of the age-associated neuropathology of sporadic Alzheimer's disease (AD). Although neuropathologies associated with the familial forms of AD are not shown, familial and sporadic AD share similar features, including the formation of neurofibrillary tangles and senile plaques. to protect against the disease's cognitive impairments. Administration of muscarinic receptor antagonists produces negative effects on memory.

Amino Acid Neurotransmitters

Glutamate The glutamate excitotoxicity hypothesis has gained considerable interest due to its possible implication in the progression of aging and multiple age-related diseases. Glutamate is the primary excitatory amino acid neurotransmitter secreted by neurons in the central nervous system. Synthesis requires the citric acid cycle intermediate α-ketoglutarate; once released, synaptic glutamate can be converted by glia into glutamine to be metabolized by glutamatergic neurons, be transported back to presynaptic neurons, or bind to postsynaptic receptors. Glutamatergic neurotransmitters most frequently bind to the *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and kainate receptors, all of which are ionotropic and pentameric; the metabotropic glutamate receptors are classified into groups I, II, and III on the basis of their pharmacological properties. Glutamate's roles in the synaptic plasticity, LTP, and long-term depression of neurons make it a crucial transmitter in learning, memory, and neuronal development.

Glutamate excitotoxicity is primarily attributed to the excessive activation of postsynaptic glutamate receptors, particularly the ionotropic receptors that mediate calcium entry, by ischemic and hyperglycemic events in the hippocampus, striatum, and cortex. Excess intracellular calcium triggers the reduction of adenosine triphosphate and generation of reactive oxygen species that attack DNA and lipid membranes. The glutamate excitotoxicity hypothesis, in which these molecular stresses on the aging neuron accelerate neuronal death, has been implicated in a wide range of neurodegenerative diseases. A probable mechanism of glutamate-associated cell death in AD brains involves cyclooxygenase, an enzyme involved in prostaglandin synthesis and an intermediate in one of the signal transduction pathways initiated by the activation of NMDA receptors. In particular, the inducible isoform cyclooxygenase-2 can potentiate cell cycle abnormalities that promote apoptotic cell death. Lipid peroxidation of Aβ, the key component of senile plaques in AD, is also believed to generate free radicals that inhibit glutamate removal mechanisms, such as the transport of synaptic glutamate back to presynaptic neurons as well as the conversion of glutamate to glutamine.

Impairments in glutamatergic circuits also have implications in the pathogenesis of PD. Studies on primates and rodents with parkinsonism reveal excessive glutamatergic transmission at synapses in the subthalamic nucleus and the substantia nigra. Administering selective group II metabotropic glutamatergic receptor antagonists to the models alleviates akinetic symptoms by reducing glutamate transmission in the subthalamic nucleus. Glutamate has also been suggested to inhibit dopamine release in the striatum through the action of ionotropic glutamate receptors mediated by hydrogen peroxide.

Excessive glutamate has been observed in the CSF of patients with amyotrophic lateral sclerosis (ALS), or Lou Gehrig's disease, of the nonfamilial type. The AMPA receptors on the spinal motor neurons of ALS patients have GluR2 subunits produced from messenger RNA that has been incorrectly processed. The receptors become more permeable to calcium, trigger excessive calcium influx, and trigger motor neuron degeneration. Alternatively, reduced numbers of glutamate transporters on glia could contribute to glutamate excitotoxicity. Glutamate transporter 1 is oxidized and inhibited by a defective superoxide dismutase (SOD1) in the familial type of ALS, preventing glutamate reuptake and prompting excessive activation of calcium-permeable glutamate receptors.

GABA Most of the inhibitory action by the interneurons of the human central nervous system, specifically occurring between Purkinje cells and the vestibular nuclei complex, is performed by γ-aminobutyric acid (GABA), which opposes the excitatory action of dopamine. GABA is synthesized from glutamate via glutamic acid decarboxylase; GABA transaminase (GABA-T) reverses the synthesis. GABA binds to the chloride-permeable ionotropic $GABA_A$ and $GABA_C$ receptors and the metabotropic $GABA_B$ receptors.

Research on GABA activity in senescent animals has presented conflicting reports. In studies on aged macaque monkeys, $GABA_A$ receptor agonists were found to improve visual cortex performance, indicating reduced GABA synthesis, GABAergic receptor density, or GABAergic receptor binding with aging in this region. Other studies showed no difference in the GABAergic system between aged and young rats; however, neurons in the lateral vestibular nucleus of senescent humans and rodents become more receptive to benzodiazepines. GABAergic neurons are also known to interact with glutamatergic and dopaminergic neurons in the nucleus accumbens and the striatum to associate the limbic system with movement. Extracellular GABA increases with aging in these regions, contributing to reduced motor activity; however, these increases may be localized, as neurons in the nucleus accumbens experience greater increases in GABA than do those in the striatum.

Neurotrophic Factors and Neuron Atrophy

Neurotrophic factors are crucial for the survival of neurons, for neurons would be unable to maintain synapses with target tissue without them and would ultimately die via suicide mechanisms, also known as apoptotic cell death. According to the neurotrophic hypothesis, after these proteins are released from a postsynaptic neuron's target cell, they assume the role of signaling molecules that bind to and activate receptors on the presynaptic nerve terminal, producing signals that travel from the axon to the nucleus and induce synthesis of proteins that promote neuronal survival. The limited amount of neurotrophic factors released by target cells drives neurons to compete for these factors. Various neurotrophic factor families influence the differentiation, growth, and development of nerve cells. Ongoing research on neurotrophic factors shows they have possible applications in the treatment of AD, PD, and other age-related neurodegenerative diseases, as well as in the delay of the neuronal death and reduction in brain volume that accompany normal aging.

Importance of Neurotrophic Factors in the Repair of Neurons Damaged by Age-Related Factors or Disease

NGF The first identified neurotrophic factor was NGF, a neurotrophin composed of three subunits (α, β, and γ). It is essential to maintain the survival of basal forebrain cholinergic neurons, sympathetic neurons, and nociceptive sensory neurons. NGF selectively binds to and activates trkA, a high-affinity tyrosine kinase receptor that promotes the expression of choline acetyltransferase and regulates NGF's effects of neuron differentiation and maintenance. The resulting NGF–trkA complex is internalized and transported to the soma by retrograde axonal transport. In addition, NGF and all other neurotrophic factors of the neurotrophin family bind to the low-affinity receptor $p75^{NTR}$, which facilitates binding of NGF to trkA but promotes the death of neurons and mature oligodendrocytes in the absence of trkA. Indeed, expression of cortical trkA receptors is reduced by 50% in patients with mild to moderate and severe AD dementia, while expression of $p75^{NTR}$ receptors remains unchanged; the resulting shift to $p75^{NTR}$ receptor-mediated NGF signaling in the absence of trkA receptors most likely predisposes these cholinergic neurons to apoptosis and possibly contributes to the death of cholinergic neurons during AD.

In vitro treatment of neuron cultures and the central nervous system of rodents with NGF significantly increases the number of neurons, dendrites, and axons, while addition of antibodies to NGF in the same cultures triggers neuronal death. Infusion of recombinant human NGF into the basal forebrain of aged rodents with cognitive impairments prevents neuronal death and stimulates the repair of cholinergic neurons that are damaged in AD. This consequently improves the rodents' performance on memory tasks, making it comparable to that of healthy younger rodents and indicating possible applications of NGF for the treatment of cognitive symptoms in AD. The promising results of recent studies employing gene therapy to treat AD with NGF are discussed further in the section titled 'Gene therapy.' However, since multiple neurotransmitter systems in widespread areas of the brain are affected in AD, the long-term benefits of NGF in its treatment remains to be established.

BDNF BDNF, found in the brain and periphery, promotes neuronal and synaptic growth and development in addition to the maintenance of existing neurons in the cortex, basal forebrain, and hippocampus. Because it aids in neuronal plasticity and regulates hippocampal LTP, an electrophysiological feature of memory, it plays crucial roles in cognition, advanced thinking, learning, and neurogenesis. Similar to NGF, BDNF selectively binds to the trkB receptor and forms the BDNF–trkB complex that is transported as a signal to the soma. In mice, learning impairments caused by reduced trkB-mediated signaling can be reversed with BDNF infusion; exercise also causes upregulation of BDNF.

Reduced levels of BDNF are observed in multiple neurodegenerative disorders, particularly Huntington's disease (HD). HD is an autosomal dominant neurodegenerative disorder in which the mutant huntingtin gene causes motor disabilities and cognitive issues by causing striatal neuron damage. Wild-type huntingtin ordinarily binds to a complex of the repressor element-1 transcription factor (REST) and the neuron restrictive silencer factor (NRSF) in the cytoplasm to prevent their entry into the nucleus and suppression of BDNF gene expression. Mutant huntingtin fails to associate with REST–NRSF, causing accumulation of REST–NRSF in the nucleus and reducing BDNF gene transcription in the cortex, thus reducing levels of BDNF in the basal ganglia.

Glial cell line-derived neurotrophic factor Glial cell line-derived neurotrophic factor (GDNF) belongs to the transforming growth factor-β family of neurotrophic factors. It associates with a receptor consisting of two parts: the GFRα1 subunit is glycosyl–phosphatidylinositol-linked and serves as a binding site, while the c-ret subunit is a receptor tyrosine kinase and participates in signaling. GDNF is critical in the

maintenance of nociceptive neurons as well as dopaminergic and motor neurons, which die during the process of PD. Localized delivery of GDNF to the substantia nigra of rodents with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridire or 6-hydroxydopamine induces dopaminergic neuron degeneration, protects cell bodies from retrograde cell death, but is unable to preserve axons that project into the striatum. However, GDNF infusion into the striatum protects the nigrostriatal circuit and preserves motor functions affected by the insults.

Ciliary neurotrophic factor Ciliary neurotrophic factor (CNTF) is a cytokine of the interleukin-6 family that is sequestered in adult glia and whose production increases during injury. It is essential in the maintenance of dopaminergic neurons of the substantia nigra and spinal cord motor neurons; when administered to mice with neuromuscular degeneration, it produces neuroprotective effects. Ligand binding of CNTF to the CNTF receptor-α (CNTFRα) subunit triggers signals via the Janus kinase–signal transducers and activators of transcription pathway by the formation of a complex with the subunits glycoprotein 130 and leukemia inhibitory factor receptor-β.

The mutant allele which deters these factors in some humans is related to ALS, characterized by motor neuron degeneration. Patients with a homozygous null mutation in the CNTF gene gain increased susceptibility to the familial form of ALS, which constitutes 5–10% of all cases and which develops approximately 10 years earlier than does ALS in patients without the mutation. This increased susceptibility has also been confirmed in mice that develop motor neuron loss due to the same mutation. In addition, reduced CNTF in glia is observed in the familial form of ALS. On the other hand, in studies of mice exhibiting motor neuron degeneration characteristic of sporadic ALS, which constitutes approximately 90% of cases, inactivation of the CNTF protein has been shown to produce few changes in adult motor neurons; however, mice lacking the gene for CNTFRα have half as many motor neurons and frequently die after birth.

Pharmacology of Age-Related Neurodegenerative Disease Treatment

Increasing knowledge of neurotransmitters and their mechanisms, their pathways, and the actions of agonists and antagonists on specific receptors has led to the development of drugs for treatment of the debilitating symptoms of aging and neurogenerative disorders. L-DOPA, the metabolic precursor of dopamine, is able to pass through the blood–brain barrier although dopamine cannot. Administration of oral L-DOPA to PD patients temporarily delays the progression of parkinsonism. Striatal dopaminergic neurons subsequently use the L-DOPA to produce the dopamine that is deficient in PD brains. To avoid its premature conversion to dopamine in the gut and periphery, L-DOPA is now administered with carbidopa, significantly reducing the dosage of L-DOPA prescribed since its first use in the 1960s. Although L-DOPA successfully reduces parkinsonian symptoms in most instances, some patients experience side effects such as dyskinesia, hypotension, and nausea.

Other antiparkinsonian drugs include dopamine agonists such as pergolide, pramipexole, and ropinirole, which act on dopamine receptors of the substantia nigra. Use of these agonists during the early phases of the disease may reduce the dyskinesia that accompanies prolonged L-DOPA treatment; studies both *in vitro* and *in vivo* have also indicated that these agonists possess neuroprotective properties. However, dopamine agonists and L-DOPA are both suitable initial treatments for PD. Monoamine oxidase B (MAO-B) inhibitors are an alternative form of treatment that prevents the breakdown of dopamine in the brain. Until the recent approval of rasagiline by the Food and Drug Administration, selegiline was the only approved MAO-B inhibitor available for use in the United States. In studies on cultured neurons, rasagiline appears to have a greater neuroprotective effect than does selegiline (Table 1, Figure 2).

Because acetylcholinesterase exacerbates AD by hydrolyzing acetylcholine at the synapse, cholinesterase inhibitors are used to increase acetylcholine levels and stimulate cholinergic activity in the brains of AD patients with the aim of reducing or delaying the onset of psychiatric symptoms. As tacrine, the first cholinesterase inhibitor, was found to be hepatoxic, the three currently used inhibitors are donepezil, galantamine, and rivastigmine. It is rare for more than one cholinesterase inhibitor to be administered at a time; side effects range from nausea to fatigue.

The incidence of PD patients with dementia has prompted research on bifunctional drugs that inhibit acetylcholinesterase without compromising the effects of antiparkinsonian drugs. Research on the compound ladostigil has revealed that it is an effective acetylcholinesterase inhibitor as well as an inhibitor of both isoforms of monoamine oxidase, MAO-A and MAO-B. Ladostigil is currently undergoing clinical trials for AD and PD.

Because of the implications of glutamate excitotoxicity in the etiology of dementia, NMDA receptor antagonists are also used in the treatment of moderate to severe AD. Patients treated with memantine have

Table 1 Approaches to treatment of age-related neurodegenerative diseases

	Alzheimer's disease[a]	*Parkinson's disease*[b]	*Amyotrophic lateral sclerosis*[c]
Pharmacological treatments	Cholinesterase inhibitors (donepezil, galantamine, rivastigmine, ladostigil) NMDA receptor antagonists (memantine)	L-DOPA and carbidopa Dopamine receptor agonists (pergolide, pramipexole, ropinirole) MAO-B inhibitors (selegiline, rasagiline) NMDA receptor antagonists (memantine)	NMDA receptor antagonists (memantine) Glutamate transport activity enhancers (riluzole)
Gene therapy	Enhanced NGF production	Enhanced GDNF production Silencing genes for α-synuclein	Enhanced VEGF production
Transplantation	Neural stem cells to produce cholinergic neurons	Neural stem cells to produce dopaminergic neurons	ES-cell derived glia to produce depleted trophic factors

exhibited moderate cognitive improvements on the 'severe impairment battery' and the 'activities of daily living inventory' and had better performance on daily functions. Memantine may also be beneficial in treating vascular dementia as well as less severe forms of AD. Current research focuses on the effectiveness of adding NO groups to memantine to prevent glutamate excitotoxicity (Table 1).

Drugs that interfere with glutamate transmission are also used to treat ALS. Riluzole reduces motor neuron degradation by enhancing glutamate transport activity in the spinal cord; however, this effect seems to be reduced as the disease progresses into its late stages, possibly due to the impaired glutamate uptake capacity of glia in severe ALS. Memantine has also been demonstrated to have protective effects on mouse models of ALS (Table 1, Figure 3).

Gene Therapy

Recent advances in gene therapy have led to possible treatments that help slow the progression of certain diseases associated with the brain and aging. Studies on primate models as well as recent phase I clinical trials on AD patients have shown positive results for *ex vivo* NGF gene delivery in the treatment of AD. Genetically altered fibroblasts that express NGF were injected into the cholinergic nucleus basalis of eight patients with familial AD. Increased cholinergic axon projections into the cortex and increased glucose uptake by these neurons were observed in the patients' brains. During the next 2 years, the patients' average rate of cognitive decline was reduced by as much as half their rate before treatment, based on their performance on the mini-mental state

Figure 2 A diagram of the age-associated neuropathology of sporadic Parkinson's disease (PD). Although the causes and neuropathologies of the familial forms of PD are not shown, including mutations in α-synuclein, studies on genetic causes have enabled researchers to produce genetic models of PD. examination and the cognitive subcomponent of the AD assessment scale.

A parallel to the gene therapy described above for PD involves GDNF gene delivery, which helps maintain dopaminergic function in the striatum. Delivery of the gene for glutamic acid decarboxylase into the brains of animal models of PD has also been found to stimulate GABAergic neurons and reduce activity in the subthalamic nucleus, helping attenuate motor symptoms; clinical trials are under way in humans. A recently developed technique involving RNA interference-based gene therapy was able to silence the gene for α-synuclein, the primary component of Lewy bodies, in dopaminergic neurons of rat models. Future research will investigate the effects of gene silencing therapy on cognition in animal models of PD.

In SOD1 transgenic mice as mouse models for ALS, vascular endothelial growth factor gene therapy using a lentiviral vector has produced protective effects in motor neurons of the spine and brain stem, slowing the progression of ALS. RNA interference enables silencing of copies of the mutated SOD1 gene and delivery of functional copies of the gene, indicating that this technique holds much promise in the treatments of various neurodegenerative diseases. Other techniques aim to increase levels of functional dystrophin via injection of antisense oligoribonucleotides into muscle cells of *mdx* transgenic mice, enabling a nonsense mutation in exon 23 of the dystrophin gene to be skipped.

Mouse models of HD that were injected with viral vectors containing the GDNF gene had reduced neuronal death and showed improved performance on tests measuring coordination and balance. A phase I clinical trial has also demonstrated the effectiveness of delivering a baby hamster kidney cell line modified to produce CNTF into striatal neurons.

Stem Cells and Their Application in the Treatment of Neurodegenerative Diseases

Stem cells have potential in the treatment of diseases associated with aging and the brain. Cell replacement therapies seek to generate viable neurons that are able to produce neurotransmitters depleted in various neurodegenerative diseases. Human neural stem cells grafted into rodent models differentiate into cholinergic neurons in the spinal cord but have not been observed in the cortex or the hippocampus. However, because more neural stem cells differentiate into glia and neurons, further research is required to determine

Figure 3 A diagram of the age-associated neuropathology of sporadic amyotrophic lateral sclerosis (ALS). Although neuropathologies associated with the familial forms of ALS are not shown, familial and sporadic ALS share similar features, in particular, motor neuron degeneration. AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid. From Dunlop J, Beal McIlvain H, She Y, and Howland DS (2003) Impaired spinal cord glutamate transport capacity and reduced sensitivity to riluzole in a transgenic superoxide dismutase mutant rat model of amyotrophic lateral sclerosis. *Journal of Neuroscience* 23: 1688–1696; Rowland LP and Shneider NA (2001) Amyotrophic lateral sclerosis. *New England Journal of Medicine* 344: 1688–1700; and Trotti D, Rolfs A, Danbolt NC, Brown RH Jr., and Hediger MA (1999) SOD1 mutants linked to amyotrophic lateral sclerosis selectively inactivate a glial glutamate transporter. *Nature Neuroscience* 2: 427–433.

the efficacy of neural stem cells in the treatment of AD. An interesting application of embryonic stem (ES) cells in familial AD research is the generation of postmitotic AD cells for *in vitro* study without the need for primary culture neurons.

Current nonpharmacological alternatives to L-DOPA in PD treatment include transplantation of dopaminergic neurons from the fetal midbrain. Although this method attenuates parkinsonian symptoms, the effect is temporary, and development of more efficient techniques is necessary. In studies on rodent models, midbrain dopaminergic neurons derived from ES cells have been shown to survive following grafting into the striatum. The recent identification of genes that promote ES cell maturation to midbrain dopaminergic neurons, including Nurr1 and Pitx3, paves the way for further studies of ES cells and their long-term effectiveness in treating PD.

Research on rodent models of ALS has shown that axons of motor neurons derived from ES cells can extend to the ventral root, though the axons' interaction with muscle tissue has yet to be observed. Additional studies on these models have revealed the benefits of ES cell-derived glial cells, which produce trophic factors that protect motor neurons from the effects of mutations in the SOD1 gene. Therefore, applications of ES cells in the treatment of ALS range from generating replacement cells to generating glia that promote the growth and repair of motor neurons, providing a wide range of options for study.

However, the ethical implications of ES cell research for the possible treatment of neurodegenerative diseases, particularly those associated with age, are widely debated. Though stem cells hold the promise of replacing damaged or dead neurons by differentiating into desired cell types, considerable time, funding, and adequate cell lines – their source is another issue – must be devoted to research to produce safe and effective treatments. Both the well-being of the aging baby boomer population and the resources invested in ES cell research are to be considered as research probes deeper into the underlying mechanisms of these disorders.

Implications of Lifestyle Factors for Aging and Neurodegenerative Disorders

Although genetic causes for several disorders related to aging and the brain, including HD, ALS, and the familial forms of AD and PD, have been identified, the sporadic and more common forms of disease may be attributed to multiple factors. Lifestyle factors such as nutrition and exercise could notably influence

one's risk for dementia and AD as our neurons are particularly receptive to our daily activities. Studies involving caloric intake on Tg2576 mouse models of AD revealed that generation of Aβ protein is enhanced in diets high in saturated fat but attenuated in caloric restriction diets low in carbohydrates. Furthermore, epidemiological evidence indicates that type 2 diabetes and obesity escalate the risk of AD more than fourfold, suggesting a strong relationship between diet and brain disorders. As a result, rising incidences of obesity in the American population in the twenty-first century could drastically increase the number of people diagnosed with AD. A study of type 2 diabetes in Tg2576 mice has also revealed that the elevated insulin levels in the blood coincided with increased Aβ production and senile plaque formation. Increases in levels of BDNF in the striatum, cortex, and hippocampus – areas of the brain affected in AD and PD – that have been observed in mouse models may explain the beneficial effects of caloric restriction.

Neurotrophic Factor Therapy: GDNF and CNTF

E-Y Chen, D Fox, and J H Kordower, Rush University Medical Center, Chicago, IL, USA

© 2009 Published by Elsevier Ltd.

Introduction

During the past decade, there has been a major increase in research associated with neurotrophic factors (NTFs), molecules that provide survival-promoting effects to developing and adult central nervous system (CNS) neurons. From a clinical standpoint, it has been hoped that research would ultimately lead to the development of novel therapeutic approaches for the treatment of various neurodegenerative disorders, such as Alzheimer's disease, Parkinson's disease (PD), Huntington's disease (HD), and amyotrophic lateral sclerosis (ALS). To date, such clinical promise has not been realized, but optimism remains high due to the potency of the NTFs to protect and augment the function of vulnerable neuronal systems, combined with novel methods for their delivery.

Glial Cell Line-Derived Neurotrophic Factor

Identification and Role

The glial cell-derived neurotrophic factor (GDNF) family is distantly related to the transforming growth factor superfamily and includes GDNF and three structurally related members named neurturin, persephin, and artemin. GDNF, the first-identified member of this family, was originally isolated from the rat B49 glial cell line. GDNF binds to a multisubunit receptor system composed of the GFRα1 subunit and the RET subunit, which function as the ligand binding and signaling components, respectively. Ret is a transmembrane receptor tyrosine kinase (encoded by the proto-oncogene c-ret) that triggers many intracellular signaling pathways, including the Ras-MAPK, the phosphoinositol 3-kinase, and Jun N-terminal kinase- and PLCγ-dependent pathways. After the initial discovery that GDNF protects embryonic nigral neurons in culture, a plethora of *in vitro* and *in vivo* studies demonstrated that this factor prevents the degeneration and augments the phenotypic expression of dopaminergic midbrain neurons. With regard to GDNF and dopaminergic systems, there have been a series of pivotal experiments. A single intraventricular injection of GDNF to a normal rat induces a long-term increase in striatal dopamine. Most critically, GDNF has been able to prevent the structural and/or functional consequences that are engendered in virtually every rodent model of PD, including those with lesions induced by 6-hydroxydopamine, methamphetamine, or axotomy, as well as the degenerative changes associated with aging. Furthermore, CNS infusions of GDNF augment motor function and reverse nigrostriatal degeneration in parkinsonian and aged rhesus monkeys, and lentiviral delivery of GDNF prevents nigrostriatal degeneration in 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridire (MPTP)-treated monkeys and augments dopaminergic function in aged monkeys. An exception to this rule is provided by one study in which GDNF failed to prevent the structural and functional consequences that result from overexpression of α-synuclein in a rat model of PD. GDNF also has well-documented effects on the survival and function of cranial and spinal cord motor neurons, brain stem noradrenergic neurons, basal forebrain cholinergic neurons, Purkinje cells, and specific groups of dorsal ganglia and sympathetic neurons.

Distribution of GDNF in the CNS

Using polymerase chain reaction (PCR) and *in situ* hybridization techniques, the regional distribution and cellular localization of GDNF have been examined in the rat and human CNS. GDNF transcripts have been identified in all major regions of the rat CNS, such as the striatum, hippocampus, cortex, cerebellum, and spinal cord. Reverse-transcriptase polymerase chain reaction (RT-PCR) analysis revealed that GDNF mRNA is also observed in the human CNS in regions such as the striatum, hippocampus, cortex, and spinal cord. Using immunohistochemical techniques, it has been shown that GDNF immunoreactive neurons are widely distributed in the normal human brain and spinal cord, including cerebral cortex, hippocampus, basal forebrain, hypothalamus, thalamus, cerebellum, and brain stem. GDNF and its signaling receptor RET are also found in human peripheral nerve axons and DRG neurons, and GDNF is found in Schwann cells. GDNF immunostaining has also been found in melanin-containing neuronal perikarya of the substantia nigra pars compacta (SNpc) in normal human brain. This region undergoes extensive degeneration in PD. Experimental studies performed using RT-PCR techniques indicate that GDNF and its receptor components are broadly expressed in the rat and human hippocampus from early embryonic age to adult life. Available quantitative data show that in the rat hippocampus, levels of GDNF mRNA and protein steadily increase from the early stages to birth, reaching a maximum during the first week after

birth and gradually decreasing to prenatal levels in adult. The occurrence and pattern of overall distribution of GDNF-positive neurons in human hippocampus appear consistently similar throughout life stages from 29 weeks of gestation to adulthood. However, the relative numerical density of labeled neurons changes with age.

GDNF and PD

PD is a neurodegenerative disorder that affects more than 1 million people in North America. PD is characterized by the selective degeneration of nigral dopaminergic neurons in the SNpc and subsequent depletion of striatal dopamine which leads to motor dysfunction. PD patients can present with a variety of symptoms (bradykinesia, muscle rigidity, resting tremor, and loss of postural reflexes), two of which are required for diagnosis of the disease. The diagnosis of PD is made on the basis of clinical criteria. Confirmation of the clinical diagnosis occurs upon neuropathologic examination. Available pharmacological treatments do not stop the progressive loss of dopamine neurons observed during the course of PD. The progressive nature of the disease provides the possibility of therapeutic interventions that slow, or completely halt, the ongoing degenerative process. The use of trophic factors has emerged as a potential therapeutic approach because of their ability to regulate the survival of specific neuronal populations in the CNS. GDNF, a member of the transforming growth factor-β superfamily, has been shown to be one of the most potent neuroprotective factors for dopaminergic neurons. Many studies have demonstrated that GDNF controls the survival and physiologic properties of mesencephalic dopaminergic neurons both *in vitro* and *in vivo*. Therefore, reduction of GDNF expression in the SNpc might lead to neuronal loss in PD, although this concept is controversial. In one early *in situ* hybridization study, GDNF mRNA expression failed to show any labeling in the mesencephalon and striatum of control subjects or patients with PD. RT-PCR analysis revealed the highest expression of GDNF mRNA in the human caudate, with low levels in the putamen and no detectable mRNA in the SN, suggesting that GDNF is synthesized and secreted by striatal neurons and then retrogradely transported to the SN in a target-derived retrograde manner. Receptor studies found that tissue sections from the SNpc of control subjects and PD patients localized RET immunoreactivity to the dopaminergic neurons. RET mRNA expression was also observed in many surviving neurons in all PD patients. GDNF is present in the adult striatum, and the dopaminergic neurons of the SNpc express mRNAs encoding the GDNF receptors, RET and GFRα1. GDNF levels were significantly reduced (approximately 20%) in all sampled surviving melanin-containing neurons in the SNpc of PD patients compared with age-matched controls, supporting a role for decreased availability of GDNF as part of the process of degeneration of SNc neurons in PD. Together, these findings indicate that GDNF may play a role in the pathology of PD and may be the most potent neuroprotective factor for PD.

These and other studies prompted researchers to investigate putative protective effects in different PD models as well as PD patients. As discussed previously, direct injection of the recombinant GDNF protein has potent neuroprotective effects in rodent and primate models of PD. In polymer-encapsulated GDNF-secreting cells, continuous release of low levels of GDNF protects the nigral dopaminergic neurons from an axotomy-induced lesion and improves dopamine graft survival in 6-OHDA-treated rats. Gene therapy is another method that has great potential for delivering trophic factors continually to focal regions of the CNS. In this regard, viral vectors are attractive candidates for delivering GDNF to the PD brain given the nature of the disease. There are numerous studies using gene therapy in animal models of PD. Overexpression of GDNF to the striatum and/or SN has been achieved primarily using adeno-associated viruses or lentiviruses. One of the most promising studies demonstrated that delivery of GDNF using a primate-derived lentiviral vector provided almost complete neuroprotection against MPTP-mediated toxicity in monkeys and augmented dopaminergic function in aged monkeys (**Figure 1**). These encouraging preclinical observations led to a series of pilot human trials in which GDNF was used in PD patients. A double-blind, placebo-controlled, sequential cohort study performed for 8 months compared the effects of monthly intracerebroventricular administration of placebo and GDNF in 50 moderately advanced PD patients. These trials were suspended because of lack of observed efficacy and frequent occurrence of nausea, anorexia, tingling (Lhermitte sign), hallucinations, and depression. GDNF did not improve parkinsonism, possibly because GDNF did not reach the target tissues – putamen and SN. A phase I safety trial reported that 1 year after long-term infusion of GDNF directly via a pump and catheter into the posterodorsal putamen of 5 PD patients, there were no serious clinical side effects, and there was a 39% improvement in the off-medication motor subscore of the Unified Parkinson's Disease Rating Scale (UPDRS) and a 61% improvement in the activities of daily living subscore. Furthermore, levodopa-induced dyskinesias were reduced by 64%. This clinical improvement was accompanied by a 28% increase in putamen PET

Figure 1 (a and b) Low-power dark field photomicrographs through the right striatum of TH immunostained sections of MPTP-treated monkeys treated with (a) lenti-βGal or (b) lenti-GDNF. (a) There was a comprehensive loss of TH immunoreactivity in the caudate and putamen of lenti-βGal-treated animal. In contrast, a near normal level of TH immunoreactivity is seen in lenti-GDNF-treated animals. Low-power (c, d) and medium-power (e, f) photomicrographs of TH immunostained section through the substantia nigra of animals treated with lenti-βGal (c, e) and lenti-GDNF (d, f). Note the loss of TH immunoreactive neurons in the lenti-βGal-treated animals on the side of the MPTP injection. TH immunoreactive sprouting fibers, as well as a supranormal number of TH immunoreactive nigral perikarya, are seen in lenti-GDNF-treated animals on the side of the MPTP injection. (g, h) Bright field low-power photomicrographs of a TH immunostained section from a lenti-GDNF-treated monkey. (g) Note the normal TH immunoreactive fiber density through the globus pallidus on the intact side that was not treated with lenti-GDNF. (h) In contrast, an enhanced network of TH immunoreactive fibers is seen on the side treated with both MPTP and lenti-GDNF. Scale bar in (g) represents the following: 3500 μm (a–d); 1150 μm (e–h).

F-DOPA uptake and evidence of neuronal sprouting in an autopsied brain. After 2 years of continuous GDNF infusion, there were still no serious clinical side effects and no significant detrimental effects on cognition. Patients showed a 57% and 63% improvement in their off-medication motor and activities of daily living subscores of the UPDRS, respectively, and health-related quality-of-life measures showed general improvement over time. A multicenter trial, however, showed no benefit from GDNF, and further studies have been suspended because of evidence of the development of GDNF antibodies in some patients. In addition, cerebellar neurodegeneration involving both Purkinjie cells and the granular cell layer in monkeys

exposed to high doses of GDNF has been found. Based on these data, clinical trials delivering GDNF protein to the putamen have been stopped.

GDNF and HD

Another potential therapeutic role of GDNF is in HD. HD is an autosomal dominant neurodegenerative disorder resulting from an expanded trinucleotide (CAG) repeat at the IT15 locus on chromosome 4 within the huntingtin gene. The abnormal DNA is translated into mutant huntingtin with an expanded glutamine stretch at the N-terminus of the protein. The excessive number of glutamine repeats is responsible for the misfolding of huntingtin and the subsequent formation of neuronal inclusions, degeneration of striatal and cortical neurons, and a triad of symptoms including severe motor, cognitive, and psychological disturbances that are ultimately fatal. To date, HD remains incurable. Toward this end, GDNF has shown promise in animal models of several different neurodegenerative disorders. In addition to its potent trophic effects on dopaminergic midbrain neurons, GDNF has also been shown to protect striatal, medium-sized spiny GABA projection neurons, the neuronal population most vulnerable in HD. Moreover, the expression of GDNF's receptors (GFRα1 and Ret) is upregulated in striatal neurons and astrocytes after injury, supporting its role as a potential trophic factor for HD. Intraventricularly administered GDNF protected striatal neurons from both excitotoxic and metabolic insult. Intrastriatal grafting of a GDNF-producing cell line or GDNF-secreting stem cells prevented the degeneration of striatal neurons in the excitotoxic rodent model of HD. Injection of adeno-associated virus (AAV) vector-mediated gene transfer of GDNF into the striatum improves behavior and provides neuronal protection in both rat and transgenic HD mice, the gold-standard animal model for HD.

GDNF and Cerebral Ischemia

Ischemic brain injury is a major cause of death and permanent disability worldwide. Cell injury and death after cerebral vascular occlusion have been postulated to result from a number of interacting pathophysiologic factors, including depolarization-induced calcium entry via *N*-methyl-D-aspartate receptors, intracellular free radical generation, damage to mitochondrial respiratory enzymes, and induction of programmed cell death. GDNF was initially considered to be a specific trophic factor and neuroprotective agent for dopaminergic neurons. It was later found that GDNF has effects on other systems. GDNF diminishes damage produced by kainate-induced tonic–clonic convulsions and axotomy of brain stem motor neurons. Since GDNF has an antiapoptotic effect in dopamine and nondopaminergic neurons after injury, it was hypothesized that GDNF could attenuate ischemic brain injury through the same mechanism. Exogenous administration of GDNF reduces the toxic effects of excitatory amino acids, attenuates nitric oxide production, and lowers apoptosis/cell death in stroke animals. Intracerebroventricular and intraparenchymal administration of GDNF potently protected the cerebral hemispheres from damage induced by middle cerebral artery (MCA) occlusion in rats. A reduction of ischemic brain injury by topical application of GDNF after permanent MCA occlusion in rats has also been reported. Intravenous application of a blood–brain barrier-penetrating form of GDNF, TAT-GDNF, reduces infarct size after ischemia in mice. Topically applied to the ischemic brain after MCA ligation, GDNF-fibrin glue reduces ischemic brain injury in chronic focal cerebral ischemia in conscious rats. Both recombinant AAV vector and herpes simplex virus amplicon-based vector expressing GDNF reduce ischemia-induced damage. These data support the concept that GDNF may play a therapeutic role in the treatment of ischemia. However, a remaining challenge is to determine how to deliver this trophic molecule in a manner in which it can be clinically useful.

Ciliary Neurotrophic Factor

Identification and Role

Ciliary neurotrophic factor (CNTF) is structurally and functionally related to members of a family of cytokines that includes leukemia inhibitory factor (LIF), interleukin-6, interleukin-11, and oncostatin M. CNTF was initially identified due to its ability to support the survival of parasympathetic neurons of the chick ciliary ganglion *in vitro* and subsequently purified to homogeneity from sciatic nerves. CNTF is synthesized by astrocytes and is generally thought to provide autocrine and paracrine signals from astrocytes which induce cellular protection and hypertrophy in response to injury. CNTF exerts its biological effects by binding to a ligand-specific α subunit, CNTF receptor α (CNTFR α), which leads to the subsequent recruitment of two signal-transducing β components, LIFRβ and gp130. Following dimerization of the β components, preassociated cytoplasmic Jak and Tyk kinases are activated, resulting in tyrosine phosphorylation of the β components and other cellular proteins. CNTF plays an important role in the maintenance and regeneration of the adult nervous system.

CNTF prolongs neuronal survival of various culture systems and enhances the survival of sensory neurons, motor neurons, cerebral neurons, and hippocampal neurons. CNTF also promotes cholinergic differentiation of noradrenergic sympathetic neurons, the differentiation of glial progenitors into astrocytes, and the maturation and survival of oligodendrocytes. Some peripheral tissues, notably skeletal muscle, are also known to respond to CNTF. Many studies have demonstrated that CNTF administration prevents injury-induced cell death and degeneration of cholinergic, dopaminergic, GABAergic, and thalamocortical neurons in various lesion models of CNS diseases. However, the majority of studies have linked CNTF with motor function in animal models of ALS, HD, and sensory function such as retinopathies.

Distribution of CNTF in the CNS

CNTF was originally identified as a survival-promoting activity for ciliary ganglion neurons in chick eye tissues. Subsequently, it was cloned from mammalian nervous tissue. The protein is mainly expressed in glial cells of both the peripheral nerve system and the CNS and has been implicated in many developmental processes in the nervous system, including cell fate determination of neural stem cells, the proliferation and transmitter choice of neuronal precursor cells, and the survival and differentiation of developing neurons as well as glial cells. In addition, it acts on a variety of mature peripheral and central neurons preventing injury-induced cell death and degeneration. Demonstrations of retrograde axonal transport of radiolabeled CNTF in the sensory neurons of the sciatic nerve suggest that CNTF may function by target synthesis and retrograde transport in central neurons. CNTF was observed only after birth and found in both the neurons and the neuroglia of the SN, mesencephalon, cerebellum, and the spinal cord from postnatal day 1 to postnatal week 3 in developing Mongolian gerbils. CNTF has been localized primarily in glial cells, with highest concentrations in Schwann cells, and in white matter tract astrocytes of the mouse CNS. The expression of CNTFR α is widely distributed in both rat and primate CNS motor, sensory, and autonomic neurons. There are no published data on the distribution of CNTF in human brain.

CNTF and Amyotrophic Lateral Sclerosis

ALS is the most common adult form of motor neuron disease. The clinical hallmarks of ALS are progressive muscle weakness, atrophy, and spasticity, which reflect the degeneration and death of upper and lower motor neurons in the cortex, brain stem, and spinal cord. Generally fatal within 1–5 years of onset, ALS has a prevalence of 1 or 2 per 100 000 people. In 90% of cases, there is no apparent genetic linkage (sporadic ALS), but in the remaining 10% the disease is inherited (familial ALS), often in an autosomal-dominant manner. Among familial cases of ALS, approximately 20% are caused by mutations in the gene encoding Cu, Zn-superoxide dismutase (SOD1). The role of CNTF in the etiology and pathogenesis of ALS is not clear. Using a sensitive enzyme-linked immunoassay, CNTF protein in the lateral corticospinal tract was markedly lower in ALS patients than in controls. In the spinal cord of ALS patients, there is a marked increase in the hybridization signal for CNTFR α subunit mRNA overlying motor neurons. CNTF improves survival in the progressive motor neuronopathy (pmn) and wobbler mutant mouse models of motor neuron disease, even though these mice do not have an obvious defect in CNTF or its receptor. Conversely, mice bred for the null mutation of CNTF or its receptor do develop motor neuron degeneration. CNTF also appears to be effective for retarding cellular and functional losses in the mouse models of ALS. CNTF significantly reduced motor neuron loss, improved motor function, and increased survival time. These observations led to the unsuccessful use of CNTF in a therapeutic clinical trial in ALS. This trial was designed to evaluate the safety, tolerability, and efficacy of subcutaneous administration of recombinant human CNTF. Unfortunately, it failed to ameliorate symptoms of ALS while producing adverse effects, such as injection site reactions, cough, asthenia, nausea, anorexia, weight loss, and increased salivation.

CNTF and HD

CNTF has also been tested in multiple animal models of HD. CNTF has been shown to protect striatal output neurons in a rat model of HD. In one study, encapsulated cells containing baby hamster kidney cells genetically modified to deliver hCNTF were implanted into the lateral ventricle and provided dose-dependent neurochemical and functional protection in a rat model of HD. Human neural stem cell transplants improved motor function in a rat model of HD, and recovery was superior in rats receiving CNTF-treated human cells compared to rats receiving transplants of untreated cells. Intrastriatal injections of adenovirus-mediated CNTF provided neuroprotection for corticostriatopallidal neurons in a rat model of progressive striatal degeneration. In nonhuman primate models of HD, intrastriatal implantation encapsulated CNTF-producing cells prevented the degeneration of vulnerable striatal populations and cortical–striatal basal ganglia circuits, and in a

Figure 2 Low-power photomicrographs of Nissl stained sections through the forebrain of monkeys receiving unilateral intracaudate and intraputamenal lesions with QA and encapsulated (a) BHK-control or (b) BHK-hCNTF implants. Note the extensive lesion area on the left side which encompasses much of the striatum in a. In contrast, the damage in b is negligible for a monkey treated with hCNTF. (c) The size of the lesion in both the caudate nucleus and putamen as quantified on Nissl stained sections was significantly decreased in BHK-hCNTF implanted monkeys (striped bars) relative to BHK-control implanted animals (gray bars). Each bar represents data from an individual animal. (d, e) Medium- and high-power (f) photomicrographs of Nissl stained sections through the striatum of BHK-control (d) and BHK-hCNTF implanted (e, f) monkeys. (d) A paucity of neurons is seen in the striatum of control implanted monkeys. (e,f) In contrast, numerous healthy neurons can be seen near a QA injection site in BHK-hCNTF implanted animals. For reference, the arrows in (e) and (f) point to the same location. Scale bar in (a) represents the following: 4000 μm (a, b); 50 μm (d, e); 25 μm (f).

primate model of HD they restored cognitive and motor functions (Figure 2). In 2004, a human clinical trial of CNTF for HD was reported. This phase I trial evaluated the safety of intracerebral administration of CNTF protein in stage 1 or 2 HD patients using a device formed by a semipermeable membrane encapsulating a BHK cell line engineered to synthesize CNTF. No sign of CNTF-induced toxicity was reported, and improvements in electrophysiological results were observed.

CNTF and Retinal Degenerative Diseases

Retinal degeneration in its various forms is responsible for vision loss in a large number of young

adults. Retinitis pigmentosa (RP), for example, affects 50 000–100 000 people in the United States and an estimated 1.5 million people worldwide. RP characterized by a progressive loss of photoreceptors through-mechanisms is not fully understood. Subsequent to photoreceptor loss, there is both vascular and neural remodeling. The pathogenesis of retinal degeneration is complicated. With the exception of vitamin A nutritional supplementation, no treatments have been shown to be effective across the range of these disorders. Regardless of the initial causative genetic defect, the end result is photoreceptor cell death. The multiplicity of mechanisms stimulated a search for therapeutic agents that are effective in slowing photoreceptor death regardless of the causative genetic mutation. Intervention studies have indicated the possibility of using neurotrophic factors as therapeutic agents for RP. CNTF is a cytokine with neurotrophic activity across a broad spectrum of peripheral and CNS cells. CNTF was first identified as a survival factor in studies involving ciliary ganglion neurons in the chick eye. CNTF mRNA expression in the retina during postnatal development increased with postnatal age. CNTF upregulation plays a role in retinal protection against light-induced damage after optic nerve section. CNTF has been shown to modulate the survival of retinal neuronal cells *in vivo* and *in vitro*. Repeated injections of a CNTF analog lead to long-term photoreceptor survival in hereditary retinal degeneration. Encapsulated cell-based delivery of CNTF reduces photoreceptor degeneration in canine models of RP, protects photoreceptors in a canine model of retinal degeneration, and does not adversely affect either rod or cone ERG function of normal rabbit retina. AAV-mediated delivery of CNTF prolongs photoreceptor survival in the rhodopsin knockout mouse and rat models of RP. Intraocular gene transfer of CNTF prevents photoreceptor degeneration in Royal College of Surgeons rats and mice. However, intraocular gene delivery of CNTF results in significant loss of retinal function in both normal mice and Prph2Rd2/Rd2 retinal degeneration mice. A phase I human clinical trial of CNTF for retinal neurodegeneration indicates that CNTF is safe for the human retina even with severely compromised photoreceptors. The approach to delivering therapeutic CNTF proteins to degenerating retinas using encapsulated cell implants may have application beyond disease caused by genetic mutations.

Conclusion

Trophic factors such as GDNF and CTNF hold great promise for the treatment of degenerative disease. However, significant challenges remain with regard to establishing biomarkers for these diseases that will allow for interventions much earlier in the disease process than are currently available. Furthermore, additional studies aimed at developing optimal delivery methods for these potent compounds would ultimately benefit their clinical use.

Neurotrophic Factor Therapy: NGF, BDNF and NT-3

A Blesch and M H Tuszynski, University of California at San Diego, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The discovery of the first nervous system growth factor in 1951, nerve growth factor (NGF), began an era of exploring potential therapeutic benefits of neurotrophins in animal models of disease. This effort gained considerable momentum with reports beginning in the mid-1980s that growth factors prevent neuronal death in the adult brain and then reports in the mid-1990s that growth factors promote extensive axonal growth in the adult central nervous system (CNS).

Numerous studies have confirmed that delivery of neurotrophins (NGF, brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), or NT-4) by intermittent injection, continuous infusion, cellular grafting, or gene therapy can augment neuronal survival in animal models of neurodegenerative diseases, increase the number of regenerating axons, and amplify the speed and distance of axonal regeneration. However, identifying a clinically practical means of neurotrophin delivery has proven to be one of the most important obstacles in translational human testing of these findings. To be tested in human trials, neurotrophins need to reach targeted regions in effective concentrations but cannot spread beyond targeted regions if adverse affects are to be avoided. Furthermore, ideally the amount and duration of growth factor delivery would be highly controllable in human testing.

This article reviews some of the data regarding physiological and therapeutic roles of neurotrophins in animal models of neurodegenerative diseases and axonal regeneration. These findings have led to potentially promising clinical trials with neurotrophins. The discussion is focused on NGF, BDNF, and NT-3.

Neurotrophins in Neurodegenerative Disorders

NGF and Alzheimer's Disease

NGF is expressed in the neocortex and the hippocampus during development and in adulthood, supporting the survival and function of basal forebrain cholinergic neurons in the nucleus basalis of Meynert and the medial septum. Beginning in 1986, the groups of Franz Hefti, Larry Kromer, and Rusty Gage separately reported that intracerebroventricular infusions of NGF prevent the lesion-induced degeneration of basal forebrain cholinergic neurons in the medial septum, elucidating for the first time the powerful effects of growth factors in preventing cell death in the brain. Because cholinergic neuronal decline is a prominent component of cell loss in Alzheimer's disease (AD), it was suggested that NGF could potentially slow or prevent the loss of this important cell population and thereby improve cognition in AD patients.

Several subsequent studies confirmed the neuroprotective effects of NGF after lesions. Furthermore, NGF was found to improve learning and memory in aged and lesioned rats. Additional effects of NGF were reported in primate models of cholinergic cell loss and aging. This collective body of work led to a small clinical trial of NGF intracerebroventricular infusion into three patients with AD in 1997, but side effects of broad dissemination of NGF throughout the neuraxis required a halt to the trial. Animal studies confirmed that nontargeted growth factor administration led to a variety of adverse effects, including weight loss, sensory axon sprouting (causing pain), sympathetic axon sprouting, and Schwann cell migration into the CNS. These adverse effects of nontargeted NGF delivery highlighted the dual need to not only achieve adequate concentrations of NGF in the brain to stimulate neurons but also spatially restrict growth factor delivery to regions of degenerating neurons to avoid adverse effects of NGF stimulation of intact neurons of other systems.

Subsequent studies attempted to achieve both effective and safe local delivery of NGF using techniques of gene therapy. The effectiveness and safety of NGF gene delivery were established in several preclinical studies using both rodent and primate models of AD (Figure 1), establishing the basis for a human clinical trial.

Based on these data, in 2001 the first human clinical trial of growth factor gene delivery was performed in eight humans with early stage AD. Patients were enrolled based on the rationale that early intervention was necessary both to prevent ongoing cholinergic neuronal loss and to allow research subjects to provide informed consent for this initial clinical trial. Gene therapy was accomplished using retroviral vectors that resulted in NGF secretion from the subjects' own skin fibroblasts, obtained several months earlier from skin biopsies. These NGF-secreting cells were then implanted into the brains of the AD patients adjacent to the cholinergic nucleus basalis of Meynert. Safety, cognitive, and neuroimaging outcomes were subsequently assessed.

Figure 1 NGF delivery by genetically modified fibroblasts rescues degenerating medial septum cholinergic neurons from lesion-induced degeneration in the primate basal forebrain. (a) Animals treated with control fibroblasts show a loss of cholinergic neurons on the right, lesioned side (boxed area) after unilateral fornix lesions that transect cholinergic axons projecting to the hippocampus (the natural source of NGF for these neurons). (b) In contrast, cholinergic neurons are preserved on the right, lesioned side of the brain (boxed area) after treatment with NGF-secreting cells.

Definitive conclusions regarding the efficacy of NGF delivery cannot be drawn from this small clinical trial in the absence of blinded assessments and placebo controls. Nonetheless, a potential benefit of NGF was identified in that the mean rate of cognitive decline in subjects was reduced by approximately 50% during the 2-year period of the trial compared to their own pretreatment rates of decline. Furthermore, comparison of cortical metabolic activity by positron emission tomography (PET) scan in NGF-treated subjects showed significant improvements in cortical glucose metabolism 6–8 months after treatment (Figure 2). No adverse effects of NGF gene delivery were detected during the 2-year period of the study. However, the trial was initially performed with subjects in a wakened state, and two subjects moved during cell injections, resulting in brain hemorrhages. Subsequent procedures were performed with subjects under general anesthesia and no further complications occurred. One subject came to autopsy 5 weeks after NGF gene transfer; examination of this subject's brain demonstrated robust trophic responses from cholinergic axons adjacent to the site of NGF delivery (axonal sprouting), definitively establishing that degenerating cholinergic neurons of the human AD brain can respond to NGF.

Although conclusions regarding efficacy cannot be drawn from this small study, if effects of this magnitude occur in proper blind and controlled trials, this would represent a significant improvement over current symptomatic therapies for AD and would provide the first long-lasting neuroprotective therapy. The findings of the phase I NGF gene therapy trial were of sufficient interest to support testing in expanded and controlled phase II clinical trials. These trials will begin following completion of a second phase I trial of NGF delivery in AD patients using newer, more efficient adeno-associated viral (AAV) vectors that is in progress.

Figure 2 Average fluor-deoxyglucose PET scans in patients grafted with NGF secreting fibroblasts to the nucleus basalis overlaid on standardized MRI templates. Comparison of the first scan (left) and the second scan (right) obtained 6–8 months later indicates a widespread increase in cortical metabolic activity after NGF delivery. Adapted from Tuszynski MH, Thal L, Pay M, et al. (2005) A phase 1 clinical trial of nerve growth factor gene therapy for Alzheimer disease. *Nature Medicine* 11: 551–555.

Since the initiation of the trial described previously, significant progress has been made in the development of viral vectors for *in vivo* gene therapy, making NGF gene delivery simpler and potentially more effective. Studies have shown that *in vivo* NGF delivery using AAV and lentivirus can effectively protect basal forebrain cholinergic neurons. Based on the results of *ex vivo* NGF gene delivery in patients with AD, and extensive preclinical safety, tolerability, and efficacy studies using AAV in rodents and primates, a phase I clinical trial evaluating AAV-mediated NGF gene delivery to the nucleus basalis in patients with

AD is currently under way. Following successful completion of current clinical studies, larger phase II/III trials will be needed to provide clear and objective data regarding the efficacy of NGF in AD. These findings will establish whether NGF can prevent or delay cholinergic degeneration, and whether NGF acting on only one of many neuronal systems undergoing degeneration in AD can improve memory and cognition or delay further cognitive deterioration.

Neurotrophins in Parkinson's Disease, Huntington's Disease, and Amyotrophic Lateral Sclerosis

Several neurotrophic factors, including BDNF, NT-3, and NT-4, have been shown to augment survival of midbrain dopaminergic neurons in the substantia nigra. This key neuronal population is the primary system resulting in the clinical signs and symptoms of Parkinson's disease. Although some promising animal studies demonstrated that BDNF can prevent the degeneration of nigral dopaminergic neurons in animal models, the majority of work has focused on glial cell line-derived neurotrophic factor (GDNF) and other members of this family of neurotrophic factors, discovered in the early 1990s.

NGF, BDNF, NT-3, and NT-4 have also been evaluated as neuroprotective agents of striatal neuronal degeneration in correlational animal models of Huntington's disease (HD). A neuroprotective strategy is particularly attractive in HD because susceptible individuals can be identified prior to disease onset by genetic testing. The excitotoxic lesion models of HD, consisting of quinolinic acid, kainic acid, or 3-nitropropionic acid injections into striatum, do not fully replicate the pathological changes in HD associated with the accumulation of polyglutamine-containing huntingtin inclusions. However, evidence does indicate a role of huntingtin in influencing BDNF transport and BDNF expression, providing additional rationale to investigate BDNF as a potential therapeutic molecule in this devastating polyglutamine disease. All the neurotrophins have in fact been reported to exert some degree of neuroprotection in animal models of HD, although the mechanism underlying these effects (rescue of medium spiny neurons) may be indirect.

BDNF has potent effects on motor neuron survival *in vitro*, during development, in adult animals, and after injuries to motor systems. These findings indicate that BDNF could be developed as a treatment for amyotrophic lateral sclerosis (ALS), in which ventral motor neuron degeneration is extensive. Indeed, several clinical trials evaluated BDNF as a neuroprotective agent in ALS. These trials were negative, however, because they encountered the conundrum of effective and safe delivery of growth factors to targeted neurons. Some trials administered BDNF via subcutaneous injection, likely leading to subtherapeutic levels in the CNS and broad distribution peripherally that would induce side effects. Other trials infused BDNF into the spinal fluid, again resulting in likely subtherapeutic concentrations in motor neurons of the spinal cord (due to low degrees of BDNF diffusion across the spinal cord surface) while inducing adverse effects from CNS-wide exposure. To test true efficacy, a means of targeting growth factors to affected motor neurons will need to be developed. Retrograde transport of gene therapy vectors after peripheral injection may be a means of achieving this goal, but further studies are required to optimize vector serotypes and envelope proteins to enhance retrograde transport.

Neurotrophins and Axonal Regeneration

Role of Neurotrophins in Peripheral Nervous System Regeneration

Axon regeneration after a nerve crush in the peripheral nervous system (PNS) is superior to regeneration observed in the CNS. Some of the factors contributing to the superiority of PNS regeneration include (1) formation of a supportive or 'bridging' extracellular matrix in sites of PNS injury, supporting new axonal growth; (2) secretion of several neurotrophic factors by Schwann cells around the lesion site, thereby attracting and guiding regenerating axons; (3) guidance of injured axons to motor end plate targets via the intrinsic detailed architecture of the peripheral nerve, including bands of Bungner that encompass the neurilemmal sheath, the injured axon, and its associated Schwann cell; and (4) an absence of inhibitors to regeneration (in contrast to the CNS, in which molecular inhibitors associated with myelin and the extracellular matrix impede axonal regeneration).

Of the factors contributing to peripheral regeneration, the production of growth factors in proper spatial and temporal gradients is essential for successful regeneration. That is, growth factors are produced in the right place and at the right time to attract regenerating axons and help guide them to targets often located very long distances distally (more than 0.5 m in humans). Neurotrophins are expressed by both Schwann cells and invading macrophages after PNS injury. Schwann cells upregulate expression of NGF, BDNF, NT-4, and other neurotrophic factors such as GDNF at the site of nerve injury and within the distal stump. In contrast, levels of NT-3 expression decrease, at least transiently. The increases in neurotrophin levels are very rapid and can be observed within a single day. At the same time that neurotrophin levels increase, Schwann cells upregulate expression

of the low-affinity neurotrophin receptor p75 on their cell surface. p75 may act as a receptor to both increase Schwann cell proliferation, and present neurotrophins to regenerating axons to achieve high localized concentrations of these growth factors.

Neurons with afferent and efferent projections in the PNS, including dorsal root ganglion (DRG) sensory neurons, spinal motor neurons, and sympathetic neurons, bind and retrogradely transport NGF, BDNF, NT-3, and NT-4. As axons regenerate, neurotrophin expression decreases at the injury site and subsequently in the distal stump. BDNF and NT-4 appear to play particularly important roles in peripheral nerve regeneration: Axon regeneration is impaired after neutralization of BDNF signaling in peripheral nerve by infusion of BDNF antibodies or in heterozygous trkB knockout mice. Consistent with these findings, both BDNF and NT-4 are upregulated in the nerve distal to an injury, and injections of BDNF enhance axonal regeneration. In addition to changes in neurotrophin levels observed in the injured nerve, increased levels of NGF and BDNF can be detected in the muscle after sciatic nerve transection, potentially contributing to target reinnervation.

These observations indicate that neurotrophins potentially initiate growth programs in injured axons and directly serve as chemotropic attractants for injured axons to stimulate localized axonal extension. Increased BDNF synthesis is also observed in DRG neurons, potentially preventing the death of these cells after injury. The exact mechanisms underlying increased neurotrophin expression by Schwann cells after PNS injury are incompletely understood and might be partially regulated by the loss of axonal contact or by the loss of a diffusible signal released by axons.

Given the importance of neurotrophins in supporting regeneration after nerve crush, their therapeutic application has been studied in models of long-distance nerve transection and root avulsion. Peripheral nerve injuries that result in gaps in the nerve generally have a poor prognosis, and the success of spontaneous regeneration declines with increased lengths of the nerve gap. To improve axonal regeneration in these injuries, autologous nerve transplants and silicone guidance tubes are currently employed to connect the nerve stumps. These strategies are relatively successful for short-distance gaps of less than approximately 0.5 cm, but they become increasingly ineffective as the bridging distance increases. Current studies are therefore investigating whether combinations of Schwann cell transplants, guidance tubes, and neurotrophin delivery will improve the speed of axonal regeneration and the distance and number of regenerating axons. Slow-release neurotrophin delivery methods such as fibrin matrices, genetically modified cells, or localized infusions in combination with nerve conduits made from biocompatible materials may provide superior regeneration compared to current techniques. Given the importance of neurotrophins for peripheral nerve regeneration, neurotrophin support in sufficient quantities for sufficient time periods will likely improve the otherwise poor degree of regeneration across long gaps in peripheral nerves.

In addition to the difficulties observed in PNS regeneration across nerve gaps, avulsion injuries disconnecting the peripheral nerve from the spinal cord have very poor clinical outcomes. This is in part due to motor neuron degeneration and cell death and in part due to the inability of dorsal root sensory axons to cross through the dorsal root entry zone and into the spinal cord as the environment transitions from the permissive regeneration milieu of the peripheral nerve to the nonpermissive regeneration milieu of the CNS. Poor axonal growth from the PNS to the CNS environment appears to be due to several factors, including myelin-based growth inhibitors present in the CNS; inhibitory extracellular matrix that forms after injury at the PNS/CNS interface, including the deposition of chondroitin sulfate proteoglycan family members; and the formation of a glial 'scar' at the dorsal root entry zone. Several studies have shown that delivery of NT-3 or NGF either by infusions or by *in vivo* gene transfer can promote regeneration across the dorsal root entry zone and reinnervation of the spinal cord in rodents. Regenerated axons can form functional synapses indicated by electrophysiological and functional recovery. Although viral NGF delivery has been shown to improve axonal regeneration after dorsal root avulsion injuries, NGF also results in sprouting of uninjured sensory axons from adjacent spinal segments, which can cause hyperalgesia and chronic pain. In fact, anti-NGF therapy might be one means of preventing aberrant sprouting of sensory axons in the spinal cord, which often leads to pain after PNS or spinal cord injury. Thus, the timing, amount, and spatial distribution of neurotrophins are likely to be the most important factors in the successful translation of neurotrophin therapy in PNS regeneration.

Neurotrophins and Regeneration in the CNS

The importance of neurotrophins in neuronal survival and axonal pathfinding during development, and peripheral nerve regeneration in the adult, has made these naturally occurring factors potentially promising targets to enhance regeneration in the adult CNS. Indeed, experiments during the past 10 years have demonstrated that neurotrophins delivered to the injured rodent or primate spinal cord can

substantially augment axonal plasticity and regeneration. Different neurotrophins influence the growth of distinct populations of axons in the spinal cord, based on the distribution of high-affinity neurotrophin receptors for trkA, -B, and -C. trkA is expressed on primary nociceptive afferent axons penetrating the spinal cord from DRG. In contrast, trkB and trkC are widely expressed in neurons with motor projections to the spinal cord, including corticospinal, red nucleus, locus coeruleus, vestibular, raphe, and reticular formation neurons. Trk receptors are actively trafficked into the axonal compartment of neurons, leading to enhanced axonal plasticity or regeneration when neurotrophins are administered to the spinal cord.

Although differences in the number, distance, and phenotype of extending axons have been reported among various studies, virtually all studies conducted to date demonstrate that axonal growth is enhanced by neurotrophins after spinal cord injury. The magnitude of this augmented axonal growth depends on the means, types, and amounts of neurotrophins applied and also on the spinal level of injury (Table 1). In particular, BDNF induces axonal growth from a diversity of descending motor systems, consistent with expression of trkB in the corresponding axonal populations. Responses to NT-4 are generally similar to those to BDNF because both growth factors signal through the same tyrosine kinase receptor, trkB. In addition, corticospinal axon growth in response to cellular or viral NT-3 delivery has been demonstrated in several studies. Ascending, proprioceptive dorsal column sensory axons also exhibit sensitivity to BDNF and NT-3, consistent with trkB and trkC expression in this group of large and medium-sized DRG neurons.

The inability of neurotrophins to cross the blood–brain barrier requires that they be delivered directly into the CNS to stimulate axonal growth. As noted previously, the administration of growth factors in models of axonal regeneration must also be restricted to specific target regions to prevent adverse effects of nontargeted delivery. These dual objectives of site-specific and site-limited growth factor delivery can be accomplished either by local neurotrophin infusions or by direct neurotrophin gene delivery using AAV or lentivirus vectors. If the objective of neurotrophin delivery is to promote axonal regrowth through a lesion cavity, neurotrophin delivery must be accompanied by the placement of a permissive extracellular matrix, or a 'bridge,' in the lesion cavity over which injured axons can extend. A common means of providing both a bridge in the lesion site and growth factors is to graft cells into the lesion site that have been genetically modified to secrete growth factors. This approach provides both a bridge (the cell graft) and the neurotrophin (via gene delivery). Cells used in such studies have included fibroblasts, Schwann cells, pre-degenerated peripheral nerve bridges, bone marrow stromal cells, and neural stem cells or progenitor cells.

The strongest growth has generally been observed following cellular or viral neurotrophin delivery due to a highly localized, long-lasting source of trophic supply. For example, fibroblasts genetically modified to express BDNF or NT-4 and grafted to the lesion site induce robust growth of serotonergic raphaespinal axons, rubrospinal axons, reticulospinal axons, coerulospinal axons, cholinergic spinal motor axons, and subtypes of sensory axons (Figure 3). Although corticospinal neuron cell bodies are known to express the high-affinity BDNF receptor trkB, and BDNF infusions can prevent the degeneration of corticospinal motor neurons after lesions close to the cell body, these axons do not respond to spinal BDNF delivery. The reasons underlying the lack of corticospinal axons growth in response to BDNF remain to be determined. BDNF might serve solely as a survival factor and not an axonal growth factor for corticospinal motor neurons, the distribution of trkB receptors might be restricted to the cortical cell body thereby preventing axonal responses, or myelin-based growth inhibitors and other inhibitory axonal inhibitors might outweigh the growth-promoting effects of BDNF.

Although neurotrophins can promote robust axonal growth into neurotrophin-producing cell grafts placed in spinal cord lesion sites, axonal bridging beyond the lesion sites has been much more difficult to achieve. The lack of extensive long-distance axonal growth can be attributed to a number of different factors, including the growth-inhibitory environment of the host spinal cord distal to the lesion site and a lack of factors attracting axons out of the favorable environment of a cellular graft. Localized neurotrophin delivery at the site of spinal cord injury is likely

Table 1 Growth of ascending and descending tracts after neurotrophin delivery to the injured spinal cord

Factor	*Response*
NGF	Nociceptive sensory, coerulospinal
BDNF	Nociceptive sensory, rubrospinal, reticulospinal, raphaespinal, coerulospinal, spinal motor axons
NT-3	Proprioceptive sensory, corticospinal
NT-4	Nociceptive sensory, propriospinal, reticulospinal, raphaespinal, coerulospinal, spinal motor axons

Figure 3 Neurotrophin-secreting fibroblasts grafted to the injured rat spinal cord enhance axonal growth. (a) Fibroblasts genetically modified to express NT-4 induce robust axonal growth into the graft (g), whereas (b) few neurofilament (NF)-labeled axons penetrate control grafts expressing green fluorescent protein (GFP) 3 months postgrafting. (c) Motor axons identified by choline acetyl transferase (ChAT) labeling and (e) numerous coerulospinal axons identified by dopamine β-hydroxylase (DBH) labeling densely penetrate NT-4 secreting cellular grafts, whereas only a few axons are found in control grafts (d, f). Scale bar = 108 μm (a, b); 88 μm (c, d); 64 μm (e, f). Adapted from Blesch A, Yang H, Weidner N, Hoang A, and Otero D (2004) Axonal responses to cellularly delivered NT-4/5 after spinal cord injury. *Molecular and Cellular Neuroscience* 27: 190–201, with permission from Elsevier.

to lead to a concentration gradient where the highest concentration of neurotrophic factors are encountered at the lesion center. Axons are therefore chemotropically attracted to the lesion center, where there is the highest concentration of neurotrophic factors, and may have no incentive for further extension beyond the lesion site. Strategies to enhance axonal regeneration by neurotrophin delivery in the injured spinal cord might therefore require neurotrophin gradients extending beyond the lesion site, combinations with other treatments to overcome axon growth inhibitors present in the CNS, or means of initiating an efficient cellular growth program to activate genes necessary for axonal regeneration (Figure 4).

As mentioned previously, injuries in the PNS result in increased BDNF expression at the injury site and the cell body. Increased BDNF expression in the cell body might contribute to the successful initiation of a genetic regeneration program in DRG neurons. Thus, in addition to the studies described previously that have primarily focused on the site of axonal transection for growth factor delivery, neurotrophin application at the site of the cell soma has been considered as a means to enhance axonal regeneration. In particular, BDNF administration to rubrospinal neuronal cell bodies in the midbrain has been shown to not only prevent lesion-induced cell atrophy but also initiate an increase in the expression of regeneration-associated

Figure 4 Schematic of positive growth-promoting stimuli (green arrows) and negative growth-inhibiting influences (red arrows) after spinal cord injury.

genes, including GAP-43 and β-tubulin. BDNF delivery at the cell soma also increases axonal growth of rubrospinal axons into a peripheral nerve bridge grafted to the lesioned spinal cord. The induction of a genetic program for axonal regeneration by neurotrophins or by other means is likely to be an important factor or even a prerequisite for optimizing the extent of axonal regeneration.

Optimization of axonal regeneration in the CNS will likely require combinatorial treatments that address several mechanisms that ordinarily limit plasticity and regeneration. Nonetheless, partial functional recovery after neurotrophin administration has been reported in several studies after targeted delivery of BDNF or NT-3 in rodent models of spinal cord injury. For example, NT-3 delivered to sites of midthoracic hemisection spinal cord injury, using genetically modified fibroblasts, induced growth of corticospinal axons for limited distances around the lesion site that was subsequently associated with partial functional recovery. Cellular BDNF delivery after a cervical transection of the dorsolateral funiculus also induced growth of rubrospinal axons for short distances beyond the lesion site, resulting in partial recovery of forelimb function. Combined delivery of both of these growth factors has also been reported to induce functional improvement. Of note, however, mechanisms of functional improvement remain incompletely understood: whereas axonal sprouting or regeneration may account for some neurotrophin-induced recovery, it is also possible that stimulation of motor programs for walking (spinal locomotor pattern generators) may be induced by growth factors independent of inputs from systems above the injury. Furthermore, neurotrophins could also influence myelination or synaptic strength as alternative means of supporting functional improvement. Identification of mechanisms underlying neurotrophin-induced recovery after spinal cord injury requires greater clarification and objective study.

Whereas the majority of studies conducted to date have focused on neurotrophin-mediated effects in acute axonal injury paradigms, patterns of neurotrophin-induced axonal growth after chronic spinal cord injury have generally been found to be similar to those observed after acute injury. Chronically injured neurons appear to remain responsive to neurotrophin delivery for prolonged time periods after the initial injury, when injured axons remain in close proximity to the lesion site. Indeed, most projecting motor systems to the spinal cord survive chronic periods of injury and remain in proximity to the lesion site, representing an axonal pool that can be recruited to potentially undergo regeneration.

Primate studies of axonal plasticity and regeneration in response to neurotrophin delivery have been undertaken. The development of a primate model is

an important step in determining whether findings to date in rodent models are likely to be of relevance to the potential treatment of human disorders.

Conclusion

At least two mechanisms appear to contribute to the regeneration-enhancing properties of neurotrophins: Growth factors attract and stimulate axon growth (a 'neurotropic' property), and growth factors appear to initiate a survival and regeneration program (a 'neurotrophic' property). Spontaneous regeneration in the PNS is accompanied by a tightly regulated program of spatial and temporal changes in neurotrophin expression. Effective therapeutic treatments in CNS regeneration will ultimately require approaches that allow a replication of these temporal and spatial changes in neurotrophin production.

Introduction

Nerve growth factor (NGF) was the first neurotrophin family member and the first nervous system growth factor to be identified. NGF was originally isolated from a mouse sarcoma based upon its ability to promote the hypertrophy of, and fiber outgrowth from, peripheral sensory neurons. Subsequently, other neurotrophin family members were identified, including brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT3), and neurotrophin-4 (NT4). Although originally described as a potentially novel growth factor, neutrotrophin-5 was found to be identical to NT4. Two other neurotrophin members, neurotrophin-6 and-7, were identified in fish but do not appear to have corresponding homologs in mammals.

Neurotrophin Production and Release

Neurotrophin proteins are synthesized as precursors of approximately 270 amino acids (30–35 kDa) and are subsequently cleaved to yield mature proteins of ~120 amino acids (13 kDa) in length. While most physiological actions of neurotrophins have been ascribed to the mature proteins that generally function as soluble, non-covalently linked homodimers, recent studies have identified potentially critical roles for the unprocessed neurotrophin precursors (see later). Elements within the precursor sequence of newly generated neurotrophins presumably direct the intracellular sorting of neurotrophin molecules into one of two distinct pathways, resulting in either constitutive or regulated secretion. This process of intracellular sorting plays a critical role in determining the possible spectrum of physiological actions mediated by a given neurotrophin molecule by determining when and where neurotrophin secretion will take place. While neurotrophins were originally believed to function exclusively as target-derived factors that mediate signaling in a retrograde manner, recent studies have provided substantial evidence that some neurotrophins function partially, or exclusively, as anterograde molecular signals.

Neurotrophin Actions Are Mediated by Distinct Cell Surface Receptors

Once neurotrophins are released from the cell of origin, their actions are mediated by binding to distinct cell surface receptors. The specificity of neurotrophin action is controlled primarily by the pattern of expression of receptors in distinct populations of neurons located at the site of neurotrophin release.

Two distinct classes of neurotrophin receptors have been identified. The p75 neurotrophin receptor (p75NTR) is a member of the tumor necrosis receptor family that binds all of the mature neurotrophins with a similar, nanomolar affinity. Recent studies have indicated that the p75NTR can also bind unprocessed neurotrophin precursors with a high affinity. The second class of neurotrophin receptors is made up of three distinct members of the tropomyosin-related kinase (Trk) receptor family. The various neurotrophins show some degree of specificity with respect to their binding of distinct Trk receptors as shown in Figure 1. Binding of neurotrophins to their respective Trk receptors occurs with an affinity 100-fold greater than binding of mature neurotrophins to the p75NTR. Moreover, the various Trk family members have highly homologous intracellular domains, suggesting they use similar signaling pathways to mediate their effects. Differential splicing of TrkB and TrkC genes can also produce neurotrophin receptors that lack the intracellular kinase domains. The functions of these truncated receptors are unknown, but studies have suggested that they may play a role in regulating the availability or presentation of secreted neurotrophins to full-length and active receptors.

The physiological role of the p75NTR has been a subject of considerable study. The p75NTR was initially thought to act as a coreceptor, conferring high-affinity binding of neurotrophins to their respective Trk receptors and promoting retrograde transport of neurotrophins from their targets. However, in the absence of Trk receptor expression, the p75NTR may promote apoptosis via multiple pathways, including an increase in nuclear factor-kappa B (NF-κB) activity and by inducing sphingomyelin hydrolysis into ceramide (Figure 2). Neurotrophin binding to the p75NTR also leads to increased activation of c-Jun N-terminal kinase (JNK), a stress-activated protein kinase that has also been implicated in cell death. Binding of the precursor for NGF to the p75NTR has recently been demonstrated to increase apoptotic death signaling; the consequence of binding other neurotrophin precursor molecules to this receptor remains to be determined. A key factor in determining the fate of neurotrophin signaling through the p75NTR appears to be the extent to which Trk receptors are co-expressed; in the presence of Trk receptors, neurotrophins primarily support cell survival, whereas

Figure 1 Neurotrophins binding to their receptors. All neurotrophin precursors associate with the p75NTR with similar high-affinity binding. Processed (mature) neurotrophin proteins also bind to the p75NTR with a 100-fold lower affinity. Mature neurotrophins bind with high affinity to members of the tropomyosin-related kinase (Trk) family. Interactions with Trk receptors show a high degree of ligand specificity, with nerve growth factor (NGF) binding selectively to TrkA, brain-derived neurotrophic factor (BDNF) and neurotrophin-4 (NT4) binding to TrkB, and NT3 binding primarily to TrkC. Figure 3 Neurotrophin signaling through Trk receptors. Binding of mature neurotrophins to Trk receptors leads to the phosphorylation of a wide variety of associated proteins, which ultimately induce alterations in gene expression. Neurotrophin actions through Trk receptors affect neuronal survival, neurite outgrowth, cell morphology, and synaptic efficacy. Adapter proteins are shown in red, kinase proteins in green, small G-proteins in blue, and transcription factors in brown. From Huang EJ and Reichardt LF (2001) Neurotrophins: Roles in neuronal development and function. *Annual Review of Neuroscience* 24: 677–736.

in the absence of Trk receptors, neurotrophin signaling through p75NTR primarily mediates cell death.

Binding of mature neurotrophins to their respective Trk receptors induces dimerization of the receptors and the activation of kinase activity. Increased phosphorylation activity mediated through activated Trk receptors drives cellular responses through three distinct molecular pathways as indicated in Figure 3, resulting ultimately in a variety of transcriptional changes. Neurotrophin signaling through Trk receptors can influence many aspects of cell function, including cell survival, neurite outgrowth, and cellular differentiation.

Neurotrophin Physiology

Cell Survival

One of the classic physiological functions attributed to neurotrophins is the regulation of cell survival, specifically within neuronal populations expressing a particular type of neurotrophin receptor. Within the peripheral nervous system, tightly regulated neurotrophin expression is thought to be responsible for controlling neuron number through the process of programmed cell death, whereby a precisely timed and limited expression of target-derived neurotrophins limits the survival of responsive neurons projecting to a given peripheral target. Data from genetically mutant mice with targeted deletions of specific neurotrophins have provided evidence supporting a role for neurotrophins as target-derived regulators of neuronal survival in the periphery. Consistent with known patterns of neurotrophin and receptor expression, targeted deletion of either specific neurotrophins or their receptors results in profound, yet specific, losses of distinct populations of peripheral neurons during development. For instance, targeted deletion of NGF results in a nearly complete loss of peripheral sympathetic and nociceptive sensory neurons that express TrkA receptors. Targeted NGF deletion, however, does not significantly reduce the number of TrkC-expressing peripheral sensory neurons.

Based upon observations made within the peripheral nervous system during development, it was initially postulated that neurons within the central nervous system (CNS) may also rely upon neurotrophin support for their survival, not only during development but also in the adult. In spite of this prediction, there is strikingly little evidence suggesting that neurotrophins play a significant role in promoting cell survival within the CNS, either during development or in the adult. For instance, basal forebrain cholinergic neurons, which possess both p75NTR and TrkA receptors throughout life and show numerous physiological responses to NGF, show minimal deficits in developmental cell survival following targeted deletions of either NGF or its corresponding TrkA receptor. Moreover, deletion of the cellular source of neurotrophins in the adult animal also fails to cause cell death. However, neurotrophins appear to have many other effects upon neurons in the CNS, especially pertaining to cellular differentiation, target innervation, and synaptic plasticity.

Cell Differentiation and Morphology

In addition to their well-defined actions on cell survival, neurotrophins have been implicated in numerous aspects of cellular differentiation. Some of the earliest studies with NGF demonstrated that this neurotrophin induced dramatic outgrowth of neurites from developing peripheral neurons. Subsequently, the various members of the neurotrophin family have been implicated in mediating a variety of morphological changes, in a multitude of distinct neuronal populations, including the extension and guidance of axons, hypertrophy of the cell body, and changes in dendritic complexity and dendritic spine density. For example, respective expression of BDNF or NT3 in cortical target regions of extending axons during brain development appears to define zones of axon growth termination in strikingly laminar patterns, helping to establish the detailed topography of mature innervation. In addition to controlling the initial outgrowth of neuronal processes, neurotrophins have been strongly implicated in the process of maintaining target innervation in both central and peripheral targets. One of the most striking effects observed in NGF knockout animals is the failure of NGF-sensitive cholinergic neurons to retain appropriate innervation of their central targets.

Neurotrophins also play an important role in other aspects of cellular differentiation, helping to determine the ultimate fate and function of certain cells. For example, NGF promotes the differentiation of sympathoadrenal precursors into sympathetic neurons, as opposed to adrenal chromaffin cells. Neurotrophins also play more subtle roles in neuronal function by regulating the expression of neurotransmitters, ion channels, and receptors, both during development and, in many cases, throughout adulthood.

Synaptic Function and Synaptic Plasticity

In addition to regulating neuronal function, neurotrophins have direct actions on synaptic function and synaptic plasticity. Application of neurotrophins at developing and mature synapses can stimulate or modulate neurotransmitter release under many circumstances. The induction of long-term potentiation (LTP), a possible electrophysiological substrate for long-term storage of information in the nervous system, is potently regulated by BDNF. *In vitro* and *in vivo* applications of BDNF to the hippocampal formation are capable of inducing long-lasting synaptic potentiation in the absence of any additional excitatory stimulus. Moreover, the ability to induce LTP in the hippocampus with an electrical stimulus is greatly attenuated when BDNF signaling is disrupted. Together, these results suggest that BDNF may play a critical and necessary role in regulating synaptic plasticity in certain populations of neurons. Whether or not the regulation of synaptic plasticity is a selective property of BDNF is unknown at present, but NGF and NT3 have not been demonstrated to influence synaptic function and LTP in a similar manner.

Neurotrophin Pharmacology

The potent survival effects of neurotrophins on neurons of the peripheral nervous system originally discovered 50 years ago fostered speculation for many years that neurotrophins may also promote the survival of CNS neurons, thereby representing pharmacological candidates for treating neurodegenerative diseases. The degeneration of specific neuronal populations is a hallmark of the most common neurodegenerative disorders, including losses of midbrain dopaminergic neurons in Parkinson's disease and the loss of basal forebrain cholinergic neurons as one component of multisystem cell loss in Alzheimer's disease. The hypothesis that neurotrophins might represent a new class of therapeutic molecules was substantiated by studies published in the mid-1980s, demonstrating that NGF prevented the injury-induced death of basal forebrain cholinergic neurons in adult rats. NGF neuroprotection of adult cholinergic neurons was also reported after lesions in the brains of adult primates. Other studies reported that spontaneous atrophy and dysfunction of basal forebrain cholinergic neurons in aged rats and primates could also be reversed by NGF administration. Further, NGF treatment significantly ameliorated

Table 1 Potential clinical uses for neurotrophins

Neurotrophin	*Targeted cell population*	*Disease*
Nerve growth factor	Basal forebrain cholinergic	Alzheimer's disease
	Sensory nociceptive	Peripheral neuropathy
Brain-derived neurotrophic factor	Cortical neurons	Alzheimer's disease
	Spinal motor neurons	Amyotrophic lateral sclerosis
	Midbrain dopaminergic	Parkinson's disease
	Cortical neurons	Acute brain injury/stroke
Neurotrophin-3	Sensory proprioceptive	Peripheral neuropathy

age-related memory impairments. Collectively, these findings established a theoretical basis for pursuing clinical trials targeting NGF therapy for the treatment of Alzheimer's disease, whereby a significant loss of basal forebrain cholinergic neurons is postulated to contribute to ongoing cognitive decline.

Analogous experimental paradigms explored the possibility that the neurotrophins could protect cell populations affected in a diverse spectrum of neurodegenerative diseases, including nigral neurons, motor neurons of the spinal cord, and dorsal root ganglion sensory neurons (see Table 1).

Clinical Trials with Neurotrophins

The potent actions of neurotrophins in preventing neuronal degeneration and augmenting cell function made them intriguing candidates for clinical testing in human neurological disorders. To date, neurotrophins and other growth factors have been tested in clinical trials in Alzheimer's disease, Parkinson's disease, amyotrophic lateral sclerosis, stroke, and peripheral neuropathy. Trials are also under consideration in treating Huntington's disease and spinal cord injury.

In spite of the extensive animal data supporting the potential use of neurotrophins in treating a variety of neurological diseases, no studies to date have yielded clear evidence of efficacy. One of the most important limiting factors in testing the clinical potential of neurotrophins has been the availability of an effective, safe, and sustained method of delivering growth factors to the brain. Because neurotrophins are large and charged proteins, they do not cross the blood–brain barrier after peripheral administration. When infused into the cerebrospinal fluid space of the brain (intraventricular or intrathecal infusions), growth factors usually fail to diffuse to neuronal targets. In the case of NGF, intraventricular or intrathecal infusions broadly disseminate the neurotrophin throughout the subarachnoid space of the brain and spinal cord, inducing the migration of Schwann cells into the CNS, stimulating nociceptive axons of the dorsal root ganglia (DRG) (resulting in pain), eliciting sympathetic axon sprouting around the cerebral vasculature, and causing weight loss. Thus, clinical testing of neurotrophins requires a delivery method that both achieves adequate growth factor concentrations at target neurons that may lie deep within the brain, and restriction of growth factor delivery to target regions in order to avoid adverse effects of broad growth factor dissemination in the cerebrospinal fluid space. Chronic intraparenchymal growth factor infusion into the brain, or growth factor gene delivery into the brain, may be a means of achieving these goals.

Indeed, recent signs of possible growth factor activity in Alzheimer's disease and Parkinson's disease have been reported using targeted intraparenchymal delivery methods. In Alzheimer's disease, a recent phase I clinical trial of NGF gene delivery to cholinergic neurons was reported to increase glucose utilization in the cortex by positron emission scanning, and to elicit new growth of axons toward the NGF source. Potential effects on cognition are being explored in phase II clinical trials of NGF gene delivery in Alzheimer's disease. A clinical trial of growth factor gene delivery in Parkinson's disease is also under way (using neurturin, a glial-derived neuronal growth factor). Three recent clinical trials using intraparenchymal infusion of glial-derived neuronal factor (GDNF) have also been conducted in Parkinson's disease. The development of these targeted, restricted, and sustained growth factor delivery methods raises the possibility that the next few years will definitively establish whether growth factors will prove useful for the treatment of CNS disorders.

Neurotrophins have also undergone clinical testing for peripheral neuropathy: NGF is a tropic factor for a subpopulation of nociceptive sensory neurons with cell bodies in the DRG, and NT3 is a tropic factor for large-diameter proprioceptive neurons of the DRG. NGF was tested in patients with diabetes using intermittent peripheral subcutaneous injections, but failed to show efficacy. Once again, problems with potentially subtherapeutic doses, inadequate targeting, and rapid peripheral degradation of NGF limited the

interpretability of the study. NT3 is also being tested in clinical trials for drug-induced peripheral neuropathy. Solutions to the challenge of targeted, sustained, and safe growth factor delivery for treatment of peripheral nervous system disorders await identification, to determine whether early potential signals of growth factor activity in the CNS may also be achievable in the peripheral nervous system.

Phases and Stages of Neurulation

The central nervous system is one of the first organ systems to develop in vertebrate embryos. The process by which this occurs is called neurulation. Neurulation is a developmental event that results in formation of the neural tube, the early hollow rudiment of the adult central nervous system. Once formed, the neural tube differentiates into a rostral portion, the future brain, and a caudal portion, the future spinal cord. The future brain further divides into three main swellings, the forebrain, midbrain, and hindbrain, and further subdivision occurs throughout the rostrocaudal extent of the neural tube with the formation of segmental swellings called neuromeres.

Neurulation occurs in two sequential phases termed primary and secondary neurulation. Primary neurulation occurs in four clearly defined but overlapping steps. In the first step, the neural plate is formed from epiblast, one of two primitive layers composing the early embryo. In the second step, the neural plate undergoes shaping, extending its length and narrowing its width. In the third step, the neural plate bends to form a neural groove, flanked by bilateral neural folds. In the final step, the tips of the neural folds meet and fuse in the dorsal midline to generate the neural tube. Secondary neurulation also involves a series of steps. In the first step, a solid mass of cells, derived from the tail bud, forms. This solid mass is called the medullary cord. In the second step, the medullary cord cavitates to form multiple lumina. In the final step, all lumina coalesce into a single, central lumen bounded by the walls of the so-called secondary neural tube. The processes of primary and secondary neurulation give rise to different rostrocaudal levels of the neural tube. Primary neurulation forms the entire brain and most of the length of the spinal cord (down to about the lumbosacral level), whereas secondary neurulation forms the tailmost portion of the spinal cord. Because much more is known about the cellular and molecular mechanisms of primary neurulation, compared to secondary neurulation, and because most of the neural tube forms during primary neurulation, further discussion herein focuses only on primary neurulation. Also, the following discussion of the tissue and cellular bases of primary neurulation is based principally on the chick, because this model system has been the main one used to unravel the morphogenetic mechanisms underlying neurulation.

Tissue and Cellular Events Underlying Primary Neurulation

The neural plate is formed during gastrulation when epiblast cells located rostral to and beside Hensen's node and the cranial portion of the primitive streak respond to signals from the node by a process known as neural induction. The epiblast cells undergo apicobasal thickening to generate a neural plate, which at this initial stage of development is broad mediolaterally and short rostrocaudally. Once the epiblast is committed to such a neural fate, formation of the neural plate becomes autonomous to the committed cells and does not require the presence of either Hensen's node or nonneural ectodermal cells.

Neural plate shaping is the process by which the broad and short neural plate becomes narrowed transversely and elongated rostrocaudally (Figures 1(a)–1(c)). This is achieved through a convergent-extension movement of the neural plate. A convergent-extension movement consists of a simultaneous rostrocaudal lengthening and mediolateral (transverse) narrowing of the neural plate (Figure 1(d)). The neural plate also undergoes further apicobasal thickening during its shaping.

The neural plate begins to bend while neural plate shaping is underway. This commences in the cranial region first, and in the spinal cord region later. The process resembles the closing of a door as it rotates around its hinges. The midline of the neural plate remains fixed during bending, creating a median hinge point (MHP) along essentially the entire rostrocaudal extent of the neuraxis, whereas the lateral aspects of the neural plate are elevated gradually, forming the neural groove and incipient neural folds (i.e., the initial folds at the lateral margins of the neural plate) (Figures 2(a)–2(c)). Subsequently, additional bending occurs in the neural plate close to its junction with the epidermal ectoderm, resulting in the formation of two dorsolateral hinge points (DLHPs) (Figures 3(a)–3(c)). This is seen at prospective cranial levels of the neuraxis, as well as the extreme caudal end of the future spinal cord region. The morphological hinge points are localized regions where the neural plate is anchored to adjacent tissues – the MHP to the prechordal plate mesoderm and notochord and the DLHPs to the adjacent surface ectoderm of the

Figure 1 Whole-mounts of chick embryos undergoing primary neurulation, viewed from the dorsal surface (a–c), and a model of neuroepithelial cell rearrangement during neural plate shaping (d). (a) The neural plate (np) has just formed; its approximate borders are outlined (hn, Hensen's node; ps, primitive streak). (b) The neural plate is undergoing shaping; its approximate borders are outlined (n, notochord). (c) The neural plate is initiating bending, establishing a neural groove (ng), while still undergoing shaping. (d) Cell rearrangement occurs during shaping of the neural plate, thereby increasing its length while decreasing its width; median hinge point neural plate cells, yellow; lateral neural plate cells, red and green.

Figure 2 (a–c) Cross-sectional views showing formation of the median hinge point (*) and elevation of the incipient neural fold (nf) at the future midbrain level of the chick. The light micrographs are transverse plastic sections at three sequential stages.

Figure 3 Cross-sectional views showing formation of the dorsolateral hinge points (*), formation and convergence of the definitive neural folds (nf), and closure of the neural groove in the chick. The light micrographs are plastic transverse sections through the future midbrain (a) and hindbrain (b) levels at one stage, and through the future forebrain level (c) at a later stage.

neural folds. Thus hinge points stabilize the neural plate during bending. Bending about the DLHPs results in convergence of the definitive neural folds, directing their tips medially until they meet in the dorsal midline in readiness for fusion (Figure 3(c)). Elsewhere (i.e., throughout most of the length of the spinal cord), where DLHPs are not formed, bending occurs about the MHP only, bringing the apical surfaces of the neuroepithelial cells into apposition with each other (Figure 4). This results in a temporary occlusion of the spinal canal. The absence of the DLHPs, and therefore neural fold convergence, in the spinal cord is one of the major differences between neurulation at cranial and spinal cord levels of the neuraxis.

The neural folds are located at the lateral margins of the neural groove and include the junction of the neural plate with the adjacent epidermal ectoderm. The incipient neural folds first appear as the neural plate folds about the MHP. Later, as folding occurs about the DLHPs, the definitive neural folds become evident. Each neural fold is double-layered, composed of an inner neuroepithelial layer and an outer epidermal ectodermal layer. Four key events occur in sequence during formation and morphogenesis of the neural folds. They are epithelial ridging, kinking, delamination, and apposition (Figure 5). Epithelial ridging is characterized by the formation of a ridge at the prospective outer epidermal–inner neuroepithelial transition zone (Figure 5(a)). It results from the difference in heights of the epidermal ectoderm (ee) and

Figure 4 Scanning electron micrograph showing apposition of the neural folds (nf) in the chick at the spinal cord level (level of the seventh somites, S) of the neuraxis. Fusion of the neural folds is in progress and the neurocele is occluded.

neuroepithelial (NE) cells, and it initiates the formation of the neural folds. The NE cells increase their heights, whereas the ee cells decrease theirs. The next step is epithelial kinking (Figure 5(a)), defined as the formation of a concave curvature centered at the prospective ee–NE interface. The main feature here is a change in cell shape within the incipient neural folds; the cells here have constricted bases and expanded apical ends, and are described as inverted wedge-shaped, in sharp contrast to the morphology of the cells at the hinge points, which are described as wedge-shaped. The third event is epithelial delamination (Figure 5(b)), defined as the splitting of a single epithelium into two epithelial layers. The process results in the formation of a linear interface at the ee–NE transition zone between the two epithelial layers. Delamination occurs by cavitation and the deposition of extracellular matrix at the interface. The cells then reorient radially with respect to the interface and acquire intercellular junctions between either adjacent ee cells or adjacent NE cells, but never across the interface between ee and NE cells. The final event of neural fold morphogenesis is epithelial apposition (Figure 5(c)). This is the increase in width of the interface formed during epithelial delamination. The hallmark of this stage of neural fold morphogenesis is a mediolateral expansion of the NE layer, coupled with an apicobasal flattening of the ee layer. Regional differences exist in the degree of epithelial apposition along the rostrocaudal extent of the neuraxis. Generally, where DLHPs are formed and convergence of the neural folds occurs, as seen at forebrain and midbrain levels, apposition is extreme. However, where true DLHPs do not form, as at rostral spinal cord levels, epithelial apposition is lacking.

The final stage of primary neurulation involves the closure of the neural groove. Of all of the steps of avian neurulation, this is the step that has been least explored. Following neural fold convergence, the tips of the neural folds are brought into apposition with each other in the dorsal midline where fusion occurs. In the chick embryo, neural groove closure commences in the prospective midbrain region before progressing rostrally to involve the forebrain, and caudally to involve the hindbrain and spinal cord.

Figure 5 Drawings and scanning electron micrographs showing the four key events of neural fold formation and morphogenesis at the future brain level in the chick embryo: epithelial ridging and kinking (a, b), epithelial delamination (b), and epithelial apposition (c). dlhp, dorsolateral hinge point; ee, epidermal ectoderm; nf, neural fold; np, neural plate. Arrow on micrograph indicates the neural ridge and point of kinking (a). Dashed lines on micrographs indicate the neural fold interface (b, c).

This leaves the rostral and caudal ends of the neural tube temporally open; these openings are known as the rostral and caudal neuropores, respectively. At the tip of each neural fold at most rostrocaudal levels, the epidermal ectoderm caps the neuroepithelium. Apposition of the neural folds, therefore, brings the two epidermal ectodermal layers in contact with each other. Hence, fusion of the neural fold commences with the epidermal ectoderm. As fusion progresses, the newly formed epidermal ectoderm layer delaminates from the neuroepithelium. This brings the neuroepithelium layers of each fold into apposition for fusion of the neuroepithelium to commence. Neural fold fusion is, therefore, described as a double fusion involving two epithelial layers.

Cell Behaviors Generate Tissue Forces in Primary Neurulation

Formation of the neural plate in the chick embryo occurs through cell palisading, which is apicobasal thickening owing to cell elongation. The neural plate so formed consists of a pseudostratified columnar epithelium with two principal cell types, namely, spindle-shaped or fusiform, and wedge-shaped or flask-shaped, as well as other cell types (spherical and inverted wedge-shaped) present in far fewer numbers. The increase in the heights of neuroepithelial cells during neural plate formation is attributed largely to the activity of paraxial microtubules aligned along the long axes of the cells. But other factors such as cell packing and changes in cell–cell adhesion may also contribute to the increase in thickness of the neural plate.

Shaping of the neural plate is largely the result of convergent-extension movements generated by cells within the neural plate. The cell behaviors that account for this movement during shaping of the neural plate in the chick embryo include neuroepithelial cell rearrangement and oriented or nonrandomized cell division. Neuroepithelial cells undergo approximately two rounds of rearrangements (i.e., cell–cell intercalation) during neurulation, narrowing the width of the neural plate by about half during each round, while simultaneously doubling its length with each round (Figure 1(d)). The process is believed to be driven by interkinetic nuclear migration, as well as by cell protrusive activity. Additionally, lengthening of the neural plate is achieved by oriented neuroepithelial cell division. On average, chick neuroepithelial cells undergo two to three rounds of cell division over a 24 h period, the plane of cleavage being at right angles to the orientation of the mitotic spindles. In about half of these divisions, daughter cells are placed in the long axis of the neural plate, thereby contributing to its rostrocaudal extension.

Bending of the neural plate involves two main events, neural plate furrowing and neural plate folding. Furrowing of the neural plate involves the formation of longitudinal furrows at the three morphological hinge points (one MHP and two DLHPs) (Figure 6). Furrowing is driven by changes in neuroepithelial cell shapes at the hinge points. A significant number of neuroepithelial cells at the MHP (70%) and DLHPs (55%) become wedge-shaped during furrowing (Figure 5). In contrast, less than 35% of neuroepithelial cells outside the hinge points become wedge-shaped during neurulation, with a majority of these cells remaining spindle-shaped. Furrowing at the hinge points, therefore, is generated through neuroepithelial cell wedging. Neuroepithelial cell wedging is achieved through both apical constriction and basal expansion of neuroepithelial cells. These processes are likely mediated by contraction of apical bands of microfilaments and translocation of cell nuclei to the bases of the cells during interkinetic nuclear migration, respectively. The signal for furrowing at the MHP comes from the underlying notochord.

Unlike furrowing, folding of the neural plate is mediated by the lateral nonneuroepithelial tissues, principally the epidermal ectoderm, assisted by the mesoderm, endoderm, and the extracellular matrix underlying the neural plate. The cell behaviors in the epidermal ectoderm responsible for folding include cell flattening, oriented cell division, and cell–cell intercalation.

Figure 6 Drawing illustrating the cooperative (hinge point) model of bending of the chick neural plate. Neuroepithelial cell wedging within the hinge points is indicated by red (median hinge point) and blue (dorsolateral hinge points). Arrows indicate mediolateral expansion of the epidermal ectoderm. Single asterisk indicates furrowing associated with the median hinge point; double asterisks indicate furrowing associated with the dorsolateral hinge points; ee, epidermal ectoderm; n, notochord.

Both Intrinsic and Extrinsic Tissue Forces Drive Primary Neurulation

Several studies demonstrate that the forces driving neurulation reside both within the neural plate (intrinsic), as well as outside of this structure (extrinsic). Intrinsic forces are responsible for neural plate shaping and furrowing, and they are generated by behaviors of neuroepithelial cells, such as changes in cell shape, position, and number. In contrast, extrinsic forces generated outside the neuroepithelium account for neural plate folding and neural groove closure. Experimental evidence implicates the epidermal ectoderm in generating a major extrinsic motive force for folding of the neural plate. First, separation of the neural plate and underlying layers from the epidermal ectoderm and underlying layers results in shaping and furrowing of the neural plate, but not folding. Second, removal of the neural plate and underlying layers, leaving intact epidermal ectoderm and underlying layers, results in medial expansion of the epidermal ectoderm. This provides direct evidence of a medially directed epidermal expansion. Third, removal of the epidermal ectoderm, leaving the underlying mesoderm and endoderm intact, stops folding, whereas folding occurs normally after removal of the mesoderm and endoderm beneath the epidermal ectoderm while leaving the latter intact. Finally, when epidermal ectodermal cells at the ee–NE transition zone are tagged with a fluorescent marker and their movement is followed over time, the labeled cells thin and spread medially during neural fold morphogenesis. Primary neurulation thus requires both intrinsic and extrinsic forces acting in concert.

Toward a Molecular Understanding of Primary Neurulation

Progress in understanding the molecular basis of primary neurulation has occurred on two fronts: neural induction and shaping and bending of the neural plate. In regard to the former, the neural plate is now known to be the default state of the ectoderm, and induction of the neural plate actually involves suppressing the formation of the epidermal ectoderm (neural induction is not considered further herein). In regard to shaping and bending of the neural plate, about 100 mutations in the mouse have been identified that result in defective shaping and/or bending and, consequently, result in neural tube defects (NTDs); thus, these mutations provide insight into which genes are involved in both normal and abnormal neurulation. Because these form-shaping events of neurulation are driven by changes in cell behavior, as discussed earlier, it is not surprising that mutation of cytoskeletal, extracellular matrix/cell adhesion, cell cycle, and cell death genes results in NTDs. Neurulation is a highly choreographed morphogenetic series of events that must be precisely timed and coordinated across multiple tissues. This presumably involves signaling among tissues. It is the hope of studies using mouse mutations that such signaling pathways will be identified, ultimately leading to an understanding of the molecular basis of neurulation and the formation of NTDs in both animal models and ultimately in humans. In the following sections, we discuss what has been learned about the molecular basis of shaping and bending of the neural plate.

Shaping and Bending of the Neural Plate

Planar-Cell Polarity Pathway and Convergent Extension

As discussed earlier, convergent extension plays a major role in neurulation. Recent studies have revealed that convergent extension is regulated by the Wnt (wingless) signaling pathway. During development, epithelial sheets become polarized not only apicobasally but also within the plane of the epithelium. In *Drosophila*, the planar-cell polarity (PCP) pathway functions in this latter polarization of the epithelium. Thus, for example, the orientation of wing hairs is established by the PCP pathway. In vertebrates, the PCP pathway is required for proper orientation of stereociliary bundles in the outer hair cells of the mouse inner ear, and for convergent extension during gastrulation and neurulation. How are the PCP and Wnt signaling pathways related?

The *Drosophila* PCP pathway consists of several core proteins that collectively act to convert an extracellular polarity cue into specific changes in the cytoskeleton. These core proteins are now known to be components of the Wnt signaling pathway, and orthologs of several of the *Drosophila* components are conserved in vertebrates. Thus, convergent extension during gastrulation and neurulation is blocked in loss-of-function mutations of the cytoplasmic protein dishevelled in *Xenopus* and its two orthologs in mouse (dishevelled 1 and 2). Wnt signaling involves both a so-called canonical Wnt pathway and a noncanonical Wnt pathway. The PCP pathway utilizes the noncanonical pathway in which certain Wnts, such as Wnt11, bind to their receptors (known as frizzleds). Several other proteins, including dishevelled, must interact in this pathway for proper signaling (and, consequently, for proper convergent extension) to occur. In addition to double dishevelled 1 and 2 mutants, four other mouse mutants exhibit convergent-extension defects: circletail, crash, spin cycle, and loop-tail.

Loop-tail mice have a mutation in the ortholog of the strabismus/van gogh-like gene (*Vangl1*, *Vangl2*), which encodes a transmembrane protein that interacts with dishevelled. Both crash and spin cycle mice have a mutation in the ortholog of the *Drosophila* protocadherin flamingo gene called *Celsr1*. In *Drosophila*, flamingo is required for PCP signaling. Circletail mice have a mutation in the ortholog of the *Drosophila* scribble gene (*Scrib*). Scribble interacts with strabismus. Thus, obtaining an understanding of the PCP pathway in *Drosophila* has had a surprising result – a better understanding also of vertebrate gastrulation and neurulation, and, potentially, a better understanding of how NTDs form in humans.

Actin-Binding Proteins and Apical Constriction

Several actin-associated proteins, when genetically ablated in mice, result in NTDs. One of these, the actin-binding protein shroom, has received considerable study. Overexpression of shroom in cultured epithelial cells is sufficient to cause apical constriction. Shroom causes apical constriction by altering the distribution of F-actin to the apical side of epithelial cells and regulating the formation of a contractile actomyosin network associated with apical intercellular junctions. When shroom is inactivated in *Xenopus* embryos, hinge point formation is drastically altered and neural tube closure fails to occur, providing further evidence for a role of cell shape changes in generating intrinsic forces important for neurulation.

Toward the Prevention of Neural Tube Defects

Neurulation is a complex developmental process that often goes awry in human embryos, leading to neural tube defects, serious congenital anomalies that are severely debilitating and sometimes life threatening. Although the tissue and cellular bases of neurulation are now well understood, the challenge for future studies will be to dissect the molecular basis and provide molecular candidates for mutational analysis in humans. Once such candidate genes are discovered, early and accurate detection of NTDs will be a realty, and their total prevention may be on the horizon. Although the underlying mechanisms remain unclear, periconceptional folic acid supplementation has been shown to reduce the incidence of NTDs in human infants dramatically. Thus, by understanding the process of neurulation better, the hope remains that some day NTDs, severely debilitating birth defects, may no longer occur.

Neutrotransmission and Neuromodulation: Acetylcholine

R M Twyman, University of York, York, UK

© 2009 Published by Elsevier Ltd.

Introduction

Acetylcholine is a major neurotransmitter in the peripheral nervous system, with release sites at synapses on all preganglionic and postganglionic parasympathetic neurons, on all preganglionic and some postganglionic sympathetic neurons, and at neuromuscular junctions of skeletal muscle fibers. It is also a neurotransmitter and neuromodulator in the brain, with particularly important roles in learning and memory. Acetylcholine is synthesized from choline and acetyl-coenzyme A (CoA), and is broken down by a dedicated enzyme rather than relying solely on reuptake to eliminate its activity, thus allowing the rapid initiation and termination of signaling when required. There are two distinct classes of acetylcholine receptor, one for rapid responses and one involving second messengers and facilitating longer term effects. Each class of receptor has multiple forms and complex expression patterns in the nervous system and target organs.

Discovery and History

The acetylcholine molecule (Figure 1) was discovered in 1914 by Henry Hallett Dale, who first suggested its possible role as a neurotransmitter. However, it was experiments carried out by Otto Loewi in 1921 that provided definitive proof. Loewi showed that an isolated frog's heart with an intact vagus nerve would continue to beat if bathed in a simple saline solution, and that electrical stimulation of the vagus nerve led to a reduction in the heart rate. If the solution bathing the first heart was then transferred to a second heart that lacked a vagus nerve, that heart too would slow down. Loewi deduced correctly that a diffusible chemical signal released from the first heart was causing the second heart to slow down, and that stimulation of the vagus nerve was triggering its release. He named the molecule 'vagusstoff' because its effects mimicked stimulation of the vagus nerve, but it was later shown to be identical to Dale's acetylcholine. Dale and Loewi were jointly awarded the 1936 Nobel prize in physiology or medicine for their work.

Synthesis, Release, and Recycling

Acetylcholine is synthesized from choline and acetyl-CoA in a reaction catalyzed by the enzyme choline acetyltransferase (Figure 2). This reaction takes place in the cytoplasm of the nerve terminal, to which both reactants are transported independently. Choline comes originally from phosphatidylcholine in the diet (this is the major phospholipid component of animal and plant cell membranes). However, choline is also scavenged from the synaptic cleft, and this is the rate-limiting process in acetylcholine synthesis. The import of choline from the extracellular fluid at the nerve terminal is facilitated by a sodium-dependent carrier. In contrast, acetyl-CoA is available in abundance since it is not only transported to the synapse but also synthesized in mitochondria which are present at the synapse in their thousands. Acetylcholine is stored and transported in synaptic vesicles which may each hold up to 50 000 molecules.

The release of acetylcholine is triggered by an influx of calcium ions, brought about by action potentials stimulating voltage-gated calcium channels in the synaptic membrane. The calcium ions in turn bind to a vesicle-associated protein called synaptotagmin, which promotes the association of a second vesicle protein called synaptobrevin with proteins lodged in the synaptic plasma membrane. This culminates in fusion between the vesicle and plasma membranes and the release of acetylcholine by exocytosis.

Once released, acetylcholine is free to interact with receptors on the postsynaptic cell surface (see the section titled 'Acetylcholine receptors'). However, it is rapidly broken down into choline and acetate by the enzyme acetylcholinesterase (Figure 3), which is present in large amounts in the synaptic cleft. The activity of acetylcholine is therefore short lived. Over 50% of the choline formed in this reaction is taken up by endocytosis at the nerve terminal and reused for acetylcholine synthesis. The empty synaptic vesicle is also recaptured by endocytosis and its components reused.

Acetylcholine Receptors

There are two main classes of acetylcholine receptor, known as nicotinic and muscarinic receptors. Nicotinic receptors are ionotropic, that is, they are ligand-gated ion channels, which are permeable to sodium, potassium, and chloride ions. They are fast acting (capable of responding in microseconds) and are activated by nicotine as well as acetylcholine, hence their name. They are selectively blocked by curare. Nicotinic receptors are made up of five subunits arranged symmetrically around the central pore. In mammals, 17 different types of subunit have been identified thus far, some expressed specifically in muscles and active at the neuromuscular junction, and some expressed specifically

in neurons. The neuronal receptors are very heterogeneous, with a wide range of possible subunit combinations and a complex distribution throughout the central and peripheral nervous systems.

The muscarinic receptors are G-protein-coupled receptors. They are metabotropic and are slower acting, responding in milliseconds but with longer-lasting effects. They work by stimulating the release of second messengers (either cyclic AMP or inositol triphosphate (IP_3), depending on the receptor class) which have downstream effects on other ion channels. The muscarinic receptors are capable of plasticity and play a significant role in learning and memory (see the section titled 'Role and distribution in the central nervous system'). They are so named because they bind selectively to the toxin muscarine, which is found in poisonous mushrooms. In mammals there are five receptors encoded by five genes, and four of these have also been identified through the use of selective radioactively labeled agonists and antagonists. They have distinct and complex distribution patterns throughout the central and peripheral nervous systems and on target muscles and glands.

Role and Distribution in the Peripheral Nervous System

Acetylcholine is the principal neurotransmitter at the neuromuscular junctions of skeletal, cardiac, and smooth muscle fibers. In the autonomic nervous system, all preganglionic and postganglionic parasympathetic neurons are cholinergic, as are all preganglionic sympathetic neurons. Most postganglionic sympathetic neurons are not cholinergic, but secretory fibers to sweat glands and vasodilator fibers to the blood vessels of skeletal muscles are exceptional in this regard. Acetylcholine is also used in preganglionic sympathetic fibers to the suprarenal medulla, a modified sympathetic ganglion. Although the distribution of receptors is complex, the preganglionic fibers of sympathetic and parasympathetic nerves are nicotinic, while the short postganglionic fibers of the parasympathetic nervous system are muscarinic. The neuromuscular junctions of skeletal muscles are nicotinic to facilitate the rapid response to voluntary impulses.

Figure 1 The molecular structure of acetylcholine.

Role and Distribution in the Central Nervous System

There are relatively few cholinergic neurons in the brain, and the most prominent sources of acetylcholine are found in the basal forebrain, particularly in the striatum and in basal nuclei such as the septal nuclei, the nucleus basalis, and the interpeduncular nucleus (Figure 4). All striatal interneurons in the primate brain are cholinergic, although this represents only about 1% of the neurons in total. These are distributed throughout the caudate nucleus, putamen, and nucleus accumbens. Despite their relative scarcity, cholinergic neurons innervate most parts of the brain including the basolateral amygdala, cortex, hippocampus, and thalamus.

Nicotinic receptors are widely distributed in the brain, but they are present in relatively low numbers. Even so, a large proportion of the world's population habitually stimulates these receptors with nicotine through tobacco use (and to a lesser extent through the chewing of betal nuts, which contain another nicotinic receptor agonist, arecoline). The euphoric addiction resulting from this practice is well documented, but the natural synaptic functions of these receptors are unclear.

Most cholinergic receptors in the brain are muscarinic, and the second messenger systems thus deployed provide scope for neuromodulatory activity and the development of synaptic plasticity. Accordingly, studies in animals and humans have suggested that the cholinergic neurons in the brain are important in cognition, learning, and memory (see the section titled 'Acetylcholine as a neuromodulator in learning and memory').

Acetylcholine as a Neuromodulator in Learning and Memory

The role of acetylcholine in cognition, learning, and memory has been established by experiments in humans and animals involving drugs that either stimulate or inhibit muscarinic receptors, and animal experiments involving lesions of basal nuclei. The central

Figure 2 Acetylcholine synthesis.

administration of drugs such as physostigmine, a reversible inhibitor of acetylcholinesterase, significantly improves the performance of humans and animals in learning and cognition tasks. In contrast, the central administration of muscarinic antagonists such as atropine and scopalomine leads to memory loss and impairment of performance in learning tasks. Similar effects can be brought about by surgical lesions of the nucleus basalis, but these effects can be partially ameliorated by treatment with physostigmine. Taken together, these data suggest that acetylcholine plays an important but not exclusive role in learning and memory through the activation of muscarinic receptors, probably by providing neuromodulatory input to cortical and hippocampal neurons.

Figure 3 Degradation of acetylcholine and reuptake of choline at the nerve terminal.

The mechanism of cortical neuromodulation by acetylcholine has been studied in brain slices and *in vivo* in the cat motor cortex. Acetylcholine enhances the activity of many cortical neurons by suppressing membrane potassium currents and hence causing depolarization and suppression of adaptation. Acetylcholine has been shown to enhance the amplitude of synaptic potentials following long-term potentiation in the neocortex and piriform cortex. It is thought that direct enhancement of currents through *N*-methyl-D-aspartate (NMDA) receptors is augmented by the indirect suppression of adaptation. Acetylcholine also causes slow depolarization by blocking tonically active potassium currents, thus increasing neuronal excitability. However, the increased spiking activity in inhibitory interneurons leads to weaker synaptic transmission from those cells. This paradoxical combination can be explained by selectivity. The suppression of synaptic transmission occurs at intrinsic synapses within the cortex, but not at the afferent synapses connecting external neurons to the cortex.

The neuromodulatory effects of acetylcholine in the hippocampus involve muscarinic receptors acting upon potassium, calcium, and mixed cation channels, decreasing the slow calcium-activated potassium

Figure 4 Midsagittal section of rat brain showing locations of important groups of cholinergic neurons and their projections.

current, the fast transient repolarizing potassium current IA, and the resting potassium current. In addition to these ion-selective currents, the hyperpolarization-activated mixed cationic current Ih is potentiated by muscarinic agonists. In pyramidal cells, acetylcholine causes a slow depolarization due to the suppression of the previously mentioned tonically active potassium current, suppresses spike frequency adaptation in pyramidal cells due to decreases in calcium-dependent potassium currents, and causes rapid excitation of hippocampal interneurons by modulating potassium conductance. Acetylcholine can also cause the presynaptic suppression of excitatory synaptic transmission, suggesting a role for the molecule in switching between learning and recall in hippocampal and olfactory networks.

Agonists, Antagonists, and Role in Disease

Given the extensive and diverse functions of acetylcholine in the central and peripheral nervous systems, it is not surprising that chemicals with the ability to enhance or inhibit the effects of this molecule are very useful in medicine and as toxins. Notably, several diseases are known to result either partially or fully from defects in acetylcholine production or signaling. Acetylcholine agonists include agents that mimic the structure of acetylcholine and activate either nicotinic or muscarinic receptors or both, and agents that act indirectly by inhibiting acetylcholinesterase and therefore increasing the availability of acetylcholine. Acetylcholine antagonists can be divided into those which selectively block nicotinic and muscarinic receptors and those which block both.

Reversible acetylcholinesterase inhibitors include galantamine, neostigmine, physostigmine, rivastigmine, and tacrine. They are clinically useful for the treatment of Alzheimer's disease and myasthenia gravis, and they are also used to reverse the effect of muscle relaxants. Given the role of acetylcholine in learning and memory, it is interesting to note that the natural decline of memory and learning ability that accompanies aging correlates with decreased synthesis of acetylcholine in the brain and the loss of cholinergic neurons. In Alzheimer's disease, patients may show a striking reduction in the number of cholinergic neurons in the nucleus basalis, and the effects can be partially reversed using anticholinesterase drugs such as tacrine. However, many other neurons are affected in Alzheimer's disease, and some patients show normal cholinergic cell numbers. There is therefore great variation in the response to anticholinesterase therapy. Myasthenia gravis is an autoimmune disease characterized by profound muscle fatigue, resulting from the production of antibodies against nicotinic receptors, eventually resulting in irreversible degeneration of the neuromuscular junction. Anticholinesterases are useful because they prolong the half-life of acetylcholine, allowing more time for it to interact with the limited number of receptors.

As well as the preceding reversible inhibitors, which work by competing with endogenous acetylcholine for the active site of the enzyme, there are also inhibitors which bind irreversibly to the enzyme and permanently block its activity. These have no medical uses but are often used as toxins. Some are used as pesticides (e.g., the organophosphate Parathion) and others as potent toxins (e.g., Sarin and VX nerve gas are based on this principle).

Centrally acting anticholinesterases worsen the tremors seen in Parkinson's disease because they affect cholinergic interneurons in the striatum. These effects can be reversed by muscarinic antagonists such as atropine, which is also the preferred treatment for anticholinesterase poisoning. Atropine has been used historically to dilate the pupils and is still used for that purpose today, although its effects can last for many days so alternative mydriatics such as tropicamide and phenylephrine are preferred. The major medical use of atropine is resuscitation by blocking the vagus nerve, thus preventing the heart rate from slowing. Nicotinic antagonists are used as muscle relaxants during therapy, and in higher doses can be used to paralyze. The plant-derived toxin curare works by blocking nicotinic receptors, as do a number of snake venoms.

Nicotine

D J K Balfour and C S Birch, University of Dundee Medical School, Dundee, UK

Nicotine is the principal pharmacologically active component of the tobacco plant *Nicotiana tabacum*, the primary source of smoking tobacco. It is now widely accepted that humans inhale tobacco smoke in order to experience the psychopharmacological properties of the nicotine present in the smoke and that a majority of habitual smokers become addicted to the drug. Nicotine has reinforcing or rewarding properties which are thought to be central to its ability to cause dependence. Additionally, it enhances arousal and sustained attention. It also increases information processing, especially of visual information, and shortens reaction times. Furthermore, nicotine might have anxiety-reducing (anxiolytic) properties and might heighten mood.

The evidence that people smoke in order to experience the pharmacological effects of nicotine is compelling. For example, if the nicotine content of tobacco is manipulated artificially, most smokers adapt their smoking behavior in order to self-administer the dose of the drug which they find most reinforcing. This may be achieved either by smoking more cigarettes or, more commonly, by inhaling the smoke more deeply in order to extract the nicotine more efficiently. Nicotine exerts its effects in the brain by stimulating nicotinic cholinergic receptors located on target neurons. If smokers are given drugs which block these receptors, they tend to adjust their smoking behavior to overcome this blockade. Conversely, the prior administration of nicotine diminishes the desire to smoke and attenuates the withdrawal symptoms experienced by many smokers when they first try to quit the habit. This provides the pharmacological basis for using nicotine replacement therapy as an aid to smoking cessation. It is assumed that the addiction to tobacco depends principally upon the rewarding or reinforcing properties of nicotine, although it seems likely that other factors such as the irritant nature of the smoke might also contribute to the development of addiction. Although studies with human subjects have provided clear evidence that nicotine is the principal addictive component of tobacco smoke, research into the mechanisms underlying nicotine addiction is more easily undertaken using *in vitro* or *in vivo* techniques in experimental animals.

Evidence that Nicotine Has the Properties of a Drug of Addiction

In animal models, nicotine exhibits the principal behavioral characteristics of a drug of dependence. It has reinforcing or rewarding properties which can be detected using, for example, the place preference paradigm or the intravenous self-administration (IVSA) paradigm. The precipitous withdrawal of the drug following a period of chronic treatment also elicits behavioral effects which are thought to reflect a nicotine withdrawal syndrome.

The place preference paradigm utilizes an apparatus which has two compartments that can be clearly distinguished by their appearance and texture. On alternate training days, animals are either injected with nicotine and restricted to one of the compartments or injected with saline and restricted to the other compartment. During the test session, the animals are not given an injection, but are allowed free access to both compartments. The rewarding or reinforcing properties of the drug are demonstrated by the fact that the animals tend to spend more time in the compartment which had previously been paired with the drug.

In the technically more difficult IVSA paradigm, animals are trained to perform a task such as lever-pressing or nose-poking in order to receive small, intravenous injections of a drug. Importantly, such intravenous doses reach the brain rapidly, and, as a result, the animal readily associates performance of the task with delivery of the drug. Similarly, the inhalation of nicotine in tobacco smoke also results in a rapid transfer of nicotine to brain. Thus, although the experimental paradigm does not model completely the inhalation of nicotine in tobacco smoke, it provides a good model for the pharmacokinetic and pharmacodynamic factors which are likely to be important to the development of dependence. Nicotine IVSA is, therefore, now widely accepted as a reliable measure of the reinforcing properties of nicotine which are thought to underpin the addiction to tobacco. However, it has often proved difficult to train animals to self-administer nicotine intravenously, and, indeed, when compared with the IVSA of other psychostimulant drugs of dependence, such as amphetamine or cocaine, the reinforcing properties of nicotine as assessed using this paradigm seem to be relatively weak. Thus, the reinforcing properties of nicotine alone do not seem to explain the powerful addictive properties of the drug when inhaled in

tobacco smoke. The self-administration of addictive drugs is, however, often enhanced significantly if their administration is associated with the presentation of another stimulus which, alone, has little or no efficacy as a reinforcer. When a stimulus of this type (generally a light and/or a tone) is used, it can acquire the properties of a conditioned stimulus (CS) by being closely associated with delivery of the primary rewarding stimulus, in this case an addictive drug. This is the case with nicotine IVSA; when a CS is incorporated into the protocol, the behavior is acquired more readily and reproducibly. As a result, a substantial majority of the studies which have sought to investigate the reinforcing properties of nicotine using an IVSA protocol have employed a CS. Once the relationship between a CS and nicotine has been established, responding can also be maintained for a significant number of days by presentation of the CS alone, indicating that the CS has acquired the ability to act as a reinforcer in its own right. In human smokers, the tobacco smoke vehicle in which nicotine is usually delivered is a rich source of stimuli which could serve as conditioned stimuli. It has been suggested, therefore, that the powerful addiction to tobacco reflects the development of a close association between the pharmacological effects of nicotine in the brain and the sensory stimuli present in tobacco smoke which irritate the mouth, throat, and bronchi of the smoker. This hypothesis gains powerful support from studies reported by Rose and colleagues, which show that smokers find denicotinized cigarettes, which retain a majority of the sensory properties of the smoke inhaled from nicotine-containing cigarettes, satisfy their craving to smoke. Moreover, these sensory stimuli seem to be particularly important to the most heavily addicted smokers.

The other primary characteristic of a drug of addiction shown by nicotine is a withdrawal effect when it is precipitously withdrawn or its effects are antagonized by the administration of a nicotinic receptor antagonist. These effects are best shown in animals which have been given nicotine by constant infusion from a minipump for a number of days, and include teeth chattering, chewing, gasping, writhing, head shakes, body shakes, and tremors. Such withdrawal effects are attenuated or abolished by the administration of nicotine and by some, but not all, of the drugs which are used to aid smoking cessation in humans, and are therefore thought to model the abstinence syndrome experienced by many smokers when they first quit smoking. Some of the behavioral changes observed when nicotine is precipitously withdrawn are thought to be mediated by changes within the brain, whereas others may reflect physiological and biochemical adaptations within the peripheral nervous systems. One behavioral change which clearly depends upon neuroadaptation within the brain has been demonstrated using intracranial self-stimulation (ICSS), which can be used to measure the effects of nicotine withdrawal on reward thresholds. In this paradigm, animals are trained to perform a task to stimulate electrodes, commonly implanted into the lateral hypothalamus, one of the 'reward' pathways of the brain. The current required to elicit this behavioral response is seen as a physiological measure of the reward threshold. Nicotine injections reduce the brain reward threshold, suggesting that the intensity of reward required to evoke a reward-seeking behavioral response is decreased. By contrast, the abrupt withdrawal of nicotine, following a period of chronic treatment, increases the brain reward threshold, suggesting that the intensity of reward required to evoke a reward-seeking behavioral response is increased. This increase in the brain reward threshold is thought to be a behavioral correlate of the anhedonia experienced by many newly abstinent smokers. The increase in reward threshold, evoked by nicotine withdrawal, is attenuated by the administration of nicotine.

Neurobiological Mechanisms Underlying the Reinforcing Properties of Nicotine

Nicotine exerts its effects in the brain by acting on neuronal nicotinic acetylcholine receptors which, physiologically, are stimulated by acetylcholine (ACh) released from adjacent neurons. These receptors are pentameric structures commonly composed of two alpha subunits and three beta subunits, although some receptors composed entirely of alpha subunits (e.g., those containing $\alpha 7$ subunits) are also thought to exist. There is evidence that a number of different subtypes of the receptor, composed of different receptor subunits, are expressed on neurons within the brain. The effects of nicotine on each subtype of the receptor reflect both the affinity of the receptor for nicotine and the physiological effects that the drug exerts at that receptor. Transgenic methods, employing mice in which the expression of different nicotinic receptor subunits has been knocked out or manipulated in some other way, have been used increasingly to investigate the subunit composition of the receptors which mediate the effects of nicotine in the brain. Studies with transgenic mice have shown that deletion of the $\beta 2$ subunit of the nicotinic receptor results in the generation of a mouse strain in which the expression of $\alpha 4\beta 2$ nicotinic receptors is abolished

and nicotine no longer has reinforcing properties. These results have been used as circumstantial evidence that the reinforcing properties of nicotine depend upon stimulation of this subtype of the nicotinic receptor.

The administration of nicotine to experimental animals results in complex changes in the release of various neurotransmitters in many areas of the brain. Many of these changes potentially could contribute to the mechanisms underlying nicotine dependence. However, there is a considerable body of evidence to support the conclusion that the mesolimbic dopamine (DA)-secreting neurons, which innervate the nucleus accumbens from the ventral tegmental area (VTA), play a pivotal role in nicotine-seeking behavior. For example, selective 6-hydroxydopamine lesions of these neurons significantly and substantially attenuate both responding for nicotine in rats trained to lever-press for the drug and the locomotor stimulant response (the increase in spontaneous locomotion) to nicotine. Studies with human subjects have also shown that blocking DA receptors within the brain elicits changes in smoking behavior, which reinforces the idea that brain DA pathways play an important part in the reinforcing properties of tobacco smoke. These observations imply that systemic injections of nicotine stimulate DA release in the nucleus accumbens. This has been confirmed in a number of laboratories, principally using *in vivo* microdialysis which permits the measurement of DA overflow in discrete areas of the brain of conscious freely moving rats. More recently, positron emission tomography (PET) studies have confirmed that the inhalation of tobacco smoke also stimulates DA overflow in the human brain. A majority of the studies which have sought to explore the role of neuronal nicotinic receptors in the mesolimbic DA response to nicotine *in vivo* have found that the DA responses to nicotine are mediated, to a significant extent at least, by nicotinic receptors in the VTA. The results of these studies imply that nicotine stimulates DA overflow in the nucleus accumbens by influencing impulse flow to the terminal field. Furthermore, behavioral responses such as locomotor stimulation and nicotine-seeking behavior, both of which are dependent upon increased DA release from mesolimbic neurons, are also preferentially attenuated by the administration of nicotinic receptor antagonists into the VTA. More recent microdialysis studies employing transgenic strains of mice in which the $\beta 2$ subunit of the nicotinic receptor has been deleted have shown that the effects of nicotine on DA release in the nucleus accumbens depends upon the expression of these $\beta 2$ subunits. Since nicotine also has no reinforcing properties in these mice, the studies provide further evidence that mesolimbic DA neurons play a central role in mediating the reinforcing properties of nicotine. The nucleus accumbens is composed of two principal anatomically and morphologically distinct subdivisions, the shell and the core, which are thought to subserve different functions. These two subdivisions have been shown to respond differentially to several drugs including nicotine: acute administration of nicotine to drug-naive animals selectively stimulates DA overflow in the nucleus accumbens shell whereas administration of a nicotine challenge to animals that have been pretreated with the drug for some days also results in increased DA overflow in the nucleus accumbens core. The accumbal core sends major projections to areas of the brain related to motor function. Initially, therefore, it seemed reasonable to conclude that enhanced DA release in the accumbal core explained the increased locomotor response, observed in rats challenged with nicotine following a period of chronic treatment. However, further research using a variety of experimental approaches has demonstrated a clear dissociation between the enhanced DA response in the accumbal core and the expression of the increased locomotor response to the drug observed in nicotine-pretreated rats. For example, drugs which antagonize *N*-methyl-D-aspartate (NMDA) glutamatergic receptors in the brain attenuate the effects of nicotine on DA overflow in the accumbal core but have no effect on the enhanced locomotor activity seen in nicotine-pretreated rats. Selective sensitization of the DA projection to the accumbal core is a property which nicotine shares with other drugs of dependence such as amphetamine, cocaine, and morphine, and it now seems more likely that the effect is implicated in the neurobiology underlying dependence. Other evidence suggests that the sensitized locomotor response to nicotine, observed in pretreated animals, is associated with sensitization of postsynaptic DA receptors in the shell subdivision of the accumbens.

More recently, it has been suggested that the increased DA overflow in the shell and core subdivisions of the accumbens may play complementary roles in the development of drug addiction, with increased DA overflow in the accumbal shell being thought to facilitate or promote responding for the drug. Di Chiara argues that increased DA overflow in this subdivision of the nucleus accumbens enhances incentive or habit learning of the behaviors that deliver addictive drugs. The presentation of natural reinforcers, such as food or water, has been shown to increase DA overflow in the shell subdivision of the nucleus accumbens. However, the effects of addictive

drugs, including nicotine, on DA overflow in this area of the brain are substantially larger and more prolonged than those normally evoked by natural rewards. Thus, Di Chiara hypothesized that the unphysiological magnitude and duration of the effect results in behaviors associated with the acquisition of drug-seeking behavior which come to dominate the behavioral repertoire of the individual in the manner that is characteristic of dependence. Robinson and Berridge have long argued that the sensitized DA responses, observed in animals pretreated with psychostimulant drugs of dependence, play an important role in mediating the way in which conditioned stimuli influence drug-seeking behavior. More recently, Balfour has summarized evidence which suggests that the sensitized responses to nicotine, observed in the accumbal core of nicotine-pretreated rats, serves this specific function. He hypothesized that the increase in extracellular DA, which can be measured in the accumbal core and shell in response to a nicotine challenge, reflects increased burst firing on the neurons through a process which is dependent upon the co-stimulation of NMDA glutamatergic receptors in the VTA. This causes the substantial and sustained increases in DA overflow which can be measured using *in vivo* microdialysis. Balfour further suggested that the DA released as a consequence of burst firing of these neurons functions as a local hormone which serves to influence the intensity of events mediated by the accumbal shell and the core (Figure 1).

It is proposed that increased DA overflow in the shell increases the probability that an individual will repeat a behavioral response, thereby facilitating acquisition of behaviors that generate rewards. Increased DA overflow in the core is hypothesized to increase the probability that a CS will elicit reward-seeking behavior. The mechanisms which mediated the sustained effects of nicotine on these neurons remain a matter for debate, although Mansvelder and colleagues have suggested that the effect is maintained by a sequence of events within the VTA in which $\alpha 4\beta 2$ subunit-containing nicotinic receptors located on both the DA neurons and γ-aminobutryic acid (GABA) terminals are initially stimulated and then desensitized by exposure to nicotine. The increased activity of the neurons is maintained, however, by the persistent stimulation of $\alpha 7$ subunit-containing nicotinic receptors located on glutamate terminals which facilitate the release of glutamate within the VTA. This, the authors argue, maintains increased activity of DAergic neurons and, thus, increased DA overflow in the nucleus accumbens.

Figure 1 This figure illustrates the DA pathways that are hypothesized to contribute to the development of addiction to nicotine and tobacco. In nicotine-pretreated individuals, injections of nicotine increase DA overflow in the both the shell and core subterritories of the nucleus accumbens. The increased DA overflow in the accumbal shell is hypothesized to increase the 'pleasure' or 'hedonic impact' derived from behaviors associated with the delivery of the drug. As a result, the probability that the individual will repeat the behavior is greatly enhanced. Furthermore, stimuli that are paired with drug delivery acquire pleasurable reinforcing properties. Once the association between the delivery of nicotine and the presentation of the conditioned stimuli has been established, presentation of stimuli alone can reinforce nicotine-seeking behaviors. The hypothesis posits that the increase in DA overflow in the accumbal core elicited by a nicotine injection greatly increases the probability that presentation of the CS will elicit nicotine-seeking behavior; thus, nicotine evokes the compulsive drug-seeking behavior which is characteristic of addiction. Reproduced from Balfour DJK (2006) Complementary roles for the accumbal shell and core in nicotine dependence. Chichester and New York: Wiley, with permission from Novartis Foundation.

The Neurobiology of Nicotine Withdrawal

The other important behavioral response evoked by sustained exposure to nicotine is an abstinence syndrome which is evoked by the abrupt withdrawal of the drug. The mechanisms which mediate this syndrome remain to be established, although Malin and colleagues have suggested that they might be related to the stimulation of brain opioid receptors since administration of the opiate receptor antagonist naloxone will also evoke the syndrome. Recent studies with transgenic mice have shown that expression of these nicotine-withdrawal effects is not altered by deletion of neuronal nicotinic receptors which contain $\beta 2$ subunits. Thus, since the reinforcing properties of the drug depend upon stimulation of these receptors (see above), it is likely that different populations of neuronal nicotinic receptor mediate the two principal components of nicotine dependence, reinforcement and withdrawal. It is important to remember, however, that the withdrawal effects described by Malin and colleagues are likely to reflect changes in both the brain and the peripheral nervous system. The nature of the neuronal nicotinic receptors which mediate this effect remain to be established.

Other studies have shown that nicotine can inhibit the release of serotonin (5-hydroxytryptamine; 5-HT) in the rat hippocampus and that chronic exposure to nicotine is associated with a regionally selective decrease in the concentration and formation of 5-HT in this area of the brain. Changes in 5-HT release in this area of the brain have been implicated in the psychopathology and treatment of anxiety and depression. Smoking is significantly more prevalent in people with an underlying depressive disorder, and these smokers tend to be more dependent upon nicotine than smokers in the general population. It seems reasonable to propose that these effects may be implicated in the neurobiology underlying nicotine dependence, because other studies have shown that chronic exposure to the nicotine present in tobacco smoke also elicits regionally selective changes in the concentrations of 5-HT and its principal metabolite, 5-hydroxyindoleacetic acid (5-HIAA), and the density of 5-HT_{1A} receptors in human brain. These data imply that inhaling nicotine in tobacco smoke exerts the same effects on the 5-HT pathways which innervate human hippocampus as those observed in response to nicotine in the rat brain. A more recent study has shown that the increase in brain reward threshold, evoked by nicotine withdrawal in rats, can be attenuated by the co-administration of the 5-HT-selective reuptake inhibitor fluoxetine (more widely known as Prozac), with a 5-HT_{1A} receptor antagonist. This observation implies that the neuroadaptive changes in serotonergic function, evoked by chronic nicotine, may also mediate components of the nicotine abstinence syndrome. This conclusion is consistent with report of Seth and colleagues, which also concluded that elements of the nicotine abstinence syndrome are mediated by stimulation of 5-HT_{1A} receptors.

Effects of Nicotine on the Responses to Stressful and Anxiogenic Stimuli

There are consistent reports that tobacco smoking is more prevalent among individuals who suffer from stress-related psychiatric disorders, especially depression, and that these individuals often smoke more heavily and are more dependent upon tobacco than the general population. This has led Markou and colleagues to suggest that smokers with an underlying depressive disorder might use nicotine as a form of self-medication for their condition. In studies with experimental animals, nicotine has been shown to have properties similar to those of an anxiolytic drug in a number of behavioral models including the elevated plus-maze test and the social interaction test. These results are inconsistent, however, being influenced to a significant extent by the experimental protocol employed, the dose of nicotine used, the duration of treatment, and the route of administration. Other studies have shown that nicotine can exhibit the properties of an antidepressant drug in paradigms employing the forced swim test or learned helplessness. Again, however, the results of these studies are not always consistent and seem to depend upon the protocol used.

The neurobiological mechanisms underlying the putative anxiolytic and antidepressant properties of nicotine remain to be established. One hypothesis which may explain its antidepressant properties posits that the stimulation of DA overflow in the nucleus accumbens, evoked by nicotine administration, attenuates the anhedonia experienced by people who suffer from the condition. Certainly, as mentioned above, there is evidence that nicotine injections reduce brain reward thresholds, an effect which is thought to model the 'hedonic' response to nicotine inhaled in tobacco smoke. Thus, it seems reasonable to conclude that this effect could contribute to the antidepressant properties of the drug. However, it seems unlikely that this provides a complete explanation for the antidepressant-like effects of nicotine because, in some studies, the response was observed in animals given the drug by constant infusion, a protocol that is unlikely to maintain raised extracellular DA in the nucleus accumbens. Nicotine has also been shown to have anxiogenic properties, and

both the anxiogenic and anxiolytic properties have been related most clearly to its effects on 5-HT release in the hippocampus. The anxiogenic properties seem to be mediated by stimulation of 5-HT_{1A} receptors in the dorsal hippocampus and lateral septum while the anxiolytic properties have been related to stimulation of somatodendritic 5-HT_{1A} receptors in the dorsal raphe nucleus which, presumably, serves to inhibit 5-HT release predominantly in the ventral hippocampus.

The Effects of Nicotine on Attention and Cognition

It is widely accepted that cholinergic pathways play an important role in cognition and attention and that important components of these effects are mediate by neuronal nicotinic receptors. In humans, the administration of nicotine is reported to enhance attention and cognitive performance, and it has been suggested that this property of the drug may contribute to the 'beneficial' effects sought by the smoker. Behavioral studies with experimental animals have also shown that the administration of nicotine and other nicotinic receptor agonists can improve performance in a range of cognitive tasks such as the working memory component of radial arm maze tasks, passive avoidance, and water-maze tasks. The nature of the nicotinic receptors which mediate these responses remains to be established with certainty, although there is evidence that $\alpha4\beta2$, $\alpha3\beta2$, and $\alpha7$ receptors located in the hippocampus play an important role in the effects of nicotine on working memory.

The effects of nicotine on spatial learning in a water-maze are most apparent in animals in which learning has been impaired by septal lesions. The administration of neuronal nicotinic receptor antagonists impairs performance in many of these tasks. The neurobiological and neuroanatomical substrates for these effects of nicotine have not been established with certainty, although it seems likely they are mediated, in part, by the increase in ACh release, evoked in the brain, by nicotine, in areas of the brain such as the hippocampus and frontal cortex. This ACh then acts upon muscarinic receptors. More recent studies suggest that nicotine, through stimulation of nicotinic receptors, may also influence the expression and the processing of amyloid precursor protein (APP), increasing the secretion of neuroprotective soluble APP. These data, when taken together, provide support for the possibility that nicotinic agonists may have value as a treatment which slows the progression of Alzheimer's disease and alleviates some of the cognitive deficits observed during the early stages of the condition.

Another mechanism by which nicotine may bring about improvements in tests of cognition is by enhancing attention. This property of the drug seems to contribute significantly to its beneficial effects on cognition and information processing. Studies in experimental models have demonstrated clear effects of the drug on attention in the five-choice serial reaction time task. The response is blocked by the prior administration of nicotinic receptor antagonists, confirming the role of these receptors.

Nicotinic Acetylcholine Receptors

J-P Changeux, Institut Pasteur, Paris, France

© 2009 Elsevier Ltd. All rights reserved.

Following Claude Bernard's investigations on the effect of curare, Langley proposed in 1905 that a 'receptive substance,' presently designated as a receptor, "receives the stimulus from the nerve and transmits it to the effector cell." On the basis of the resemblance of acetylcholine (ACh) effects to those of naturally occurring plant alkaloids, Sir Henry Dale distinguished in 1914 between two main classes of receptors for ACh, the muscarinic and the nicotinic receptors. Typically, muscarinic receptors are activated by muscarine and blocked by atropine, whereas nicotinic receptors are activated by nicotine and blocked by curare. Subclasses have also been described. Only nicotinic ACh receptors (nAChRs) are present at the motor endplate of vertebrate skeletal muscles. Muscarinic receptors are found on smooth muscles and gland cells and, together with nicotinic receptors, on autonomic ganglion cells and neurons from the central nervous system.

The nAChR Has an Intrinsic Cationic Channel

Binding of ACh to the nAChR causes the opening of a cationic channel that is physically linked to the receptor site (Figure 1). This intrinsic channel is permeable to Na^+, K^+, and, in many nAChR-subunit combinations, Ca^{2+} ions. By contrast, muscarinic ACh receptors transduce extracellular signals into the cell by interacting with a G-protein to regulate indirectly effector systems such as adenylate cyclase and ion channels.

In 1970, the nAChR became the first neurotransmitter receptor to be isolated and purified and, in 1983, it was the first to be chemically defined by molecular genetic methods. Two factors played a decisive role in this fundamental progress: (1) the presence of very high concentrations of nAChR in the electric organs of the electric fish *Electrophorus electricus* and *Torpedo*, and (2) the availability of small polypeptide α-toxins from snake venoms that bind with very high affinity and selectivity to the nAChR from electric organs.

The nAChR is an oligomeric glycoprotein of about 300 000 Da. In side views obtained by cryo-electron microscopy, it appears as a transmembrane cylinder of ~8 nm diameter and ~16 nm length; the long axis being perpendicular to the membrane plane (Figure 1(a)). In a top view, it looks like a rosette of five subunits organized around a symmetry axis (Figure 1(b)).

Combinatorial Assembly of Subunits Encoded by Homologous Genes Results in a Wide Diversity of nAChRs

In the electric organ and muscle, the nAChR oligomer is composed of four different polypeptide chains associated into a pentamer with the α_1, γ, α_1, δ, β_1 subunits organized in a counterclockwise manner (Figure 1(b)). In nerve cells, combinatorial assembly of up to nine different α subunits (α_2 to α_{10}) and three β subunits (β_2 to β_4) contributes to a wide diversity of pentamers, which may include one, two, or three different types of subunits and possess distinct pharmacological, electrophysiological, and kinetic properties. Each subunit traverses the cell membrane four times and all subunits are in contact with the lipid bilayer.

The complete amino acid sequences of the electric organ, muscle, and neuronal subunits in vertebrates and invertebrates have been deduced based on the nucleotide sequence of their cloned cDNA. The primary structure of the nAChR subunits is highly conserved throughout the vertebrate phylum from *Torpedo* to humans. For instance, the α_1 subunit of *Torpedo* shares 77% sequence identity with the human α_1 subunit. Likewise, the human α_1 subunit shares 36%, 33%, 30%, and 34% identity with the human β_1, γ, ε, and δ subunits, respectively (in mammals, an ε subunit replaces the fetal γ subunit early in postnatal life). These striking homologies suggest that the various subunits evolved by gene duplication from a common ancestral gene. Tissue-specific expression accounts for the muscle and neuronal subunit subfamilies.

Three Major Domains Arise from the Transmembrane Topology of the nAChR Subunits

Each subunit is a polypeptide of 450–700 amino acids that consists of a long extracellular N-terminal segment, four transmembrane hydrophobic segments of about 20 amino acids each (termed M1–M4), a long cytoplasmic segment, and a short extracellular C-terminal tail. The five long extracellular segments fold and assemble into a large extracellular hydrophilic ACh-binding domain (Figure 1). The transmembrane segments form a membrane-embedded domain whose elements are closely organized around

Figure 1 Structural model of the nACHR from the *Torpedo* electric ray. Ribbon representations were prepared using coordinates deposited in the research collaboratory for structural bioinformatics (RCSB) protein data bank (PDB) under ID# 2BG9. The ribbon representations are shown on the background of the gray-colored molecular surface. The two facing α_1 subunits are colored in orange while the β_1, γ, and δ subunits are shown in cyan, yellow, and green, respectively. (a) Side view, from within the membrane. The thick gray lines delineate the membrane borders. (b) Top view, from the extracellular side. The M2 segments are five α helices closely organized around the axis of ion conduction that is at the center of the molecule and is perpendicular to the viewer. In both panels, the extrcellular end of M2 of the right α_1 subunit is labeled with a black asterisk. Note that most of the cytoplasmic domain is missing due to the lack of 3-D structural information.

an axis perpendicular to the membrane plane, delineating thereby an aqueous pore. The five cytoplasmic segments fold into a hydrophilic domain that is thought to associate with components that anchor the receptor to the cytoskeleton, for example, the 43-kDa-Rapsyn protein. The cytoplasmic domain also contains structural elements that modulate channel activity. Notably, the nAChR-subunit topology is common for all other pentameric neurotransmitter receptor channels that are gated by serotonin, glycine, γ-aminobutyric acid (GABA), glutamate, or histamine. These ionic channels constitute the Cys-loop receptor superfamily whose members share a conserved disulfide bridge in their extracellular ligand-binding domain.

The binding pockets for ACh are formed by the interface between each α subunit and the adjacent subunit. The α subunit contributes, to the ACh-binding pocket, the so-called principal component, which consists of a series of loops carrying highly conserved ACh-binding residues, mainly aromatic but also a cysteine pair. The neighboring subunit contributes a series of complementary ACh-binding residues. Affinity labeling, binding studies, and electrophysiological recordings performed with wild-type (WT) and mutated nAChRs identified ACh-binding pockets at the α/γ and α/δ interfaces in the case of the electric organ and muscle nAChRs (**Figure 1(b)**), α/β interfaces in the case of neuronal heteromeric nAChRs, and α/α interfaces in the case of homomeric neuronal nAChRs.

The acetylcholine-binding protein (AChBP) is a glial pentameric water-soluble protein sharing structural homology with the extracellular neurotransmitter-binding domain of the nAChRs' α subunits. It does not have the transmembrane channel and the cytoplasmic domains (**Figure 2**). The AChBP is secreted to the synaptic cleft between neurons of the mollusk *Lymnaea stagnalis* and of *Aplysia*, where it apparently sequesters ACh, regulating thereby cholinergic transmission. The high-resolution X-ray crystal structure of the AChBP also supports the concept of intersubunit ligand-binding pockets (**Figure 2**).

The five M2 helical segments of the full-length nAChRs line the ion-channel pore (**Figure 1**), which was initially identified with noncompetitive pore blockers such as chlorpromazine or triphenylmethylphosphonium. Residues belonging to the M2 segments define the activation gate, which acts as a barrier obstructing the flow of ions when the receptor is at rest (i.e., displaying a closed pore). The location of the activation gate is still controversial. On the one hand, three-dimensional (3-D) structural models built on the basis of cryo-electron microscopy suggested that the activation gate is a 'hydrophobic girdle'

Figure 2 X-ray crystal structure of the AChBP from the mollusk *Lymnaea stagnalis*. Ribbon representations were prepared using coordinates deposited in the PDB under ID# 1UW6. Nicotine molecules are shown at the interface between each two neighboring subunits, as green and blue spheres (carbon and nitrogen atoms, respectively). Note that the five subunits share identical primary, secondary, and tertiary structures. (a) Side view; (b) top view.

located midway between the extracellular and intracellular pore's vestibules. It was further suggested that the 'hydrophobic girdle' breaks apart when the M2 segments rotate, around their own longitudinal axis, upon activation (i.e., upon channel opening). On the other hand, state-dependent accessibility of methanethiosulfonates or zinc ions to cysteines or histidines introduced along the pore revealed that the activation gate is a constriction located close to the intracellular end of the M2 segments, that is, close to the bottom of the pore. These and other structure–function relation studies also indicate that (1) the resting and active states share similar patterns of amino acid accessibility to the pore's solvent and (2) channel gating predominantly involves rigid tilting motions of the M2 segments, which widen (open) or narrow (close) the bottom-pore constriction. Amino acids located within the M1–M2 connecting segment, close to the intracellular end of the M2 segments, contribute to the cationic (versus anionic) selectivity of the channel. As these residues are also part of the bottom-pore constriction, it is concluded that components of the activation gate act as a selectivity filter upon channel opening.

The nAChR is an Allosteric Protein

Cryo-electron microscopy, affinity labeling, binding kinetics of various nicotinic ligands, and rapid kinetic measurements of ion-channel opening and closing events showed that the ACh receptor exhibits properties typical of allosteric proteins. That is, first, the ACh-binding site and the ion channel are spaced far apart (~35 Å). Second, the nAChR can undergo reversible transitions between distinct allosteric conformations even in the absence of an agonist, including rare but detectable spontaneous channel openings. The various allosteric states, which preexist in reversible equilibrium already before ligand binding, are stabilized not only by agonists or competitive antagonists that bind to the ACh-binding sites, but also by 'allosteric' effectors (e.g., Ca^{2+} ions) that bind to topographically distinct sites.

The ion channel of cloned nAChRs expressed in heterologous cell systems opens at relatively high concentration of ACh (K_D in the 50–100 μM range), which is close to the concentration of ACh found in the synaptic cleft during transmission. On the other hand, prolonged exposure of the nAChR to the neurotransmitter leads to stabilization of states that display (1) higher affinity for the agonists ($K_D \approx 1$ μM or 5 nM for ACh in case of neuronal or muscle nAChR, respectively) and (2) a closed pore conformation that does not conduct ionic currents. These states are referred to as 'desensitized,' and they are stabilized by ACh at equilibrium. Hence, the high-affinity binding states do not take part in the transduction of the physiological signal at the synapse; rather, they play a role in the regulation of the efficacy of signal transmission.

Compartmentalized Expression of Muscle nAChRs Depends on Electric Activity and Release of Neurotrophic Factors

In the adult neuromuscular junction, nAChR is localized almost exclusively in the postsynaptic (muscle) membrane of the motor endplate, with a density of 10 000 to 25 000 molecules μm^{-2} at the crest of the folded membrane. In the embryonic muscle fiber, nAChR molecules are evenly distributed extrasynaptically on the surface of the muscle cell, freely mobile and metabolically labile (half-life of about 18 h). During the formation of the endplate, nAChR molecules aggregate on postsynaptic membrane regions,

opposite to the motor-nerve ending, where they become immobile and metabolically stable (half-life of about 11 days). Around birth, in some species, an ε subunit replaces the fetal γ subunit, giving rise to an adult form with changed channel properties. Meanwhile, the extrasynaptic receptors disappear owing to repression of their synthesis, which takes place as soon as the muscle electric activity starts. In the adult, preventing stimulation of the muscle by sectioning of the motor nerve reactivates the biosynthesis of extrasynaptic nAChR, leading to the so-called phenomenon of 'denervation hypersensitivity.' Electrical stimulation of the muscle or its reinnervation by neurons restores the original postsynaptic distribution. Such compartmentalized expression of nAChR genes results, in part, from the regulation of transcription, which is active in most sarcoplasmic nuclei of developing myotubes. In the adult, this process becomes restricted to the subsynaptic 'fundamental' nuclei. In the promoter of the receptor genes, distinct elements (N Box vs. E Box) control subsynaptic transcription versus activity-dependent extrasynaptic repression. Posttranslational mechanisms include the conformational maturation of the receptor protein, its transit via a specialized Golgi apparatus (in the mature endplate), and its targeting, aggregation, metabolic stabilization, and immobilization in the postsynaptic membrane.

Factors of neural origin that are involved in compartmentalizing nAChR gene expression include acetylcholine receptor-inducing activity (ARIA), a factor homologous to human heregulin, and glial growth factor, which binds to tyrosine kinase receptors of the erbB family. Another important component, the acetylcholine receptor-aggregating factor, referred to as AGRIN, elicits formation of nAChR clusters. A cytoskeletal protein 43-kDa-Rapsyn, which is considered to be associated with the nAChR, contributes to AGRIN immobilization and stabilization in the postsynaptic membrane.

In the nematode *Caenorhabditis elegans*, a transmembrane protein, LEV-10, was found to be required for clustering of nAChR molecules in cholinergic neuromuscular junctions. Another transmembrane protein of *C. elegans*, RIC-3, is involved in enhancing the maturation (subunit folding and assembly) of nAChRs.

nAChRs Play Decisive Physiological and Pathological Roles

Activation of nAChRs on the muscle fibers initiates a cascade leading to muscle contraction. Hence, elimination of nAChR molecules from the neuromuscular junction, as occurs in myasthenia gravis, results in severe muscle weakness. The latter is an autoimmune disease induced by anti-nAChR autoantibodies and aggravated by activation of autoimmune T lymphocytes. Congenital myasthenic syndromes are human disorders resulting from a range of mutations in the muscle nAChR that impair channel activity and may lead to degeneration of the endplate.

In the brain, nicotinic receptor genes are expressed exclusively in neurons and display different patterns of expression, from highly restricted to a few nerve cells (e.g., the α_2 subunit) to widespread ones (e.g., the β_2 subunit). Inactivation of the β_2-subunit gene by homologous recombination in mice interferes with their passive avoidance learning and alters a cognitive behavior referred to as 'exploratory,' while a more automatic 'navigatory' behavior is preserved.

nAChRs are responsible for autosomal dominant nocturnal frontal lobe epilepsy and modulate pain transmission, and are also considered to be involved in autism and schizophrenia. Correlations have been reported between cigarette smoking and protection against ulcerative colitis and Parkinson's disease. Addiction to nicotine involves high-affinity nicotinic receptors associated with midbrain dopaminergic neurons, as demonstrated in laboratory mice lacking the nAChR $\beta 2$ or $\alpha 4$ subunit. These mice are also useful animal models of attention-deficit activity disorders and sudden infant death syndrome. Nicotinic receptor-binding drugs are considered as potential therapeutic agents in Alzheimer's disease, Tourette's syndrome, and anxiety disorders.

Nicotinic Receptors: Autonomic Neurons

M De Biasi, Baylor College of Medicine, Houston, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

The Role of Nicotinic Acetylcholine Receptors in the Autonomic Nervous System

In vertebrates, the autonomic nervous system (ANS) is responsible for maintaining homeostasis under changing physiological demands. Autonomic ganglia are the peripheral sites where preganglionic neurons arising within the brain stem and spinal cord form connections with postganglionic neurons that send their axons to visceral and vascular targets. Fast synaptic transmission, which allows communication between pre- and postganglionic neurons, mainly relies on the release of acetylcholine (ACh) from preganglionic neurons. ACh binds to neuronal nicotinic acetylcholine receptors (nAChRs) located on postganglionic neurons. Nicotinic AChRs are the main mediators of ganglionic fast synaptic transmission, and, in this respect, they function as an interface between nervous system and peripheral organs. The key role of nAChRs in the ANS was established in the 1800s by Langley, who found that autonomic ganglia are first activated and then blocked by nicotine. The necessary role of nAChRs for synaptic transmission in the peripheral nervous system (PNS) contrasts with the role of the receptors in the central nervous system (CNS), where the most commonly observed nAChR role is to act presynaptically to enhance neurotransmitter release.

Neuronal nAChRs are cation-selective, ligand-gated ion channels expressed in both the CNS and the PNS. They are members of a protein superfamily that includes neuronal and muscle nAChRs, and receptors for γ-aminobutyric acid (GABA), glycine, and serotonin $(5HT)_3$. So far, eleven genes have been identified that encode neuronal nAChR subunits: eight α subunits ($\alpha2$–$\alpha10$) and three β subunits ($\beta2$–$\beta4$). The alpha subunits contain the ligand binding sites, whereas beta subunits are structural subunits that contribute to the function of the receptor. The mammalian nervous system expresses transcripts for all subunits except $\alpha8$, which is found only in avians. In the rat there are two functional splice variants for the $\alpha7$ subunit. The $\alpha7$–2 isoform contains an 87-base-pair insert that represents the incorporation of a novel exon between exons 4 and 5 of the conventional $\alpha7$ gene product ($\alpha7$–1). The two isoforms are found in both the CNS and PNS.

Neuronal nAChRs are formed by the assembly of five subunits, each consisting of four membrane-spanning domains. The majority of functional neuronal nAChRs are composed of two α and three β subunits, with 'duplex' (α/β) or 'triplex' combinations ($\alpha_x\alpha_y\beta$ or $\alpha\beta_x\beta_y$). Heteromeric nAChR channels are composed of $\alpha2$, $\alpha3$, $\alpha4$, $\alpha5$, $\alpha6$, $\beta2$, $\beta3$, and $\beta4$ subunits. $\alpha7$ can form either homopentamers or α/β heteropentamers. $\alpha9$ and $\alpha10$ are believed to assemble as α-only heteropentamers. The $\alpha5$ subunit participates in nAChR receptors with $\alpha_x\alpha_y\beta$ combinations but cannot yield functional receptors when expressed alone or in combination with β subunits only. The $\beta3$ subunit participates in $\alpha\beta_x\beta_y$ combinations, and, similar to $\alpha5$, it cannot yield functional receptors unless coexpressed with another β subunit.

Autonomic Ganglia Integrate and Transfer Neural Signals

Autonomic ganglia, once considered mere relay stations for the transfer of information from the CNS to the periphery, contain circuits capable of integrating and modulating neural signals before they reach the neuroeffector junction. The modulation of the neural signal occurs at preganglionic, postganglionic, and extraganglionic sites by either excitatory or inhibitory mechanisms. Differences in morphology, biochemical profile, and electrophysiological properties among ganglion cells, as well as sensory inputs from the viscera, account for the modulation of ganglionic function. The expression of multiple nAChR subtypes on individual ganglionic neurons also contributes to such complexity, as these receptors are likely to have different roles in the processing and integration of neural signals. For example, the subunit composition affects the speed of activation, the ionic current, the rates of desensitization and recovery from desensitization, and the pharmacology of nAChRs. Another important factor is the anatomical location of the receptors. nAChRs can have presynaptic, axonal, somal, and postsynaptic locations. At presynaptic locations nAChRs can enhance neurotransmitter release, while at postsynaptic locations they mediate excitatory synaptic transmission. Furthermore, even if expressed in the same neuron, nAChRs are likely to mediate different cellular mechanisms.

nAChR Subtypes in Autonomic Ganglia

Virtually every autonomic neuron contains transcripts for nAChR subunits. The $\alpha3$ nAChR subunit is highly expressed in both sympathetic and parasympathetic ganglia and is likely to participate in the

majority of nAChR subtypes expressed by autonomic neurons. α3 is found in a phylogenetically conserved gene cluster that also comprises α5 and β4. All three nAChR subunit genes are coexpressed in neurons of the sympathetic and parasympathetic nervous systems where they may form α3β4 and α3α5β4 nAChRs. The α7 nAChR subunit is also expressed in autonomic ganglia. The subunit has been shown to form homomeric channels in heterologous expression systems, but the literature suggests that it might also form heteromeric channels in native ganglionic neurons. In addition, autonomic ganglia contain transcripts for the α2, α4, β2, and β3 nAChR subunits. Pharmacological analyses suggest that the β2 and β4 subunits may co-assemble into the same receptor. The lack of nAChR subtype-selective ligands has so far delayed the study of the role of α2- and β3-containing nAChRs.

Some insight into the contribution of various nAChR subunits to autonomic function has been gained by the creation of mice lacking one or combinations of nAChR subunits. Those studies revealed that synaptic transmission is abolished in ganglia when the α3 nAChR subunit is deleted via genetic engineering techniques. The absence of α3-containing nAChRs *in vivo* produces a severe multi-organ dysfunction that leads to lack of pupillary response to light, impaired bladder contractility, and cardiac rhythm abnormalities. Mice lacking the α3 nAChR subunit develop distended, urine-filled bladders due to absence of nAChR-mediated ACh release onto the bladder smooth muscle and consequent abnormal parasympathetic control of bladder voiding. Interestingly, lack or malfunction of α3-containing nAChRs in peripheral neurons has been suggested as the possible cause of a rare human disorder, megacystis, microcolon intestinal hypoperistalsis syndrome (MMIHS).

Absence of α3-containing nAChR also alters sympathetic function and causes bradycardia and the appearance of several electrocardiographic abnormalities.

While the absence of α3 is fatal, the lack of β4 does not affect survival, despite the fact that nAChR-mediated whole cell currents are significantly reduced in ganglionic neurons with a β4 null mutation. So far, the role of β4-containing nAChRs has been explored in heart and urinary bladder. Although not evident in basal conditions, the effects of a null mutation on various organ systems can be unmasked under physiological or pharmacological manipulations. Lack of β4 does not affect heart rate in unchallenged, baseline conditions but attenuates the bradycardic response observed during high-frequency stimulation of the vagus nerve. The influence of β4 on cardiac parasympathetic innervation may also contribute to the greater-than-normal heart rate increases measured when mice lacking β4 are exposed to isolation-induced stress. Absence of β4 significantly impairs the bladder's contractile responses but, unlike the absence of α3, does not cause bladder distension and urine retention. This phenomenon could be explained by partial redundancy between the β4 and the β2 subunits.

Similarly to β4, lack of the α5 nAChR subunit does not affect survival rates. Its influence on ganglionic function is subtle and depends on the location of the receptors. While the presence of the α5 subunit in somatic nAChRs does not dramatically affect the biophysical and pharmacological properties of the channels, its presence in prejunctional nAChRs modulates the magnitude of nAChR-mediated neurotransmitter release. *In vivo*, lack of α5 does not alter basal heart rates but mitigates the bradycardic response to high-frequency vagal stimulation. No other α5-associated phenotype has been described.

nAChRs in the Enteric Nervous System

The enteric nervous system (ENS) was first established by Langley as a separate division of the ANS. A complex integrated circuit composed of sensory neurons, modulatory interneurons, and motor neurons, the ENS controls motility, exocrine and endocrine secretions, and microcirculation of the gastrointestinal tract. It is also involved in the regulation of gut immune and inflammatory processes. Enteric neurons are found in two networks or plexuses of neurons, embedded in the wall of the digestive tract: the myenteric plexus, located between the circular and longitudinal gut muscles, and the submucous plexus, embedded in the submucosa. Excitatory neurotransmission in the ENS is predominantly mediated by ACh acting at nAChRs, although adenosine triphosphate (ATP) and other neurotransmitters can also mediate fast excitatory postsynaptic potentials (fEPSPs). The contribution of nAChR-mediated neurotransmission varies depending on the anatomical localization. In the submucous plexus, fEPSPs are almost entirely inhibited by nAChR antagonists, but in the myenteric plexus only about 25% of neurons studied exhibit fEPSPs that are completely blocked by nAChR antagonists.

Immunohistochemical studies indicate that mRNAs for the α3, α5, α7, β2, and β4, but not the α4 nAChR subunit, are expressed in many myenteric and submucosal neurons. α3 is expressed at high levels in enteric neurons where it likely combines with β2 and/or β4 to yield heteromeric nAChRs with pharmacological and biophysical properties similar to those of ganglionic neurons. Absence of α3 impairs gastrointestinal motility in mice and might underlie the

gut-related pathophysiology of MMIHS. Gut motility disorders are also observed in patients with autonomic neuropathies produced by auto-antibodies against α3.

Information is also available on the role of α5 in gut physiology. The nAChR subunit might participate in the control of intestinal smooth muscle contractile responses. In addition to being expressed in enteric neurons, α5 is expressed in the epithelial cells of the gastrointestinal tract where it might participate in ACh-mediated anti-inflammatory responses. Colonic epithelial cells are the main target of ulcerative colitis, a bowel inflammatory condition caused by several factors, including the release of proinflammatory cytokines and prostaglandins, altered gut motility, and reduced colonic mucin synthesis. The influence of nAChR on bowel inflammatory disease is also suggested by epidemiological studies indicating that ulcerative colitis becomes more severe upon smoking cessation, while it ameliorates during smoking. Colonic epithelial cells express α5, and, interestingly, absence of α5 exacerbates an experimental model of colitis. At the same time, the mutation seems to increase nicotine's beneficial effects on colitis, probably due to a change in nAChR affinity.

Nonneuronal nAChRs

As in the previous colonic epithelial cell example, a number of nonneuronal cells express nAChRs. Those receptors might be located at the neuroeffector junction or might be present on cells that are not directly innervated by autonomic nerve terminals. Several nonexcitable, nonneuronal cells have the ability to synthesize and release ACh. In those cells ACh might function as a local hormone to influence both the cells that synthesize the neurotransmitter (autocrine function) and those located in the proximity of the ACh-synthesizing cells (paracrine function). Nonneuronal ACh appears to be involved in the regulation of several cellular processes, including mitosis, cell growth, automaticity, locomotion, ciliary activity, cell–cell contact, cytoskeletal organization, and barrier and immune functions. Among the cells that release ACh are lymphocytes, macrophages, dendritic cells, adipocytes, keratinocytes, endothelial cells, and epithelial cells of intestine, bladder, and lung. These cells express the ACh-synthesizing enzyme choline acetyltranferase and the high-affinity choline transporter but seem to have a different ACh release machinery than neuronal cells. As opposed to the cholinergic nerve endings, where ACh is stored in synaptic vesicles and released following an action potential or cell membrane depolarization, in nonneuronal cells ACh can be released under pharmacological inhibition of the vesicular ACh transporter or the vesicular exocytotic machinery. How ACh is released across the plasma membrane is not yet clear. The activity of the ACh released by nonneuronal cells is mediated by both muscarinic (metabotropic) and nicotinic (ionotropic) receptors, which, due to different coupling mechanisms, will yield intracellular responses on different timescales.

The discovery of nAChRs in nonneuronal cells brings a new perspective on the effects of smoking on the whole organism, as the nicotine contained in tobacco, besides acting at central and peripheral nAChRs, can impact several peripheral functions by binding to nonneuronal nAChRs.

Lung

Messenger RNA for the α3, α5, α7, α9, β2, and β4 but not the α2, α4, α6, or β3 nAChR subunits is found in bronchial epithelial cells. Functional bronchial epithelial nAChRs have been reported to have pharmacological and biophysical properties similar to those of ganglionic receptors and are involved in maintaining the flat shape necessary for those cells to line the bronchial surface. Receptors composed of the α3, α5, and β2 subunits are present in migrating epithelial cells during wound repair in the bronchial epithelium. The presence of mRNA for muscle-type AChRs has also been described in bronchial epithelial cells, but the role of those receptors in lung physiology is yet to be determined.

Airway fibroblasts also express mRNA and protein for nAChRs. α7-containing nAChRs are likely the most abundant neuronal-type receptors in this cell type. Those receptors seem to modulate the synthesis of the extracellular matrix glycoprotein fibronectin. Fibronectin is implicated in tissue injury and repair and is highly expressed in tobacco-related lung diseases. Interestingly, mRNA for muscle α1, β1, δ and ε AChR subunits is highly expressed in fibroblasts as well, but no function for muscle-type nAChRs has been described.

Blood Vessels

The endothelial cells that line blood vessels express functional nAChRs. α3 is the predominant subunit, but mRNA and proteins for α4, α5, α7, β2, and β4 are also detected. Endothelial nAChRs demonstrate ion-gating properties similar to those on ganglionic neurons and might be involved in several ACh-mediated actions, including mitosis, differentiation, organization of the cytoskeleton, cell–cell contact, locomotion, and migration. It is also known that α7-containing nAChRs participate in the mechanisms underlying the migration of endothelial cells induced by

angiogenic growth factors such as vaccinia virus growth factor (VGF).

Vascular smooth muscle cells that lie beneath the endothelial cell layer express the α2, α3, α4, α5, α7, and α10 nAChR subunits. The distribution of those subunits depends on the localization of the vessels. The α7 subunit was found in all vessels examined except those in the kidney. α3 and α5 are widespread but are not present in intrapulmonary or kidney vessels. The role of the various nAChR subtypes in vascular smooth muscle physiology remains for the most part elusive. α7 nAChRs might influence the migration of the vascular smooth muscle cells. nAChRs other than α7 might modulate the synthesis of vascular endothelial growth factor.

The presence of nAChRs on endothelial and smooth muscle cells of the vasculature can explain some of the effects of nicotine on the vascular system, including its ability to increase endothelial cell proliferation, expand capillary networks, and enhance the angiogenic response to inflammation, ischemia, atherosclerosis, and neoplasia.

Urothelium

The ACh released from autonomic nerves regulates urinary bladder function by affecting the activity of the detrusor muscle and the nerve terminals at the neuroeffector junction. Another bladder component affected by ACh is the urothelium. Urothelial cells line the bladder cavity to provide a diffusion barrier. At the same time they can actively release signaling molecules that act in an autocrine or paracrine fashion. ACh is one of those signaling molecules. Because ACh is released when the urothelium stretches, it has been suggested to influence the extent of bladder filling. ACh actions on the urothelium are mediated by both muscarinic and nicotinic receptors. mRNA for the α3, α5, α7, β2, and β4 nAChR subunits has been identified in rat urothelial cells using reverse transcription polymerase chain reaction (RT-PCR). Functional studies conducted in rodents suggest that α3- and α7-containing nAChRs might have opposite roles in controlling bladder filling and voiding by promoting the release of mediators with antithetic functions. Investigations on the human urothelium have so far indicated the presence of the α7, α9, and α10 subunits with a rank order of expression of $\alpha7 \gg \alpha10 > \alpha9$, although ganglionic-type nAChRs are likely to be expressed in the urothelium as well. Interestingly, in human bladders the levels of expression of nAChR subunits seems to be layer specific, with a gradient decreasing in intensity from luminal to basal. The significance of this anatomical arrangement for bladder physiology remains unknown.

Skin

The cholinergic system controls basic skin functions such as terminal differentiation and barrier formation, sweat and sebum secretion, and microcirculation. Keratinocytes are stratified epithelial cells that adhere to each other to provide the skin's first line of protection from the external environment. The phosphorylation of adhesion molecules such as cadherins is one of the factors necessary for optimal keratinocyte adhesion. ACh has been shown to influence this process, as cholinergic antagonists disrupt cell–cell adhesion in keratinocyte monolayers while ACh promotes cell adhesion. Keratinocytes express mRNA for muscarinic receptors as well as that for α3, α4, α5, α7, α9, α10, β2, and β4 nAChR subunits. The epidermis of mice lacking the α3 nAChR subunit presents with loosely attached keratinocytes. In addition, the α3 null mutation decreases E-cadherin and γ-catenin levels while increasing those of β-catenin. Although absence of the α9 nAChR subunit did not alter keratinocyte adhesion, it led to comparable changes in β- and γ-catenin levels, suggesting that the α3 and the α9 nAChR subunit might be regulating either the expression or the posttranslational modification of certain adhesion molecules.

Absence of α7 produces changes that are characteristic of delayed epidermal turnover, and α3- and α7-containing nAChRs influence keratinocyte chemokinesis and chemotaxis, respectively, an effect that has interesting clinical implications for wound healing and spread of cancer metastases.

Dermal fibroblasts, the primal cellular component of the dermis, also express nAChRs. In addition to α3, they express the α5, α7, β2, and β4 nAChR subunits. Lack of α3 produces alterations in fibroblast growth and function, suggesting a role for nAChRs in dermis homeostasis. Finally, the α3, α5, α7, α9, α10, β2, and β4 nAChR subunits are also expressed in hair follicles and sebaceous and sweat glands.

Tobacco is known to aggravate diseases such as psoriasis, atopic dermatitis, acne, and lupus and cause aberrant cutaneous tissue remodeling, such as precocious skin aging and impaired wound healing. Because of those effects of nicotine, the nAChRs found in the various components of the skin are obvious candidates for the study of the mechanisms of tobacco-induced toxicity.

Blood Cells

ACh is found in the blood of several species of mammals, including humans, and it has been suggested that it may originate mainly from T lymphocytes, one of the cell types in the blood. The blood contains two different functional categories of cells:

erythrocytes and leucocytes. Erythrocytes have not been reported to express nAChRs, but leucocytes have. Leukocytes, responsible for the defense of the organism, are subdivided into two categories: granulocytes and lymphoid cells. Granulocytes are further divided into neutrophils, eosinophils, and basophils. nAChR agonists can inhibit stimulated histamine release from human basophils, which have been shown to express α7-containing nAChRs. Nicotine can also prolong neutrophil survival by suppression of apoptosis. This effect could be nAChR mediated, although there are no reports of the expression of nAChRs in neutrophils.

Lymphoid cells, the second category of blood leukocytes, are subdivided into lymphocytes and monocytes. Lymphocytes are the main constituents of the immune system and mount a defense against the attack of pathogenic microorganisms. Lymphocytes B, responsible for the humoral antibody response, express α4(α5)β2 and α7(α5β4) nAChR subtypes, whose levels of expression and roles may vary with the maturation stage of the cells. For example, those two nAChR subtypes may support lymphocyte B survival during differentiation/selection, but limit their activation upon maturation.

Monocytes are the precursors of macrophages, which, after attaining maturity in the bone marrow, enter the blood circulation where they stay for 24–36 h. Afterward they migrate into the connective tissue, where they become macrophages and move within the tissues. In the presence of an inflammation site, monocytes quickly migrate from the blood vessel and start an intense phagocytic activity accompanied by the release of a number of cytokines. The balance between the levels of pro- and anti-inflammatory cytokines and their sequential release may influence the degree of inflammatory responses. ACh released from the vagus nerve is thought to modulate monocyte/macrophage activity by inhibiting proinflammatory cytokine production and systemic inflammation. A central role in these mechanisms is played by α7-containing nAChRs found at the plasma membrane of monocytes/macrophages. Indeed, vagus nerve stimulation attenuates tumor necrosis factor (TNF) release from macrophages, and this effect is abolished in α7 null mice. In addition to inhibiting the release of TNF, α7-containing nAChRs may suppress the release of high-mobility group box 1 (HMGB1), a cytokine involved in severe inflammatory responses such as those observed during sepsis. Receptors containing α4 and β2 may also be involved in controlling the levels of TNF and certain interleukins. Finally, transcripts for the α2, α6, and α9 subunits have also been found in macrophages, but the role of the nAChR subunits that contain them has not been elucidated.

Niemann–Pick Disease

J K Fink, University of Otago, Christchurch, New Zealand

Published by Elsevier Ltd.

This article is reproduced from the previous edition, © 2004, Elsevier B.V.

History

Niemann–Pick disease refers to autosomal recessive lysosomal storage disorders due to acid sphingomyelinase deficiency (Niemann–Pick disease, types A and B) or defective cholesterol esterification (Niemann–Pick disease, types C and D). Early descriptions date to 1914 when Niemann, a German pediatrician, described an 18-month-old child with hepatosplenomegaly, progressive neurologic deterioration, and postmortem evidence of lipid accumulation. Over the next 10 years, Pick analyzed similar patients and distinguished the disorder from Gaucher disease on the basis of distinctive cytologic appearance of lipid-laden macrophages. In 1958, Crocker clinically classified Niemann–Pick disease into type A (NPA: acute neuropathic), type B (NPB: chronic nonneuropathic), type C (NPC: chronic neuropathic), and type D (NPD: chronic neuropathic, Nova Scotia variant). Following identification of sphingomyelin and to a lesser extent cholesterol and other phospholipids as the accumulating substances, Brady described marked deficiency of the lysosomal enzyme sphingomyelin phosphodiesterase (acid sphingomyelinase) in NPA and NPB. The acid sphingomyelinase gene was subsequently cloned and mutations identified in NPA and NPB. NPC patients were considered initially to be clinical variants of NPA because they had partial reduction in sphingomyelinase and variable accumulation of sphingomyelin. Subsequent work led by Pentchev et al. showed that the underlying defect in NPC was not sphingomyelinase deficiency but rather defective esterification of endogenous and exogenous cholesterol. Although the underlying biochemical abnormality (or abnormalities) for defective cholesterol esterification in NPC is not known, NPC is genetically linked to a locus on chromosome 18p that is clearly distinct from the acid sphingomyelinase gene on chromosome 11p15.4–15.1. Continued use of terms Niemann–Pick variants or Niemann–Pick disease type C for these patients serves historical purposes and should not be interpreted to imply that these patients share the underlying etiology (primary deficiency of acid sphingomyelinase) of NPA and NPB.

Sphingomyelinase Deficient Forms: NPA, NPB, and NPF

There are marked clinical differences between Niemann–Pick disease types A through F. NPA is a subacutely progressive neurodegenerative disorder of infancy. Developmental milestones may be attained normally for the first several months or occasionally for the first year. Failure to thrive, progressive hepatosplenomegaly, and progressive psychomotor deterioration begin in the first year of life and lead to death in early childhood. Clinical diagnosis, based on the presence of infantile onset, progressive neurodegeneration, accompanied by organomegaly, macular cherry-red spots (in 50% of patients), and bone marrow evidence of lipid-laden macrophages is confirmed by demonstrating acid sphingomyelinase deficiency (less than 5% of normal control subjects) in circulating white blood cells. The recurrence risk of NPA in subsequent progeny (25%) is typical for an autosomal recessive disorder. Prenatal diagnosis can be performed by acid sphingomyelinase assay of amniocyte or chorionic villus samples.

Beginning in infancy or childhood, NPB patients develop progressive hepatosplenomegaly and progressive, diffuse, and pulmonary infiltration. Morbidity is related primarily to pulmonary, hepatic, and skeletal involvement. NPB patients often live to adulthood, but obstructive and restrictive lung disease associated with dyspnea, asthma, recurrent pulmonary infections, and cor pulmonale may limit survival. Accumulation of sphingomyelin-laden macrophages in liver may result in portal hypertension complicated by esophageal varices. Skeletal involvement includes osteopenia and may lead to vertebral body and other skeletal fractures. With rare exception, subjects with NPB do not exhibit progressive neurologic disturbance. Nervous system involvement in NPB is limited to lipid storage and degeneration of retinal ganglion neurons manifested as asymptomatic retinal discoloration (macula halo or granular pigmentation) in a subset of patients. Clinical diagnosis of NPB is based on childhood-onset, progressive organomegaly and pulmonary infiltration, asymptomatic macular abnormalities (in a subset of patients), and bone marrow evidence of lipid-laden macrophages and is confirmed by demonstrating marked deficiency of sphingomyelinase in circulating white blood cells. Like NPA, prenatal testing of NPB is possible by acid sphingomyelinase assay of amniocyte or chorionic villus samples.

Both NPA and NPB are caused by mutations in the acid sphingomyelinase gene, yet only NPA has

prominent neurologic involvement. The specific sphingomyelinase gene mutations responsible for NPA are different than those for NPB. Sphingomyelinase gene mutations associated with NPB generally have a higher amount of residual enzyme activity (~10% sphingomyelinase activity relative to normal control subjects) compared to mutations that cause NPA (<5% activity compared to normal control subjects). Slightly greater residual sphingomyelinase activity in NPB compared to NPA is apparently sufficient to protect central nervous system (CNS) neurons in NPB patients from sphingomyelin storage and degeneration.

Niemann–Pick disease type F (NPF) is a rare benign, nonneuropathic form associated with thermolabile-deficient acid sphingomyelinase, moderate splenomegaly, and mild thrombocytopenia. NPF has been described in two families. It is not known if these patients have mutations in the sphingomyelinase gene.

Cholesterol Esterification Deficiency: NPC, NPD, and NPE

NPC refers to clinically heterogeneous patients with hepatosplenomegaly in whom progressive neurologic deterioration becomes evident in infancy, childhood, adolescence, or adulthood. Separate designations including down gaze paralysis, ataxia foam cell (DAF syndrome), Niemann–Pick variants, neurovisceral storage disease with vertical supranuclear ophthalmoplegia, and juvenile dystonic lipidosis are useful to highlight the phenotype of these patients and emphasize that they do not represent the primary sphingomyelin storage process seen in Niemann–Pick disease types A, B, and F. Three general clinical patterns have been observed in NPC. The first pattern is an early-onset, rapidly progressive form associated with severe hepatic dysfunction and psychomotor delay during infancy and later with supranuclear vertical gaze paresis, ataxia, marked spasticity, and dementia. This infantile-onset, rapidly progressive form is quite rare and clinically similar (although etiologically unrelated) to NPA. The second NPC phenotype is the most common. This delayed-onset, slowly progressive form is heralded by the appearance, usually in early childhood, of mild intellectual impairment, supranuclear vertical gaze paresis, and ataxia, and later associated with dementia and, variably, seizures, and extra pyramidal deficits. Gelastic cataplexy, manifested as momentary episodes of laughter-induced loss of muscle tone with maintenance of consciousness, is occasionally noted in this group of NPC patients. The term juvenile dystonic lipidosis may be appropriate for NPC patients with prominent generalized dystonia. The existence of the first (infantile-onset, rapidly progressive) and second (child through adolescent onset, slowly progressive) NPC phenotypes within the same sibship suggests that they are variant expressions of the same clinicopathologic disorder. The third NPC pattern is a late-onset, slowly progressive form and is distinguished from the second pattern by later age of onset (adolescence or adulthood), much slower rate of progression, and variable presence of organomegaly. Some of these later patients present with dementia or psychiatric symptoms including psychosis. It is important to recognize that virtually all NPC subjects exhibit variable degrees of vertical supranuclear ophthalmoplegia. This important clinical sign is nearly pathognomic for NPC (although it may also be present in olivopontocerebellar degeneration, Huntington's disease, Parkinson's disease, Whipple's disease, and progressive supranuclear palsy). Although subjects with vertical supranuclear gaze paresis are able to maintain fixation and move their eyes passively in response to head movement through all ranges of motion, voluntary vertical eye movements are either very slow or absent entirely. This is readily demonstrated as follows: with the subject visually fixating on a central object, the subject's head is rotated forward and the subject's eyes passively move upward. The subject is then asked to look down. Downward eye movements, if accomplished at all, will be performed by slow, horizontally looping saccades. It is noteworthy that organomegaly, a hallmark of NPA, NPB, and childhood-onset forms of NPC, may be absent or clinically unapparent in adolescent and adult onset NPC. NPC should be considered not only in infants and children with typical signs of organomegaly, progressive ataxia, and vertical supranuclear gaze disturbance, but also in adolescents and adults whose insidiously progressive neurologic dysfunction includes variable degrees of ataxia, dystonia, dementia, supranuclear vertical gaze paresis, or psychosis and in whom liver and spleen size is normal or only slightly enlarged.

Type D (Nova Scotia variant), occurring in French-Canadian descendants of Nova Scotia, is phenotypically and biochemically indistinguishable from NPC and is not considered to represent a separate disease entity.

Lipid accumulation in reticuloendothelial macrophages and CNS neurons in NPC and D is related to impaired esterification of intracellular cholesterol. The molecular basis of impaired cholesterol esterification is not known, although there is evidence that the primary defect involves impaired intracellular translocation of cholesterol leading to delayed induction of cholesterol metabolism and storage as nonesterified cholesterol. The existence of the first and second NPC phenotypes within the same sibship suggests that they

are variant expressions of the same clinico-pathologic disorder. The ability of cultured skin fibroblasts to esterify exogenous-derived cholesterol is markedly impaired (<10% activity compared to cells from control subjects) in each of the NPC phenotypes described above and in phenotypically indistinguishable Nova Scotia variant (NPD). Clinical diagnosis of NPC is based on a constellation of clinical signs including insidiously progressive ataxia, supranuclear vertical gaze paresis, cognitive impairment, and variable splenomegaly and is confirmed by demonstrating deficient cholesterol esterification in cultured skin fibroblasts. This magnitude of impaired ability to esterify cholesterol is associated uniquely with NPC and is not present in NPA, NPB, neuronal ceroid lipofuscinosis, Gaucher disease type III, Friedrich's ataxia, cystinosis, Tay-Sach's disease, Wolman's disease, or Fabry disease. Sphingomyelinase activity in NPC may be normal or mildly reduced. The recurrence risk of NPC in subsequent progeny (25%), like NPA and NPB is typical for autosomal recessive disorders. Assay of cholesterol esterification of cultured amniocytes has been used in prenatal diagnosis of NPC.

The historical term Niemann–Pick disease type E (NPE) referred to adults with chronic lipid storage including sphingomyelin. Individuals with NPE have presented in adulthood with splenomegaly, respiratory problems, or sea-blue histocytes detected in bone marrow during the course of other medical investigations. Other NPE patients have had nervous system involvement including ataxia and cherry red spots. Clearly, the term NPE includes subjects with chronic, nonneuropathic (probable mild NPB) as well as subjects with probable late-onset NPC. Given the availability of acid sphingomyelinase and cholesterol esterification assays, these subjects should now be diagnosed definitively as NPA, NPB, or NPC rather than grouped together as NPE.

Biochemical and Pathologic Features

Patients with Niemann–Pick disease contain lipid-laden macrophages throughout the reticuloendothelial system, particularly in the spleen, liver, lymphoid tissues, and bone marrow. Distension of lysosomes by lipid accumulation and increased numbers of lysosomes create a foamy appearance of these macrophages. Although Giemsa staining may reveal 'sea-blue histiocytes', such cells are not associated specifically with Niemann–Pick disease. The nature of the accumulating lipid varies according to the underlying metabolic defect. Sphingomyelin, an important membrane component of erythrocytes and other cells, accumulates in NPA and NPB because acid sphingomyelinase deficiency prevents cleavage of sphingomyelin into ceramide and phosphorylcholine. In NPC, defective cholesterol esterification causes accumulation of nonesterified cholesterol. Accumulation of other lipids in NPA, NPB, and NPC includes cholesterol (in NPA and NPB), bis(monoacylglycero)phosphate, and glycospingolipids (notably glucosylceramide and lactosylceramide), and G_{M3} ganglioside is attributed to secondary disturbance in other lysosomal enzymes as a result of abnormal lysosomal structure and function due to primary storage of sphingomyelin (in NPA and NPB) or nonesterified cholesterol (in NPC). It is important to recognize the storage of these additional lipids in NPC since the toxic intermediates responsible for regional neuronal degeneration (affecting particularly the cerebellum, for example) have not been defined.

Accumulation of lipid-laden macrophages leads to marrow crowding, hepatomegaly, splenomegaly, and lymphadenopathy. In the liver, storage is primarily in Kupffer cells, leading to organomegaly, portal hypertension, and variable hepatic cirrhosis. Skeletal involvement, particularly in NPB, includes osteoporosis, widening of metaphyses, and pathologic fractures. Accumulation of alveolar macrophages in the lungs (particularly in NPB) leads to diffuse pulmonary infiltration. Involvement of retinal ganglia neurons is evidenced as macular cherry-red spots in 50% of NPA patients. Infiltration of the intestinal mucosa with lipid-laden macrophages leads to chronic diarrhea, malabsorption, and failure to thrive in NPA. Widespread, profound CNS involvement in NPA and NPC is characterized by neurons swollen with vacuolated cytoplasm that is lipophilic in NPA and PAS positive in NPC. Marked loss of cerebral neurons may occur. Electron microscopic examination of brain neurons in NPA and NPC shows multilaminated, membranous cytoplasmic inclusions with electron-dense cores and amorphous electron-dense material similar to lipofuscin. Neuroaxonal dystrophy and accumulation of paired helical filaments (similar to those seen in Alzheimer's disease) have also been observed. Demyelination within the brain is quite variable. Pathologic involvement in NPA and NPC is not limited to the CNS; similar involvement of spinal roots, autonomic plexus, and peripheral nerves has also been observed.

Treatment

Presently, there is no specific treatment to retard or reverse NPA, NPB, or NPC. Cloning the acid sphingomyelinase gene and the feasibility of producing abundant quantities of recombinant acid sphingomyelinase raise the possibility that enzyme replacement therapy, similar to that successfully applied to

Gaucher disease, will benefit patients with NPA and NPB. Alternatively, somatic cell gene therapy may be appropriate for NPA and NPB. Indeed, retroviral-mediated transfer of acid sphingomyelinase cDNA has been shown to correct the biochemical abnormality of NPA fibroblasts *in vitro*. NPB is particularly a good candidate for this approach since the disorder is largely due to lipid accumulation in marrow-derived cells, the precursors of which may be transduced readily by vectors containing the acid sphingomyelinase cDNA. Gene therapy for NPA is more problematic and would require correction of the defect *in utero* (since substantial lipid accumulates prior to birth) and correcting the enzyme deficiency in CNS neurons. In the future, enzyme replacement therapy targeting acid sphingomyelinase to CNS neurons may be efficacious for NPA. The clinical effectiveness of reducing circulating low-density lipoprotein (LDL)-bound cholesterol and suppressing *de novo* cholesterol synthesis is being explored as potential therapy for NPC. Administration of dimethyl sulfoxide (DMSO) in NPC has been tried following observations that cultured DMSO addition to NPC fibroblasts reduced storage of nonesterified cholesterol. Bone marrow and liver transplantation have also been attempted with limited clinical benefit in NPA and NPB. Bone marrow transplantation in NPA and NPC faces the potential limitation that although marrow-derived macrophages may be genetically and biochemically normal, clinical benefit depends on correcting sphingomyelin and cholesterol metabolism in CNS neurons. Recently, subcutaneous implantation of amniotic epithelial cells in NPB yielded promising results.

Future Directions

The greatest importance is placed on developing treatments for these disorders. Enzyme replacement and somatic gene replacement therapies hold significant promise for NPA and NPB. Such treatments for NPC will depend on identification of the underlying genetic defect (the search for which is under intense investigation). Clearly, use of naturally occurring murine and feline models of NPC will provide insight into the underlying biochemical abnormality and facilitate treatment strategies for this disorder. In addition, it is important to understand the molecular basis for clinical heterogeneity in NPC. Finally, it is important to identify among the various accumulating substances, the precise factors that mediate neurotoxicity in NPC. Such information will help explain regional neuronal degeneration in these disorders and hopefully provide insight into the biochemical basis of other degenerative neurologic disorders (including olivopontocerebellar atrophies) that show similar patterns of regional CNS degeneration.

Nightmares

M Schredl, Central Institute of Mental Health, Mannheim, Germany

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Nightmares are very common; 70–90% of young adults have reported that they experienced a nightmare at least once in their lifetime. In this article, the definition and etiology of nightmares are reviewed, and a brief and simple treatment technique is presented.

Definition

Nightmares are usually defined as frightening dreams that awaken the dreamer. However, there are two problems with this restricted definition. First, several researchers have demonstrated that very negatively toned dreams that do not wake the dreamer can be as disturbing as nightmares and have coined the term 'bad dreams' for this class of dreams. On average, the emotional intensity of nightmares is higher than that of bad dreams, but there is a large overlap. Whether or not the sleeper is able to judge if the dream emotion was really the cause for waking is still an open question. Some characteristic dreams, such as being chased and waking up just before the attacker grabs you or falling dreams with waking up just before hitting the ground, are obvious examples of dreams that awaken the dreamer, but other dream themes may not be that clear. Second, detailed studies revealed that up to 30% of the nightmares are not dominated by fear but, rather, by other emotions such as extreme sadness, anger, disgust, and confusion.

Nightmares are rapid eye movement (REM) sleep phenomena and often occur in the second half of the night (Table 1). Upon awakening, the person is oriented about her or his surrounding and can give a detailed description of the dream action. Nightmares should be differentiated from night terrors and posttraumatic reenactments. Night terrors are associated with slow-wave sleep and occur predominantly in the first part of the night (usually 1 h after sleep onset). The attack often begins with a piercing cry and – although the eyes are open – the person is not fully awake, experiences intense anxiety (with scarce or no mental content), and does not recall the event in the morning. Sleepwalking often follows a night terror attack. Posttraumatic reenactments also differ from nightmares in that they can occur during REM sleep as well as non-REM sleep (and also during the day – known as 'flashbacks'). Regarding content, there is a continuum from exact replays of the trauma to the nightmares without any obvious reference to the trauma.

Typical nightmare contents are being chased (50%), death or injury (20%), death or injury of close persons (15%), and falling (10%).

Prevalence

The prevalence of children experiencing nightmares once a week or more often is estimated to be approximately 5%. Although nightmare frequency decreases with age (peak prevalence rates occur at ages 6–10 years), large-scale representative studies indicate that approximately 5% of the adult population suffers from nightmares (presumably nightmare frequency is less than once a week in many people). Nightmare frequency is higher in girls and women (with medium effect sizes for the gender difference).

Etiology

Throughout the centuries, many hypotheses regarding the causes of nightmares have been formulated, ranging from devils and demons having sexual intercourse with the dreamer ('succubus' for men and 'incubus' for women) to modern disposition-stress models (Table 2). For the factors depicted in Table 2, empirical evidence of their role in nightmare etiology has been compiled. A large-scale Finnish twin study clearly demonstrated that genetic factors play a role in the etiology of nightmares. Whereas trait anxiety was often not related to nightmare frequency in adults, studies in children and adolescents often found an association between the two. Ernest Hartmann and others have shown that the personality dimension called 'thin boundaries' is associated with nightmares. People who are creative, sensitive, and have intense but problematic relationships, unusual sensory perceptions, and extraordinary occupations suffer from nightmares more often. With respect to the Big Five Factor model of personality, the neuroticism factor is strongly related to nightmare frequency.

Regarding state factors, the presence of a current stressor increases nightmare frequency in children, in nonclinical student samples, and also in nightmare sufferers. Interestingly, one study was able to demonstrate that the effect of personality (neuroticism and thin boundaries) is mediated by the occurrence of stress; that is, people with high neuroticism scores

Table 1 Nocturnal awakenings associated with anxiety

	Nightmare	*Night terror (Pavor nocturnus)*	*Posttraumatic reenactment*
Time of the night	Predominantly in the second part of the night	Predominantly in the first part of the night	Both parts of the night
Sleep stage	REM sleep	Slow-wave sleep	REM sleep or sleep stage 2
Physiological anxiety measures	Moderate	Very strong	Strong to very strong
Dream content	Detailed dream	Rarely a threatening image	Replay of the trauma
Orientation upon awakening	Often fully oriented, although the dream anxiety persists	Not oriented, does not respond properly if addressed	Often fully oriented, strong fear persists
Recall in the morning	Good recall of the dream story	No recall	Good recall
Highest prevalence	6–10 years old	3–7 years old	Event related

Table 2 Etiology of nightmares

Disposition-stress model
Genetic factors
Trait factors ('thin boundaries,' trait anxiety, neuroticism)
State factors (stress)
Trauma
Drugs
Maintaining factors (cognitive avoidance)

experience more stress in their waking life and, therefore, experience nightmares more often. Experiencing a trauma (war experiences, sexual abuse, natural disasters, and severe accidents) can result in a full-blown posttraumatic stress disorder (PTSD) with nightmares as one of the core symptoms, but often nightmare frequency is elevated even if no other PTSD symptoms are present. Within a detailed nightmare history the question about current medication should always be included since quite a few compounds, such as antidepressants (e.g., selective serotonin reuptake inhibitors), acetylcholinesterase inhibitors, or antihypertensive medication, can cause nightmares.

In addition to disposition and triggering factors, one has to keep in mind that nightmares are anxiety phenomena like phobias which persist if the person avoids an active confrontation with the fear. In the case of nightmares, the largest percentage of an adolescent sample reported that trying to forget the nightmare was their primary coping strategy (Table 3). Statements such as "This was only a dream" can be considered as cognitive strategy to avoid confronting the anxiety experienced within the dream. Therefore, the avoidance behavior maintains the nightmares even if the original trigger is no longer active.

Nightmares and Sleep Quality

Several researchers conceptualize nightmares as a primary sleep disorder, although they are categorized into the group of parasomnias and not into the group of dyssomnias such as primary insomnia. Empirical evidence has clearly demonstrated low subjective sleep quality in nightmare sufferers, presumably due to direct effects (waking up from the nightmare and prolonged periods of wakefulness after the nightmare before falling asleep again) and indirect effects (fear of falling asleep in the evening because of the reoccurrence of nightmares). Since stress is associated with poor sleep quality and nightmares, partial correlational analyses were carried out to determine whether nightmares are associated with poor sleep quality even if the stress level is statistically controlled. The results clearly indicate that nightmare frequency and severity of insomnia complaints were associated. The therapy studies performed by Barry Krakow and co-workers also showed that a reduction of nightmare frequency is paralleled by an increase in sleep quality.

Nightmare Frequency versus Nightmare Distress

The hypothesis has been put forward that poorly adjusted people (i.e., those with high neuroticism scores) are more distressed by their nightmares – regardless of frequency – than well-adapted people. This would explain the inhomogeneous findings regarding the relationship between waking-life psychopathology and nightmare frequency and the higher correlation coefficients for the relationship between nightmare distress and psychopathology compared to the correlation coefficients between nightmare frequency and psychopathology. However, most studies have relied on the Belicki scale for measuring nightmare frequency, but this measure is strongly confounded with nightmare frequency (correlation coefficients ranging from $r = 0.24$ to 0.47). To avoid this methodological issue, we developed a scale that measures the distressing effect of a single nightmare and correlated this measure with neuroticism. As expected, neuroticism was correlated with

Table 3 Coping strategies used for bad dreams and nightmares

Category	*Total (N = 606) (%)*	*Boys (n = 329) (%)*	*Girls (n = 277) (%)*
No bad dreams	13.5	19.5	6.5
Tell the dream	22.9	14.3	33.2
Draw a picture	2.0	2.4	1.4
Record (diary)	2.5	0.9	4.3
Try to forget the dream	39.9	41.0	38.6
Image a positive ending	10.1	11.6	8.3
Other	9.1	10.3	7.6

nightmare frequency ($r = 0.39$) and with the sum score of the Belicki scale ($r = 0.42$) but not with the single nightmare distress scale ($r = 0.19$) or nightmare intensity ($r = 0.04$). The hypothesis that people with high neuroticism scores overestimate nightmare distress can be rejected; nightmare frequency is the major factor in determining distress attributed to nightmares.

Nightmares and Sleep Physiology

In the nineteenth century, several scientists held the view that nightmares are caused by a shortage of oxygen. It was sometimes said that a living creature was sitting on the chest ('Nachtmahr' or 'Alpdrücken' in German) or choking the dreamer. Based on experience with his own nightmares, Boerner concluded that blocking the mouth and nose by the bedspread or by the pillow (sleeping in the prone position) caused nightmares. Using a cloth to block the mouth and nose, Boerner was able to induce nightmares in three different sleepers. It seems obvious that studying patients with nocturnal breathing disorders, such as the sleep apnea syndrome, is a promising approach to test the oxygen hypothesis. The sleep apnea syndrome is characterized by apneas (minimal duration of 10 s) which can be accompanied by severe oxygen desaturation. An alarm reaction with an arousal terminates the apnea by increasing muscle tone and reopening the upper airways. In pilot studies, a few examples of breathing-related nightmares have been collected. A 39-year-old male patient with sleep apnea (respiratory disturbance index, 68.1 apneas per hour; maximal decrease in blood oxygen saturation, 43%) stated the following:

> During the dream I felt tied up or chained. I saw thick ropes around my arms and was not able to move. I experienced the fear of suffocation without being able to cope with the situation. Powerlessness and also resignation came up.

One patient reported having recurrent nightmares of the following type: He was lying in a coffin – dead. He cried, "My god, please don't let me die, I am still young and I have small children," and woke up, gasping for breath.

Despite the illustrative examples, a large-scale study with 323 apnea patients did not find any correlation between nightmare frequency measured retrospectively via questionnaire and respiratory parameters (respiratory disturbance index and nadir of oxygen desaturation). Overall, nightmare frequency was not elevated in comparison to that of healthy controls. That is, the oxygen hypothesis is not supported by modern research findings.

Anne Germain and Tore Nielsen carried out a polysomnographic study in 11 nightmare sufferers. They reported a nightmare frequency of one or more nightmares per week. Although they reported considerable nightmare distress, their sleep parameters recorded in the sleep laboratory did not differ from those of healthy controls (e.g., sleep efficiency (92.1 vs. 92.7%), sleep onset latency (14 vs. 11 min), and REM sleep percentage (21.2 vs. 21.5%)). However, they found an elevated index of periodic limb movements during sleep which might be an effect of intense negative dreaming. The sleep laboratory findings (very few studies with small numbers have been carried out) contrast with the subjective reports of the patients. This might be an effect of the laboratory surroundings: many sleep researchers have reported that nightmares occur less often in the lab than at home. This effect might be attributed to the 'caring' environment – the presence of a sleep technician, someone interested in their history, listening to them empathically and taking them seriously. Similar effects (discrepancy between subjective sleep quality and polysomnographic findings) have been reported for other patient groups, such as patients with borderline personality disorder, patients with panic disorders, and adult patients with attention deficit/hyperactivity syndrome.

Charles Fisher and co-workers carried out an extensive laboratory study to investigate the physiology of nightmares. They included 38 patients suffering from three or more nightmares per week and studied

their sleep over 162 nights. Although they recorded a fair number of night terror attacks ($n = 50$), only 22 nightmares occurred in the laboratory. From the patients' evaluations, the attacks in the lab were much less severe than those at home – again the lab effect. Only in three very intense nightmares were marked increases in heart rate (an increase of 20 beats per minute), respiration rate (an increase from 18 to 30 breaths per minute), and the number of eye movements measured in the 8 min prior to the awakening. This is in contrast with the night terror findings: documented increases in heart rate from 64 to approximately 120–150 beats per minute during the attacks. Despite the intense anxiety experienced during a nightmare, the autonomic reaction is moderate (Table 1).

Therapy of Nightmares

The question arises as to when nightmares should be treated. Similar to other mental disorders, it is important to evaluate whether the person suffers from her or his nightmares in a considerable way. Treatment should be offered to patients reporting negative effects on daytime mood and functioning, worries at sleep onset (fear that a nightmare might occur), and insomnia complaints. If a cutoff is needed, for example, for evaluating nightmares in children, a frequency of one or more nightmares per week is reasonable.

Whereas drugs such as REM sleep-suppressing tricyclic antidepressants are often ineffective in the treatment of nightmares, several different psychological interventions seem promising. Although several case report series indicate that lucid dreaming is an effective tool in coping with nightmares, the major problem with this technique is the fact that induction of lucid dreams (learning to have dreams when you know you are dreaming) is a highly expensive and protracted process. Systematic desensibilization was shown to be effective in the treatment of nightmares in two carefully performed studies. The most effective and simplest treatment strategy was developed by Barry Krakow and co-workers and is called imagery rehearsal treatment (IRT). Based on my clinical experience, a reduced form of IRT including the basic steps necessary for the effective treatment of nightmares is depicted in Table 4. For most patients, it is helpful to point out the analogy of coping with fear and anxiety in the waking life.

The first step consists of confrontation, which is simply writing down the dream or, for children, the drawing of the most important dream scene. In the second step, the person is asked to imagine a new ending to the dream. Children were asked to draw something in the picture which reduced anxiety. Ideally, the therapist should encourage the person to develop his or her own personal coping strategy for the nightmare situation and refrain from giving suggestions. The coping strategy should include active behavior. Flying away or hiding is often not helpful (because these reflect avoidance), so one simply asks whether other strategies might be applicable as well. The 'solution' of the dream must not be realistic; most psychologists advise not to increase violence (e.g., killing the opponent) while coping with the dream situation. The 'new dream' should be written down. The last step consists of internalizing the new strategy by imagining the new ending 5–10 min every day during a 2-week period. The repetition during waking life affects subsequent dreams. Interestingly, the effect of the intervention often generalizes; that is, nightmares with other topics are affected and include more adequate coping strategies.

Table 4 Therapeutic principles

Step 1: Confrontation
Record or draw the dream
Step 2: Coping with the situation in the nightmare
Construct a new dream ending or add something to the drawing that reduces the fear
Step 3: Training of the coping strategy
Approximately 5–10 min per day over a 2-week period

For IRT, several randomized controlled trials have been carried out including life-long nightmare sufferers (idiopathic nightmares) and sexually assaulted women with PTSD. In one of the studies by Barry Krakow and co-workers, a single $2\frac{1}{2}$ h group session was effective in reducing nightmare frequency in 39 patients with idiopathic nightmares from six nightmares per week to two. In addition, sleep quality and daytime mood improved. To illustrate the procedure, two case reports from my clinical practice are presented here.

Case Report – Adult

A 22-year-old woman consulted our sleep center due to nightmares that started several months ago. The anamnesis also indicated that several night terror attacks also occurred. Two polysomnographic recordings (including breathing parameters and tibialis EMGs) were normal, with the exception of low sleep efficiency (first night, 67.8%; second night, 76.7%). Nightmares and night terrors did not occur in the sleep laboratory. The psychometric measurement of sleep behavior and sleep quality revealed that sleep quality and the feeling of being refreshed in the morning were not reduced but daytime sleepiness

score was elevated (1.6 standard deviations above the mean of a comparable student sample).

In the first session, the patient reported current stressors. A severe conflict in the core family resulted in a complete cessation of her relationship with her parents. The therapeutic principles, including confronting, coping, and training, were explained to the patient. It was easy for her to understand this approach because it was similar to the treatment of anxiety. In the nightmare of the previous night, the patient was in the dressing room of a fitness club. At first, her complete family was present. Then, her mother was in the center and verbally attacked and criticized the dreamer. She felt very helpless with respect to the accusations. Answering the question as to how the dream could be altered, she came up with several suggestions: ignoring the mother and active acting, such as saying something to her mother and expressing her needs. The 'new dream' included the active confronting of the mother and the sentence, "I can manage my life myself."

In the second session 2 weeks later, the patient reported that she trained the new dream ending regularly during the first week and that no new nightmares including her mother occurred. However, several other negatively toned dreams occurred, one of which was a recurring nightmare. In it, the dreamer stays at the house of her grandmother and is now in the kitchen. At first, the overall emotional tone is positive. Then she senses that there is something threatening outside the house that might come inside and threaten her. The scene changes: the dreamer finds herself in a white room with several fantasy characters (pleasant characters). Two of the characters encourage her to step outside the house and confront the threatening something alone. At this point, she usually wakes up. The awakening from the last dream was at 5 a.m., and the anxiety she felt in the dream was still present after waking up. After talking about the different dream elements (e.g., the relationship to her grandmother, to whom she has a positive connection), the patient was again asked to imagine a new ending to the dream. The patient visualized how she goes outside and confronts the unknown threat with the help of the friendly fantasy characters.

In the follow-up session 2 weeks later, the patient reported a complete cessation of nightmares and that the dreams she recalled incorporate new and active behavior patterns. The dreamer felt more confident in dealing with other dream characters and was able to express her needs. She also reported a marked lessening of daytime sleepiness. Although the stressors did not change over the treatment period, the intervention did reduce nightmare frequency by strengthening the dream ego – that is, the negative effect of the stressor on dreaming and sleep was significantly reduced.

Case Report – Child

A mother consulted our sleep center because her son (5 years old) suffered from nightmares every night during the past month. Before that, nightmares rarely occurred. Common topics are ghosts, shadows, and horrid monsters. At night, he calls out for his mother and needs comfort for up to 2 h because after the nightmare he cannot fall asleep easily. The mother was not aware of any incidents triggering the period of intense nightmares. The boy was somewhat shy but free from any psychopathology or somatic problems.

After taking the nightmare history, the boy was asked to draw a recent nightmare (**Figure 1**). The dreamer is walking within a castle (**Figure 1**, lower left) and carrying a book. He is very frightened by the sight of two enormous ghosts (the differences in size between the figures and himself clearly reflect the fear involved). After he was asked what might help reduce his anxiety, the boy drew a large spider between him and the ghosts, facing the ghosts and protecting him.

After the first session, the boy continued this work with the help of his mother by drawing several pictures of other nightmares and concentrating on one of them each day for approximately 10–15 min. Within 2 weeks, nightmare frequency was drastically reduced. Although the topics of the dreams did not change much, the fear associated with these pictures was almost completely gone. Sleep behavior and quality were back to normal. A follow-up session 1 year later revealed that nightmares were still rare (approximately once a month) and the boy did not feel distressed by them. For several nightmares, he invented new solutions (one involving a magic spray). He has developed a positive attitude toward his dreams which can be seen in the fact that he occasionally asks his mother to record a dream in the booklet which she had kept during the study period.

Conclusion and Future Directions

Nightmares are common and approximately 5% of the population report that they suffer from nightmares. Fortunately, nightmares can be treated effectively with a brief and simple intervention method which can be classified as a cognitive technique. The beneficial effect has been demonstrated for idiopathic nightmares as well as posttraumatic nightmares in children and in adults. The basic principle of confronting and coping with the nightmare situation is easily understandable to patients and can be done

Figure 1 Drawing of a nightmare with a coping strategy included.

without professional assistance, thus encouraging self-help.

In addition to the clinical aspect, nightmares are also an interesting topic for basic sleep and dream researchers. The body–mind interaction can be studied – for example, the correlation between emotional intensity and brain activation related to emotions in waking life (limbic system). Techniques such as magnetic resonance imaging will be applicable to sleep if the scanner noise can be markedly reduced. Since nightmares occur quite rarely in the sleep laboratory, large-scale studies with ambulatory measurement units should be conducted to shed light on the physiological parameters during REM sleep before awakening from a nightmare. The lack of consistent results from sleep laboratory studies may be attributable solely to the 'lab effect' (reducing emotional dream intensity due to the 'caring' environment). Since nightmares reflect stressors and PTSD-related nightmares often replay the trauma experienced by a person, they may help in elucidating the role of dreams in general in sleep-related memory consolidation. Research has shown that sleep facilitates consolidation of declarative and procedural memory tasks. Whether dreams play a crucial role in that relationship remains to be determined.

Nitric Oxide

G Wilson and J Garthwaite, University College London, London, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Nitric oxide (NO) is a unique type of cell-to-cell signaling molecule found in almost all tissues of the body and throughout the central nervous system. NO rose to biological fame in 1987 when it was identified as the factor released from endothelial cells lining blood vessels to cause relaxation of the underlying smooth muscle, thereby influencing blood flow and blood pressure. The following year, it was found to be the mysterious substance known to be produced following activation of the *N*-methyl-D-aspartate (NMDA) class of glutamate receptors on brain neurons to relay signals to neighboring cells, and also a molecule generated by activated macrophages as part of their repertoire of defense against foreign organisms. These three diverse functions – smooth muscle relaxation, neural communication, and immune defense – remain at the core of NO biology and are subserved largely by specialized NO-generating proteins known, respectively, as endothelial, neuronal, and inducible NO synthases (eNOS, nNOS, and iNOS, respectively). As well as being a key physiological signaling molecule, NO has been invoked as an important player in many different disorders affecting humans, including neurodegenerative diseases, pain, atherosclerosis, and septic shock.

The physicochemical properties of NO set it apart from conventional signaling molecules, such as neurotransmitters. First, like oxygen and carbon dioxide, NO lacks chemical specialization. It does, however, possess an extra (unpaired) electron, making it a radical. Whereas some other radicals are chemically reactive and can cause damage to cells, NO is stable in physiological concentrations, which are thought to be approximately 1 nM or less. Second, also like oxygen and carbon dioxide, NO diffuses very quickly through membranes, obviating the need for a specialized release mechanism and giving it the ability to act on neighboring cells within microseconds of its manufacture. This property gives the recipient cell temporal information about the events causing NO to be formed. Finally, NO binds very avidly to heme groups possessing vacant coordination sites. Indeed, the capacity of hemoglobin to bind and inactivate NO was well known long before NO was recognized as a biological messenger, and this property proved to be an important one in developing the hypothesis that the biological messenger was NO and also in testing that hypothesis. Although many cellular heme groups do not possess the necessary vacant binding site, this property has been exploited to provide highly sensitive NO detectors within cells, initiating physiological NO signal transduction.

How Is NO Made?

The NO synthase family of enzymes catalyzes the stereoselective conversion of the amino acid L-arginine to NO. The reaction requires molecular oxygen and L-citrulline is formed as a by-product. The enzymatic conversion of L-arginine into NO was first shown in 1989 and, later, the three different isoforms were identified in molecular terms (chronologically, nNOS, eNOS, and then iNOS).

The enzymes exist as homodimers, with each constituent subunit containing an N-terminal oxygenase domain and a C-terminal reductase domain. The former contains binding motifs for heme, tetrahydrobiopterin (BH_4, a cofactor), and the substrate, L-arginine. The reductase domain possesses binding sites for NADPH, FAD, and FMN. Functionally, electrons are donated by NADPH to the reductase domain and proceed via the FAD and FMN redox carriers to the oxygenase domain, whereupon interaction with the heme iron and BH_4 at the active site catalyzes the generation of NO. The two domains are linked by a binding site for calmodulin and the binding here of calmodulin complexed with calcium facilitates electron flow through the enzyme (Figure 1). The calcium dependence of NO synthesis varies with the NOS isoforms, with nNOS and eNOS having a much higher requirement than iNOS. The calcium insensitivity of iNOS is the result of the lack of an autoinhibitory loop insert within its FMN-binding subdomain that, in the other two isoforms, acts by destabilizing calmodulin binding at low calcium concentrations. Loss of eNOS activity at low calcium concentrations is circumvented when the protein is phosphorylated, typically by the kinase known as Akt, or protein kinase B. Physiologically, eNOS phosphorylation may be the most important device for maintaining NO output in blood vessels.

Knowledge of the enzymatic mechanism for NO synthesis led to the identification of inhibitors, which have become invaluable tools for investigating the biological roles of NO. First-generation inhibitors were L-arginine derivatives with substituents on the guanidino nitrogen normally used for NO synthesis,

Figure 1 NO biosynthesis. The NO synthases are homodimers, with each subunit containing a reductase and oxygenase domain. Electrons donated by NADPH proceed through the reductase domain via FAD and FMN redox carriers. On reaching the oxygenase domain, electrons interact with the heme group and BH_4 cofactor at the active site to catalyze the reaction of L-arginine with molecular oxygen, yielding NO. CaM, calmodulin.

compounds such as N^G-monomethyl-L-arginine and N^G-nitro-L-arginine. These inhibitors are able to inhibit all NOS isoforms, but compounds showing good selectivity for nNOS or iNOS over the other isoforms are now available.

NO Generation in the Nervous System

The nNOS isoform is found predominantly in neurons and has a distribution in the brain and spinal cord as wide as that of the major neurotransmitters glutamate and γ-aminobutyric acid, although the amounts vary from region to region (Figure 2(a)). In some brain areas, such as the cerebellum, nNOS is found in virtually all cells, whereas in others, such as the striatum and cerebral cortex, it is found in a subpopulation of interneurons comprising only a few percentage of the total neuronal number. Nevertheless, even in those regions that are relatively sparsely endowed with nNOS-containing neurons, dense nNOS-containing fiber networks are to be seen ramifying throughout the neuropil, suggesting that the majority of neurons receive NO signals.

In many of these brain regions, NO formation is coupled to the stimulation of the NMDA class of glutamate receptor, which is found in almost all excitatory synapses. This special relationship is the result of the NMDA-receptor-associated ion channels having a high permeability to calcium ions and of the compartmentalization of the nNOS and NMDA receptor proteins into a complex at synaptic sites. The scaffold for this complex is postsynaptic density-95 (PSD-95) protein, which contains several PDZ domains – the modular protein–protein interaction motifs. The N-terminus of nNOS contains a PDZ domain which interacts with the second PDZ domain on PSD-95. PSD-95 also binds the C-terminal PDZ domain of NMDA receptors, leading to the colocalization of the two proteins. In general, NMDA receptors play only a minor role in fast synaptic transmission but are brought into action when there is a concomitant depolarization of the postsynaptic membrane which, by removing a block of the NMDA receptor channel by magnesium ions, allows calcium ions to pass into the cell. One result of NMDA receptor activation in many synapses is the induction of long-term increases or decreases in synaptic strength, phenomena considered relevant to learning and memory formation and ones in which NO is also commonly involved.

In addition to the coupling with NMDA receptors postsynaptically, there are other instances in which NO is formed presynaptically. The best examples of this neurotransmitter-like mode of action are to be found in the peripheral nervous system, where NO is released from nonadrenergic, noncholinergic nerves to act on smooth muscle (e.g., in the intestine) and relax it. The trigger for NO release here is the activation of voltage-dependent calcium channels by invading action potentials. Also, in parts of the brain, nNOS is concentrated strongly in axons (e.g., in the parallel fibers in the cerebellum) and it may perform

Figure 2 The NO–cGMP signaling pathway in rat brain. Shown are the distributions of (a) NO synthase as indicated by NADPH diaphorase histochemical staining and (b) NO-stimulated cGMP accumulation after perfusion *in vivo* of the NO donor, sodium nitroprusside. The images are of adjacent parasagittal sections and are displayed as heat maps, with red indicating strong staining intensity and blue indicating weak staining intensity. Generally, there is a good match between the presence of NO synthase and cGMP production. Pictures of unmodified sections and experimental details can be found in Southam E and Garthwaite J (1993) The nitric oxide–cyclic GMP signalling pathway in rat brain. *Neuropharmacology* 32: 1267–1277.

an analogous 'orthograde' transmitter function at these locations.

Because it is such an unconventional transmitter, developing a conceptual framework for synaptic NO signaling has been problematic, not least because NO is very difficult to measure at physiological concentrations and in discrete synaptic locations. By analogy with the numbers of NMDA receptors, there may be only 10–100 nNOS molecules per synapse. Assuming that the nNOS has a similar activity to that exhibited by the purified enzyme and that, once made, it is dispersed by diffusion, active NO concentrations (in the 0.1–1 nM range) would only be found very locally, within a submicrometer radius. Hence, NO from nNOS may only be able to function in subsynaptic dimensions, implying that it signals between closely juxtaposed elements, such as the pre- and postsynaptic specializations.

Although nNOS is the main isoform in the nervous system, emerging evidence suggests that NO from eNOS in the microvasculature can also influence neurons. This represents a conceptual departure from the traditional view of brain function, in which signal processing is perceived as being performed by neurons with the support of nearby glial cells. On the other hand, any point in the brain is maximally only approximately a cell diameter (approximately 25 μm) away from a capillary and the geometry of the capillary network is ideal for distributing a molecule such as NO within a tissue volume, just as it is for oxygen. At least *in vitro*, the global NO signal deriving from the endothelium can influence the membrane potential of axons in the optic nerve and the capacity for synaptic plasticity in the hippocampus.

How Does NO Act?

Curiously, the answer to this question preceded the identification of NO as a biological messenger. In the 1970s, it was found that NO was a powerful

activator of guanylyl cyclase (GC) enzymes, causing the synthesis of cyclic GMP (cGMP). This observation provided crucial evidence for the hypothesis that endothelium-derived relaxing factor was NO because the factor was found to cause relaxation through cGMP generation. Because of its location in the soluble fractions in tissue homogenates, the enzyme activity became known as 'soluble' GC, but it is now clear that the proteins constitute major physiological receptors for NO and we refer to them here as NO(GC) receptors. In the rodent brain, NO-evoked cGMP accumulation has a similarly broad distribution to that of the NO-forming enzyme (**Figures 2(a) and 2(b)**).

The NO(GC) receptors are designed to capture and transduce low-level NO signals, even very transient ones. The ligand-binding site is a specialized heme group that excludes oxygen, allowing NO to bind without becoming oxidized, in contrast to its reaction with oxyhemoglobin when nitrate ions are formed. The proteins to which the heme is attached are heterodimers of α- and β-subunits and exist in two main isoforms. The β_1 subunit appears to be the common subunit and it is partnered by either α_1 or α_2. Both isoforms are found abundantly in brain tissue but have an uneven distribution, with some areas or cells showing prominently $\alpha_1\beta_1$ and others showing $\alpha_2\beta_1$. A special feature of the $\alpha_2\beta_1$ isoform is that it binds to pre- or postsynaptic scaffold proteins, which would be convenient for transducing localized NO signals from nNOS, whereas the $\alpha_1\beta_1$ may have a less localized distribution in neurons and can also be found in some glial cells. A β_2 subunit is present in low levels at the mRNA level, but there is no evidence that a β_2 protein is expressed.

The binding of NO to the vacant coordination site on the heme group of the NO(GC) receptor is extremely rapid, being nearly diffusion limited. Initially, a six-coordinate nitrosyl–heme complex is formed, but the subsequent snapping of a bond between the heme and a nearby histidine residue results in a five-coordinate species. This bond breakage causes a conformational change that propagates to the catalytic domain, accelerating conversion of GTP into cGMP by 1000-fold or more. Although both subunits contribute to the catalytic domain, there is only a single active site. The second 'pseudo-symmetric' site, which is thought to be analogous to the forskolin binding site in adenylyl cyclase, may have a regulatory function.

Binding of NO to other heme groups is so tight that it often takes hours or days for it to unbind, a property that would preclude a dynamic signaling role for NO. Although of high affinity (dissociation constant of approximately 1 nM), binding of NO to the NO(GC) receptor heme is readily reversible so that, on removal of NO, the associated GC activity switches off in the 100 ms timescale. Overall, the properties of the receptors mean that they can sense NO concentrations of approximately 0.1 nM or more, convert them into approximately 1000-fold higher concentration of cGMP within 1 s, and then cease activity when NO production stops, again within 1 s. Thus, although many details of their functioning remain to be explained, the NO(GC) receptors are highly effective proteins for transducing NO signals into greatly amplified levels of cGMP with good temporal fidelity. Whether or not other NO receptors exist remains to be determined.

Inactivation of NO

Brain tissue avidly consumes NO such that its half-life at physiological concentrations is estimated to be in the 10 ms timescale. Although rapid, this process is unlikely to contribute much to localized NO signaling because diffusion alone ensures rapid dissipation of the molecules from small volumes. Active NO inactivation is more likely to be of importance in shaping the NO concentrations when there are many nearby sites of simultaneous NO synthesis. Despite much research, the means by which the NO signal is actively quenched remains unclear. Reaction with oxyhemoglobin in red blood cells in the vasculature probably plays some role. Chemically, NO can also react with oxygen, but the rate is too slow to be of physiological importance. NO can, however, react very rapidly with lipid peroxyl radicals, although this process is likely to be significant mainly in pathological conditions associated with oxidative stress. The major mechanism of NO consumption in normal brain tissue remains to be identified.

Downstream Targets

On being generated in response to NO, cGMP may act on protein kinases to initiate phosphorylation cascades, on phosphodiesterases responsible for the hydrolysis of cGMP and/or cAMP, or on cyclic nucleotide-gated/modulated ion channels located in cell membranes.

cGMP-dependent protein kinases (cGKs) are activated by submicromolar cGMP concentrations and then phosphorylate serine or threonine residues. There are three types: cGKIα and -1β (splice variants) and cGKII. Activation appears to involve a conformation change that removes the autoinhibitory domain from the catalytic site. Autophosphorylation can also occur, causing a more persistent kinase activity that could outlast the original cGMP signal. In brain, cGKIα is concentrated in Purkinje cells in the cerebellum,

neurons that also express a 23 kDa target protein known as G-substrate which functions as a protein phosphatase inhibitor. By engaging this cascade in Purkinje cells, NO contributes to synaptic plasticity and motor learning in the cerebellum. The hippocampus is enriched in the cGK1β isoform, which is important in the NO-dependent initiation of synaptic plasticity in this region, whereas cGKII is more widespread, being found particularly abundantly in the cerebral cortex, thalamus, olfactory bulb, and superior colliculi. One role of cGKII is in the regulation of circadian rhythms.

Phosphodiesterases (PDEs) catalyze the hydrolysis of cyclic nucleotides to the corresponding noncyclized monophosphates. In mammals, there are 11 PDE families encoded by genes with several splice variants that may exhibit different subcellular locations or tissue distributions. Most of the PDEs can hydrolyze cGMP; those with the greatest affinity are PDE1–3, -5, -6, and -9 through -11. The first family, PDE 1, is a widely expressed, calcium/calmodulin-dependent isoform that hydrolyzes both cGMP and cAMP. Competition between the two cyclic nucleotides could occur, potentially allowing a rise in one to inhibit breakdown of the other. This scenario is more probable with PDE3, however, because this isoform binds both cGMP and cAMP with similar affinities but hydrolyzes cGMP at a much lower maximal rate. In effect, therefore, cGMP can act as a PDE3 inhibitor and raise the levels of cAMP. Although there is little information available on PDE3 in brain, there is evidence that cGMP signals are transduced through this mechanism in terminals of the vagus nerve in the heart, with the increased level of cAMP ultimately causing increased release of acetylcholine. Another cGMP-regulated PDE, PDE2, is a dual-substrate enzyme equipped with a noncatalytic cGMP binding site (called a GAF domain) whose occupation stimulates enzyme activity. PDE2 is found widely in the brain and plays a major role in hydrolyzing NO-evoked cGMP responses in regions such as the cortex, hippocampus, and striatum. In some peripheral tissues, a rise in cGMP causes a lowering of cAMP levels through PDE2 activation. In the adrenal gland, for example, engagement of this mechanism results in a decrease in aldosterone secretion. However, there is no clear evidence for a similar cross-talk mediated by PDE2 in the brain.

The final category of known receptors for cGMP are members of the family of cyclic nucleotide-gated/modulated ion channels. Cyclic nucleotide-gated (CNG) channels are heteromeric proteins that are directly opened in response to the binding of cAMP or cGMP. They were first discovered in retinal rod photoreceptors and then in olfactory receptor cells and retinal cone cells, but there is now evidence for a more widespread distribution, both within the brain and outside. Molecular cloning has identified two subfamilies of subunits, with one (CNGA1–4) being the core subunits (with all except CNGA4 being channel-forming subunits) and the other (CNGB1 and -B3) having a modulatory effect on ion selectivity, ligand sensitivity, and gating properties. cGMP is the preferred agonist for rod- and cone-type channels, whereas olfactory-type channels are relatively nonselective. Under physiological conditions, CNG channels carry inward currents of sodium and calcium ions and are relatively voltage independent. Unfortunately, the pharmacology of CNG channels is poorly developed, making studies of their participation in NO signal transduction difficult. Nevertheless, there is evidence that in response to activation of the NO–cGMP pathway, the channels can promote neurotransmitter release from presynaptic terminals and increase neuronal firing postsynaptically.

Related structurally to CNG channels are the hyperpolarization-activated cyclic nucleotide-modulated (HCN) channels. As the name suggests, HCN channels are activated at more hyperpolarized membrane potentials (typically negative to approximately -60 mV) and convey a depolarizing, cationic current, known as I_h, largely carried by sodium ions. The channels have an important role in cells that fire rhythmically, such as thalamocortical neurons. Here, the hyperpolarization that follows action potential firing activates HCN channels, which provides a depolarizing drive leading to the activation of other voltage-dependent conductances and further action potential generation. This hyperpolarization-dampening role is also important in setting the resting membrane potential of neurons. Two of the four known HCN channel isoforms (HCN2 and HCN4) are particularly sensitive to regulation by cyclic nucleotides, which shift activation to more depolarized membrane potentials, speeding up rhythmic firing or making the resting membrane potential more depolarized. Being tenfold more potent, cAMP is generally regarded as the natural ligand, but there are several examples in which the NO–cGMP pathway brings about changes in neuronal excitability using HCN channels.

What Does NO Do in the Central Nervous System?

NO has been implicated in numerous behaviors in mammals, including learning and memory formation, feeding, sleeping, reproductive behavior, aggression, and anxiety. Interestingly, some of these roles appear conserved across many millions of years of evolution. For example, the jellyfish *Aglantha digitale* (phylum Cnidaria) first appeared approximately half a billion

years ago and contains a very primitive nervous system consisting of a nerve net, photoreceptors, and mechanosensitive nerve cells. NOS-containing neurons are found in the tentacles and NO plays a key role in swimming behavior associated with feeding, with cGMP being the effector molecule. The NO–cGMP pathway is also important in the feeding behavior of mollusks and honeybees, in which it contributes to the formation of long-lasting associations between scent and food reward. In mammals, NO regulates both food intake and the passage of food through the intestine.

At a more cellular level, NO and cGMP have frequently been found to participate in synaptic plasticity, which refers to the capability of synapses to adjust their strength enduringly upward or downward in response to brief periods of altered input, and which is commonly regarded as a cellular correlate of learning and memory formation. Long-term potentiation in the hippocampus, cerebral cortex, cerebellum, amygdala, and spinal cord has been reported to involve the NO–cGMP pathway, as has long-term depression (LTD) in the cerebellum and striatum. The precise roles of NO remain to be elucidated. In some cases, it appears to act as a retrograde transsynaptic messenger, conveying information about postsynaptic NMDA receptor activity to the presynaptic terminal and influencing neurotransmitter release. In others (e.g., in cerebellar LTD), it appears to be formed presynaptically and act on the postsynaptic neuron. Later phases of the plasticity may require cGMP-dependent alterations in gene expression.

In addition to its abundant physiological roles, NO is important in brain pathology. The emphasis of much research has been on the damaging effect of NO, which is usually considered to be caused by the reaction between NO and superoxide ions, forming peroxynitrite. Peroxynitrite can react with proteins, lipids, or DNA and also break down to yield the noxious hydroxyl and nitrogen dioxide radicals. An alternative mechanism contributing to damage by NO is inhibition of mitochondrial respiration. This occurs in competition with oxygen at the level of cytochrome c oxidase, the terminal complex of the respiratory chain. There has been a shift toward the appreciation of the important protective roles of NO. Protection by NO may be multifaceted. First, NO is a very potent inhibitor of lipid peroxidation which causes membrane damage in many neuropathological conditions. It does so by reacting directly with lipid peroxyl radicals, preventing propagation of the oxidative damage. Second, NO release from endothelial cells is important in maintaining blood flow and preventing adhesion of platelets and leukocytes to vessel walls. Third, NO exerts antiapoptotic effects on many different cell types through multiple mechanisms, including the inhibition of caspases, the release of neurotrophic factors, and the stimulation of the expression of cytoprotective genes. Finally, brain repair may be augmented by the NO–cGMP pathway enhancing the generation of new neurons (neurogenesis) and the formation of new blood vessels (angiogenesis).

NMDA Receptor Function and Physiological Modulation

Introduction

With key roles in essential brain functions ranging from the basics of excitatory neurotransmission to the complexities of learning and memory, the *N*-methyl-D-aspartate (NMDA) receptor can be considered one of the fundamental neurotransmitter receptors in the brain. Named for its most potent exogenous agonist, the NMDA receptor has been thoroughly characterized via electrophysiological and pharmacological techniques, as well as through molecular manipulations and transgenic knockout strategies. The NMDA receptor belongs to a family of ionotropic receptors for the excitatory amino acid glutamate and is characterized by high affinity for glutamate, a high unitary conductance, high calcium permeability, and a voltage-dependent block by magnesium ions. this article focuses on the basic biophysical properties and physiological functions of NMDA receptors and how these are modulated by various signaling molecules and biochemical cascades under physiological conditions.

Biophysical Properties of NMDA Receptors

During excitatory neurotransmission, presynaptic release of glutamate activates glutamate receptors in the postsynaptic membrane, resulting in the generation of an excitatory postsynaptic potential (EPSP). Contributing to the EPSP are two classes of glutamate receptors, the non-NMDA receptors (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)/kainate receptors) and the NMDA receptors (Figure 1). The rise times for NMDA receptor currents (10–50 ms) are much slower than those of non-NMDA receptors (0.2–0.4 ms). NMDA receptors also deactivate with a slower time course (~50–500 ms vs. ~2 ms for non-NMDA glutamate receptors), much longer than the time course of glutamate in most synaptic clefts (~1.2 ms). Therefore, during synaptic transmission, the non-NMDA glutamate receptors provide rapid depolarization in response to neurotransmitter release, and the NMDA receptor kinetics determine the duration of the synaptic current.

Activation of NMDA receptors by the neurotransmitter glutamate requires glycine as an essential coagonist. Glutamate and glycine molecules bind different subunits of the receptor; two of each are thought to be required for maximum activation of the receptor. Recent experiments have shown that D-serine can also bind at the glycine site and might represent another physiological coagonist. Compared with glutamate receptors of the non-NMDA type, which have low-affinity binding sites for glutamate (EC_{50} ~500 μM), NMDA receptors bind glutamate with high affinity (EC_{50} ~1 μmol l^{-1}). Despite this high affinity for glutamate, NMDA receptors are not saturated during synaptic transmission at synapses of cortical pyramidal neurons.

NMDA receptor activation leads to opening of an ion channel that is selective for cations, resulting in the influx of Na^+ and Ca^{2+} ions and efflux of K^+ ions. Although most glutamate receptors are cation selective, few are permeable to calcium ions. Its exceptional calcium permeability is the first of two key properties of the NMDA receptor that form the basis for its regulatory role in synaptic plasticity. Entry of calcium into the postsynapse via the NMDA receptor (Figure 2) permits coupling of electrical synaptic activity to biochemical signaling via activation of Ca^{2+}-dependent enzymes and downstream signaling pathways. In this way, calcium influx through the NMDA receptor can lead to long-term changes in synaptic strength and other cellular modifications, including alterations in synaptic structure or connectivity.

The NMDA receptor has a high single channel conductance (~30–50 pS) compared with that of other glutamate receptor types (~4–15 pS). The open probability of agonist-bound receptors has been estimated to range between 0.04 and 0.3, and open times can vary from 0.1 to 8 ms. The molecular events that underlie the opening of NMDA receptors are predicted to include two independent agonist-binding steps preceding a single, concerted conformational change that results in channel opening. Channel closing is thought to be controlled both by the unbinding rate of glutamate and by receptor desensitization. In fact, NMDA receptors can enter long-lived desensitized conformations in which glutamate is bound but the channel remains closed.

The second key biophysical property of the NMDA receptor, and the one that bestows its proposed role in learning and memory, is that it is blocked by magnesium ions in a voltage-dependent manner. At resting membrane potential, NMDA receptors are blocked by magnesium ions; however, if excitation by synaptic inputs causes sufficient depolarization of the neuron, the Mg^{2+} block is relieved and those NMDA receptors which have glutamate bound will open (Figure 3).

Figure 1 NMDA receptor component of excitatory postsynaptic potentials (EPSPs) and excitatory postsynaptic currents (EPSCs). (a) Unitary EPSP ('EPSC') recorded in a L2/3 cortical pyramidal neuron. The NMDA receptor-mediated component (subtraction) was obtained by subtracting the non-NMDA receptor-mediated component (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPAR) component) when NMDA receptors were blocked with the NMDA receptor antagonist AP5. (b) Unitary EPSC ('EPSC') recorded in a L2/3 cortical pyramidal neuron. The NMDA receptor-mediated component (subtraction) and the non-NMDA receptor mediated component (AMPAR component) were determined as in (a). Since opening of the NMDA receptor requires simultaneous activation by glutamate and depolarization to relieve the magnesium block, the NMDA receptor can act as a coincidence detector for pre- and postsynaptic activity.

Glutamate and glycine affinities, calcium permeability, ion conductance, channel kinetics, and sensitivity to Mg^{2+} block of the NMDA receptor are all determined in part molecularly, by alternative splicing and subunit composition. Most of these biophysical properties of NMDA receptors can also be modulated by various ionic and molecular interactions and signaling pathways (described below).

NMDA Receptor Physiological Function

The outstanding physiological function of NMDA receptors is the coupling of electrical to biochemical signaling in neurons by mediating calcium influx in response to synaptic activity. However, NMDA receptors also serve important functions in electrical neurotransmission alone. Despite the voltage-dependent magnesium block, NMDA receptors can contribute significantly to the amplitude of unitary evoked postsynaptic potentials. The slow kinetics of NMDA receptor-mediated excitatory postsynaptic currents (EPSCs) facilitates temporal summation and reduces

Figure 3 Magnesium block of NMDA receptors. (a) Voltage dependence of glutamate-induced currents in Mg^{2+}-free (circles) and Mg^{2+}-containing solution (500 μM; squares). At resting potential, the pore of the NMDA receptor channel is blocked by magnesium ions. Upon depolarization, the magnesium ions are removed from the pore, and the channel can pass current.

dendritic filtering of synaptic inputs. In addition, coactivation of multiple synapses can trigger NMDA receptor-dependent dendritic spikes by generating sufficient depolarization to overcome the magnesium block. Such dendritic spikes cause nonlinear synaptic integration, which enhances the computational power of neurons and may allow neurons to detect the synchrony of inputs (Figure 4).

The NMDA receptor plays an essential role in brain plasticity, that is, the ability of the brain to change in response to external stimuli, such as during learning and memory. First investigated pharmacologically, chronic blockade of the NMDA receptor by infusion of an antagonist into the ventricles of rats was shown to impair spatial learning. Since that time, similar behavioral experiments have been performed using knockout mice lacking NMDA receptor subunits from specific subregions of the hippocampus. These experiments have repeatedly provided evidence for the importance of the NMDA receptor in learning and memory processes.

The role of the NMDA receptor in learning and memory is attributed to its ability to regulate excitatory synaptic transmission. The NMDA receptor has been shown to play an essential role in both the strengthening of synapses, through long-term

potentiation (LTP), and the weakening of synapses, through long-term depression (LTD). LTP and LTD are proposed to be cellular mechanisms underlying learning and memory. Via its role as a coincidence detector, the NMDA receptor is capable of signaling coincident pre- and postsynaptic activity. Detailed studies of the relationship between the temporal correlation of pre- and postsynaptic activity and the resulting type of plasticity have led to the discovery of spike-timing dependent plasticity. If the presynaptic action potential (AP; and thus synaptic activity) repetitively precedes the generation of the postsynaptic AP by less than ~50 ms, the synapse is potentiated; however, if the postsynaptic AP occurs within ~50 ms before the presynaptic AP (and thus independently of presynaptic activity), the synapse is depressed (Figure 5). With respect to the more complex and irregular patterns of neuronal activity that are likely found *in vivo*, it has been suggested that both rate and timing determine the direction of neuronal plasticity.

The NMDA receptor also acts as a coincidence detector during development, where it plays a critical role in the maturation of synapses and the activity-dependent establishment of topographic maps in the brain. By acting to strengthen neighboring connections of similar activity patterns, the NMDA receptor enforces the principle that 'cells that fire together, wire together.' In addition, early in development, many excitatory synapses appear to contain only NMDA receptors, and therefore these synapses are thought to be at first silent (no EPSP in response to synaptic stimulation). It is hypothesized that only through coincident activity sufficiently robust to depolarize the postsynaptic cell and relieve the voltage-dependent Mg^{2+} block of the NMDA receptors does the insertion of non-NMDA receptors at these synapses occur.

While presynaptic NMDA receptors have been detected by immuno-electron microscopy, their function remains far less established compared with their postsynaptic counterparts. As autoreceptors, presynaptic NMDA receptors have been shown to modulate synaptic transmission in the spinal cord, cerebellum, and entorhinal cortex and to play a role in cerebellar and cortical LTD.

Calcium influx through the NMDA receptor is thought to be responsible for its roles in LTP and LTD and for both neuroprotective and neurotoxic effects. Although these various effects may at first seem contradictory, the explanation lies in the spatial

and temporal patterns of calcium influx. Calcium influx at synaptic sites is thought to activate signaling pathways that lead to LTP or LTD, depending on the temporal pattern and amplitude of the calcium transient. Synaptic calcium influx also leads to activation of cyclic adenosine monophosphate response element binding protein (CREB), a transcription factor, resulting in activation of gene expression. One of the genes upregulated in response to activated CREB is brain-derived neurotrophic factor (BDNF), which acts to promote prosurvival programs. In contrast, calcium influx through extrasynaptic NMDA receptors is thought to lead to CREB deactivation and inhibition of BDNF expression, which can have deleterious effects on cell health. In fact, overstimulation of NMDA receptors results in neuronal excitotoxicity, which has been implicated in the loss of neurons associated with ischemic stroke; Alzheimer's, Parkinson's, and Huntington's disease; and amyotrophic lateral sclerosis.

Physiological Modulation of NMDA Receptors

Although glycine and/or D-serine are essential co-agonists of the NMDA receptor, and thus, strictly speaking, not modulators, their cytosolic levels nevertheless regulate NMDA receptor activation. One of two amino acids appears to predominate, dependent on the brain region. The cytosolic concentrations are controlled by release and uptake by both neurons and glia. Stimulated release of glycine and D-serine can be induced by depolarization or non-NMDA glutamate receptor activation. In the spinal cord, glycine spillover from inhibitory synapses has been shown to enhance NMDA receptor currents.

Desensitization

As the NMDA receptor is a ligand-gated ion channel, it can display a decrease in conductance despite the continuous presence of agonist, a process referred to as desensitization. Three different types of desensitization have been reported for NMDA receptors, a glycine-sensitive, a glycine-insensitive, and a calcium-dependent type. The glycine-sensitive desensitization refers to the transition of the NMDA receptor into a glutamate-bound closed state, reflecting a negative allosteric interaction between the glutamate and the glycine binding sites, which results in a reduced glycine affinity in the presence of high glutamate concentrations. High glycine concentrations can overcome this type of desensitization. Glycine-insensitive desensitization has been observed only in dialyzed cells and excised membrane patches and thus does not appear to be physiologically relevant. The calcium-dependent desensitization (also referred to as calcium-dependent inactivation) provides a negative feedback loop by which calcium entering the cell via NMDA receptors in turn leads to the desensitization of the receptor (Figure 6), although calcium from other sources (voltage-gated calcium channels or release from intracellular stores activated by second messenger cascades) has the same effect. In a current model, calcium influx activates calmodulin to displace α-actinin2 from the NMDA receptor. The resulting dissociation of the NMDA receptor from the cytoskeleton is proposed to cause a conformational change in the receptor, which reduces its open probability.

Endogenous Allosteric Modulators

NMDA receptor function is fine-tuned by various forms of allosteric modulation involving endogenous extracellular substances such as zinc ions, protons, polyamines,

Figure 6 Calcium-dependent desensitization of NMDA receptors. Whole cell currents of cultured rat hippocampal neurons (left and right panels) were evoked in low calcium (0.5 μM) solutions by application of NMDA. During a train of seven excitatory postsynaptic currents (EPSCs) evoked in 2.7 μM calcium, the NMDA receptor mediated EPSC was inactivated to ~50% of control (middle). The whole cell current was inactivated to a similar degree and recovered within 4 min. Used from The American Physiological Society: figure 3 in Rosenmund C, Feltz A, and Westbrook GL (1995) Calcium-dependent inactivation of synaptic NMDA receptors in hippocampal neurons. *Journal of Neurophysiology* 73: 427–430.

and reducing and oxidizing agents (Figure 7). Zinc and polyamines mediate a voltage-dependent block of NMDA receptors, which is weaker but appears to involve the same intrapore residues as block by magnesium. Some of the voltage-independent effects of allosteric modulators are mutually interdependent, and structural evidence suggests convergence by overlapping binding sites or common downstream structural modifications. Zinc, protons, and oxidizing agents inhibit NMDA receptor function, while polyamines and reducing agents cause potentiation by modifying channel open frequency and time or agonist or modulator affinities. These modulations are considered to be physiologically relevant during synaptic transmission, when synaptic activity can cause shifts in pH, co-release of Zn^{2+} occurs at certain synaptic terminals (e.g., mossy fiber-CA3), and the amine histamine is released from modulatory afferents (e.g., those arising from the anterior hypothalamus). An important aspect of the negative regulation of NMDA receptor function by pH and oxidizing agents is that it can limit or delay cell damage under pathological conditions such as stroke and ischemia.

Phosphorylation

NMDA receptors can be phosphorylated by the serine/threonine kinases protein kinase C (PKC), protein kinase A (PKA) and calcium/calmodulin-dependent protein kinase II (CaMKII), as well as by the tyrosine kinases Src and Fyn. In general, phosphorylation enhances NMDA receptor function (Figure 7).

A significant percentage of NMDA receptor subunits in the brain are estimated to be phosphorylated by PKC or PKA at one or more sites (10–70%, depending on the region of the brain). Phosphorylation by PKC reduces the affinity for extracellular magnesium ions and increases the open probability. Calcium influx through the NMDA receptor itself can enhance the potentiation mediated by PKC. However, in some preparations, phosphorylation by PKC reduced NMDA receptor-mediated responses by preventing NMDA receptor subunit clustering. Less is known about the regulation of NMDA receptors by PKA and CaMKII. Active CaMKII directly associates with the NMDA receptor, and this association is required for some forms of activity-driven synaptic potentiation. PKA activation has been shown to increase the fractional Ca^{2+} influx through the NMDA receptor; however, some of the effects of PKA activation on NMDA function appear to be indirect.

In contrast, fewer NMDA receptor subunits on neural membranes are phosphorylated on tyrosine residues (2–4%). Phosphorylation by Src enhances NMDA receptor function (Figure 8) by reducing the potency of Zn^{2+} block of recombinant NMDA receptors expressed heterologously; however, evidence is lacking for this mechanism in hippocampal or spinal cord neurons. An alternative view proposes that phosphorylation of NMDA receptor subunits by Src-family kinases could affect downstream signaling proteins, either by recruiting them to the NMDA receptor, by

Figure 7 Schematic overview of modulators of NMDA receptor functions. Activation of the NMDA receptor requires binding of glutamate (Glu) and glycine (or serine) together with membrane depolarization to release the magnesium block (center). Modulators causing depression of NMDA receptor currents (left) include H^+, Zn^{2+}, polyamines, reducing agents, and the protein phosphatases PP1, PP2A, and PP2B/calcineurin. Polyamines and Zn^{2+} cause a voltage-dependent block similar to that caused by Mg^{2+}. Modulators causing potentiation of NMDA receptor currents (right) include external polyamines, oxidizing agents, and the protein kinases PKC, PKA, CaMKII, Src, and Fyn. For details see text.

protecting them against degradation, or through blocking the assembly of signaling complexes. Src-mediated phosphorylation appears to play a role in LTP induction and seems to be modulated by BDNF. Phosphorylation by Fyn may target the NMDA receptor to the plasma membrane by antagonizing its interaction with spectrin.

In some cases, Src activity is required for PKC-mediated activation of NMDA receptor currents, placing Src downstream of PKC on the same pathway. PKC stimulation leads to the activation of the nonreceptor protein tyrosine kinase, cell adhesion kinase-β, which activates Src by disrupting the intramolecular interactions that maintain Src in a low-activity state. Activation of Src then leads to the potentiation of NMDA receptor currents. The effects of Src on NMDA receptors can be modulated by H-Ras, a small guanosine triphosphate (GTP)-binding protein, which binds Src and inhibits its activity. Hippocampal pyramidal neurons from H-ras homozygous null mice displayed enhanced NMDA receptor synaptic responses.

The activation of NMDA receptors by phosphorylation can be reversed by serine and threonine phosphatases 1, 2A, and 2B (calcineurin) and endogenous tyrosine phosphatases. Inhibition of endogenous protein tyrosine phosphatase activity led to potentiation of NMDA receptor currents, indicating that these phosphatases participate in determining the basal phosphorylation level of the NMDA receptor.

Figure 8 The protein tyrosine kinase pp60$^{c\text{-}src}$ potentiates NMDA currents. Whole cell recordings were made from mouse cultured hippocampal neurons. Peak currents evoked by rapid application of NMDA (100 μM) are plotted in the graph on the left. The tyrosine kinase pp60$^{c\text{-}src}$ (30 U per milliliter) was actively perfused through the recording electrode. The period of the perfusion is indicated by the horizontal bar on the graph. On the right, representative currents recorded before (Control) and after (Src) intracellular perfusion with pp60$^{c\text{-}src}$ are shown. NMDA was applied as indicated by the trace above the currents. Reprinted by permission from MacMillan Publishers Ltd: *Nature* (Wang YT and Salter MW (1994) Regulation of NMDA receptors by tyrosine kinases and phosphatases. *Nature* 369: 233–235), copyright 1994.

Calcineurin can be activated by calcium influx through the NMDA receptor itself.

Modulatory Signaling Receptors

Modulation of NMDA receptors by kinases and phosphatases occurs downstream of a number of membrane receptors, the largest group of which are the G-protein-coupled receptors (GPCRs). GPCRs are integral membrane proteins which transmit extracellular signals to the cytoplasm by coupling to heterotrimeric GTP-binding proteins. Activation of a subset of GPCRs, including metabotropic glutamate receptors (mGluRs), muscarinic acetylcholine receptors, μ opioid receptors, lysophosphatidic acid (LPA) receptors, and the protease-activated receptor PAR1, enhances NMDA receptor currents. Those GPCRs that are coupled to Gq proteins, such as mGluR5, m1 muscarinic receptor, and the LPA receptor, are thought to act through a PKC-Src signaling pathway, and mGluR1 also activates Src, but through a PKC-independent pathway. A second set of GPCRs, those coupled through Gs, are thought to enhance activity of the NMDA receptor through activation of Src-family kinases via PKA and receptor for activated C kinase 1 (RACK1). One such GPCR, the pituitary adenylate cyclase activating polypeptide (PACAP) receptor, is activated by the neuropeptide PACAP(1–38), which has been shown to potentiate NMDA receptor-mediated excitatory postsynaptic field potentials in hippocampal slices. Finally, NMDA receptors have been shown to interact directly with G-protein-coupled dopamine receptors. Depending on the class of dopamine receptor, activation of dopamine receptors has been reported both to enhance and to inhibit NMDA receptor currents.

NMDA receptor currents are also influenced by downstream signaling from receptor protein tyrosine kinases, including the EphB receptors, platelet-derived growth factor (PDGF) receptors, and insulin receptors. EphB receptors interact directly with NMDA receptors in cultured neurons, and their activation by ephrinB2 increases NMDA receptor-dependent calcium responses via the activation of Src. Insulin has been shown to enhance NMDA receptor activity in hippocampal slices via a mechanism that requires PKC and tyrosine kinase activity. In contrast, application of PDGF depresses NMDA receptor currents in hippocampal pyramidal neurons via a phospholipase C-IP_3 receptor-cyclic AMP-PKA pathway that inhibits Src activity.

Cytokine receptor activation has been shown to enhance NMDA receptor currents. One group of cytokines, leptins, enhances NMDA receptor-mediated EPSCs in hippocampal slices via activation of the leptin receptor Ob-R_b. The leptin-mediated potentiation was

reduced by inhibitors of PI3-kinase, mitogen-activated protein kinase, and Src-family kinases. Another cytokine, interleukin (IL)-1β, enhanced the rise in intracellular calcium following application of NMDA to cultured hippocampal neurons, a response mediated by the IL-1RI receptor.

NMDA Receptor Complex

The ability of modulators to influence NMDA receptor currents is dependent on their abundance and proximity to the receptor. Proteomic characterization identified synaptic NMDA receptors as part of a remarkably large macromolecular signaling complex called the NMDA receptor complex. NMDA receptors were found linked to receptors, adhesion molecules, scaffolding proteins, signaling molecules, cytoskeletal proteins, and various novel proteins, in complexes lacking non-NMDA receptors. Among the signaling proteins were kinases, phosphatases, GTPases, and GTPase-activating proteins. Physical linkage of these receptors, signaling molecules, and the cytoskeleton to the NMDA receptor is an important way to facilitate rapid modulation of the receptor in response to synaptic activity.

Developmental Expression of Diverse NMDAR Subunits

The *N*-methyl-D-aspartate (NMDA) receptors (NMDARs) are tetrameric ion channels that are ligand-gated by glutamate and glycine and voltage-gated by postsynaptic depolarization. These properties make it an excellent coincidence detector of simultaneous presynaptic glutamate release and postsynaptic depolarization. The main pore-forming units of the NMDAR convey on it different kinetic and conducting properties that are changed through a maturational program of gene expression and synaptic activity. The channel pore is cation-selective and highly permeable to calcium, an important second messenger and the most intensely studied player in investigations of NMDAR function. Compared to other glutamate receptors, the time course of NMDAR activation and deactivation is relatively slow. These properties make the receptor a poor candidate for mediating high-frequency spike transmission but an excellent candidate for mediating long-term structural changes in response to the recent activity history of inputs to particular synapses.

Most NMDARs contain two obligate NR1 subunits, and any two of the four NR2 subunits, NR2A–2D. There are up to eight known splice variants of the NR1 subunit that are expressed heterogeneously in the brain and during development; however, virtually every brain region expresses at least one NR1 subunit by E19. Genes encoding the NR2 family of subunits can be regulated by a developmental program, activity, or both. Although detailed expression patterns of individual subunits vary greatly, consistent patterns have emerged (Figure 1). In most regions, NR2B and NR2D are expressed at highest levels in the embryo and early postnatal period, and they yield receptor currents with slow deactivation kinetics (ratios of deactivation time constants *in vitro* for NR2A : 2B : 2C : 2D are 1 : 3 : 3 : 40). NR2B expression usually persists in the adult brain, although at somewhat lower levels, whereas NR2D subunits are virtually eliminated. NR2A and NR2C are present in mature receptors, with NR2C expression largely confined to the cerebellum and thalamus.

The fact that immature NMDARs in most parts of the brain have much slower deactivation kinetics than mature NMDARs is thought to have important implications for receptor function in the young brain, where lower frequency activity patterns predominate. These patterns tend to correlate pre- and postsynaptic firing on a slow timescale (hundreds of milliseconds). Thus, a receptor with a correspondingly slow deactivation permits coincidence detection even at low frequencies. Additional mechanisms appear to exist in the immature brain to facilitate NMDAR activation because immature receptors in some regions lack voltage-dependent gating *in vivo*, a property that may arise from the presence of NR2D subunits. This could potentially eliminate coincidence detection by the NMDAR, and could contribute to the different effects of NMDAR activation observed in the immature brain, compared to the mature brain. Faster kinetics of receptors containing NR2A subunits could allow tighter temporal control in the detection of coincident activity in mature animals, where high-frequency activity predominates.

Two unusual, recently cloned subunits, NR3A and NR3B, are thought to be important in dampening NR2-containing NMDAR currents. They inhibit channel opening and calcium flux in response to glutamate when co-assembled with NR2 subunits both *in vitro* and *in vivo*. Whereas NR3A expression is widespread, NR3B subunits are restricted to motor nuclei of the brain stem and spinal cord.

In these regions and others with high fidelity, nonplastic synapses, NR2 and NR3A subunits are embryonically expressed and postnatally downregulated, often to undetectable levels. As they disappear, inhibitory NR3B subunits appear and persist into adulthood, accompanying the effective loss of detectable NMDA currents in these structures. This downregulation over development may be critical for the prevention of activity-dependent rearrangements in critical hardwired circuits, but it does not preclude the possibility that the more plastic, immature forms of the receptor can return when circuit conditions are changed by trauma, disease, pharmacology, or behavior. Thus, the impetus for biomedical scientists to study the mechanisms of NMDAR regulation and the pathways it uses to effect synaptic change remains strong.

NMDARs in Early Brain Development

NMDARs have diverse but poorly understood roles in the immature brain. At embryonic stages, NMDAR

Figure 1 Developmental patterns of NMDAR subunit expression in the rodent brain. Summary of approximate expression levels of each of the known NMDA receptor subunits NR2A–2D and newly cloned subunits NR3A and NR3B over postnatal development. Where possible data from quantitative protein expression studies were used. Note the similar expression patterns of NR2B, NR2D, and NR3A, expressed early and downregulated in approximately the second postnatal week, and NR2A, NR2C, and NR3B, which appear after the first postnatal week. However, there is significant heterogeneity across different brain regions and even within brain regions, where subunits can be expressed in a laminar- and cell-specific manner. In addition, detection methods with lower sensitivity and spatial resolution (e.g., western blotting and histoblots) may not detect weak or sparsely expressed subunits in a given region.Data compiled from Dunah AW, Yasuda RP, Wang Y, et al. function is probably independent of synaptic communication because most glutamatergic synapses form after birth. It is possible that in embryonic structures, ambient glutamate is secreted from glial processes or immature axons in a paracrine manner, and this is how early NMDARs are activated.

Migration

NMDAR activation stimulates neuronal migration in vertebrate embryos. Functional NMDARs are expressed on neurons in the embryonic cortical plate (prior to synapse formation) and on some tangentially migrating neurons during the formation of cortical layers. NMDA agonist stimulates chemotaxis in cultured embryonic cortical neurons. Cerebellar granule cells express functional NMDARs before they have begun migration through the molecular layer and prior to synapse formation with mossy fibers. The migratory movements of these cells are slowed up to 50% by NMDAR antagonists and are not affected by blockade of other glutamate receptors.

Differentiation

NMDARs are also involved in the tuning of local circuitry once the migrating neurons reach their targets. Prior to synapse formation, electrical and chemical signals among groups of neurons are coordinated by gap junction connections between them. In neonatal

mice, cortical neurons are spontaneously active and calcium responses are synchronized among groups of adjacent neurons. Mice deficient in NR2B, and hence most early NMDAR current, have fewer coupled groups of neurons in the cortex. Gap junctions have been investigated closely in the hypothalamus, where NMDAR-mediated activity downregulates the Connexin36 gap junction protein. Both NMDAR blockade and elimination of the NR1 gene extend the period of gap junction coupling in the developing hypothalamus; similar results have also been reported for spinal motor neurons. The data suggest NMDARs might be able to regulate the switch from gap junction-connected cells to synaptically connected circuits in multiple brain regions, and can either speed or slow the rate of that development depending on the region and, potentially, the form of the receptor complex that is expressed.

Sculpting Neural Circuits

After neurons have reached their final destinations and begun to differentiate, they extend axonal and dendritic processes and begin to form synapses. This early neurite extension and synaptogenesis proceeds in the absence of synaptic activity. However, subsequent neuronal survival and the refinement of axonal and dendritic connections are dependent on neuronal activation and synaptic release. Early activity is spontaneous, often in the form of slow bursts. Guidance cues initially set up connections between sensory organs and target structures, where incoming axons are organized in a topographical map. As the map is forming, grossly ectopic axons are eliminated, and competition between axons with different activity patterns within the same topographic location results in the further segregation of axons within the target tissue. With the onset of high-frequency sensory-driven stimulation comes the more precise organization of synapses between cells that enables high-resolution sensory detection in the young adult.

NMDARs are important during afferent development for both the removal of incorrectly positioned axons during the formation of topographically organized connections and for the later stages of input-specific segregation and refinement. NMDAR involvement in these activity-dependent processes has been most extensively studied by pharmacological blockade during the development of visual pathways and by targeted genetic manipulation in somatosensory pathways: vertebrate retino-recipient nuclei (the optic tectum of amphibians and the superior colliculus (SC) and dorsolateral geniculate nucleus (dLGN) of mammals), and somatosensory whisker afferent pathways in rodents.

Competition and Segregation – Visual Pathways

NMDAR involvement in the segregation of competing inputs was first described in the amphibian optic tectum. In a normal tadpole, retinal axons from each eye connect to the contralateral tectum, where they each form synapses with multiple tectal neurons (Figure 2(a)). Retinal axons are initially targeted to approximate anteroposterior topographic locations in the tectum using ephrin and Eph receptor

Figure 2 Development of the retinotectal pathway: (a) retinotectal pathway; (b) initial stage of topographical map formation; (c) final stage of topographical map formation. In (a), retinal ganglion cell axons from the retina of each eye travel to the brain as the optic nerve, cross to the other side of the brain at the optic chiasm, and make terminal arbors in the contralateral optic tectum of the brain. In (b), axons initially overshoot their target location in the tectum. Eph receptors expressed on retinal axons and ephrin ligands on postsynaptic membranes are required for this initial stage of map formation. Axons from the temporal side of the retina, destined for the anterior portion of the tectum, are repulsed from posterior tectum; axons from nasal retina are not as repulsed and terminate in posterior tectum. This process sets up a topographical map of the retina (and hence visual space) in the tectum. Ephrin-dependent cues must be present for the elimination of axon branches that are inappropriately topographically placed in the chick optic tectum, but do not affect the elaboration and refinement of branches in the appropriate location. In (c), eventually individual axonal branches become limited in both their mediolateral and anteroposterior extent.

guidance cues. They develop dense arbors in their target zone, through the maintenance of correctly placed branches and/or the elimination of ectopic ones (Figure 2(b)). In three-eyed tadpoles, produced by the embryonic addition of an extra eye primordium, retinal axons from two eyes innervate the same optic tectum, and the terminals of both sets of axons sort out from one another within a topographically appropriate location in a dynamic process called eye-specific segregation (Figure 3). Clusters of axons from the same regions of each retina have more similar activity patterns, and these axons sort within topographically appropriate tectal locations to optimally reproduce the point-to-point order of their cell bodies in each retina. In a tectum exposed to the NMDAR blocker AP5, axons from each eye desegregate and overlap within topographically appropriate regions (Figure 4). When AP5 is removed, the same axons resegregate.

Competitive NMDAR-dependent arbor rearrangement in the optic tectum is a form of the refinement process that keeps similarly active inputs together during normal development of many axonal projections within the brain. In the superior colliculus, NMDAR blockade disrupts the elimination of ectopic arbors during the formation of the retinocollicular map (Figure 5). Clearly, NMDARs are involved in the refinement of retinal axons, although they are not the sole mechanism by which the map refines. NMDARs perform a similarly modulatory function during retinal axon segregation in the developing lateral geniculate nucleus (LGN). In the ferret LGN, retinal axons sort within topographically appropriate regions according to their response properties to light (ON responds to light onset, OFF to light offset) within eye-specific laminae. Without NMDAR activity in the LGN during the refinement period, some axonal arbors spread across both laminae within an eye-specific layer, whereas others refine normally.

In vivo imaging of axonal dynamics during competitive arbor rearrangement provides some insight as to how this process might occur. Branches of a single axon growing into a tectal area dominated by the other eye are eliminated, and branches that grow

Figure 3 Eye-specific segregation in the optic tectum: (a) growth of axons when third eye is implanted; (b) pattern of axon terminals in the contralateral tectum. (a) When a third eye (dark blue) is implanted in the developing embryo, axons from this eye grow into one of the optic tecta at the same time as axons from the endogenous eye (red). Axons from both eyes undergo normal ephrin-dependent topographical refinement. Within a topographical location, however, individual axons sort out from one another, so that they occupy slightly different territory. In (b), when all the axons from one eye are labeled (here, the blue eye), the pattern of their axon terminals in the contralateral tectum can be observed. The image on the right is a whole mount showing the midbrain of a three-eyed frog in which one eye is labeled with the enzyme HRP, which is taken up and transported by retinal axons and catalyzes a colorimetric reaction in the tissue. Groups of axons from the two eyes segregate into dense stripes of clumped terminal arbors within appropriate topographic locations in the tectum. Retinal axon segregation can also be observed in the neuropil of Bellonci (B.), an amphibian structure most reminiscent of the dorsal lateral geniculate nucleus of mammals. Adapted from Constantine-Paton M and Law MI (1978) Anatomy and physiology of experimentally produced striped tecta. *Science* 202: 741–759, with permission from AAAS.

Figure 4 NMDAR-dependence of axon segregation in the optic tectum of a three-eyed frog: (a) control; (b) with NMDAR antagonist. In (a), eye-specific groups of axon terminals segregate into stripes in the three-eyed frog. In (b), when the NMDAR antagonist AP5 is applied chronically over the tectum, eye-specific axon terminals desegregate and are found in overlapping, although topographically appropriate, locations. The application of an agonist sharpens the stripe borders and the removal of the antagonist allows stripe recovery (not shown). NMDAR, *N*-methyl-D-aspartate receptor. Adapted from Cline HT, Debski EA, and Constantine-Paton M (1987) *N*-methyl-D-aspartate receptor antagonist desegregates eye-specific stripes. *Proceedings of the National Academy of Sciences of the United States of America* 84: 4342–4345.

into the area dominated by its own eye are elongated and stabilized. NMDAR blockade prevents the specific elimination of axon branches from areas dominated by the other eye (Figure 6). Thus, when an axon from a disparate retinal locus strays into a region where axons from a similar locus are concentrated, its inability to effectively stimulate tectal neurons results in its elimination. Clusters of axons from nearby retinal sites can cooperate to fire tectal neurons, and they continue to generate and stabilize axons in those areas in the absence of NMDAR activity. Thus, the specific elimination of these less efficient or incorrectly placed axons is NMDAR-dependent, after axons have already formed and elaborated using other (non-NMDAR) mechanisms.

The evidence suggesting that cooperative near-neighbor input activity is critical for activity-dependent refinement during development is strong. In the developing retina, slow cholinergic waves of activity sweep across local populations of ganglion cells and synchronize the firing of neighboring cells. Mice with a deletion of the $\beta 2$ nicotinic acetylcholine receptor subunit lack these spontaneous waves, and their ganglion cells fire in uncorrelated bursts. As a result, neighboring axons in the SC cannot cooperate to fire collicular neurons, and all axons are similarly inefficient at inducing their postsynaptic partners to fire. Retinal axons in the SC of these mice become abnormally dispersed across each collicular lobe. Postsynaptic glutamate receptors are probably involved in this refinement because retinal axons are glutamatergic; however, this has not been directly investigated.

NMDAR-induced synaptic weakening in the absence of correlated pre- and postsynaptic activity has been observed in the visual cortex at later stages of development. Axons of LGN neurons projecting to the cortex segregate into eye-specific domains early in the development of binocular animals, but remain plastic and sensitive to monocular deprivation by lid suture during a critical period. As a result, most cortical cells become responsive to the nondeprived eye, and responsiveness to the deprived eye is lost. When correlations between pre- and postsynaptic activity are disrupted by the suppression of postsynaptic action potentials, NMDAR-dependent depression of the connections between the open eye and the silenced postsynaptic neurons results. Thus, NMDAR-induced synapse weakening is an active process, in which high levels of synaptic activation are detrimental when the postsynaptic neuron cannot spike.

Figure 5 NMDAR-dependence of the elimination of ectopic axons in the mammalian superior colliculus (SC): (a) retinocollicular pathway; (b) dye labeling of a small population of axons; (c) in the control and with NMDAR antagonist. In (a), retinal axons project to the contralateral SC, with a minor sparse projection to the ipsilateral SC; the inset shows a coronal section of rat SC (only the superficial, retino-recipient layers of the SC are shown). In (b), dye is injected into a small portion of temporal retina labels retinal axons in the anterior SC; the inset shows a parasagittal section through the rat SC. In (c), dye injections are made at various times during the postnatal refinement of the topographical retinal map, which is largely complete by eye opening (postnatal day 13 (P13)). When NMDARs are blocked by chronic implantation of the NMDAR antagonist AP5 in a slow-release plastic implanted over the developing SC, some axons are found in inappropriate topographical locations, even at P19. The crude topography of most of the retinal axons is unaffected. NMDAR, *N*-methyl-D-aspartate receptor. Adapted from Simon DK, Prusky GT, O'Leary DD, and Constantine-Paton M (1992) *N*-methyl-D-aspartate receptor antagonists disrupt the formation of a mammalian neural map. *Proceedings of the National Academy of Sciences of the United States of America* 89: 10593–10597.

Competition and Segregation – Somatosensory Pathways

NMDARs are also crucial for the establishment of appropriate axonal and dendritic arbors in the developing somatosensory system, where genetic manipulations of the receptor have been applied. The patterning of rodent whisker-driven afferents in the pathways from the whisker pad to trigeminal nucleus to somatosensory thalamus to cortex have been extensively studied in genetically engineered mice with absent or reduced NMDAR activity. Mice lacking either the NR1 or the NR2B subunit of the NMDAR lack whisker-related patterns of sensory axons in the spinal trigeminal nucleus at birth. These mice die soon after birth from respiratory failure (NR1) and an inability to suckle (NR2B); thus, later stages of development cannot be studied. The addition of low levels of NMDARs to these mice with transgenesis permits their longer survival. In these NR1 knockdown mice, whisker patterns fail to form at all levels of the somatosensory pathway. They lack barrellettes in the trigeminal brain-stem nucleus, barreloids in the somatosensory thalamus, and whisker barrels in the somatosensory cortex (Figure 7).

Figure 6 Ocular dominance: (a) partial lesion of one optic tectum inducing intereye competition; (b) NMDAR-dependence of the elimination of minority axons in areas dominated by other inputs. In (a), axons normally destined for a lesioned region of tectum (left) grow into the adjacent tectum and terminate in the appropriate topographical region. Ocular dominance patterns are set up by the two eyes in the doubly innervated region of the unlesioned tectum. In (b), the clear tadpole skull and proximity of the tectum at the top of the head make it possible to follow single axons over time in a living animal. Single axons were labeled with a fluorescent dye, and the pattern of branch additions and retractions over many hours was imaged by fluorescent microscopy. At the end of the experiment, whole retinal projections were labeled to determine the pattern of ocular dominance in the imaged tectum. This combined information revealed that axon branches are preferentially eliminated from territory dominated by the opposite eye. When the tadpole is raised with the NMDAR blocker in the growing media, axon branches are equally eliminated from same and opposite eye territories. These data are consistent with a role for the NMDAR in correlation-based branch elimination. NMDAR, *N*-methyl-D-aspartate receptor. (a) From Constantine-Paton M (1981) Induced ocular dominance zones in tectal cortex. In: Schmidt FO, Worden FG, and Denis SG (eds.) *The Organization of the Cerebral Cortex*, pp. 47–67. Cambridge, MA: MIT Press. Data from Ruthazer ES, Akerman CJ, and Cline HT (2003) Control of axon branch dynamics by correlated activity *in vivo*. *Science* 301: 66–70.

NR1 deletion restricted to excitatory cortical neurons has more subtle effects on cortical barrel patterns. In these mutant mice, gross whisker-related patterns form normally at all levels of the somatosensory pathway and there is a normal critical period for barrel fusion after one or several whiskers are removed. However, cortical barrel patterns are smaller and not well defined, suggesting later stages of activity-dependent refinement have been disrupted (Figure 7). Indeed, careful study of individual thalamocortical axonal afferents to the barrel shows that axonal arbors are not properly restricted to whisker boundaries (Figure 7). As in the visual system, NMDARs in the somatosensory pathways are required for the elimination of branches that are inappropriately positioned. In addition, in cortical barrels NMDAR activity also sculpts postsynaptic dendrite structure to orient dendrites within the appropriate target zone. In the cortex of the same mutant mouse, dendrites of cortical layer IV spiny stellate cells are improperly oriented and lack a normal inwardly polarized orientation with respect to the barrel walls (Figure 7).

Structural Refinement – Synapses

The exact mechanisms through which NMDAR stimulation is coupled to synaptic change and the eventual synaptic rearrangement that takes place are not yet determined. Disruption of NMDAR activity affects the development of excitatory synapses and dendritic spines, and also affects the overall axonal and dendritic structure. It is not known whether the proximal cause of these rearrangements is synaptic or extrasynaptic NMDAR activation or whether changes in synaptic strength that precede structural rearrangements are causal. However, in the immature brain there is growing evidence that the dominant effect of NMDAR activation is to weaken synapses, resulting in a net reduction of contacts and continued sprouting.

In developing pyramidal neurons of somatosensory cortex, refinement occurs via the elimination of dendritic spines, the sites of excitatory synapses on these neurons. Sensory deprivation slows this refinement in single neurons imaged over time *in vivo*, and NMDAR blockade mimics the effects of sensory

Figure 7 NMDARs as necessary for normal refinement of whisker afferents to somatosensory nuclei. Summary of generalized results from the genetic deletion of NMDARs in mutant mice. Three somatosensory nuclei are described: brain-stem nuclei (ventral Pr), thalamic nuclei (VPM), and somatosensory cortex (SI). Each barrel-shaped structure represents the organization of afferents from a single whisker. Barrels visualized with multiple anatomical methods yielded similar results, and a representative case has been drawn here. The Control column shows whisker maps in an adult, wild-type mouse, shown in similar orientation. There are sharp borders between adjacent whisker regions (first column), and whisker afferents to the brain stem have refined terminal arbors (fourth column). Thalamo cortical axons have terminal arbors that are contained within a single barrel structure in SI (fourth column), and cortical stellate cell dendrites are oriented toward the center of the barrel (sixth column). The ↓NMDAR column shows transgenic mice generated in a background strain containing an NR1 deletion, in which minimal NR1 expression has been restored by transgenesis. This permits survival beyond the first few days after birth (up to ~8 days). Whisker maps with distinct whisker regions are not detected in any somatosensory nuclei within a week after birth (second column). Reconstruction of single whisker afferent axons in the brain stem reveals that axonal terminals are larger than controls (fifth column). The knocked-out NMDAR column shows mice that had normal levels of NMDAR expression in the embryo and early postnatal life (columns three and seven). Postnatal deletion of NR1 that is restricted to excitatory forebrain neurons permits barrel formation in the SI of adult mice. However, the barrels are smaller than normal, and the borders are ill-defined (third column). Individual thalamocortical axons are not contained within the barrel walls (fifth column), and cortical stellate cell dendrites are not as polarized in orientation as cells from wild-type controls (seventh column). ↓, decreased; NMDAR, *N*-methyl-D-aspartate receptor; Pr, principal sensory nucleus of the trigeminal nerve; SI, primary somatosensory cortex; VPM, ventral posterior medial nucleus of the thalamus. deprivation. Similarly, NMDAR blockade slows the elimination of spines from immature retinal ganglion cells. Thus, in retina and somatosensory cortex, NMDARs are required for developmental and sensory-dependent spine elimination.

Studies in the SC have found that NMDARs eliminate synapses and axonal branches only during a transient developmental period while retinal axons are refining and synaptic depression dominates. Chronic NMDAR blockade in the SC from birth increases the density of glutamatergic synapses and glutamate release sites on incoming retinal axons, until the middle of the second postnatal week (Figure 8(c)). NMDAR blockade has no net effect on synapse number or axonal sprouting in older colliculus, where there is balanced potentiation and depression, and the neuropil has a high synaptic density. Pushing the balance back toward depression with the application of an NMDA agonist pushes synapses toward functional depression in older colliculus and reduces the number of retino-collicular synapses (Figure 8(c)).

If, early in development, NMDAR-mediated synapse elimination is the primary mechanism by which axonal arbors retract, the expectation is that axonal branch elimination will follow synapse loss. Indeed, in the zebra fish and amphibian tecta, in the absence of a mature presynaptic site (identified as clusters of vesicle-release proteins), axon branches retract to the nearest synaptic site on the terminal, where they become stabilized. This is evidence that NMDAR-dependent

Figure 8 NMDA receptor activity eliminating synapses in the young SC: (a) dye labeling of contralateral and ipsilateral retinal axons; (b) identification of synapses on retinal axons; (c) NMDAR-dependence of synapse elimination during refinement. In (a), complete labeling of all retinal ganglion cells by intravitreally injected cholera toxin subunit B conjugated to fluorophores allows the visualization of both the ipsilateral and contralateral retinal projection from one eye. In (b), confocal microscopy and immunohistochemical localization of clustered presynaptic (or postsynaptic) markers and quantitative overlap analysis allows visualization of synapses along labeled retinal terminals. In accord with observations from electron microscopy, presynaptic release sites occur frequently at swellings or terminal bulges on the axon. In (c), the chronic blockade of NMDARs from birth increases the synaptic density along retinal axons during the first ~10 days. Synaptic density is already low at this time, and treatment with the agonist (NMDA) has no effect. By postnatal day (P)14, treatment with agonist reduces synaptic density and the antagonist ceases to have an effect. NMDAR, *N*-methyl-D-aspartate receptor; SC, superior colliculus. Adapted from Colonnese MT and Constantine-Paton M (2006) Developmental period for N-methyl-D-aspartate (NMDA) receptor-dependent synapse elimination correlated with visuotopic map refinement. *Journal of Comparative Neurology* 494: 738–7351.

sculpting of axon and dendrite structure may result from its proximal effect on synapse formation/elimination. Cytoskeletal organizing pathways involving Rho-family GTPases translate NMDAR activity into rearrangements of the cytoskeleton in dendritic processes; however, it is unknown whether this involves or is preceded by NMDAR-driven synaptic elimination.

Refinement of receptive fields and response properties

Given the importance of NMDA receptors in structural and synaptic refinement, modifications of receptive fields and response properties would also be expected when NMDAR activity is manipulated. Indeed, NMDAR activity is required for the compression of collicular receptive fields after a partial lesion limits the amount of target space available for retinal axon arborization. Similarly, enlarged receptive fields result when NMDARs are blocked during auditory map formation. The map of auditory space does not refine normally, and more neurons are broadly tuned. Finally, visual cortical neurons in NR2A knockout mice show dramatically reduced orientation preferences. Due to the complicated contribution of afferent innervation, dendritic structure, and local inhibition to receptive field responses, the locus and precise nature of these deficits are unknown. All are consistent, however, with a model in which NMDAR activity refines circuits by modifications of synaptic strength, followed by synaptic elimination or stabilization.

NMDAR Subunits and Developmental Long-Term Depression and Long-Term Potentiation

Near-simultaneous activation of pre- and postsynaptic neurons is believed to modify synaptic strength via NMDARs through mechanisms such as long-term potentiation (LTP), long-term depression (LTD), and spike-timing-dependent plasticity (STDP). These are important models of NMDAR function in the developing nervous system because nascent synapses are thought to be stabilized or eliminated by repeated synaptic potentiation or depression, respectively. STDP is a more specific form of LTP/LTD that also requires NMDARs. STDP causes potentiation if the postsynaptic cell responds within $\sim<40$ ms of a presynaptic stimulation (effective inputs), and causes depression if the postsynaptic cell responds between $\sim$40 and 100 ms after stimulation (ineffective inputs). STDP can be induced by sensory stimuli, and may therefore represent the natural mechanism by which long-lasting synaptic changes are induced via NMDAR activation. However, in developing systems the effects of STDP can be rapidly reversed by spontaneous activity, indicating that a stabilizing process must occur before STDP permanently shapes connectivity.

NMDAR-driven synaptic modifications are bidirectional, in that either LTP or LTD of synaptic strength can be induced by receptor activation. LTD tends to be easier to induce in the young brain, and as the brain matures, the induction of LTP becomes possible. This switch from LTD to LTP induction correlates with the developmental progression of NMDAR subunit expression from slowly deactivating NR2B-rich receptors to mixed slowly and rapidly deactivating receptors and with other subunit-specific changes in the gating properties of these receptors that occur with development. Given this correlative evidence, it has been tempting to functionally link NR2B-rich receptor complexes to LTD and NR2A-rich complexes to LTP. At certain ages, a carefully controlled blockade of receptors containing NR2B eliminates hippocampal LTD, without affecting LTP. Mice lacking NR2A show a progressive deficit in LTP in the hippocampus with age that parallels the normal increases in hippocampal NR2A expression in wild-type mice.

However, there are many regions of the brain where tight correlations between LTD/NR2B and LTP/NR2A do not exist. It is unknown how mixed NR2A/NR2B receptors contribute to LTP and LTD. It seems reasonable that the dynamics of the calcium signal through these receptors may differ at different synaptic sites, due to the inherent subunit-specific differences, location, and association with different kinases and phosphatases that regulate calcium flux. Thus the NMDAR is likely sending mixed signals through the same synapses, and the net effect is a result of this diverse network of signals.

Changes in NMDAR subunit composition are also correlated with changes in the expression of scaffold proteins associated with the NMDAR at postsynaptic sites. These proteins may prove to be critically important in linking calcium influx through NMDARs to specific signaling pathways by tethering the necessary molecules close to the channel pore. In this way, both the electrophysiological responses of the NMDAR channel and the effector proteins it binds might interact to control the direction of synaptic strength changes during development.

A Developing NMDA Receptor Complex

Membrane-associated guanylate kinases (MAGUKs) are important components of the NMDAR protein complex in the postsynaptic density (PSD). Recent studies have begun to explore their contribution to the divergent functions of the NMDAR during synaptogenesis and developmental plasticity. These intracellular NMDAR-binding proteins contain multiple protein–protein interaction domains and bind to both scaffolding and signaling molecules at the PSD. In this way, NMDARs are connected to other transmembrane receptors in the PSD through a dynamic horizontal lattice of protein interactions. This complex links the receptor to the cytoskeleton, to receptors such as α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), G-protein-coupled glutamate, and inositol triphosphate receptors (which release calcium from intracellular stores). Signaling molecules that drive cytoskeletal rearrangements and other calcium-dependent processes are also tethered near the NMDAR channel pore by MAGUKs.

Two MAGUKs in particular, synapse-associated protein (SAP-)102 and postsynaptic density protein (PSD-95, are differentially expressed during development. SAP-102 is the only MAGUK present at the young ages when immature NMDARs predominate. Like NR2B, SAP-102 expression does not disappear, but continues to be expressed in the adult, along with the mature MAGUK, PSD-95. They appear to have some specificity for NMDAR complexes containing NR2B or NR2A, respectively. PSD-95 has recently been shown to produce synapse potentiation by anchoring stargazin AMPA receptor (AMPAR) complexes in the PSD, and the activation of NMDARs containing NR2A have been reported to promote insertion of AMPARs containing GluR1 (a critical step in LTP induction). With eye-opening in the developing visual pathway of rodents, PSD-95 is rapidly inserted

into visual synapses, and synaptic potentiation and a second wave of synapse refinement follows soon after.

Calcium-sensitive proteins couple NMDAR activation to downstream transcription/translation, cytoskeletal rearrangements, changes in synaptic strength, and cell death pathways. The exact mechanism linking calcium influx through NMDARs with the activation of these pathways is not well defined. Guanine exchange factors (GEFs) and small GTPases are known to be downstream of NMDAR activation and to drive bidirectional changes in synaptic strength and cytoskeletal rearrangements. MAGUK scaffold proteins may be critically important in localizing these calcium-responsive proteins and their effector proteins to NMDARs, although some, such as Ras GTPase, are also independently targeted to membrane microdomains, and some, such as CaMKII-α, are able to bind the NMDAR directly. One GEF, RasGRF1, binds the NR2B subunit directly. Thus, subunit-specific MAGUK binding may not entirely account for the differential effects of NR2B versus NR2A activation. Existing data on subunit-specific protein interactions and developmental expression do suggest that entirely different NMDAR signaling complexes exist, depending on the subunit composition of the receptor and the proteins that are available to bind. Such distinctions are exceptionally difficult to establish with biochemistry and molecular biology alone because each synapse can contain a heterogeneous array of receptor-signaling complexes, but they may hold the key to the mechanisms of NMDAR function through development.

Summary

Data from the visual and somatosensory systems support the concept of the NMDAR as a causal effector of changes in synaptic strength and structural rearrangements during the activity-dependent development of sensory pathways. Mechanisms similar to LTP and LTD appear to be involved, where NMDARs detect the coincident activation of pre- and postsynaptic neurons and strengthen or weaken synapses based on this information. Early in development when immature subunits permit synaptic depression, NMDARs eliminate synapses. In many cases of NMDAR function during development, synaptic potentiation or depression precedes the structural reinforcement or withdrawal of connections. The subunit-specific interaction of NMDARs and scaffold proteins may direct changes in synaptic strength that underlie developmental refinement of neuronal connectivity and structure; however, this has not yet been directly examined. The heterogeneity of the receptor subunits and associated proteins permits a modifiable NMDAR complex that is exquisitely sensitive to changing patterns of activity in the developing brain.

Introduction

N-Methyl-D-aspartate (NMDA) receptors are a major subtype of ionotropic excitatory glutamate receptors that mediate synaptic transmission at the vast majority of excitatory synapses in the central nervous system. Functional NMDA receptors are heterotetromeric complexes of NR1, NR2A–NR2D, and NR3A and NR3B subunits. The subunit compositions of the receptors affect both their functional properties and subcellular distributions. Like other types of ionotropic glutamate receptors, NMDA receptors are ion channels that allow major monovalent cations such as sodium and potassium to cross the plasma membrane, either into or out of the neuron, depending on the chemical and electrical gradients of these ions at a given time. However, NMDA receptors possess several unique properties that distinguish them from other ionotropic glutamate receptors. In addition to monovalent cations, NMDA receptors are also highly permeable to the divalent cation Ca^{2+}, which has numerous important intracellular functions. (Note: the only other type of glutamate receptor that exhibits similar Ca^{2+} permeability is the GluR2 subunit-lacking α-amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA) receptor, which represents a minor proportion of AMPA receptors in the brain.) The permeability of NMDA receptors to Ca^{2+} places them in a unique position to control the initiation of a lengthy list of Ca^{2+}-dependent cellular events. NMDA receptors also have two unique requirements that control their activation. Unlike other glutamate receptors, NMDA receptors require co-agonists such as glycine to bind to specific sites at the same time as glutamate binds, in order to be activated. Additionally, under resting conditions, magnesium ions block the channel pore of NMDA receptors. In order for the magnesium block to be removed, the membrane must be depolarized, which enables NMDA receptors to function as a detector for the coincidental presynaptic release of glutamate and postsynaptic depolarization, a process critical for computation of neuronal signals and for the establishment of certain forms of activity-dependent synaptic plasticity. These unique properties place NMDA receptors in a position to regulate various neuronal functions, ranging from synaptic plasticity at a single synapse to complex cognitive functions such as learning and memory. However, abnormal activation of NMDA receptors may also result in cellular dysfunction and contribute to the symptoms of many disorders of the nervous system. Therefore, the contribution of NMDA receptor abnormalities to the pathogenesis of several disorders will be discussed in the following sections, with a particular focus on progress made in the last decade.

Potential Mechanisms Underlying the Roles of NMDA Receptors in Brain Dysfunction

Excitotoxicity: A Common Mechanism by which NMDA Receptors Contribute to the Pathogenesis of Neurodegenerative Disorders

Excitotoxicity refers to the overactivation of glutamate receptors as a result of increased release and/or decreased uptake of excitatory amino acid transmitters, primarily glutamate. During pathological conditions such as those experienced during ischemia, excessive release of glutamate overactivates glutamate receptors, resulting in a massive influx of sodium ions, chloride ions, and water, which cause neurons to swell and may ultimately lead to rapid neuronal loss from necrosis. Because of the high calcium permeability of NMDA receptors, their overactivation is also accompanied by an accumulation of excessive amounts of intracellular calcium, which initiates other intracellular cascades, leading to slow (delayed) apoptotic neuronal loss. The mechanisms through which excessive calcium influx leads to apoptosis are complex and not fully understood. Accumulating evidence has implicated several intracellular molecules and signaling pathways, including mitochondrial dysfunction, reactive oxygen species production, activation of catabolic enzymes which degrade proteins, nucleic acids, and other cellular components. While the detailed mechanisms through which overactivation of NMDA receptors lead to excitotoxicity may differ between disorders, a large body of evidence implicates NMDA receptor-mediated excitotoxicity as a common mechanism mediating the pathogenesis of many neurodegenerative disorders, ranging from acute events such as stroke and brain trauma to chronic neurodegenerative disorders such as Alzheimer's disease, Parkinson's disease, and Huntington's disease. Evidence for the involvement of NMDA receptor-mediated excitotoxicity in the pathogenesis of central nervous neurodegenerative disorders will be discussed in later sections using stroke and Alzheimer's disease as examples of acute and chronic neuronal degeneration, respectively.

Altered NMDA Receptor-Mediated Synaptic Plasticity May Contribute to the Pathophysiology of Brain Disorders with Abnormal Synaptic Function

Synaptic plasticity refers to the ability of synapses to change their strength. Such plastic changes in synaptic efficacy are fundamental for both neuronal development and normal brain functions. Because of the unique features of high calcium permeability and the voltage-dependent blockade by extracellular magnesium, NMDA receptors are essential for mediating many forms of synaptic plasticity in the brain throughout development. The best characterized forms of NMDA receptor-mediated synaptic plasticity are long-term potentiation (LTP) and long-term depression (LTD) of AMPA receptor-mediated synaptic transmission at CA3–CA1 synapses in the hippocampus. LTP and LTD are prominent cellular models of certain forms of learning and memory. Not surprisingly, alterations in LTP and LTD are correlated with cognitive impairments in rodent models of brain disorders such as Alzheimer's disease and fragile X syndrome. In addition, accumulating evidence supports the hypothesis that abnormal NMDA receptor function and synaptic plasticity are involved in the pathogenesis of brain dysfunctions in a number of neurological and neuropsychiatric disorders not characterized by evidence of cell death or gross structural damage to the brain. In these disorders, it is hypothesized that relatively subtle functional and structural alterations in synaptic connections between neurons in affected brain regions may underlie some of the symptoms. Examples of such brain disorders include pain, addiction, and schizophrenia. In the following sections there is a discussion of research on these disorders that has demonstrated the pathological effects of abnormal synaptic plasticity and has provided insight into a number of therapeutic strategies for reversing these abnormalities.

Examples of Disorders Hypothesized to Occur as a Result of NMDA Receptor Dysfunction

Stroke

Stroke is a sudden loss of blood supply to part of the brain that occurs when a blood vessel either bursts or is blocked. Neurons in the affected area are severely injured or die as a result of the interrupted supply of oxygen and nutrients from the blood. The specific consequences of a stroke depend on a number of factors, including the duration of blood loss and the specific brain area affected. Different cellular processes underlie neuronal injury following stroke, but particularly strong evidence suggests that excitotoxicity is the primary cause of neuronal death following stroke. For example, in both *in vitro* and *in vivo* experimental models, levels of extracellular glutamate are rapidly elevated after stroke to concentrations that produce massive increases in intracellular calcium. The levels of intracellular calcium reach concentrations sufficient to cause excitotoxic necrotic and apoptotic neuronal loss. Most importantly, administration of NMDA receptor antagonists before or immediately after stroke onset is effective in reducing the neuronal damage in various preclinical animal models.

Significant evidence thus supports the critical involvement of NMDA receptor-mediated excitotoxicity in mediating stroke-related neuronal loss and NMDA receptors as an important target for stroke therapy. As a result, numerous pharmaceutical companies have spent considerable resources in an attempt to design effective NMDA receptor antagonists for treatment of stroke. However, the effectiveness of NMDA receptor antagonists in clinical trials for stroke and traumatic brain injuries has been low. A number of factors, including undesirable side effects at therapeutically effective doses, an inability to administer the drugs within their neuroprotective windows, and heterogeneity in the patient population, likely underlie these disappointing results.

Importantly, recent advancements in understanding the detailed molecular mechanisms of NMDA receptor-mediated excitotoxicity may aid in developing novel NMDA receptor-based neuroprotective therapeutics that would reduce neurotoxicity without causing significant side effects. For example, one potential challenge in using NMDA receptor antagonists for stroke therapy is to avoid inhibiting the normal functions of NMDA receptor signaling, which are essential for neuronal survival. One promising approach to avoid completely block NMDA receptors is to use low-affinity NMDA receptor antagonists such as memantine to treat stroke. Memantine is a low-affinity, open-channel blocker of NMDA receptors. Due to its relatively low affinity, memantine only blocks significant numbers of NMDA receptors when they are highly overactivated, such as during stroke. Therefore, memantine has minimal effects on NMDA receptors in areas unaffected by the stroke, thereby reducing the side effects typical of potent NMDA receptor antagonists. Another promising therapeutic approach for stroke is to specifically target the cell death signaling pathways downstream of NMDA receptors without blocking normal functioning of the receptors. For example, one of these pathways is initiated by the association of NR2B subunit-containing NMDA receptors with the scaffolding protein PSD95. Recent experiments using preclinical models of stroke have shown that administration of a synthetic peptide that disrupts the association of the C-terminal tail

of NR2B subunits with PSD95 substantially reduces ischemia-induced damage without noticeable side effects. Given their promise in preclinical models of stroke, both low-affinity NMDA receptor antagonists and interference peptides are currently being tested in clinical trials for use in human patients suffering from stroke.

Alzheimer's Disease

Alzheimer's disease (AD) is the main cause of dementia in the elderly. Pathologically, AD is characterized by cortical atrophy, the presence of amyloid plaques and neurofibrillary tangles, and the granulovacuolar degeneration of neurons in vulnerable brain areas such as the neocortex and the hippocampus. While the mechanisms underlying AD neuropathology are not well understood, emerging evidence suggests that altered NMDA receptor function and enhanced NMDA receptor-mediated excitotoxicity may contribute to both pathological and functional abnormalities of AD. For example, amyloid plaques are primarily composed of the amyloid beta peptide (Aβ peptide). Recent studies have shown that the Aβ peptide enhances NMDA-receptor-mediated neurotoxicity by either potentiating NMDA receptor function or increasing available glutamate by inhibiting glutamate transport.

The Aβ peptide also has significant effects on NMDA receptor-mediated synaptic plasticity in the hippocampus and may be a cellular substrate for dementia in AD. Application of the Aβ peptide inhibits hippocampal LTP in both *in vitro* and *in vivo* preparations. LTP is also greatly reduced in transgenic AD animal models expressing high levels of Aβ peptide. Interestingly, the Aβ peptide may not affect or even potentiate LTD in the hippocampus. Since LTP and LTD may be mediated by distinct subpopulations of NMDA receptors, the differential effects of the Aβ peptide on LTP and LTD may result from subunit-specific actions on NMDA receptors. Future studies of the effects of Aβ peptide on NR2A- and NR2B-containing NMDA receptors are required to test this hypothesis. Whether the effects of the Aβ peptide on LTP and LTD contribute to the neurodegeneration in AD remains unclear. However, a recent study provides compelling evidence that the enhanced LTD caused by the Aβ peptide may mediate the spine and neuronal loss typically observed in AD. The importance of altered NMDA receptor signaling and synaptic plasticity for the neuropathology and cognitive dysfunction in AD is further supported by the beneficial effect of treatment of AD patients with memantine at various stages of dementia. These results also provide strong support for using NMDA receptor modulators/antagonists as part of the treatment of AD.

Pain

Pain is an unpleasant sensation associated with actual or potential tissue damage in the body. While normal pain responses are adaptive, pathological pain disorders are common and debilitating for many people. Pain disorders are caused by a number of conditions, including chronic inflammation or aberrant activity in peripheral nerves and nervous tissue (neuropathic pain). Neuropathic pain may be caused by either increased pain responses toward noxious stimuli (hyperalgesia) or decreased pain threshold to the point that normally nonnoxious stimuli such as touch or gentle pressure produce pain (allodynia). These pathological alterations are produced by hyperresponsiveness of nociceptive afferents sending sensory information to the dorsal horn of the spinal cord. After synapsing in the dorsal horn, this information is transmitted to the brain. Importantly, these pain pathways can be experimentally sensitized by repetitive stimulation of pain afferents, an effect that is mediated primarily by glutamate. Sensitization of glutamatergic transmission after noxious stimuli has also been reported in the cingulate cortex, an important forebrain region for nociception. Given the importance of the NMDA receptor in glutamatergic transmission and plasticity, it has become a research target for understanding the mechanism of central pain sensitization.

Using preclinical models, the involvement of NMDA receptors in the induction and expression of pain-induced sensitization in the spinal cord is supported by a number of findings. For example, direct administration of NMDA receptor antagonists on dorsal horn neurons abolishes the postsynaptic hyperexcitability caused by repetitive stimulation of primary pain afferents. Additionally, the intrathecal application of either NMDA receptor agonists or allosteric modulators such as D-serine induces hyperalgesia. NMDA receptor antagonists are also clinically effective in reducing hyperalgesia in patients with chronic pain.

Although NMDA receptors are important for central sensitization to pain, little is known about the mechanisms of how NMDA receptor activation contributes to causing hyperexcitability of dorsal horn neurons. However, a number of possibilities exist. For example, central sensitization may alter glutamate receptor function. Consistent with this possibility, the expression levels and kinetics of NMDA and AMPA receptors in the dorsal horn are altered in an animal model of inflammatory pain. Intriguingly, levels of AMPA receptor expression are increased in neuropathic pain, and this increase parallels the time course of hyperalgesia, suggesting an important role of increased AMPA receptor expression in the hyperexcitability of dorsal horn neurons. Given that potentiated AMPA

receptor function is also the underlying mechanism of hippocampal LTP, these enhancements of AMPA receptor function in sensitized dorsal horn neurons may be the result of an NMDA receptor-mediated mechanism similar to LTP. It is noteworthy that NMDA receptor-mediated LTP is readily induced in dorsal horn neurons by high-frequency stimulation of the primary nociceptive afferents. The recent discovery of 'silent synapses' in dorsal horn neurons also supports a potential role of LTP-like synaptic plasticity in the formation of central pain sensitization. Silent synapses are glutamatergic synapses that contain NMDA but not AMPA receptors; therefore, they are not activated during low levels of synaptic activity. Evidence suggests that during LTP, silent synapses are converted into functional synapses by recruiting AMPA receptors into the postsynaptic membrane. Recent experiments have shown that silent synapses can be activated in dorsal horn neurons, suggesting that recruitment of AMPA receptors could be a potential mechanism underlying central pain sensitization.

Available evidence also suggests that NR2B subunit-containing NMDA receptors may mediate the central sensitization of pain perception. The expression of NR2B subunits is enriched in dorsal horn neurons compared to other NR2 subunits. Additionally, specific antagonists of NR2B-containing NMDA receptors are effective analgesic agents for neuropathic pain. Finally, inflammation causes an increase in NR2B-containing NMDA receptors in the anterior cingulate cortex, while overexpression of NR2B subunits in the anterior cingulate cortex facilitates hyperalgesia caused by inflammation. Taken together, these findings highlight the importance of NR2B-containing NMDA receptors as therapeutic targets for chronic pain.

Drug Addiction

Drug addiction is a brain disorder that may be caused by maladaptive alterations in synaptic networks involving the mesocorticolimbic dopamine system. The mesocorticolimbic system consists of dopaminergic neurons which project from the ventral tegmental area (VTA) in the midbrain to forebrain areas such as the nucleus accumbens (NAc), amygdala, hippocampus, and prefrontal cortex. Alterations of dopaminergic inputs from the VTA to NAc and other forebrain regions have been investigated extensively in an effort to determine their potential role in addictive behavior. Both the VTA and NAc also receive glutamatergic inputs that undergo long-lasting modifications in response to commonly abused drugs such as cocaine and amphetamine. Accumulating evidence supports the hypothesis that the formation of addictive behavior involves plastic changes of glutamatergic inputs to various areas of the mesocorticolimbic system. Not surprisingly, there is strong evidence for the role of NMDA receptors in these plastic changes. For example, a single exposure to cocaine readily induces NMDA receptor-mediated LTP of glutamatergic inputs to the VTA (VTA-LTP). Biochemical experiments suggest that this VTA-LTP results from an increase in AMPA/NMDA receptor ratio on the postsynaptic membranes of VTA neurons. In addition, repetitive drug exposure reduces the induction threshold of VTA-LTP. However, a causal role for altered VTA synaptic plasticity in drug addiction remains to be established, partially due to a lack of specific inhibitors that interfere with the expression of LTP without affecting the normal function of NMDA receptors and downstream signaling pathways.

In addition to the plastic changes observed in the VTA, repeated administration of psychostimulants to rats enables LTD of glutamatergic inputs to the NAc (NAc-LTD), an effect which requires activation of NMDA receptors. Similar to hippocampal CA1 LTD, the expression of NAc-LTD is also mediated by the removal of synaptic AMPA receptors through GluR2 subunit-dependent clathrin-mediated endocytosis. Importantly, when a short synthetic peptide derived from the carboxyl tail region of GluR2 that blocks clathrin-mediated endocytosis was delivered into the NAc neurons, it blocked the formation of NAc LTD and the expression of amphetamine-induced behavioral sensitization. (Note: behavioral sensitization is a common behavioral model used to model some aspects of drug addiction.) Given that the peptide did not affect normal AMPA or NMDA receptor function, basal synaptic transmission, or LTP, these results provide strong evidence that NAc-LTD underlies the expression of amphetamine sensitization. These findings from the VTA and NAc provide strong evidence that abnormal NMDA receptor function and glutamatergic synaptic plasticity are involved in the pathogenesis of certain drug addition-related behaviors. Targeting these processes may provide a new avenue for developing novel drug addiction treatments.

Schizophrenia

Schizophrenia is a severe psychiatric disorder that affects approximately 1% of the population. The neurobiological causes of schizophrenia remain largely unknown but are likely related to relatively subtle structural abnormalities in various limbic areas and an imbalance of various neurotransmitters in the brain. The positive symptoms of schizophrenia, which include hallucinations and paranoia, are at least partially caused by dopamine hyperactivity, as they are reduced by dopamine antagonists (typical antipsychotics) and exaggerated by dopamine agonists. However, the cognitive and negative symptoms of schizophrenia, which are particularly debilitating, are generally resistant

to treatment with typical antipsychotic drugs. This suggests that other neurotransmitter systems may be abnormal in schizophrenia. Indeed, strong evidence suggests that alterations in the glutamatergic system exist in schizophrenia. For example, a number of psychotomimetic drugs, such as the NMDA receptor antagonists phencyclidine and ketamine, induce schizophrenic-like psychosis in normal people as well as exaggerate some of the symptoms of patients with schizophrenia. Interestingly, the effects of NMDA receptor antagonists more closely resemble those of schizophrenia than the primarily positive symptoms induced by dopamine agonists such as amphetamine. These findings suggest that hypofunction of NMDA receptors contribute to a variety of schizophrenia symptoms.

Several lines of emerging evidence support the NMDA receptor hypofunction hypothesis of schizophrenia: (1) biochemical analyses of the brains of patients with schizophrenia demonstrate abnormal distribution and expression levels of NMDA receptors in some studies, (2) various genetic approaches to disrupting NMDA receptor function are sufficient to model some of the symptoms of schizophrenia in mice, and (3) augmenting NMDA receptor function with positive modulators of the glycine binding site has displayed subtle but promising antipsychotic effects.

The complexity of schizophrenia makes determining the exact role of NMDA hypofunction in the disorder difficult. Since NMDA receptors are important for mediating the basal activity of inhibitory interneurons in cortical and limbic regions known to be involved in schizophrenia, NMDA receptor hypofunction may disrupt normal processing in these areas by decreasing inhibitory synaptic drive. Additionally, NMDA receptors have significant neurotrophic roles during early development. Current theories suggest that the etiology of schizophrenia has a strong developmental component that is likely caused by a combination of genetic and environmental effects. Therefore, early alterations in NMDA receptors could interact with other genetic or environmental effects and contribute to the development of the disorder.

Concluding Remarks

Evidence from both preclinical and clinical studies demonstrates the importance of NMDA receptor dysfunction in numerous acute and chronic neurological and psychiatric disorders. Although the detailed cellular signaling pathways likely vary between the disorders, excitotoxicity and abnormal modification of synaptic transmission are two primary mechanisms by which NMDA receptor dysfunction is involved in these disorders. Unfortunately, the results of clinical trials testing generalized NMDA receptor-based modulators and antagonists for the treatment of these disorders have achieved limited success at the present time. Ongoing research aimed at delineating the downstream signaling pathways mediated by specific subpopulations of NMDA receptors provides a rich avenue for the development of new NMDA receptor-based treatments with greater therapeutic benefits and fewer side effects. The use of low-affinity NMDA antagonists like memantine for reducing NMDA receptor-mediated excitotoxicity highlights the importance of developing NMDA receptor-based therapies with different pharmacological profiles for treating brain disorders. The success of this strategy could be further enhanced by better understanding the subunit-specific mechanisms involved in individual disorders. In addition to directly targeting the NMDA receptor, a second promising strategy is to develop novel drugs that specifically target signaling molecules downstream of NMDA receptor activation, as exemplified by the recent success in ameliorating ischemic damage by disrupting the interaction between NR2B subunits of the NMDA receptor and PSD95. Given the rapid pace of research in the area of NMDA receptor function, significant advancements in treating these disorders are likely in the near future.

NMDA Receptors, Cell Biology and Trafficking

R J Wenthold and R S Petralia, National Institute on Deafness and Other Communication Disorders, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

The *N*-methyl-D-aspartate (NMDA) receptor is present at the postsynaptic membrane of nearly all glutamatergic synapses, where it is found with other glutamate receptors, particularly α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors. It is a key player in synaptic plasticity, and its malfunction has been implicated in a wide range of neurological and psychiatric disorders ranging from ischemia to schizophrenia. It is unique among neurotransmitter receptors since it requires activation by two agonists, glutamate and glycine, which interact with the NR2 and NR1 subunits, respectively. The ion channel of the NMDA receptor is normally blocked by magnesium, and the channel opens only after the neuron is depolarized by activation of AMPA receptors, thus allowing the NMDA receptor to serve as a coincidence detector. Finally, the ion channel of the NMDA receptor is permeable to calcium, a universal intracellular signaling molecule. These properties have made the NMDA receptor one of the most intensely studied molecules in the brain. Since neurons are highly compartmentalized, forming synaptic connections with thousands of other neurons, and the NMDA receptor has a restricted distribution within a neuron, trafficking of this receptor is central to its functional regulation. Here we define trafficking as the nonrandom movement of a protein within a neuron to, or from, a site where it is required for function. This process undoubtedly depends on interactions with other molecules, particularly other proteins, lipids, sugars, and small molecules.

Structure and Subunits

Three subunits of the NMDA receptor complex have been identified. A single NR1 subunit has eight splice variants. There are four NR2 subunits (NR2A–D) and two NR3 subunits. NR2A and NR2B are the most abundant NR2 subunits, with NR2B being predominant early in development and NR2A appearing later, along with a general decrease in NR2B expression. All subunits have the same topology, with three transmembrane domains, a reentrant loop, an extracellular N-terminus, and a cytoplasmic C-terminus, which is unusually long in all NR2 subunits. Supporting several previous functional and biochemical reports, the recent determination of the crystal structure of the extracellular domains of the NMDA receptor indicates a tetrameric protein made up of two NR1 and two NR2 subunits. In a tetramer, the NR2 subunits can be the same, such as two NR2B subunits, or different, such as one NR2B and one NR2A, in this complex. While NR3 can also assemble into complexes with NR1 and NR2, the function of NR3 remains unclear, and it has been reported that NR3 can assemble with NR1 alone to produce a functional glycine receptor. The NMDA receptor subunits interact with a large number of other proteins, which modify their function and influence their trafficking (Table 1).

The subunit composition determines the functional properties of the NMDA receptor. This is dependent mostly on the NR2 subunits forming receptors, with kinetics ranging from the slowest (containing NR2D) to the fastest (NR2A). Thus, channels with faster kinetics allow less calcium to enter the neuron, and would probably be less effective in developing plasticity. When NR3 is assembled into a complex with NR1 and NR2, it decreases channel function. NR3A knockout mice are normal, but show enhanced NMDA responses early in development.

NMDA Receptors in the Endoplasmic Reticulum

All NR2 subunits and some NR1 subunits, depending on the splice variant, are retained in the endoplasmic reticulum (ER) in their unassembled form and are released after assembly (Figure 1). This is a standard mechanism of quality control to assure that unassembled or misfolded proteins do not reach the cell surface. For the NR1 subunit, ER retention is controlled by an RXR motif (X indicates any nonacidic amino acid) in the C-terminal domain of the major splice variant, NR1-1. NR1 splice variants (NR1-2 and NR1-4) that lack this retention motif are not retained, and others (NR1-3) that contain this motif plus the C2′ cassette are also not retained. Thus, only the NR1-1 splice variant is retained in the ER; this is the major splice variant, accounting for about 60% of the total NR1. The C2′ cassette causes the subunit to terminate in the amino acid sequence – STVV, and this motif is required for overriding the RXR retention motif. This is a postsynaptic density/disc/zonula occludens-1 (PDZ) binding motif and also a site of interaction for components of the coat protein complex II (COPII),

Table 1 Proteins that bind directly to NR1 and/or NR2

NR1[a]	*NR2*
PSD-95 (to NR1-3, NR1-4)	PSD-95
SAP102 (to NR1-3, NR1-4)	SAP102
PSD-93 (to NR1-3, NR1-4)	PSD-93
SAP97 (to NR1-3, NR1-4)	SAP97
α-Actinin	α-Actinin
Tubulin	Tubulin
Spectrin	Spectrin
Myosin regulatory light chain	Myosin regulatory light chain
Dopamine D1 receptor	Dopamine D1 receptor
CaMKII	CaMKII
NADH dehydrogenase subunit 2 (ND2)[b]	NADH dehydrogenase subunit 2 (ND2)[b]
Calmodulin	S-SCAM (= MAGI-2)
Neurofilament-L	CIPP
Yotiao	mLin-7 (= Veli = Mals)
EphB receptors	Phospholipase C-γ
Apolipoprotein E receptor 2	Rack1
SALM1	μ subunit of adaptor protein complexes (AP1–4)
Sec23/24 of COPII	α1-Chimerin
	RasGRF-1
	Cyclin-dependent kinase-5 (cdk5)[b]

[a] NR1-3 and NR1-4 are splice variants.
[b] cdk5 may bind directly to NR2A, and ND2 appears to bind Src to NMDA receptors, but the exact nature of these interactions has not been determined.

which is involved in ER-to-Golgi trafficking. Thus, the PDZ or COPII interaction, or both, may control the ER export of these NR1 splice variants and override the retention that is mediated by the RXR motif. It remains unclear why some NR1 splice variants can exit the ER unassembled, or if they actually do in neurons, since there is no evidence that NR1 homomeric complexes exist in neurons or serve any function. NR1 subunits lacking retention motifs may be more readily exported from the ER assembled with NR2.

The mechanism by which NR2 subunits are retained in the ER is more complex than that of NR1 and not well characterized. There appears to be an ER retention signal(s) in the C-terminus although the specific site has not been identified. There is also an additional mechanism for ER retention since deletion of the C-terminus does not allow the remainder of the molecule to reach the cell surface unassembled, as is the case for NR1; however, this C-terminus-deleted construct can assemble with NR1 to produce functional receptors. Equally poorly understood is the mechanism by which the retention signals on NR1 and NR2 are negated to allow the assembled complex to exit the ER. Mutual masking of the retention motifs in the C-terminus, as has been demonstrated for some other proteins, does not

Figure 1 Assembly of the NMDA receptor in the ER. All NR2 subunits and the NR1-1 splice variant are retained in the endoplasmic reticulum (ER). Assembly negates retention and allows exit from the ER. NR1 subunits are synthesized in excess of NR2, and most are retained in the ER and rapidly degraded. In heterologous cells, some splice variants that lack the ER retention signal present in the C1 cassette, or contain the C2′ cassette, can exit the ER unassembled, probably as homodimers. It is not known if this is also the case in neurons or if it is of functional significance. Assembly can lead to receptor complexes with two identical or two different NR2 subunits. Receptors can assemble and be functional in the ER based on MK801 binding, but export requires a four-amino-acid segment (HLFY in NR2A and NR2B) immediately following transmembrane domain 4.

appear to play a role in the NMDA receptor, since subunits with a deletion of either the NR1 or NR2 C-terminal tails alone can form functional receptors. An interesting finding that further complicates our understanding of the ER retention of NR2 is that the NR2 subunit does not need to be intact to form functional receptors. The NR2A subunit can be divided into two polypeptides in the extracellular loop between transmembrane domains 3 and 4 (TM3 and TM4). Co-expression of these two fragments with NR1 produces functional receptors on the cell surface. A single neuron can contain a variety of NMDA receptor complexes (such as NR1/NR2B, NR1/NR2A, and NR1/NR2A/NR2B), and the question arises whether or not the formation of these complexes simply reflects the availability of subunits, or is regulated in some way. There is a large excess of NR1 subunits synthesized, which would ensure that most NR2 subunits would find an NR1 binding partner and form a functional receptor. This fits with the fact that the particular NR2 subunit controls the properties of the receptor.

Figure 2 Proposed complexes involved in the transport of NMDA receptors. Two kinesins that indirectly interact with NMDA receptors are KIF17 and KIF1Bα, and additional kinesins may also play a role. Delivery of receptors to spines is likely to involve myosins, which remain to be identified. Both Sec8, probably in a complex with other exocyst proteins, and mPins bind to SAP102 and other related PDZ proteins (MAGUKS) and may target the NMDA receptor/PDZ protein complexes to the plasma membrane. Also, G-protein signaling via the interaction of mPins and $G_{\alpha i}$ may regulate the effect of mPins on NMDA receptor trafficking and postsynaptic spine structure.

Trafficking of NMDA Receptors in the Dendrite

NMDA receptors are concentrated at postsynaptic sites on dendrites while synthesis occurs predominantly in the cell body, requiring a mechanism to transport receptors from the cell body to synapses. This could be done in two ways. Receptors could be delivered to the plasma membrane at the cell body, and the receptors could reach the dendrite by lateral diffusion or through some form of regulated transport while they are in the plasma membrane. Alternatively, receptors can be delivered to dendritic sites through association with intracellular transport vesicles. The latter is assumed to be the major mechanism of delivery, but lateral movement to the synapse is probably also necessary for movement into the synapse after delivery to an extrasynaptic location (Figure 2). NMDA receptors can associate early in the biosynthetic pathway with PDZ proteins, including members of the PSD-95 family of membrane-associated guanylate kinases (MAGUKs), which are transported in the dendrite as a complex with the NMDA receptors. The MAGUK allows the indirect association of the NMDA receptors with multiple other proteins that can influence the trafficking of the NMDA receptor. The exocyst, a complex of eight proteins, associates with the receptor through a PDZ interaction with the PSD-95-family MAGUK, SAP102 (synapse-associated protein), and perhaps with other PDZ proteins; disruption of this interaction will dramatically reduce the surface expression of receptor. Another trafficking molecule, mPins/LGN (mammalian homolog of *Drosophila* partner of inscuteable) interacts with the receptor complex through the Src homology 3/guanylate kinase (SH3/GK) motifs of the MAGUK and disruption of this interaction also reduces NMDA receptor surface delivery. mPins/LGN interacts with a number of additional proteins, including $G_{\alpha i}$, suggesting a possible link between G-protein signaling and NMDA receptor trafficking.

Transport vesicles carrying NMDA receptors appear to be largely distinct from those carrying AMPA receptors, suggesting that these two receptor populations are packaged into distinct populations of transport vesicles as they exit the *trans*-Golgi network (TGN). In young neurons transport in dendrites involves multiple rounds of endo- and exocytosis with the plasma membrane and association of the transport vesicles with SAP102. Two motor systems

have been identified in the transport of NMDA receptors and MAGUKs. The kinesin KIF17 associates indirectly with NMDA receptors through a complex with mLin-7, mLin-2, and mLin-10 and may mediate the transport of NMDA receptors along microtubules. MAGUKs can associate directly with the kinesin KIF1Bα, making it a candidate for transporting NMDA receptors associated with SAP102. Myosin motors, which can mediate transport of proteins along actin filaments, are also likely to play a role. NMDA receptors are regulated by myosin light chain kinase and show a direct interaction with myosin regulatory light chain. The NMDA receptor, therefore, is transported as part of a macromolecular complex. However, unlike the presynaptic active zone, the postsynaptic density, a structure with which the NMDA receptor is associated at synapses, is not transported as a completely preassembled complex. The NMDA receptor complex may remain intact as it is delivered to the synapse, but a more likely scenario is that the addition and removal of proteins are a normal parts of the trafficking process to change parameters as the local environment changes.

Trafficking of NMDA Receptors at the Synapse

Synaptic Delivery and PDZ Proteins

The steps involved in delivering NMDA receptors present in transport vesicles in the dendrite to the synapse are largely unknown. This process may involve an intermediate stop in an endosomal compartment, where they may mix with recycling receptors, or direct delivery to the plasma membrane. The site of delivery is also unknown but is likely adjacent to the synapse rather than directly at the synapse. This will require movement within the plasma membrane, and these receptors may represent the extrasynaptic pool of NMDA receptors (discussed later). The number and composition of NMDA receptors at the synapse are relatively stable compared to those of AMPA receptors. However, the mechanism regulating synaptic NMDA receptors is not well understood. The number of receptors is not based on availability, since overexpression of NR2 subunits does not increase the synaptic number of receptors, but does increase the extrasynaptic number, indicating a local mechanism of control for synaptic receptors. The NR2/PSD-95 interaction was the first PDZ interaction identified (subsequent studies have shown that the other three members of the PSD-95 family of MAGUKs, SAP102, SAP97, and PSD-93, also can interact with the NR2 subunits), and it generally has been assumed that synaptic NMDA receptors are tethered to the PSD through this PDZ interaction. A number of studies have supported this by showing that the PDZ binding domain is required for an NR2 subunit to be admitted to the synapse. However, recent studies have shown that the NMDA receptor/PSD-95 interaction is not straightforward. Knockout of PSD-95 or its overexpression does not change synaptic NMDA receptors, but overexpression does increase AMPA receptors. Studies have also shown that an NR2A subunit lacking its PDZ binding motif can enter the synapse, although NR2B subunits without the PDZ binding motif cannot.

A variety of adhesion proteins are found associated with NMDA receptors at synapses and these proteins may help regulate NMDA receptor distribution and function. Postsynaptic EphB2 receptors are activated by their presynaptic ligand, ephrin-B, and bind directly to the extracellular domain of NR1, affecting NMDA receptor function directly and subsequent dendrite arborization indirectly. SALM1 can bind to the extracellular domain of NR1 and this and some other SALMs also can associate with NMDA receptors via a mutual PDZ-mediated binding to MAGUKs of the PSD-95 family. SALM1 can enhance surface expression of transfected NR2A. A number of other adhesion factors do not bind directly to NMDA receptors but instead form associations with them at the synapse and may affect NMDA receptor trafficking and activation and subsequent neuronal structure and function; examples are neuroligin, cadherin/catenin, and a number of members of the L1/NrCAM and NCAM (neural cell adhesion molecule) families of adhesion proteins. Neuroligin binds to neurexin in the presynaptic terminal and to PSD-95 and other NMDA receptor-associated MAGUKs in the postsynaptic density. Neuroligin localization at synapses may help determine if developing synapses become excitatory or inhibitory. In fact, a number of adhesion proteins such as neuroligin, cadherin, NCAM, and EphB receptors may mediate the earliest stages of synaptogenesis that are required for subsequent trafficking of MAGUKs and NMDA receptors to the nascent postsynaptic membrane.

Clathrin-Mediated Internalization and Regulation of NMDA Receptors

The number of molecules of any protein on the cell surface can be regulated by internalization, and several studies have now shown that a number of factors can increase the internalization of NMDA receptors. These include synaptic activity, activation of type 1 metabotropic receptors, and exposure to the agonist glycine. In addition, run down of extrasynaptic receptors appears to depend on internalization.

Figure 3 (a) Model for regulation of NR2B-containing receptors at the synapse. Internalization is mediated by the interaction of AP2 with the YEKL motif in the distal C-terminus of NR2B. At the synapse, Y1472 in this motif is phosphorylated by Fyn kinase and is unable to interact with AP2. Fyn is recruited by PSD-95, which associates with NR2B through its PDZ binding domain. Loss of phosphorylation of Y1472 facilitates the interaction with AP2 and leads to removal from the synapse and internalization. Retention of NMDA receptors at the synapse may involve additional anchors. (b) NR2A- and NR2B-containing receptors are regulated differently at the synapse. Several studies have suggested that NR2A-containing receptors are more abundant at the synapse while NR2B-containing receptors are more abundant at extrasynaptic sites. Several factors could contribute to this differential localization. Receptors can enter the synapse by lateral diffusion in the plasma membrane. A filter may selectively exclude NR2B-containing receptors from the synapse. Alternatively, NR2B-containing receptors may be more likely to be removed from the synapse through internalization (as described in panel (a)). Finally, internalized NR2A-containing receptors are more susceptible to degradation while NR2B-containing receptors are recycled. If they enter the extrasynaptic pool, the recycled receptors would contribute to the enrichment of NR2B-containing receptors in this pool.

NMDA receptors can be removed from the plasma membrane through a clathrin-dependent route involving the adaptor protein AP2 (Figure 3). Clathrin-dependent internalization requires the recognition of a particular motif in its cytoplasmic domain by the adaptor protein. The NR2B subunit has such a motif, YEKL, near its C-terminus, that has been shown to play a role in the surface stability of the receptor. Interestingly, a similar motif in the NR2A subunit is not involved in the internalization of this subunit, but rather an upstream dileucine motif (also a substrate for the AP2 adaptor) was shown to play such a role. The differences in the trafficking of these two subunits are highlighted in the different pathways followed by the internalized receptors. While both initially enter early endosomes, NR2B is trafficked to recycling endosomes while NR2A is trafficked to late endosomes. Therefore, NR2B-containing receptors are more likely

to be recycled and NR2A-containing receptors are more likely to be degraded after internalization.

Does internalization play a role in regulating the number of synaptic NMDA receptors? It is unlikely that internalization *per se* regulates the number of receptors, but the availability of endocytic motifs such as the YEKL motif on NR2B may. This motif contains a tyrosine, Y1472, which is a major substrate for Fyn kinase. In the striatum, synaptic membranes have a high level of phosphorylated Y1472 while intracellular membranes have a low level of phosphorylated Y1472. In cultures of cerebellar granule cells and hippocampal neurons, using transfection of NR2B subunits with mutations in this motif, it was shown that mutations that block the interaction of AP2 increase the number of synaptic receptors. Furthermore, while the PDZ binding domain of NR2B is required for synaptic localization, NR2B subunits that lack this domain and have mutations of the YEKL motif still localize to the synapse. One explanation is that the PDZ interaction may not be critical for anchoring the receptor complex to the postsynaptic protein complex, but rather plays a role in maintaining the phosphorylation of Y1472. PSD-95 has been shown to interact with Fyn kinase, and, at the synapse, PSD-95 may recruit Fyn kinase, thus maintaining the phosphorylation of Y1472 and preventing its interaction with AP2 and its subsequent internalization. The fact that the internalization of NR2A is not affected by mutations in a homologous motif, YKKM, indicates that different factors control the surface stability of NR2A-containing receptors.

The YEKL and dileucine motifs near the distal end of the C-terminus of NR2B and NR2A, respectively, are not the only endocytic motifs found on the NMDA receptor. Another tyrosine-containing motif is present in the proximal part of the C-terminus, near the last transmembrane domain. This motif was functionally characterized in receptors with the NR2A subunit, but it is present in all NR2 subunits and the NR1 subunit. Since mutation of neither this motif nor the distal motif can block all internalization, there are likely other motifs present in the NR1 and NR2 C-termini that mediate clathrin-dependent internalization. Nonclathrin mechanisms may also exist.

Extrasynaptic Receptors

NMDA receptors are found not only at the postsynaptic membrane but have also been reported on glia, presynaptic terminals, the perisynaptic membrane, and the extrasynaptic membrane. Most extensively studied are perisynaptic and extrasynaptic receptors, which may be functionally important and activated when glutamate that is released at the synapse is not sufficiently sequestered and is able to diffuse outside the synapse. While most neurons contain both synaptic and extrasynaptic receptors, in a few specific cases such as the retinal ganglion cell, NMDA receptors are found only outside the synaptic cleft. In other neurons, NR2A-containing receptors are preferred at the synapse and NR2B-containing receptors are preferred at the extrasynaptic membrane, although the separation is not complete. This subunit preference may reflect functional differences between these two pools of receptors. This, however, is difficult to reconcile with studies that show diffusion of receptors from the extrasynaptic plasma membrane into the synapse. In one study, synaptic receptors were blocked with the use-dependent antagonist, MK801, and recovery of function was monitored. The recovery of function was surprisingly rapid, and controls ruled out sources other than the extrasynaptic membrane. The preferential localization of NR2A- and NR2B-containing receptors would be consistent with these findings if there was a filter that favors the entry of NR2A into the synapse or the removal of NR2B from the synapse. NMDA receptors do recycle, although not as fast as AMPA receptors, and the enrichment of NR2B in the extrasynaptic membrane could reflect this. As noted earlier, internalized NR2B receptors are more likely to be recycled and NR2A receptors are more likely to be degraded. If receptors are recycled to the extrasynaptic membrane, the difference in intracellular trafficking could favor NR2B at the extrasynaptic membrane. Such a mechanism would also assume that there is an exchange between the synaptic and extrasynaptic pools of receptors. The functional consequences resulting from activation of these receptors is also an area of intense study. Activation of extrasynaptic receptors promotes cell death. A series of controversial studies has indicated that NR2A-containing receptors mediate long-term potentiation (LTP) and that NR2B-containing receptors mediate long-term depression (LTD). This requires more work, and it will be interesting to determine if position of the receptor – for example, synaptic versus perisynaptic – plays a role.

Developmental Changes in NMDA Receptors

During development, most neurons begin expressing predominantly NR2B, which then gradually decreases as NR2A expression increases. The functional implication of this switch is that NMDA receptors in young animals have slower kinetics (due to a preponderance of NR2B), and receptors in older animals are faster (due to a preponderance of NR2A). It has been proposed that this change, in which 'adult' NMDA receptors are faster and admit less calcium, may be related

to the decrease in synaptic plasticity in older animals. While most neurons continue to express NR2B in older animals, and therefore have a mixture of NR2A- and NR2B-containing receptors and perhaps those containing both subunits, cerebellar granule cells completely stop synthesizing NR2B. During development, NR2A and NR2C expression increases in these neurons. Trafficking plays a role in the preferential localization of subunits during development. A series of elegant studies has shown that, within hours, visual experience can cause synaptic NMDA receptors in the visual cortex to become more NR2A-like. Thus, either NR2A-containing receptors are preferentially added or NR2B-containing receptors are preferentially lost, or both. While this could depend somewhat on new protein synthesis, it is unlikely that such a change could be effected in the time period, and a more likely explanation is that NR2A-containing receptors are recruited from extrasynaptic or intracellular sites. Similar transitions from NR2B- to NR2A-containing receptors may be occurring at other synapses during development, or even at mature synapses. Thus, the mechanism underlying this switch is fundamentally important to NMDA receptor trafficking.

Phosphorylation and Trafficking of NMDA Receptors

As discussed in the preceding section, Fyn kinase phosphorylation has a major impact on trafficking of the NR2B subunits. The NMDA receptor is a substrate for several other kinases, including other members of the Src family of protein tyrosine kinases, calcium/calmodulin-dependent protein kinase II (CaMKII), cyclin-dependent kinase-5 (cdk5), cyclic AMP-dependent protein kinase A (PKA), protein kinase C (PKC), casein kinase II, and others. The NMDA receptor directly interacts with CaMKII at the postsynaptic density. This interaction is important for the translocation of CaMKII to the synapse. CaMKII has been shown to interact with all three of the common subunits, NR1, NR2A, and NR2B, through their C-termini, although the affinities of the interactions and the functional implications are very different. A recent study in which the interacting domains on NR2A and NR2B were switched showed that the CaMKII interaction with the NR2B subunit is required for LTP.

Phosphorylation of NMDA receptor subunits affects the trafficking of the individual subunits. The subcellular distribution of the NR1 subunit expressed alone in heterologous cells can be regulated by PKC phosphorylation of the serine residues in the C1 domain. These amino acids are near the ER retention signal, and mutations that mimic phosphorylation greatly increased surface expression of NR1/tac chimeric constructs.

Phosphorylation by several other kinases, particularly casein kinase II and PKC, affects the trafficking of the assembled receptor. The NR2B subunit terminates in ESDV, which is a PDZ binding domain. Serine-1480, present in this domain, is a substrate for casein kinase II, and phosphorylation of Ser1480 blocks interaction with PDZ proteins. Therefore, this may be an important mechanism for regulating receptor/PDZ interactions. PKC activation increases the delivery of NMDA receptors to the cell surface.

Degradation of NMDA Receptors

While trafficking can regulate local amounts and distributions of a protein effectively, altering either synthesis or degradation can effect global changes in proteins. Like other proteins, the NMDA receptor is continually degraded and, at steady state, replenished by synthesis of new receptors. In cultured cerebellar granule cells, the half-life of assembled NMDA receptor is about 1 day. Unassembled NR1 subunits, which are synthesized in excess compared to NR2, are retained in the ER and degraded rapidly, with a half-life of 1–2 h. As presented previously, there is a developmental change in the relative amounts of NR2A and NR2B, which could be achieved by altering synthesis or degradation. Since mRNA expression often matches protein levels, it suggests that synthesis is the main controlling factor. The degradation of NMDA receptors may not be entirely random, but may depend on the subunit composition and activity of the neuron; degradation, therefore, could change the subunit balance or the total number of receptors at a particular synapse. As noted above, receptors containing NR2A or NR2B follow different pathways after internalization. Recent studies have shown that ubiquitination plays a major role in the removal of postsynaptic proteins, including NMDA receptors. Covalent attachment of ubiquitin can cause internalization of membrane proteins and degradation in the proteasome. Several proteins of the PSD are ubiquinated, including PSD-95. NR1 can be ubiquitinated on its extracellular domain. In this case, activity-dependent NMDA receptor degradation may be mediated by retrotranslocation followed by ubiquitination, although the mechanism is not well understood.

Nociceptor Responses

C Belmonte and F Viana, Universidad Miguel Hernández-Consejo Superior de Investigaciones Científicas, San Juan de Alicante, Spain

Nociceptors are peripheral terminals of a subpopulation of primary sensory neurons located in the dorsal root and cephalic ganglia that are functionally specialized in the detection of potentially or overtly injurious stimuli acting on bodily tissues (mechanical, chemical, and thermal). They can be considered damage-sensing terminals that encode the intensity and duration of noxious stimuli into a discharge of nerve impulses that is transmitted to upper levels of the central nervous system, ultimately evoking sensations of discomfort and pain. The name 'nociceptor' was coined by Sherrington a century ago to emphasize the noxious nature of their adequate stimulus, in contrast with the low-threshold mechano- and thermal receptors that signal innocuous forces and serve to detect non-noxious changes in the environment.

Somatic nociceptors are formed by naked (free) nerve endings of thinly myelinated (Aδ) or unmyelinated (C) sensory afferents that branch extensively within the skin, mucosae, muscles, and joint tissues. In addition, other population of Aδ and C nociceptor axons innervate the viscerae, preferentially hollow viscerae from the cardiovascular, respiratory, genitourinary, and digestive tract. The cell bodies of neurons responding to noxious stimuli of somatic tissues are exclusively located in dorsal root and cephalic ganglia, whereas those innervating the viscerae are also found in the nodose ganglion.

Nociceptors innervating the body surface have received comparatively more experimental attention than those innervating deep tissues. Cutaneous nociceptors are distinct from low-threshold receptors subserving innocuous skin sensations not only because of the high intensity of the physical force required for their stimulation – several orders of magnitude higher than in the other receptor classes – but also by their unique response to repeated stimuli. In low-threshold receptors, sustained or repetitive stimulation tends to reduce the magnitude of the evoked impulse firing (i.e., they develop adaptation and fatigue). Some nociceptors also fatigue immediately upon repeated stimulation but a few minutes afterwards they augment their response to new noxious stimuli. This process, called 'sensitization,' is characterized by a reduction of the impulse firing threshold such that propagated impulse discharges are now evoked by intensities of the stimulus within the innocuous range. Moreover, noxious stimuli elicit a stronger and more sustained impulse discharge in sensitized nociceptors (Figure 1). Finally, sensitized nociceptors often develop an irregular, low-frequency ongoing activity in the absence of stimulation. This spontaneous activity, coupled with the enhanced responsiveness to stimulating forces, is the peripheral substrate of the skin tenderness to mechanical or thermal stimulation and of the presence of pain sensation in the absence of stimulus, exhibited by injured peripheral tissues ('primary hyperalgesia').

Functionally, nociceptor neurons constitute a heterogeneous population. They differ in the presence or absence of myelin at their peripheral axons and also in the variable expression of integral membrane proteins such as certain transducer ion channels (TRPs, ASICs, P2X, and 2-pore domain K^+ channels) and receptor proteins for endogenous mediators. The content of certain enzymes, such as fluoride-resistant acid phosphatase, neurofilament 200, and certain neuropeptides (substance P, calcitonin gene-related peptide (CGRP), and somatostatin), also varies among nociceptive neurons. The structural and molecular diversity of nociceptors is reflected in differences in their preferred responses to certain forms of stimulating energy and the characteristics of their firing patterns. Such differences in responsiveness have been used to distinguish different functional subclasses of nociceptors (Figure 1).

Most information concerning the firing pattern characteristics of the different classes of nociceptor fibers has been obtained from electrophysiological recordings in anesthetized animals. However, the development of recording techniques for single fibers in sensory nerves innervating leg or arm skin in human subjects enabled researchers to correlate impulse activity with conscious sensations, confirming the fundamental analogy between nociceptors of humans and those of other mammalian species.

Functional Types of Nociceptors

Somatic Nociceptors

Nociceptors innervating superficial and deep somatic tissues have been classified by their responsiveness to mechanical forces, heat, and exogenous irritant chemicals into three main groups:

1. Mechano-nociceptors that respond initially only to mechanical forces ranging from moderate pressure with a blunt object to overtly tissue-damaging stimuli with a short discharge of impulses whose frequency increases with the intensity of the stimulus

Figure 1 (a) Extracellular recording of impulse activity of a myelinated cutaneous mechano-nociceptor fiber. The top trace shows the lack of response to squeezing of the skin with blunt forceps. The middle trace shows the calibrated force record. The bottom trace shows the response to a pinch applied with serrated forces. (Figure 1(a)). They belong generally to the Aδ fiber type, although mechano-nociceptors with C fibers have also been described.

2. Polymodal nociceptors that are activated by intense mechanical deformation producing an irregular tonic discharge roughly proportional to stimulus intensity that often outlasts the stimulus; they also respond with a sustained impulse activity to diluted acid or other irritant chemical stimuli, to heating of the skin over 40 °C, and, occasionally, to noxious cold, and they sensitize to repeated stimuli (Figures 1(b) and 1(c)). Polymodal nociceptors belong mainly to the class of C fibers, although some of them are thin myelinated, particularly in the trigeminal system.

3. Silent nociceptors, which are Aδ or C fibers characterized by their complete insensitivity or very high threshold to mechanical stimulation in the intact skin, responding only when the supporting tissue (skin and joint) is stimulated with sustained pressure or becomes inflamed (Figure 2).

Experimental studies have used mainly mechanical and thermal stimuli for nociceptor identification; for this reason, mechano- and polymodal nociceptors have also been classified as mechanically sensitive afferents (MSAs), in contrast with silent nociceptors, which form the group of mechanically insensitive afferents (MIAs) that apparently represent more than 30% of nociceptors in primates.

Within each functional type of nociceptors, those with Aδ or C fibers exhibit a number of differences. In general, nociceptors with Aδ axons respond faster and more vigorously to stimuli. Accordingly, Aδ MSA nociceptors (mechano- and polymodal) appear to be responsible for the initial sharp pricking pain experienced when a punctuate, noxious mechanical stimulus is applied to the skin, whereas long-lasting activity of MSA C polymodal nociceptor fibers generates the ensuing, persisting pain. When active, silent C nociceptors (MIAs) appear to be gradually recruited by maintained pressure and also contribute to the building pain generated by the stimulus. Likewise, the initial sharp pain sensation experienced with noxious heat is caused by nerve impulses in a subtype of fast Aδ polymodal nociceptors (type 1), followed by a transient silence and the building impulse discharge of C fibers that leads to burning pain. However, persistent heating causes adaptation of C fibers while it increases gradually in a second type of Aδ polymodal fibers (type 2), suggesting that these nociceptors maintain pain caused by continuous heat.

Visceral Nociceptors

Receptors innervating tissues of the respiratory, cardiovascular, genitourinary, and gastrointestinal systems also belong to the Aδ and C groups. Most are part of the peptide-containing class of nociceptors. Compared to those of somatic origin, the proportion of visceral afferent nerve fibers is low, which explains the diffuse nature of visceral painful sensations. Many visceral nociceptors appear to be polymodal. In hollow viscerae, nociceptors terminate in muscle, mucosa, and serosal layers. Mechanical forces, such as distension or direct prodding, and thermal and chemical stimuli have been used to characterize the

Figure 2 (Left) Response of a silent nociceptor fiber innervating the cat knee joint after experimental induction of inflammation by intra-articular injection of kaolin–carrageenan. Prior to inflammation, this fiber was recruited only with electrical stimulation of its receptive field but was unresponsive to mechanical stimulation performed by controlled flexion, nonnoxious (OR), and noxious (n.OR) outside rotation or to direct mechanical stimulation of the receptive field. (Right) Mean impulse response of low- and high-threshold pelvic visceral receptor fibers innervating the colon (top) and the urinary bladder (bottom) to graded distension of both organs, expressed as the mean increase in impulses/second over resting activity. (Right) Reproduced from Sengupta JN and Gebhart GF (1995) Mechanosensitive afferent fibres in the gastrointestinal and lower urinary tracts In: Gebhart GF (ed.) *Progress in Pain Research and Management: 5. Visceral Pain*. Seattle: IASP Press, with permission from International Association for the study of pain.

response properties of these receptors. Some of them, predominantly located in muscular layers, respond to low distending pressures but increase the firing frequency of their tonic discharge when noxious pressure levels are attained. They have been classified as low-threshold or intensity-encoding mechanoreceptors. High-threshold mechanoreceptors, responding only to distension that reaches the noxious range, are less abundant (approximately 20% of the afferents exhibiting mechanosensitivity). It has been suggested that low-threshold visceral receptors evoke sensations that evolve from nonpainful to painful when the intensity of the stimulus increases gradually, such as when the bladder becomes increasingly filled, whereas high-threshold visceral receptors activated only by overtly noxious stimuli mediate distinct pain sensations (Figure 2).

Transduction Mechanisms in Nociceptors

The detection of stimuli by nociceptor neurons is based on membrane signaling molecules which convert the stimulus energy into a conformational change, leading to an alteration in ionic permeability and depolarization of the nerve terminal. In nociceptors, most transduction molecules are ion channels that are directly gated by the stimulus or by intracellular messenger systems activated by a variety of chemical substances. Several classes of ion channels have been associated with the transduction of the various forms of energy and the production of generator potentials at nociceptor nerve terminals (Figure 3).

The nature of the molecular entities involved in the transduction of mechanical forces by nociceptors is uncertain. Extracellular matrix attachments have been proposed as the mechanism involved in the transmission of external mechanical forces to the neuronal surface and, subsequently, to ion channels activated or inactivated by stretch. In a second class of mechanosensitive channels, lateral forces in the membrane bilayer can directly gate the channel. Several classes of ion channels have been implicated in nociceptor mechanotransduction, but evidence from *in vivo* experiments is lacking in all cases. These include various members of the TRP superfamily of ion channels (Figure 3), such as TRPV2 and TRPV4, TRPC1, and TRPA1. Studies in mutant mice suggest that ASIC1–3 sodium channel subunits of the DEG/ENaCs superfamily contribute to mechanosensation, but the phenotypes are mild and restricted to select populations of afferents. The ionotropic ATP receptor P2X3 is located in sensory terminals and epithelial cells of hollow organs, such as the bladder and colon. Mechanical distension of these structures gives rise to ATP release and afferent activation. The role of the lipid-sensitive, mechanogated K^+ channels TREK-1, TREK-2, and TRAAK of the 2-pore domain K^+ channel family in nociceptor mechanotransduction is open to discussion.

TRPV1 is a nonselective cation channel with pronounced permeability for Ca^{2+} ions. It is the main molecular substrate for the ability of polymodal nociceptors to respond to acid, heat, and certain pungent chemicals. *In vivo*, this channel serves as a molecular integrator for multiple types of stimuli. These include exogenous chemicals, such as capsaicin and other vanilloids, and many endogenous substances that are released or locally produced upon injury, such as protons, membrane-derived lipids, cytokines, bradykinin, ATP, adenosine, and protons accumulated during tissue injury or ischemia. Other TRP channels (TRPV2, TRPV3, and TRPV4) are also gated by temperature, with thresholds ranging from warm to very hot ($>52\,^{\circ}C$) temperatures.

TRPA1 is a TRP channel initially proposed as a specific transduction molecule for noxious cold (threshold $\sim 18\,^{\circ}C$) in peripheral nociceptive neurons. *In vivo* findings have not lent full support to this view. In contrast, it is well established that TRPA1 channels are also activated by various natural pungent compounds such as cinnamaldehyde, allylisothiocyanate, and allycin (which are active ingredients of cinnamon oil, mustard oil, and garlic, respectively), by environmental irritants such as unsaturated aldehydes, and by cannabinoids, evidencing the polymodal nature of this TRP channel. TRPV1 and TRPA1 channels colocalize on many nociceptors. Furthermore, they are regulated through signaling pathways that are activated by metabotropic membrane receptors coupled to G-proteins. These include receptors for inflammatory mediators such as bradykinin, ATP, and nerve growth factor (NGF) that are coupled to phospholipase C activation. Hence, it is possible that such pathways are used by algesic substances to activate both TRPV1 and TRPA1, depolarizing nociceptor nerve terminals and giving rise to nociceptor sensitization.

In vivo data also support a role for the TRPM8 channel, which is gated by low temperatures and cooling agents such as menthol and icilin, in innocuous and noxious cold sensing (Figure 3).

Transduction channels in nociceptors are integral membrane proteins forming selective ion conductance pathways with variable permeability to monovalent (Na^+ and K^+) and divalent (Ca^{2+}) ions. Their change in activity by sensory stimuli leads to the flow of ionic currents that collapse membrane potential in the area where channels are active, acting as a sink for generator currents from neighbor, unstimulated axonal regions, thereby generating propagated action potentials. The detailed membrane biophysical

Figure 3 Transduction channels and voltage-gated channel types present in nociceptive neurons. Modulation of neuronal excitability is mediated by the activation of different classes of membrane receptor proteins by extracellular chemical agents. (Bottom) A nociceptor ending represented schematically. Noxious physical and chemical stimuli activate transduction channels. Endogenous chemical mediators acting through intracellular messenger pathways exert excitatory or inhibitory effects on channel gating. Long-term changes in membrane protein expression and channel function are determined by gene regulation triggered by injury and inflammation.

properties of the various functional types of nociceptor fibers at their terminal branches, branching points, and parent axons are not known. There exist marked differences in postspike excitability recovery and the ability to sustain repetitive discharges among nociceptor types, which suggests a variable density and distribution of voltage-dependent ion channels along the distal axonal tree of the different subclasses of nociceptive neurons.

Nociceptor Activity Following Tissue Injury

Noxious mechanical forces, extreme hot or cold, and a large number of exogenous irritants and endogenous substances released by injured tissues acting on the transduction molecules discussed previously depolarize nociceptor axons to their firing threshold, thereby evoking an immediate impulse discharge

whose duration and frequency depend on the intensity and duration of the stimulus as well as on the adaptation properties of the activated fiber. In addition, tissue injury resulting from the aforementioned stimuli acting on the tissues where nociceptors are located changes their local chemical environment and, by activation of modulatory pathways, modifies their responsiveness and firing pattern for longer time periods.

Injury causes the rapid accumulation of a large variety of inflammatory products at the lesioned area, such as ions and small chemicals contained within destroyed cells and mediators locally released by resident and blood-derived cells (mast cells, fibroblasts, leukocytes, and platelets) or formed from plasma proteins and membrane phospholipids. Molecules found in damaged tissues include H^+ and K^+ ions, adenosine and ATP, serotonin, histamine, platelet-activating factor, bradykinin, prostaglandins, leukotrienes, tromboxanes, interleukins, tumor-necrosis factor, and NGF. These mediators are responsible for local inflammatory reactions (vasodilatation, plasma extravasation, and cell migration) that act on membrane channels and receptor proteins at nociceptor nerve endings, provoking short-term changes in their gating properties. The altered ion flow and increased membrane excitability create the augmented impulse activity and reduced threshold that characterize the process of sensitization of injured nerve terminals. As discussed previously, the type of mediators released at the injured site varies with the tissue and the type of injury. In addition, the various classes of nociceptor fibers possess distinct second messenger pathways to modulate their equally characteristic population of nociceptor channels. Hence, alterations of the firing behavior of nociceptors vary according to the type of lesion and nociceptor fibers affected. For instance, sensitization to heat appears to be more prominent in type I Aδ nociceptors in the glabrous skin of humans and primates, whereas in the hairy skin, C polymodal nociceptors become sensitized by heat. Inflammatory mediators use different signaling pathways to exert their effects on channel activity. For instance, prostaglandin E_2, ATP, and adenosine or 5-HT activate the PKA signaling pathway, whereas other mediators such as bradykinin act on protein kinase C to produce sensitization (**Figure 3**). Nociceptor endings also possess receptor molecules whose activation reduces their excitability, thus causing inhibition. These include opioid, muscarinic, and GABA receptors.

In addition to the short-term, direct and indirect effects on channel behavior at the peripheral nerve endings, some of the inflammatory products released at the injured site have longer-lasting effects on nociceptive neurons through transcription-dependent changes in gene expression. This leads to the synthesis of new channel and receptor proteins, thereby producing more durable modifications of nociceptor excitability and, consequently, of the discharge pattern of propagated nerve impulses that constitutes their sensory message to consciousness.

For instance, NGF is a trophic factor that plays a critical role in the development of nociceptors in early life so that mutation of the gene encoding TrkA, the high-affinity receptor for NGF, causes the specific loss of nociceptors and congenital insensitivity to pain in humans. In adult animals, NGF also regulates channel and receptor protein expression in intact peripheral nociceptive neurons. Moreover, NGF released in augmented concentrations in injured tissue acts on nociceptive ganglion neurons containing TrkA receptors (approximately 40%, mostly CGRP and substance P peptidergic neurons), modifying their sensitivity. This effect occurs directly through interaction with TrkA receptors at the nociceptor membrane, which causes posttranslational phosphorylation of ion channels (particularly TRPV1 and voltage-sensitive Na^+ channels) through various intracellular cascades and also indirectly by releasing other inflammatory agents from local immune cells. Finally, an increased concentration of NGF in inflamed tissues affects gene expression in TrkA-expressing neurons and modifies the expression of ion channels involved in sensory transduction and impulse coding at nociceptor terminals (TRPs, ASICs, and TTX-resistant sodium channels). Upregulation of other receptor proteins and growth factors such as brain-derived neurotrophic factor, neuropeptides, and central neurotransmitters is an additional mechanism that explains the phenotypic changes experienced by nociceptive neurons during persistent inflammation. This is the basis of enhanced sensitivity and impulse firing in response to non-noxious and noxious stimuli exhibited by nociceptor terminals that defines primary hyperalgesia of the injured area.

Abnormal Firing in Injured Nociceptors

In acute pain resulting from sudden stimulation of nociceptors by tissue injury and also in inflammatory pain produced by activation of sensitized peripheral nociceptors, neural pathways involved in the detection and transmission of nerve impulses from the periphery to higher centers remain intact. Differences in the characteristics of the sensory message produced at primary sensory neurons are attributable to the previously described short- and long-term changes in neuronal excitability affecting peripheral nerve terminals, secondary to peripheral inflammation.

On the other hand, a number of pathological processes may directly affect nociceptive neural pathways, causing its defective functioning. Traumatic injuries, bacterial and viral infections, metabolic disorders, toxic effects, ischemia, hemorrhage, autoimmune diseases, and inflammation are the main causes of damage to peripheral as well as higher-order nociceptive pathways. This altered function of peripheral or central nociceptive pathways is the origin of an abnormal type of pain called 'neuropathic pain.' Neuropathic pain due to injury of the peripheral axon, cell body, or spinal branches of the primary nociceptive neurons located at dorsal root or cephalic ganglia is called 'peripheral neuropathic pain' and is far more common than central neuropathic pain.

Injured peripheral nerves form distal endbulbs entrapped in a tangled mass of fibers called 'neuroma.' Neuroma endings produce growing sprouts that may allow some of the damaged axons to regenerate into the distal nerve while many cut nerve fibers remain trapped at the injured area or grow in the retrograde direction. Recordings of electrical activity in the proximal portion of injured peripheral axons show that some of them, particularly the Aδ type but also unmylelinated C axons, develop an irregular, often bursting or paroxistic spontaneous activity (**Figure 4(a) and 4(b)**) that may have its origin in neuroma endbulbs or in more proximal regions, including demyelinated portions of the axon and the soma of the primary sensory neuron, where subthreshold oscillations of membrane potential and spontaneous firing become apparent after peripheral axotomy representing up to 75% of the total ectopic activity. In addition to the development of spontaneous ectopic activity, peripherally injured primary sensory neurons also become abnormally responsive to external stimuli of different quality. Response to mechanical stimulation with an impulse discharge of variable duration is a prominent feature of peripheral neuromas (**Figures 4(c) and 4(d)**) and may also develop along the trajectory of the injured nerve or in the dorsal root ganglion when these are directly affected by pathological process, as occurs during compression by herniated intervertebral disks. Abnormal, ectopic impulse activity is also induced by other stimuli, such as hypoxia, temperature oscillations, metabolic and ionic changes, as well as a large variety of endogenous inflammatory mediators and various neurotransmitters (particularly catecholamines), giving rise to neuropathic pain. Finally, 'cross-talk' also develops between injured and intact neurons at the peripheral axon and the cell body due to electrical coupling between membranes of neighbor cells at points where, due to the pathological process, they become in direct apposition, causing an 'ephaptic' excitation of fibers or somas not directly affected by trauma or viral infection. Chemically mediated cross-excitation due to local release of ions and neurotransmitters within the injured nerve or ganglion has also been proposed to explain hyperexcitability of intact neuron. The spread of simultaneous, abnormal repetitive activity among an increasing number of neurons caused by cross-talk has been proposed as the background mechanism for the paroxystic pain experienced by patients with trigeminal neuralgia and other peripheral neuropathies.

Figure 4 (a and b) Examples of ectopic, spontaneous nerve impulse activity in neuroma fibers of the cut saphenous nerve of the rat recorded *in vitro*; a segment of the recording in b has been expanded six times. (c and d) Intraneural microelectrode recordings of median nerve fibers at the wrist of a patient with an amputated hand suffering from phantom pain syndrome. Tapping the neuroma (arrows), which accentuated the phantom limb pain, induced afferent discharges in A and C nerve fibers (c). Blocking the neuroma with lidocaine (d) completely abolished the tap-induced afferent discharges and the tap-induced accentuation of the phantom pain). (a,b) Reproduced from Rivera L, Galler J, Pozo MA, and Belmonte C (2000) Responses of regenerating nerve fibres of the rat saphenous nerve neuroma to mechanical and chemical stimulation. (c,d) Reproduced from Nystrom B and Hagbarth KE (1981) Microelectrode recordings from transected nerves in amputees with phantom limb pain. *Neuroscience Letters* 27: 211–216.

It is well established that when sensory nerves are cut, the ganglion neurons from which they originate also experience a number of molecular changes. After peripheral damage, the absence of the chemical signals that under normal conditions are transported along the axon centripetally to the soma, such as NGF and glial cell line-derived neurotrophic factor, modifies the expression of genes that encode ion channel and receptor proteins and regulate their trafficking to and from the periphery. In the injured neuron, the molecules transported distally by axonal flow accumulate at the neuroma endings. They include various classes of Na^+ and K^+ channels. Somatic and visceral nociceptor neurons normally express various subtypes of sodium channels. Among

these, $Na_v1.7$, $Na_v1.8$, and $Na_v1.9$ are largely responsible for the different currents that sustain the initiation and propagation of nerve impulses at their axon and cell soma. Axonal damage induces a significant upregulation of the previously silent sodium channel gene $Na_v1.3$ and downregulation of the $Na_v1.8$ and $Na_v1.9$ genes. Expression of other voltage-gated ion channels, such as K^+ and Ca^{2+}, and nonselective cation channels, such as HNC channels, which regulate the excitability and firing pattern of primary sensory neurons, is also variably altered by axotomy. This determines the modification of ionic currents present in neuroma endings and favors the development of ectopic discharges and the abnormal responsiveness to mechanical and chemical stimuli.

Nogo-A: Its Role in Axon Regeneration

Introduction

Injuries of the adult central nervous system (CNS) had been considered incurable over many centuries. CNS injuries such as spinal cord injury (SCI) impair basic functions of the body and lead to disability. The major cause of disability after injury is a disconnected nervous system rendering sections of the spinal cord denervated. For the past 20 years, great progress has been made toward understanding why the injury-induced disconnection in the adult CNS is persistent. One reason for the absence of spontaneous regrowth of CNS nerve fibers after injury is the presence of growth-inhibitory factors, especially in CNS myelin as well as in the scar that forms at the injury site. A key factor is a protein of the mammalian CNS now known as Nogo-A. In this article we summarize the knowledge gained over two decades that led to the conceptualization of Nogo-A as an inhibitor of growth and regeneration, and how the application of this concept has given a new perspective of making CNS injury curable.

Identification of Nogo-A and Its Expression

The Rationale behind Nogo-A and Its Identification

It had been long observed that CNS injuries at very immature ages often result in significant regeneration and sufficient plasticity to restore lost functions, contrary to the situation in adults. Moreover, the peripheral nervous system (PNS) in contrast to the CNS is able to regenerate injured axons even over long distances (Figure 1(a)). This difference in regeneration capacity does not lie in the neurons but rather in their environments: when injured neurons of the CNS are exposed to PNS tissue, they regenerate and elongate in the PNS tissue, demonstrating that adult neurons of CNS indeed have the capacity to regenerate in a favorable environment (Figure 1(b)). Experiments were then carried out to dissect the constituents of the CNS that are particularly inhibitory to neuronal growth resulting in an inhibitory environment. It was observed that neurons seeded on dissociated CNS cells particularly avoid the oligodendrocytes, the myelinating cells of the CNS (Figure 1(c)). In case of young CNS, myelination is still absent or incomplete allowing a more favorable environment for outgrowth compared to the adult. An inhibitory effect of CNS myelin was further demonstrated by induction of growth cone collapse by oligodendrocytes or myelin.

Identification of a growth-inhibitory cell type in the CNS led to the crucial hunt for the particular inhibitory constituents of the cell. Inhibition through myelin was abolished by proteases, pinpointing the role of one or several proteins. Circumstantial evidence, such as contact-based inhibition of neurite outgrowth by oligodendrocytes, pointed toward a membrane protein as a potential inhibitory candidate. Several membrane proteins were extracted from myelin and the one most inhibitory to neurite outgrowth was named NI-220/250. Antibodies were raised against NI-220/250, and their application on myelin substrates showed neutralization of myelin's inhibitory effect on neurite outgrowth. IN-1 (neutralizing antibody against NI-220/250) paved the way for regeneration after SCI, as discussed later.

The identification of peptide sequences of NI-220 led to the discovery of the gene, which was called *nogo*. It gives rise to three different protein products based on alternative splicing. The protein products are Nogo-A, Nogo-B, and Nogo C, which are 1163, 360, and 199 amino acids long rat sequences, respectively. Out of these splice variants, Nogo-A corresponds to the myelin inhibitor NI-220/250 and is recognized and neutralized by IN-1. It shares a common sequence of 188 amino acids at the carboxyl-terminus with Nogo-B and Nogo-C (Figure 1(d)). This common sequence is homologous to three other members of the reticulon (RTN) protein family. The similarity of Nogo-A to other RTN proteins is restricted to this carboxy-terminal end. RTNs are present in all eukaryotes; however, only its new member Nogo-A has known neurite inhibitory capacities. The middle Nogo-A-specific fragment of Nogo-A, together with a 66-amino-acid sequence at the carboyxl-terminus ('Nogo-66'; Figure 1(d)) gives it most of its outgrowth-inhibitory capabilities in mammalian CNS. The functions of Nogo-B and -C remain illusive.

Expression of Nogo-A

In the adult CNS, Nogo-A is prominently present in the myelin-forming oligodendrocytes. It is largely localized in the compartments of the endoplasmic reticulum, a significant proportion is expressed on the cell membrane, with the two inhibitory sites facing the extracellular space. In the developing nervous

Figure 1 Key observations leading to regeneration in the adult CNS. (a) Axons of the adult CNS degenerate upon axotomy, whereas in the PNS axotomized neurons can regenerate over very long distances. (b) The inability of the CNS to regenerate is not due to the axons themselves. Experiments done by Aguayo (repeated from Tello in 1911) showed that the axons of CNS neurons can regenerate in the more permissive PNS environment. (c) CNS tissue and oligodendrocytes were identified to be inhibitory to neurite growth *in vitro*. Oligodendrocytes are myelinating cells present in the CNS and not in the PNS. (d) Nogo-A: proteins were extracted from myelin membranes and the most potent inhibitory protein was identified as Nogo-A. Neutralization of Nogo-A after SCI: neutralization of Nogo-A led to significant alternation of CNS inhibition *in vivo* resulting in enhanced sprouting and long-distance regeneration of axons after adult CNS injury.

system, Nogo-A is also transiently expressed by many neurons, especially projection neurons with long axons. Its role as a repulsive axonal guidance molecule is currently under investigation.

Spinal Cord Injuries

Majority of studies on CNS regeneration, including those on the effect of neutralization of Nogo-A after SCI, have been done in adult rats. In order to further discuss the aspects of injury on which Nogo-A neutralization acts to cause regeneration, a brief introduction to SCI and the animal models used is essential.

Brief Overview of Relevant Changes Induced by SCIs

SCI leads to a complex cascade of events, many of which are still poorly understood. Ischemia and inflammation enlarge the lesion (secondary tissue loss), and activated microglia together with astrocytes laying the foundations of the scar at the site of injury. There is a temporary opening of the blood–brain barrier. Axons that are injured but still connected to the cell body often sprout, but then retract. Axons detached from their cell bodies undergo Wallerian degeneration. For injured axons to re-innervate their targets, the axons would need to either grow through or bypass the lesion site.

Often SCIs in humans are anatomically incomplete, where some tissue is spared even if it appears insufficient to mediate functions. This spared tissue, as discussed later, can act as a bridge for regenerating fibers to reach their sites of innervations. Interestingly, CNS injury also results in a neuronal growth response. This transitory growth response manifests itself as sprouting; near the site of injury, these sprouts could be a source for regenerating fibers. In adult CNS tissue, these sprouts have often been observed to grow only over short distances and to be unable to pass through the lesion scar or across the spared tissue bridges. The occurrence of sprouting after CNS injury has been known for a long time but its regulation and possible consequences were not well studied. It was shown only recently that spontaneous sprouting after SCI in adult rats could lead to the formation of specific new intraspinal circuits that correlated with

spontaneous behavioral recovery. However, in cases of complete or near-complete SCIs, the extent of such spontaneous recovery is not large enough to lead to a recovery making the search for interventional therapy necessary.

Animal Models Used to Study SCIs

Contusion by controlled impact (weight drop or electromechanical 'impactors') or clipping, or partial or full transection of the spinal cord in rats or mice are the most frequently used models at present. The approach is by a dorsal laminectomy. Human injuries, however, are mostly ventral closed contusions. To study axonal regeneration unequivocally, a full lesion of a well-defined tract that can be traced neuroanatomically is required. Only the corticospinal tract (CST), to some extent the rubrospinal tract (RST), and the ascending dorsal column sensory tracts fulfill these requirements. Unilateral hemi or overhemisections, dorsal bilateral lesions, or the so-called T lesions (including the CST, which runs mainly in the dorsal part of the rodent spinal cord, as well as its ventral and medial components) are therefore most frequently used. These models of SCI mimic incomplete injuries, with moderate to severe functional loss. The spared tissue also makes a bridge possible, which plays a critical role in the ability of the axotomized fiber tracts to regenerate; full transactions produce a scar and often a several-millimeter-long gap that is impermeable for the growing axons.

Many studies have also used injury models that are less complicated than a large SCI. Such injuries involve transection of only certain chosen fiber tracts: for example, the dorsal column or, without any injury at the level of the spinal cord itself, the CST at the pyramidal decussation. This lesion model results in a spinal cord deprived of CST projections.

Axonal Regeneration after Neutralization of Nogo-A

Regeneration in Adult Rodents

In vitro evidence clearly showed a strong growth-inhibitory effect of Nogo-A. Immediately after conceptualization of the inhibitory effect of Nogo-A, several experiments were carried out in young and adult spinal cord-injured rats with complete CST lesions to examine the role of Nogo-A in CNS regeneration. In the initial experiments, hybridoma cells, secreting IN-1 antibody to neutralize Nogo-A, were grafted into the cortex of immune-suppressed rats (Figure 2(b)). The CST, visualized using the anterograde tracer horseradish peroxidase (HRP), was seen to regenerate up to 11 mm in the presence of IN-1 antibody in adult animals within 2–3 weeks. Control antibody-treated rats showed only the well-known, short (0.1–1 mm) sprouting response. This inducible regeneration, then seen for the first time in the absence of Nogo-A's inhibitory activity, occurred at a maximal rate of 0.5–1 mm per day. Regenerating fibers used the spared tissue as a bridge to bypass and get below the site of injury (Figure 1(d)). To date, no artificial bridges in combination with Nogo-A neutralization have been successful.

Figure 2 Strategies for neutralizing Nogo-A activity. (a) Cloning of the gene *nogo* led to the possibility of knocking out the gene and thus producing mice without Nogo-A. Such mice show enhanced regeneration compared to wild-type. However, such an approach is limited to mice and is difficult to interpret due to compensation during development by other inhibitory proteins. An inserted PKG-neo gene disrupted the production of Nogo-A and the inserted Diptheria toxin A (DTA) gene was used to select against random insertions of the gene. Transfected ES cells were screened using primes A, B, I, and J out of primers A–J. (b) Hybridoma cells were designed to secrete the antibody IN-1, which neutralizes Nogo-A. Cells are transplanted into the brain at the time of injury. This results in neutralized Nogo-A and regeneration and behavioral recovery in spinal cord- and brain-injured rats and monkeys. (c) Osmotic pumps deliver neutralizing anti-Nogo-A antibody into the cerebrospinal fluid bathing the spinal cord and brain. This gives more temporal control regarding delivery, and the dosage can be determined precisely. Nogo-A-neutralizing antibodies or peptide reagents induced axonal regeneration and behavioral recovery in mice, rats, and monkeys.

Figure 3 Regeneration and behavioral recovery after Nogo-A neutralization. (a) Nogo-A neutralization leads to enhanced regeneration after adult SCI. Regeneration is seen within a few weeks after treatment. Corticospinal neurons, thought to be difficult to regenerate, bypass the lesion site using spared tissue to re-innervate the denervated spinal cord in mice, rats, and monkeys. (b) Behavioral recovery is observed after Nogo-A neutralization in the adult spinal cord-injured animals. Spinal cord-injured rats show better coordination and body weight support and a more precise grip after treatment when crossing a horizontal ladder. (c) Macaque monkeys with high cervical SCIs resulting in loss of fine finger movements recover hand control after Nogo-A neutralization, as seen in a food-catching test.

Upon the observation of successful regeneration, challenging experiments immediately followed to examine its functional effects. Animals were tested on batteries of behavioral read-outs after SCI in the presence of Nogo-A antibody. One of the first recoveries noted was in a sensorimotor reflex, known as the contact placing response, which is strictly dependent on the CST. Rats place their limbs on a surface for support in response to a slight stimulation of the dorsal shin of the foot. This CST-dependent reflex showed a significant recovery in the presence of IN-1 antibody, but not in the controls. In addition, the spinal cord-injured rats showed improvements in a variety of locomotion tests in the presence of IN-1.

The results seen with IN-1 antibody treatment in rats led to experiments with Nogo-A inhibition in a clinically closer setting. Two new monoclonal monospecific Nogo-A antibodies (11C7 and 7B12) were generated against inhibitory fragments of Nogo-A and administered intrathecally to spinal cord-injured rats (T lesion) with osmotic minipumps at the time of injury (Figure 2(c)). Just as after IN-1 treatment secreted from hybridoma cells, the application of the new neutralizing antibodies resulted in long-distance regeneration of the CST (Figure 3(a)). They also resulted in significant overall improvement in coordination during locomotion in an open field and during swimming. Exposing animals to tests such as walking on a narrow beam or a horizontal ladder resulted in more precise hindlimb foot placements and a close to normal pattern of body weight support during walking (Figure 3(b)). These findings encouraged the possible usage of Nogo-A neutralization in a clinical setting in humans. One of the major concerns in spinal cord-injured patients is pain and allodynia. Animals treated with Nogo-A antibodies show no significant differences to control antibody-treated injured animals in tests that detect pain or allodynia.

Enhanced regeneration of injured CST axons was also observed in mice after genetic deletion of Nogo-A (Figure 2(a)). The extent of regeneration was, however, also influenced by background genes of specific mouse strains, that is, more extensive in SV 129 than in C57Bl/6.

Regeneration in Adult Primates

The rodent studies revealed Nogo-A neutralization as a potential treatment for human SCI. As a prerequisite to enter clinical trials it was essential to show that Nogo-A neutralization was effective in primates.

Initial experiments focused on using IN-1 antibody in adult marmosets (*Callitrix jacchus*). Following injury of the CST in the spinal cord, the treated marmosets showed an increase in sprouting, and regenerating fibers in the spinal cord caudal to the lesion. The much larger Macaque monkeys were studied then using anti-Nogo antibodies delivered intrathecally from subcutaneous pumps. The animals were subjected to a cervical unilateral hemisection including the CST, which rendered the corresponding hand paretic, but only minimal effects on hindlimb locomotion or vegetative functions. Upon application of the anti-Nogo-A antibodies for 4 weeks, the Macaque monkeys showed regeneration of CST axons around the lesion scar as seen in marmosets and rats. Moreover, there was a dramatic improvement in the dexterity of the hand in response to the antibody as seen in tasks like catching food (Figure 3 (c)), opening drawers, and taking raisins from wells using the precision grip.

Regeneration in Injuries Other Than That of the Spinal Cord

Regeneration due to Nogo-A neutralization is widely studied in the spinal cord; however, it is not limited to the cord. When Nogo-A was neutralized in the presence of trophic factors, the crushed optic nerve was able to regenerate. The extent of regeneration was higher than that seen due to application of the trophic factor alone. Application of anti-Nogo-A antibodies after auditory nerve lesion (the auditory nerve is myelinated mainly by oligodendrocytes) led to similar results. Functional assessments also showed some recovery of sound perception in these animals.

Compensatory Fiber Growth after Neutralization of Nogo-A

While regeneration is thought to be critical to achieve complete recovery, several other forms of anatomical changes can take place in response to a CNS injury that can play a role in functional recovery. The spontaneous growth response, known as sprouting, is one such anatomical change. A well-studied example is the sprouting of the intact CST system after unilateral CNS lesions, such as stroke or pyramidotomy. These lesions result in a permanent loss of fine movements of the forelimb, in particular the hand and fingers. Some spontaneous sprouting occurs from the intact uncrossed ventral CST fibers in the denervated half of the spinal cord. Neutralization of Nogo-A, however, leads to sprouting of the main CST from the intact side of the spinal cord; these sprouts cross the midline to innervate the denervated half of the spinal cord, leading to full recovery of fine limb movements such as those used in grasping.

After bilateral pyramidotomy, where the spinal cord has lost all its input from the cortex, the RST shows no detectable sprouting. Anti-Nogo-A antibodies resulted in pronounced sprouting of the rubrospinal fibers into areas previously innervated by the CST. Again, a very high degree of functional recovery was observed. The lack of increase in pain or allodynia after Nogo-A neutralization indicates a high degree for specificity of newly formed connections. Little is known about the underlying mechanisms, especially for the role of activity in stabilizing and fine-tuning the new connections and circuits.

Possible Mechanism of Action of Nogo-A and Its Neutralization

Neurite Growth Inhibition by Nogo-A

Nogo-A induces growth cone collapse correlated with calcium surge in the growth cone and with a pronounced activation of the small GTPase RhoA. Purified Nogo-A acts at extremely low concentrations. These observations indicated the presence of a receptor on the neuronal membrane surface coupled to an amplifying signaling pathway. As discussed above, Nogo-A has two main inhibitory regions. For one of them, the Nogo-66 sequence, an interaction partner was found, the so-called Nogo receptor, NgR. NgR binds not only to Nogo-66, but also to myelin-associated glycoprotein (MAG), oligodendrocyte myelin glycoprotein (OMgp), and probably additional ligands. Interestingly, MAG and OMgp show *in vitro* inhibitory neurite growth activity along with Nogo-A. N_gR alone does not account for the potent inhibition by Nogo-A *in vitro*. Knockout mice lacking NgR show only little regeneration. This result confirms the importance of a second, still unknown receptor (subunit) for the Nogo-A specific active site ('amino-Nogo' in Figure 1(d)) of the molecule.

Nogo-66 and Nogo-A activate the Rho family of proteins, in particular RhoA and the Rho effector ROCK. Blockade of Rho or ROCK attenuates the inhibitory effect of Nogo *in vitro*, and enhances regeneration after spinal cord lesions *in vivo*. The complete signaling cascade leading to the destabilization of the growth cone cytoskeleton as well as the precise role of receptor-associated proteins like p75, Troy, or Lingo remain to be defined.

Induction of Growth Due to the Absence of Active Nogo-A

When neutralizing antibodies against Nogo-A were applied to the CNS of intact adult rats, an increase in growth-associated protein GAP-43, neuronal cytoskeletal proteins, growth factors, transcription factors, and axon guidance molecules was observed. We speculate that Nogo-A, present in the myelin

that surrounds the mature axons, sends a retrograde signal to the cell bodies, acting as a negative regulator of growth in the adult CNS. Thus, Nogo-A neutralization enhances regeneration and sprouting not only by making the CNS tissue more permissive for growing fibers but also by the enhancement of the neuronal growth mechanisms.

Potential of Nogo-A Inactivation for Other CNS Injuries

Neutralization of Nogo-A induces regeneration in the adult CNS but it also increases structural plasticity and is potentially neuroprotective. In stroke studies, adult rats recover the lost fine motor movements to a large extent after Nogo-A neutralization. Increased plasticity in the form of sprouting of the spared cortifugal fibers to innervate the denervated regions in the spinal cord and brain is thought to be a key factor causing such recovery. Delayed treatment with anti-Nogo-A antibodies or treatment in aged rats is also effective. These findings open an exciting outlook for a possible use of Nogo-A neutralization in the clinic, not only for SCI but also for brain trauma and stroke.

Recently, Nogo-A has been shown to be involved in autoimmune demyelination as seen in the experimental autoimmune encephalomyelitis (EAE), an animal model of multiple sclerosis (MS). Mice vaccinated against Nogo-A or Nogo-A knockout mice showed reduced inflammation, demyelination, and axon loss in this model. While the exact mechanisms that led to such effects remain unknown, clearly Nogo-A is a key contributor to the growth-inhibitory nature of the adult mammalian CNS and its neutralization may alleviate the loss of neuronal connectivity in various forms of degenerations.

The identification and neutralization of Nogo-A has led to not merely an inhibitory protein, but a concept that has instead resulted in the identification of several other growth inhibitors in the CNS. Identification of growth inhibitors in CNS myelin such as MAG, OMgp, ephrinB3, and several semaphorins (4d, 5A) are part of a potentially long list of proteins being understood as negative growth regulators. The utility of the concept of Nogo-A is clearly demonstrated in the swift transformation to clinically relevant studies raising the hope of meaningful regeneration and repair of CNS injuries in humans. Clearly, regeneration in the adult CNS is not a simple phenomenon. The identification of Nogo-A has emphasized the illusive complexity of the biological system that results in an inhibited and balanced adult nervous system. Nogo-A has given us many answers; however, it has also raised many challenging questions that remain to be solved in the coming years.

Non-Photoreceptor Photoreception

K Y Wong, Brown University, Providence, RI, USA

© 2009 Elsevier Ltd. All rights reserved.

The mammalian visual system processes photic information from the external world in two ways. Image-forming vision entails the analysis of spatial details in the environment and requires retinal rod and cone photoreceptors. Non-image-forming vision, on the other hand, is concerned with the measurement of the overall brightness of the surroundings and leads to various reflexive responses. Examples of these non-image-forming visual responses include constriction of the pupil, synchronization (i.e., entrainment) of the master circadian clock in the suprachiasmatic nucleus (SCN) and consequently circadian behaviors to the solar cycle, inhibition of melatonin release from the pineal gland, and acute suppression of locomotor activity (i.e., negative masking) of nocturnal animals.

Non-Image-Forming Vision Does Not Require Classical Photoreceptors

Contrary to image-forming vision, non-image-forming photoreception does not require rod or cone photoreceptors. In 1927, Clyde Keeler made the initial observation that *retinal degenerate* (*rd*/*rd*) mice which lacked rods and possessed few functional cones still had the ability to constrict their pupils in response to light. Subsequently, researchers found that the circadian behaviors of *rd*/*rd* mice could be entrained to the external light–dark cycle, and that the level of plasma melatonin in some blind patients could be reduced by exposure to bright light. The possibility that these non-image-forming visual responses were mediated by a few surviving rod/cone photoreceptors was ruled out by two studies performed in the 1990s. First, Takashi Yoshimura and Shizufumi Ebihara demonstrated that the most effective wavelength (λ_{max}) for phase-shifting circadian activity rhythms in *rd*/*rd* mice is around 480 nm, significantly different from the λ_{max} for the classical photoreceptors in mice (ultraviolet cone, 359 nm; rod, 498 nm; green cone, 510 nm), implicating a previously unidentified photoreceptor. Second, Russell Foster and colleagues developed a transgenic mouse line lacking all functional rods and cones (*rd*/*rd cl*) and found that these animals were still able to exhibit light-evoked phase shifts of circadian locomotor activity, a pupillary light reflex, negative masking, and light-induced inhibition of pineal melatonin release. In the retinas of *rd*/*rd cl* mice, the entire photoreceptor layer is missing, suggesting that the photoreceptors responsible for driving the residual non-image-forming visual behaviors reside in the inner retina.

The Novel Photoreceptor Is a Ganglion Cell That Expresses Melanopsin

The non-rod, non-cone photoreceptor that can mediate non-image-forming visual functions in the absence of rods and cones was discovered in 2002 by David Berson to be a rare subtype of retinal ganglion cells (RGCs). These cells are capable of generating robust responses to light stimulation even when pharmacologically or mechanically isolated from synaptic inputs, and they are thus intrinsically photosensitive and function as photoreceptors.

Light Response Properties

Consistent with Yoshimura and Ebihara's behavioral measurement mentioned previously, the endogenous light response of these intrinsically photosensitive retinal ganglion cells (ipRGCs) has a λ_{max} of approximately 480 nm. In addition, the intrinsic ipRGC photoresponse has the following characteristics that are strikingly different from the light responses of rod and cone photoreceptors:

1. The ipRGC light response is generated by the opening of cation-selective channels in the plasma membrane, resulting in depolarization from a relatively negative resting potential (typically approximately-65 mV), similar to the case for invertebrate photoreceptors. The amplitude of the ipRGC photoresponse increases as the intensity of the light stimulus increases. In contrast, illumination closes cation channels in rods and cones, hyperpolarizing them from relatively positive resting potentials (typically approximately −40 mV).
2. The ipRGCs can generate sodium-based action potentials, which are required for these cells to propagate electrical signals along their long axons to higher brain targets. The frequency of action potentials increases as the intensity of the light stimulus increases. By contrast, rod and cone photoreceptors encode irradiance information through graded potentials only.
3. The light response of ipRGCs is extremely sluggish (Figure 1). Responses to light steps of near-threshold intensities rise slowly and can take up to several minutes to reach the peak amplitude. The time to peak decreases as light intensity increases, and the

Figure 1 A melanopsin-driven light response recorded from a rat ipRGC. This response was recorded in the presence of pharmacological agents that blocked synaptic input from rod/cone-driven circuits, thus isolating the melanopsin-based photoresponse. The intensity of the light stimulus was approximately 1.5 $\log_{10}$ units above the threshold.

brightest stimuli can evoke responses that peak within several seconds. The ipRGCs also recover from light stimulation very slowly, requiring up to tens of minutes for their membrane potentials to return to baseline levels. By contrast, the photoresponses of rods and cones are always much faster, peaking within approximately 500 ms and usually returning to resting levels within a few seconds after the cessation of light stimulation.

4. Although ipRGCs can adapt to light stimulation by reducing their sensitivity, such adaptation is relatively limited and the ipRGC response to prolonged light illumination can be sustained for many hours. By contrast, cone photoreceptors adapt to light far more rapidly and completely, resulting in much more transient light responses. Thus, ipRGCs can integrate light information over much longer timescales than cones.

5. The photoresponse of ipRGCs has a threshold of approximately 10^{11} photons cm^{-2} s^{-1} at 480 nm, which is comparable to dawn light and is on the order of 5 $\log_{10}$ units less sensitive than rods and 2 $\log_{10}$ units less sensitive than cones at their corresponding peak sensitivity wavelengths. All three types of photoreceptors have comparable dynamic ranges, about 3 $\log_{10}$ units.

These properties of the endogenous ipRGC light response are advantageous to the various non-image-forming visual behaviors driven by these cells. The tonic nature of these responses enables the pupil to be constricted and nocturnal locomotor activity to be suppressed for many hours continuously. The relatively low sensitivity of these light responses and their requirement for prolonged illumination cause the ipRGCs to respond poorly to random, brief environmental photic fluctuations such as lightning, thus minimizing the impact of these events on the central circadian clock. In addition, the low sensitivity enables ipRGCs to complement the dynamic range of the more sensitive classical photoreceptors, which also contribute to non-image-forming vision (see the section titled 'Conventional photoreceptors also contribute to non-image-forming photoreception').

Some RGCs in rodents already express the photopigment melanopsin before birth (see the section titled 'Photopigment and transduction cascade') and have been shown by c-fos immunoreactivity, calcium imaging, and extracellular recording techniques to be light responsive from postnatal day 0 (P0), approximately 12 days before eye opening. By contrast, rods and cones do not become light responsive until approximately P10. The light responses of ipRGCs are more transient and approximately 1 $\log_{10}$ unit less sensitive prior to P4 than at P6 and older ages. The ipRGCs already make functional connections with the SCN and can drive light-induced expression of c-fos in the SCN from P0. The early emergence of ipRGC photosensitivity has been speculated to fine-tune the development of the non-image-forming visual pathways.

Up to three subtypes of ipRGC light responses have been demonstrated in the mouse retina by calcium imaging and extracellular spike recording, and they differ in terms of response onset latency, absolute sensitivity, and response offset kinetics. The significance of this diversity of ipRGC responses is unknown. One possibility is that these subtypes of ipRGCs project to different brain regions.

Besides the generation of an intrinsic light response, ipRGCs also display synaptically driven, rod/cone-mediated responses to light (see the section titled 'Synaptic input to ipRGCs').

Photopigment and Transduction Cascade

The photopigment in ipRGCs is melanopsin (gene symbol, opn4), which was originally discovered in

the photosensitive dermal melanophores of the frog by Ignacio Provencio and colleagues in 1998. RGCs expressing mammalian orthologs of melanopsin have been found by Provencio and other researchers in many mammalian species, including human, mouse, rat, monkey, cat, hamster, and blind mole rat. All ipRGCs express melanopsin, and in most species the ipRGCs are the only retinal neurons that express this protein. There is evidence that certain human cone photoreceptors also express melanopsin, although its functional roles in these cells are unknown. Genetically knocking out melanopsin in mice completely abolishes the endogenous photosensitivity of ipRGCs, consistent with melanopsin being the only photopigment in these cells.

Interestingly, the amino acid sequence of mammalian melanopsin shares much higher homology with invertebrate opsins than with vertebrate rod and cone opsins. Based on its amino acid sequence, melanopsin is predicted to have seven transmembrane domains, like all G-protein-coupled receptors including other opsins. Melanopsin has a long cytoplasmic tail with more than a dozen potential phosphorylation sites, suggesting that the function of melanopsin may be finely modulated by kinases.

Similar to the rod and cone photopigments, melanopsin consists of an apoprotein covalently linked to the chromophore 11-*cis*-retinaldehyde. When illuminated, the chromophore is isomerized into all-*trans*-retinaldehyde, inducing a conformational change in the melanopsin apoprotein which in turn triggers an intracellular transduction cascade that ultimately results in an increase in cation influx across the cell's plasma membrane. However, unlike the all-*trans*-retinaldehyde in rods which gets exported to the adjacent retinal pigment epithelium for the regeneration of 11-*cis*-retinaldehyde, melanopsin retains the all-*trans*-retinaldehyde and reisomerizes it to 11-*cis*-retinaldehyde upon exposure to light with appropriate wavelengths. In other words, melanopsin is bistable and functions as both photopigment and photoisomerase, just like many invertebrate photopigments. This property is critical to the maintenance of melanopsin photoresponses because the ipRGCs are physically far removed from the retinal pigment epithelium. Indeed, ipRGCs remain light responsive even when enzymes within the retinal pigment epithelium that are necessary for regenerating 11-*cis*-retinaldehyde for the rods are genetically knocked out or pharmacologically inhibited.

Considering the structural and functional similarities between melanopsin and invertebrate photopigments, it is perhaps not surprising that the phototransduction cascade in ipRGCs also appears quite similar to that in *Drosophila* photoreceptors. Melanopsin has several invertebrate-like sequence motifs in regions thought to be involved in G-protein binding, and it has indeed been demonstrated that, similar to phototransduction in *Drosophila* photoreceptors, ipRGC phototransduction requires a $G_{q/11}$ class G-protein. This G-protein appears, in turn, to signal through phospholipase C (PLC) in these cells, although the second messengers downstream from PLC are unknown. Finally, there is pharmacological evidence that in ipRGCs, the light-activated cation channel at the end point of the transduction cascade is a transient receptor potential (TRP) channel that belongs to the TRPC family.

Morphology and Distribution

The morphology and distribution of melanopsin-expressing RGCs (mRGCs) have been studied most extensively in rodent, primate, and cat retinas.

Rodents In the rat retina, melanopsin is expressed in approximately 2500 RGCs or 2.5% of all RGCs, whereas in the mouse retina approximately 750 or 1% of all RGCs express melanopsin. The density of mRGCs is slightly higher in the superior and temporal quadrants than in other parts of the retina. Approximately 95% of mRGCs are located in the ganglion cell layer, and the rest are displaced to the inner nuclear layer. The soma diameters average approximately 15 μm, which is intermediate among rodent RGCs. Each cell has two to six primary dendrites which branch sparsely, and the dendritic fields have an average diameter of approximately 500 μm (Figure 2, right). The dendrites are monostratified, usually terminating in the 'off' sublamina of the inner plexiform layer near the border with the inner nuclear layer, although the dendrites of some mRGCs appear to terminate in the proximal, 'on' sublamina instead. These two morphological types of mRGCs have been termed M1 and M2, respectively. Melanopsin is expressed in the soma, dendrites, and proximal axonal segments of each cell, and at least in the soma, melanopsin is targeted mainly to the plasma membrane. Both the soma and the dendrites of the M1 cells have been shown to be directly photosensitive, although it remains to be determined whether the M2 cells are also intrinsically photosensitive. Dendrites from adjacent mRGCs overlap extensively, forming an expansive photoreceptive net that covers the entire retina (Figure 2, left).

Primates In human and macaque retinas, melanopsin is expressed in approximately 3000 or 0.2% of all RGCs. The density of mRGC somata is the highest in

Figure 2 (Left) A photoreceptive net of ipRGCs in a flat-mounted rat retina as revealed by immunostaining against melanopsin. The image was generated by stacking images taken at several focal planes. (Right) Camera-lucida drawing of a rat ipRGC.

the parafoveal region and decreases toward the peripheral retina. Few mRGCs are found within the fovea. Approximately 60% of all mRGCs are in the ganglion cell layer, whereas the rest are displaced to the inner nuclear layer. The average soma diameter is approximately 20 μm, which is relatively large among primate RGCs. The dendrites branch sparsely and dendritic field diameters range from approximately 300 μm in the parafovea to approximately 1200 μm in the peripheral retina, much larger than those of any other known primate RGC. Each cell's dendrites are monostratified and terminate in either the on or the off sublamina in the inner plexiform layer, and both morphological types are directly photosensitive. Similar to mRGCs in rodents, the dendritic trees of adjacent primate mRGCs overlap extensively.

Cat Melanopsin is expressed in approximately 1700 RGCs or 1% of all RGCs in the cat. The density of mRGC cell bodies is fairly uniform across the entire retina. All mRGCs are in the ganglion cell layer. The average soma diameter is approximately 14 μm, which is relatively small among cat RGCs.

Axonal Projections

The axonal projections of the mRGCs have been best characterized in mice, rats, and hamsters. At least 70% of all mRGCs innervate the SCN, and at least 70% of the RGCs that project to the SCN express melanopsin. As mentioned previously, these retinal inputs synchronize the master circadian pacemaker in the SCN to the external light–dark cycle. Three other brain regions that receive most of their retinal inputs through mRGCs are the ventral subparaventricular zone (vSPZ), which is involved in photic and circadian modulation of sleep and locomotor activity, including negative masking; the intergeniculate leaflet, which integrates photic and nonphotic cues for the regulation of circadian rhythms; and the lateral habenula, which integrates signals from the limbic, motor, and circadian systems. The olivary pretectal nucleus, which controls the pupillary light reflex, receives substantial input from mRGCs, although it is also heavily innervated by conventional RGCs.

Melanopsin-expressing RGCs also make weaker axonal projections to several other parts of the brain, which derive most of their retinal inputs through non-mRGCs. These regions include the ventrolateral preoptic nucleus, which is involved in sleep–wake regulation; the peri-supraoptic nucleus, which modulates the release of hormones from the supraoptic nucleus proper; the medial amygdala, which integrates signals from the retina and the olfactory system to modulate reproductive behaviors; the superior colliculus, which controls eye movements; the ventral lateral geniculate nucleus, which is implicated in visuomotor functions such as optokinetic nystagmus; and the dorsal lateral geniculate nucleus (dLGN), which is the thalamic relay of retinal information to the primary visual cortex in the image-forming visual pathway. Innervation of the dLGN by ipRGCs has also been reported in primates, raising the possibility that ipRGCs might directly contribute to conscious visual perception.

The mRGC projections to the SCN and the vSPZ are bilaterally symmetrical, whereas all other mRGC targets receive predominantly contralateral mRGC inputs. This presumably indicates that most uncrossed mRGC axons terminate at the SCN and the vSPZ and do not continue to higher brain centers.

Despite ipRGCs' role in light-induced nocturnal suppression of melatonin release from the pineal gland, these cells do not directly project to this brain region. Instead, they signal through a polysynaptic circuit that begins at the SCN, followed by the paraventricular nucleus of the hypothalamus, the intermediolateral

nucleus of the spinal cord, the superior cervical ganglion, and, finally, the pineal gland.

Conventional Photoreceptors Also Contribute to Non-Image-Forming Photoreception

Although many non-image-forming visual functions do not require rods or cones, the classical photoreceptors nevertheless contribute to their generation in wild-type animals. Together, rod/cone photoreceptors and ipRGCs account for all types of non-image-forming photoreception in the mammalian retina.

Differential Roles of Melanopsin and Classical Photoreceptors

As discussed previously, melanopsin-driven ipRGC photoresponses differ from rod/cone light responses in various respects, and these photosensory systems indeed make largely nonredundant contributions to non-image-forming vision:

1. The rod/cone photoreceptors are more sensitive than melanopsin and have been shown to increase the absolute sensitivities of the pupillary light reflex and circadian photoentrainment. On the other hand, melanopsin is required for maximal constriction of the pupil in response to bright light stimulation. Thus, the dynamic ranges of classical photoreceptors and melanopsin complement each other.
2. Rods and cones generate faster light responses than the melanopsin-based ipRGC response, and they have been shown to shorten the latency of the pupillary light reflex. Classical photoreceptors are also important for the circadian phase-shifting response of mice to short-duration (e.g., 1 min) light pulses that are relatively ineffective in triggering melanopsin responses.
3. Melanopsin photoresponses are far more tonic than the light responses of rods and cones. In mice, melanopsin is required for prolonged light pulses to continuously suppress nocturnal locomotion, and the rod/cone photoreceptors alone can sustain negative masking for no more than 2 h. Similarly, in humans, blue light near the λ_{max} for melanopsin can continuously inhibit the release of pineal melatonin for at least 6 h, whereas longer wavelength light selective for the classical photoreceptors can maintain such inhibition for much shorter durations.

Synaptic Input to ipRGCs

The various brain regions that mediate non-image-forming visual functions receive retinal inputs through conventional RGCs as well as ipRGCs. Thus, these conventional RGCs presumably provide a pathway through which rod/cone signals can reach these brain targets. However, besides functioning as photoreceptors, the ipRGCs also receive synaptic input from rod/cone circuits, as do all other RGCs. Preliminary data have shown that at least for photoentrainment, pupillary constriction, and negative masking, genetically ablating the ipRGCs severely impaired these responses, suggesting that rod/cone signals regulating these behaviors are conveyed primarily through the ipRGCs.

As mentioned previously, ipRGCs extend their dendrites into the inner plexiform layer, the synaptic layer in which bipolar and amacrine cells transmit rod and cone signals to the RGCs. Electron microscopic data have shown that in the mouse retina, melanopsin-immunopositive dendrites are postsynaptic to both amacrine and bipolar cell terminals. The functional roles of these synaptic inputs have been best characterized in the primate and rat ipRGCs.

In primate ipRGCs, light stimulation evokes both a slower melanopsin-based response and a faster synaptically driven response that is mediated mainly by rods in dim light and by cones under light-adapted conditions. The rod-driven responses are depolarizing and fairly sustained, reflecting the relatively limited capacity of the rod photoreceptors to light adapt. These depolarizing rod-driven light responses are observed not only in ipRGCs with dendrites terminating in the 'on' sublamina of the inner plexiform layer but also in those with dendrites stratifying in the 'off' sublamina, suggesting that ipRGCs may receive unconventional 'on' bipolar cell input in the 'off' sublamina. By contrast, the cone-driven responses adapt rapidly, and the polarity of these responses is wavelength dependent: Stimuli selective for the short-wavelength (i.e., 'blue') cones elicit hyperpolarization, whereas longer wavelengths evoke depolarization. As the ipRGCs in primates project to the dorsal lateral geniculate nucleus, such color-opponent responses might lead to conscious color perception, although their relevance to non-image-forming vision remains to be determined.

The pharmacology of the synaptic inputs to ipRGCs has been studied in greater detail in rats. Rat ipRGCs receive both inhibitory GABAergic and excitatory glutamatergic inputs, presumably from amacrine and bipolar cells, respectively. These inputs are spontaneously active and can also be triggered by light. In ipRGCs, both amacrine cells and ON bipolar cells mediate light-evoked responses at light onset, although at the resting membrane potential, the ON bipolar cell input dominates, resulting in depolarizing

responses. In most ipRGCs, OFF bipolar cells also trigger a depolarization at light offset, although this OFF response is always smaller than the ON bipolar cell-driven ON response, suggesting that rat ipRGCs receive stronger synaptic input from the ON bipolar cells than from the OFF bipolar cells. This is surprising because the dendrites of rat ipRGCs terminate mainly in the 'off' sublamina of the inner plexiform layer. When most excitatory and inhibitory inputs are blocked pharmacologically, the intrinsic light response of ipRGCs increases in amplitude, suggesting that these synaptic inputs serve in part to modulate the gain of the intrinsic light response.

Besides generating light-evoked responses in ipRGCs and acutely modulating the melanopsin photoresponse, synaptic inputs have also been shown to induce longer term biochemical changes in rat mRGCs. Dopaminergic amacrine cells have been found to be presynaptic to some mRGCs, and pharmacological activation of the D2 class dopamine receptors upregulates the mRNA levels of both melanopsin and pituitary adenylate cyclase-activating peptide, one of the transmitters released by ipRGCs onto postsynaptic cells in the SCN. Since dopamine is released from the dopaminergic amacrine cells upon light exposure, its effect on melanopsin expression might allow ambient light to modulate the sensitivity of the melanopsin phototransduction cascade.

Evidence for Intraretinal Output from ipRGCs

There is preliminary evidence that ipRGCs can exert synaptic influences on rod/cone circuits within the retina. The first line of evidence has come from measurements of the electroretinogram b-wave, a retinal field potential that reflects ON bipolar cell light responses. The latency of the b-wave in the human electroretinogram is longer at night than during the day. Exposure to prolonged light stimulation at night can shorten the nocturnal b-wave latency through an intraretinal mechanism that appears to be mediated by ipRGCs because it is relatively insensitive and has a λ_{max} of approximately 480 nm. Furthermore, in mice, the amplitude and latency of the b-wave exhibit diurnal rhythms that are much more pronounced in wild-type mice than in melanopsin knockout animals, suggesting the involvement of ipRGCs in the generation of these rhythms. The second line of evidence has been obtained by analyzing light induction of c-fos expression in rodless–coneless mouse retinas. Light induces c-fos expression in neurons in both the inner nuclear layer and the ganglion cell layer, and the total number of these cells is several times greater than the number of mRGCs, suggesting that ipRGCs can signal to other retinal neurons. Finally, prolonged illumination has been shown to induce the release of dopamine in rat retinas in which nearly all of the rod/cone photoreceptors have degenerated, suggesting that the dopaminergic amacrine cells can receive light signals from ipRGCs.

The precise mechanism(s) through which ipRGCs can influence other retinal cells remains unknown. In general, RGCs are considered the output neurons of the retina and have not been shown to be presynaptic in mammalian retinas. It has been proposed that ipRGCs form gap junctions with other cells in the ganglion cell layer, and that some of these coupled cells are amacrine cells capable of modulating retinal functions through the release of neuromodulators.

Nonphotoreceptor Photoreception in Nonmammalian Retinas

Much less is known about non-rod/cone photoreception in nonmammalian vertebrate retinas. Melanopsin is expressed in some horizontal, bipolar, and ganglion cells in chicken, a few horizontal and amacrine and/or ganglion cells in cod and roach, and in some horizontal cells in frog. In addition, two other non-rod/non-cone opsins, the vertebrate ancient (VA) and the VA-long opsins, are expressed in a subset of horizontal cells in roach and zebrafish, respectively. The functional roles of these opsins are unknown. Some chicken RGCs appear to be intrinsically photosensitive because light has been shown to inhibit melatonin synthesis in some isolated RGCs, although it remains to be determined whether such an effect is mediated by melanopsin. Melanopsin and/or VA opsin has been proposed to generate a novel, delayed depolarizing light response in approximately 0.5% of the roach horizontal cells. However, this response is abolished when synaptic transmission is blocked pharmacologically, inconsistent with it being initiated within these cells.

Non-Primate Models of Normal Brain Aging

C T Siwak-Tapp and P D Tapp, University of California at Irvine, Irvine, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

An important goal of aging research is the preservation of cognitive function with age, which is becoming more critical as the proportion of aged people continues to rise. Despite successful modeling of numerous specific features of aging, no single animal model fully replicates all aspects of human aging. It is thus necessary to continue developing new models to explore the unique aspects of each known model and combine information from convergent studies. The most commonly used animal models of human brain aging have employed rats, transgenic mice, and nonhuman primates. Companion animals, such as the dog and cat, are now living longer due to advances in animal health care. Consequently, age-related cognitive and behavioral changes comparable to those in humans are now being observed in dogs and cats. The work described herein assesses normal brain aging in other mammalian species, with our primary focus on the dog and cat.

Brain Aging in the Dog

Veterinarians have long been aware of geriatric behavior problems in pet dogs. The field of veterinary behavioral medicine has introduced the term 'canine cognitive dysfunction' to describe age-related behavioral changes not attributable to a medical condition in dogs. Canine cognitive dysfunction is a progressive neurodegenerative disorder of senior dogs characterized by a gradual decline in a variety of behaviors over a long period of time. Five general categories of behavioral changes have been defined: (1) signs of disorientation, that is, becoming trapped in corners or behind furniture; (2) signs of decreased social interactions with family members or changes in recognition; (3) disturbances in the sleep–wake cycle, such as increased daytime sleeping and less nighttime sleeping; (4) loss of house-training; and (5) decreased activity. These behaviors involve learning and memory processes, and changes in such behaviors are used as indicators of cognitive dysfunction.

Evaluation of these behaviors is usually achieved by owners completing a checklist of noticeable changes in their dogs' behavior. These behavioral signs are observed in dogs that were normal when younger; over 60% of owners with dogs aged 11 years and older report one or more behavioral changes consistent with cognitive dysfunction, after other medical conditions have been eliminated. The prevalence of canine cognitive dysfunction increases from 32% of 11-year-old dogs to 100% of 16-year-old dogs. No sex differences have been reported.

Cognition and Behavior in the Aging Dog

The measurement of cognitive functions in the aging beagle dog using neuropsychological tests has been the focus of a series of laboratory studies for more than 15 years. Like humans, cognitive aging in the dog is not a uniform process and individual differences become more common with age. Some cognitive processes remain intact with age while others deteriorate, each at different rates. Additionally, learning and memory impairments can occur independently of one another. Cognitive decline is not, however, an inevitable consequence of aging, as some old dogs perform just as well as young dogs on some tasks. Others show a mild impairment or become severely impaired. This section will discuss the cognitive and behavioral changes that occur with age in dogs.

Age-related learning impairments in dogs In order to administer neuropsychological tests, the dogs must first learn how to perform the procedures. Learning is the process of acquiring knowledge or skills through study or experience and generally becomes more difficult with age. Procedural learning is the acquisition of new skills. The procedural learning task for the dog is designed to teach the animal the skills necessary to perform in the testing apparatus, a modified version of the Wisconsin General Test Apparatus (Figure 1) used for nonhuman primates, and consists of reward–approach and object–approach learning. Dogs learn that there is a food reward, that they can approach the food, and that they must move objects to obtain the food. The procedural learning performance of aged dogs varies with previous life experience. Old dogs raised as companion animals learn these procedures as quickly as do young dogs raised in the same way. Aged dogs raised in a kennel setting, however, are slower to acquire these tasks compared to young kennel-reared animals. This simple task reveals the importance of the rearing environment and previous experience in assessing cognitive ability in aged animals.

In a discrimination learning paradigm, used to assess associative learning, the animal must learn to associate a specific object or set of object characteristics with a food reward. Simple discrimination learning tasks, such as an object discrimination

Figure 1 Toronto general test apparatus used to collect cognitive data in dogs. Objects and food rewards are placed on a sliding tray (a) and presented to the animal by lifting a door (b). Adjustable gates (c) allow animals to make responses, which are observed through a one-way mirror (c). An example of the setup for a size discrimination task is shown (e).

whereby two different objects must be compared, are easily acquired by dogs and are not sensitive to age. Increasing the complexity of discrimination problems, however, makes these tasks more sensitive to age differences. For example, the size discrimination task uses two blocks that are identical in all attributes (e.g., color, shape, texture) except size – one is taller than the other. Old dogs are slower to learn this task and make more errors relative to young dogs. A second way to increase task complexity is to increase the number of choices available. The oddity discrimination task uses three objects, two that are identical and a third that has different physical attributes. On this task, the animal must learn to choose the odd object to receive a food reward. Aged dogs are slower to learn this task compared to young dogs. Further testing using objects that appear more and more similar exacerbates the age-related impairment.

Discrimination learning tasks are often followed by reversal learning tasks, whereby the reward contingencies of the objects are switched such that the previously correct object now becomes incorrect. Reversal learning tasks are age sensitive and are often used as measures of executive functions. This will be discussed in further detail in the section titled 'Executive functions in dogs.'

Object recognition learning is more difficult than discrimination learning because correct responses are based on rule learning and not just an association between an object and reward. Object recognition learning involves identifying a previously viewed object. In the delayed-non-matching-to-sample (DNMS) task, dogs are first shown a single object covering a food reward and are allowed to respond and obtain the food. After a delay period, two objects are presented – the original object and a novel object. Each trial of the task uses random sets of objects drawn from a large assortment. The dog must learn the rule of selecting the nonmatching object in the second presentation. The object recognition learning task is very difficult for dogs to acquire. Most young dogs are able to learn the task, but only some aged dogs are successful. The aged dogs that successfully learn the DNMS task perform more poorly relative to the young dogs.

The delayed-non-matching-to-position (DNMP) task is another rule-based learning task that assesses egocentric spatial learning – the ability to locate objects in space with reference to one's own body position. The simple version of the DNMP task is the two-choice (2c) DNMP. In this task, the dog is presented with a single object over one of two lateral food wells. After a delay period, a second identical object is presented over the remaining lateral food well along with the first object still in the same location. The dog must learn to choose the object in the novel location. All young dogs and some old dogs

acquire this task, but a subset of aged dogs will show impairments in spatial learning and perform significantly more poorly. The complex version of the DNMP uses a three-choice (3c) paradigm. In the 3cDNMP, three locations are used (two lateral and one middle well). This version of the task is much more difficult for dogs to learn. Compared to the 2cDNMP, which all young dogs learn, 12% of young dogs are unable to solve the 3cDNMP problem. Similarly, only 18% of aged dogs fail the 2cDNMP but 83% are unable to learn the more complex 3cDNMP task.

The landmark task is another rule-based spatial learning task, but unlike the 2c- and 3cDNMP tasks, the landmark task measures allocentric spatial learning – the ability to locate objects in space with reference to another object or landmark. In the landmark task, dogs are rewarded for selecting the one object, of two objects, that is closest to an external landmark or referent. Thus, information about the correct response is only provided by the landmark. Like the egocentric spatial learning tasks, performance on the landmark discrimination task declines with age in dogs.

Age-related memory impairments in dogs An important observation in the canine model of cognitive aging is that learning and memory are differentially impaired with age. Some aged dogs that successfully learn a task may exhibit memory impairments. Two protocols used to examine memory function in the dog are the variable delay and maximal memory paradigms. Both protocols have been applied to the DNMP and DNMS tasks.

In the variable delay paradigm, the duration between the sample presentation and the matching phase of the task is varied between 20, 70, and 110 s. Each delay occurs an equal number of times per 12-trial session. Increasing the time between the sample and match presentation of a trial increases the demands placed on memory. On both the DNMP and the DNMS tasks, accuracy declines as the length of delay increases in both young and old dogs. The decline represents a working memory impairment since the animal successfully learned the task but has difficulty retaining the information over longer delay periods. Aged dogs perform more poorly than young dogs do at all delays.

The maximal memory paradigm uses a progressively increasing delay period until a preset number of sessions is reached. On the 2cDNMP, young dogs perform accurately at delays of over 210 s while old dogs only reach 30–50 s, indicating they have more difficulty retaining the spatial information as long as young dogs do. With the more difficult 3cDNMP, young dogs usually only reach 110 s and old dogs often fail to complete delay intervals longer than 5 s. Results from the maximal memory paradigm demonstrate that old dogs can acquire spatial information but are unable to retain information in memory for long periods of time. The age differences are more apparent on the DNMS task, in which young dogs respond accurately up to delays of 300 s.

Executive functions in dogs Executive functions describe a set of cognitive abilities that control and regulate other abilities and behaviors. These higher order cognitive processes include inhibitory control, concept abstraction, set shifting, set maintenance, and manipulation. Executive functions can be difficult to assess directly, and many of the tasks used to measure other abilities can be modified to evaluate executive functions.

Discrimination reversal tasks are often used to obtain measures of inhibitory control. Inhibitory control is the ability to inhibit interfering information or previously activated cognitive processes in order to focus attention on the relevant task requirements. On reversal tasks, animals must inhibit the previously correct response to learn a new stimulus–reward relationship using the same objects. In the dog, two important findings are reported on reversal tasks. First, aged dogs are much slower to acquire an object discrimination reversal and a size discrimination reversal compared to young dogs. Second, analysis of the types of errors made on the size discrimination reversal task indicates that the cause of reversal learning impairments changes with age. In old dogs (8–11 years old), reversal learning impairments are caused by an inability to learn the new stimulus–reward contingency. In senior dogs (over 11 years old), reversal deficits are caused by both an inability to learn new reward contingencies and an inability to inhibit a previous response. The perseverative responses observed in senior dogs suggest a deficit in inhibitory control, an executive function.

Another executive function impaired with age in the dog is the manipulation component of working memory. Maintenance involves actively holding information in working memory, while manipulation occurs when additional reorganization or updating of this information is required, an executive function. Tasks that require the manipulation of information held in working memory place greater demands on the cognitive process of working memory. The DNMP and DNMS tasks discussed earlier are tests of working memory performance. The previous protocols described varied the demands on working memory through the time required to hold the information in memory. A second way to change working memory demands is to increase the amount of information to

be retained. The spatial list learning (SLL) task assesses the manipulation component of working memory in dogs.

In the SLL task, dogs are presented with a single red disk randomly located over one of three food wells during the first phase of a trial. After a response is made, a brief delay interval occurs, followed by the second phase of the trial in which two identical red disks are presented, one in the original location and a second in one of the two remaining spatial locations. Only responses to the novel location are rewarded on the second phase, and this component forces the dog to update or manipulate the information held in working memory. After a second delay period, the third phase of the task occurs in which the dog is presented with three identical red disks, two in the familiar locations and a third in the final novel location. Only responses to the novel location are rewarded. Locations of each object are randomized across trials.

Young and aged dogs successfully learn the task but old dogs perform significantly worse than young dogs do. Old dogs take longer to acquire the task and are unable to perform at delays longer than 10 s. Even old dogs that perform well on the 3cDNMP are unable to complete the SLL task. Modified versions of the SLL which place even greater demands on working memory manipulation exacerbate age differences between young and old dogs. Together, the results suggest that age-related impairments on the SLL reflect deficits in manipulation rather than maintenance, since many of the old dogs tested on the SLL task had performed the 3cDNMP with high accuracy. Thus executive processes associated with the manipulation of information in working memory can decline even if the ability to hold information in working memory does not.

Concept learning, the ability to categorize or sort objects based on a particular dimension, is also impaired with age in the dog. In the dog, the size concept task was developed to assess concept learning. On this task, dogs are trained on a series of 2c and 3c size discrimination tasks, using various combinations of the same set of four blocks to teach the animals that size is the feature of interest. Following this training, novel stimuli differing only in size are presented to determine if the dogs learn that size could be used conceptually to solve the new tasks. In tests of size concept learning, young dogs successfully transfer the concept of size to new tests. Older dogs are unable to solve the concept tests, suggesting that dogs are capable of learning conceptual dimensions but the ability declines significantly with age.

Age-related changes in noncognitive behaviors in dogs Changes in noncognitive behaviors with age are another manifestation of the underlying brain pathology that contributes to cognitive dysfunction. Many of the noncognitive changes observed in aging dogs correlate with cognitive status. Locomotor activity, for example, decreases with age in dogs, but this decrease depends upon several factors, including the testing situation, cognitive status, and life experience. Aged dogs raised in a kennel or laboratory-type setting do not show a decrease in locomotor activity in a novel testing environment, such as an open field arena, while pet dogs show a decrease in open field activity with age. In a home area test, however, kennel/laboratory-reared dogs show declines in locomotor activity with age. This suggests that the open field and home area tests are measuring different aspects of locomotor activity. The open field test occurs in a novel setting and locomotor responses may reflect behavioral reactivity rather than spontaneous motor activity. Moreover, aged dogs that are cognitively impaired are also hyperactive in both the novel and the familiar test situation, compared to aged unimpaired dogs. Laboratory/kennel-reared dogs are also more active compared to pet raised or companion animals. Thus, environmental enrichment over the life of a dog may interact with genetic factors and contribute to the extent of locomotor decline and cognitive dysfunction.

Locomotor activity in laboratory dogs follows a circadian activity–rest pattern whereby locomotor activity is high during the day and low at night. This circadian pattern of locomotor activity also varies as a function of age, housing environment, and cognitive status. In young dogs, activity levels are higher for a longer period of time during the day compared to older dogs. In an indoor housing area, aged dogs display shorter bouts of activity during the day, more frequent rest periods, and take longer to become active once the lights are turned on compared to young dogs. These age-related differences are not observed in dogs housed in an outdoor area, suggesting that bright sunlight is effective in synchronizing and consolidating the activity rhythm. Cognitively impaired aged dogs are hyperactive and show fewer periods of rest during the day compared to old unimpaired dogs.

In addition to locomotor activity, we adapted a series of behavioral tests to assess social and exploratory behaviors in the aging dog. These tests are modified versions of the open field test whereby specific social or exploratory stimuli are placed in the arena and the response of the dog is recorded. The expression of social and exploratory behaviors in dogs varies with age and cognitive status. In response to the presence of a person sitting in the open field arena, young dogs display active social responses, including initiating physical contact, climbing, sniffing, and licking. Age-unimpaired dogs are more passive and tend to sit or lay quietly beside the person.

The overall amount of time engaged in the social behaviors does not differ with age; only the types of behaviors show an age-related difference. Cognitively impaired dogs exhibit very little interest in the person in the room and do not engage in social behaviors.

We further measured reactions to conspecifics to assess how social responses within the species may change with age. Three different stimuli were used: a cardboard silhouette of a dog, a sandcast life-size model of a dog, and a mirror. In these tests, dogs treat the cardboard silhouette like a real dog by directing their sniffing to the face and anal regions, locations that are normally investigated when live dogs interact. Young and age-unimpaired dogs habituate rapidly to the silhouette, but cognitively impaired aged dogs spend significantly more time sniffing the cardboard figure. This could reflect a deficit in habituation or stimulus recognition. To make the conspecific more realistic, we used a life-size sandcast model of a golden retriever. Young dogs spend more time sniffing and attempting to interact with the model dog compared to old dogs. Old unimpaired and impaired dogs do not differ in the amount of time spent sniffing the model dog. To make the conspecific more interactive, we also assessed the reaction of the dogs to a mirror reflection of themselves. Reactions to the reflection in the mirror depend on the dogs' ability to recognize their own species. The reactions of the dogs toward the mirror reflection are initially other-directed, treating the reflection like another dog. Responses include jumping at, barking at, and trying to play with the dog in the mirror, as well as attempts to look behind the mirror to find the other dog. Unimpaired old and young dogs habituate to the reflected image rapidly. Old impaired dogs, however, spend significantly more time reacting to the reflection in the mirror, perhaps reflecting a deficit in habituation or stimulus recognition.

Exploratory behavior, or curiosity, is another non-cognitive behavior that changes with age. To assess changes in exploratory behavior in aging dogs, we placed several novel commercially available dog toys in a large test room and measured the amount of time the dogs spent exploring the unfamiliar objects. Results from this test show that young dogs spend more time playing with and sniffing toys than does either of two groups of old dogs. Old-unimpaired dogs show reactions similar to those of young dogs but spend less time exploring objects. Old-impaired dogs generally avoid the toys and express no interest in investigating the objects.

Neuropathology

The aforementioned cognitive and behavioral measures are often combined with analyses of neuropathology to determine whether brain pathology is linked to the age-related changes observed. β-Amyloid deposition and neurofibrillary tangle formation are thought to be related to the cognitive and behavioral decline that typically occurs during aging and have received the most investigation in the dog.

β-Amyloid deposition The dog brain is very well suited for studying early stages of β-amyloid deposition in the aging brain. The earliest and most consistent distribution of β-amyloid (Aβ) plaques in the dog occurs in the prefrontal cortex starting around 8 years of age. By 14 years of age, the entorhinal and parietal cortices are also affected but the cerebellum remains relatively clear. Dogs accumulate the longer, more toxic, less soluble form of Aβ_{1-42} prior to the shorter more soluble Aβ_{1-40} type. Plaque morphology in the dog is generally diffuse and deposits are thioflavine-S negative, suggesting a lack of β-pleated sheet formation. We have found a strong correlation between β-amyloid deposition and cognitive decline in aged dogs.

Tau phosphorylation In contrast to aging humans, dogs do not develop neurofibrillary tangles in the brain but do show early stages of tangle formation characterized by tau phosphorylation and an intracellular punctuate distribution. Hyperphosphorylated tau has been observed in select neuronal populations in older dogs. The absence of neurofibrillary tangles in the dog brain could indicate that the tau protein in the dog is different from the human tau protein. The implication of this finding is that β-amyloid and not tau pathology may be sufficient to lead to cognitive and behavioral dysfunction in the aging dog.

Neuron loss and function Several studies have reported changes related to neuronal integrity with age in the dog. Age-related loss of neurons in the canine brain has been reported in the cingulate gyrus, superior colliculus, and claustrum. Selective neuron loss has also been observed in the prefrontal, temporal, and occipital cortex as well as in the hilus of the hippocampus of aged dogs.

Neurons in the prefrontal cortex of the aged dog brain show other morphological hallmarks of dysfunction, including distorted soma, loss of dendritic spines, shrinkage of dendritic branches, and tortuous apical dendrites. The presence of DNA damage and apoptosis is an additional indicator of neuron dysfunction. In dogs, the number of neurons with damaged DNA increases with age and is positively correlated with β-amyloid load in the frontal cortex.

Oxidative damage Oxidative damage to lipids and proteins in the brain is a common hallmark of aging and may compromise neuron function. In aging dogs,

malondialdehyde levels, a marker of lipid peroxidation, increase with age in the prefrontal cortex and blood serum in the dog starting around 8 years of age. Glutamine synthetase activity, an endogenous antioxidant that protects against oxidative damage, decreases with age in the prefrontal cortex. These age-related changes in oxidative damage are concomitant with increased β-amyloid deposition in the prefrontal cortex.

A role of oxidative damage in age-related cognitive dysfunction was demonstrated in a longitudinal study in dogs. Cognitive function was significantly improved and maintained in aged dogs fed a food fortified with antioxidants and mitochondrial cofactors for almost 3 years, compared to aged dogs given a control food. The fortified food contained higher amounts of vitamin E, vitamin C, *l*-carnitine, and *dl*-lipoic acid as well as a 1% inclusion of spinach flakes, tomato pomace, grape pomace, carrot granules, and citrus pulp. In addition to improving cognition and behavior, the fortified food also led to a reduction in β-amyloid deposition in some brain regions in the aged dogs. This suggests that oxidative damage is an important contributor to cognitive dysfunction and neuropathology in normal aging, and dietary interventions may significantly reduce these events.

Neuroanatomy and Hemodynamics

Noninvasive brain imaging technology permits analyses of metabolic, vascular, and structural changes associated with brain aging. Two common methods available to evaluate volumetric changes in the brain include region-of-interest (ROI) planimetry and voxel-based morphometry (VBM) using brain images acquired from magnetic resonance imaging (MRI). ROI planimetry involves manually tracing the particular brain region of interest on several consecutive images to obtain an estimate of total volume of that region. Studies using ROI planimetry reveal that global cortical atrophy and ventricular enlargement are characteristic features of the aged dog brain. Further analysis shows that the total volume of the brain, and in particular the volume of the frontal lobes and hippocampus, will decrease with age. The volume of the occipital cortex does not change with age. Moreover, these age-related decreases in frontal lobe volume correlate with increased β-amyloid deposition and measures of executive functions.

By contrast, VBM is an automated technique that performs a voxel-by-voxel comparison of local densities of gray and white matter on the brain images. In the dog brain, VBM analysis has revealed gray matter reductions bilaterally in the frontal lobes, parietal lobes, temporal lobes, thalamus, cerebellum, and brain stem. Many of the differences in structural brain aging are sexually dimorphic. In particular, aged male dogs showed a greater reduction in the frontal lobes while changes in the temporal lobes were more apparent in females. White-matter reductions with age were observed in the internal capsula and cranial nerve bundles of aged male dogs and the alveus of the hippocampus in aged females. The additional information provided by the VBM analysis suggests that brain aging in the dog varies regionally and is sex dependent.

MRI can also be used to monitor longitudinal changes in the aging dog brain using serial MRI techniques to coregister images from different time points. With this technique, we have found that dogs spontaneously develop lesions, resembling small lacunes, with age. The majority of lesions in the aged dog brain form in the frontal cortex and caudate nucleus.

A technique called dynamic susceptibility contrast (DSC)-enhanced MRI can be used to study vascular characteristics under the same conditions as anatomical MRI scans. Administration of contrast agents during DSC-MRI procedures permits kinetic modeling to obtain measures of vascular volume and permeability. In the dog, DSC-MRI revealed a decline in regional cerebral blood volume (rCBV) with age in the gray- and white-matter regions. These changes were greater in the white matter compared to the gray matter, even though gray-matter rCBV was consistently higher relative to white-matter rCBV. The decreased rCBV and increased blood–brain barrier permeability developed in tandem with cortical atrophy in this study.

Brain Aging in the Cat

Cognition and Behavior

Many of the behavioral changes typical of cognitive dysfunction in dogs also occur in elderly cats, but the age of onset may be later in cats. Information on behavioral changes with age in cats comes largely from observations in veterinary practice. Behavioral changes observed in aged cats that are consistent with feline cognitive dysfunction include signs of wandering, confusion, excessive vocalization, decreased grooming, lethargy, decreased awareness, greater time sleeping or other disruptions in the sleep/wake cycle, inappropriate elimination or loss of house-training, increased displays of affection or other alterations in social interactions, decreased recognition of owners, and increased anxiety. Estimates of prevalence suggest that 35% of aged cats, once those with possible underlying medical causes were removed, have clinical signs related to cognitive dysfunction. In cats 11–15 years old, the most common change was in social interactions, while changes in cats over 15 years of age primarily

affected activity and vocalization. Laboratory studies of cats have reported altered patterns of habituation, increased reactivity to auditory stimuli, and superior performance on spatial reversal learning tests with increasing age. No decrements in fine motor coordination were observed and locomotor activity levels did not change with age.

Neuropathology

Studies of brain pathology in cats indicate that cats develop β-amyloid and tau abnormalities. In aged cats, the β-amyloid plaques are of the diffuse variety and are localized in the prefrontal cortex, hippocampus, parahippocampal gyrus, occipital cortex, and parietal cortex. The diffuse plaques contain predominantly the $A\beta_{1-42}$ species, consistent with findings in dog and human brain tissue, but the morphology of the diffuse plaques in cat brain is different than what is usually observed in the human brain.

Hyperphosphorylated tau is also present in the aged cat brain. The pattern is consistent with that in the human brain, including area CA1 of the hippocampus, subiculum, and entorhinal/parahippocampal cortex. Aged cats with clinical signs of cognitive dysfunction are frequently positive for dystrophic neurites, but not all exhibit phosphorylated tau accumulation within neuronal cell bodies.

Brain Aging in Other Mammals

The dog and cat are more widely studied than are other mammals, likely due to the prevalence of these animals as pets. Some isolated studies exist that have examined brain aging in other animals, and are described in the following sections.

Rabbit

Eyeblink classical conditioning (EBCC) in older rabbits is used as a model system for studying the neurobiology of learning, memory, and the aging brain. Age-related impairments in EBCC occur relatively early in aging in both rabbits and humans. EBCC is also sensitive for identifying patients with Alzheimer's disease and is abnormal in Down's syndrome individuals over 35 years of age.

Investigation into the aged rabbit brain shows cell loss and gliosis in the cerebellum and hippocampus but no evidence of β-amyloid deposits or abnormal tau accumulations, even in rabbits over 7 years of age. Manipulating dietary cholesterol, however, induces neuronal accumulation of β-amyloid in New Zealand white rabbits, and this increases when copper is administered in the drinking water. Thioflavine-S-reactive features are also observed in animals supplemented with copper. Emerging evidence implicates cholesterol in the production and accumulation of β-amyloid by the 'mismetabolism' of the amyloid precursor protein. This mismetabolism causes the 42-amino-acid form of β-amyloid to form oligomers that, in turn, start a chain of events leading to the accumulation of amyloid plaques. Thus, the rabbit may be a valuable model to study initiating factors and perhaps the role of cholesterol in the deposition of β-amyloid.

Horse

Learning studies with horses are designed to provide a better understanding of trainability in this animal. Discrimination learning ability has been examined in horses using visual cues in a 3c test with food as the reward. In this study, quarter horses learned faster than thoroughbreds, and both groups learned a second discrimination task faster than the first task. In both tasks, however, there was a significant negative correlation between age and rate of learning. Separate neuropathological analysis of the brains of horses up to 27 years of age showed that all regions were devoid of hyperphosphorylated tau. No reports have been published to our knowledge about the existence of β-amyloid in the brains of horses.

β-Amyloid and Tau in Other Mammals

There are various reports of naturally occurring β-amyloid deposition or neurofibrillary tangle-like formations in several other mammals. β-Amyloid deposition has been reported in the brains of camels, coyotes, and polar bears. Tangle-like pathology has been observed in brains of sheep, goats, bears, wolverines, guanacos (similar to llamas), bison, and reindeer. To our knowledge there are no data available concerning behavioral changes with age in any of these animals.

Conclusion

Additional animal models for human brain aging have new insights to offer. A complete replication of human aging does not exist in a single animal system, but a more comprehensive picture emerges when information from several animal models is consolidated and integrated.

Introduction

From its humble beginnings, with biochemical analysis of adrenal glands and neurotransmitter release, we have come to realize that sympathetic neurotransmission is not quite as simple as first thought. We are taught that noradrenaline (norepinephrine) is the major neurotransmitter released from sympathetic nerves, and that with adrenaline (epinephrine), it is a key player in the 'fight-or-flight' response. Indeed, few people can escape the discussion of the 'adrenaline-high' associated with athletes and thrill-seekers alike, and few of us will avoid the use of drugs to alter sympathetic signaling for cardiovascular problems, anxiety or depression as we age. We might think that such an important and familiar neurotransmitter system would be well characterized, but it has not always been so. In the past, noradrenaline proved to be an elusive agent to identify when the concepts of 'neurochemical transmission' were being formed, and even today, there are a myriad of questions surrounding its co-storage, release, and postjunctional receptor mechanisms. Here, we give a brief overview of some of the facts, and unravel some of the mysteries of this celebrated molecule.

A Brief History of the Discovery of Noradrenaline

Galen (AD 130–200), arguably the greatest anatomist and physiologist of antiquity, first described the gross anatomical features of autonomic nerves. He suggested that, being hollow, they allowed the transfer of so-called 'animal spirits' between organs, producing the phenomena of 'sympathy', which was a vague term used to describe the coordination or cooperation of organs. However, the anatomical division of the parasympathetic and sympathetic nervous systems can be traced to Eustachius in the sixteenth century, who regarded the sympathetic and vagus nerves as separate, although describing incorrectly that the 'sympathetic nerve' was a continuation of the abducens (cranial nerve VI). Through the work of Winslow, Whytt, and Bichat two centuries later, an important outline of the sympathetic nervous system was laid out, with the visceral organs controlled by the ganglia, whereas voluntary action was concerned with the brain.

The first functional studies on true sympathetic nerves began with Bernard, who dilated vessels by sectioning the sympathetic nerves, and Brown-Séquard, who contracted the vessels by stimulating the cut end of the nerve. Irritation of various neuronal structures had been shown to increase the heart rate and its contractility; however, modern work on the autonomic nervous system and its functional divisions has been based largely on the work of Gaskell and Langley, who defined the essentials of the macroscopic functions of the sympathetic nervous system in the early to mid-1900s. Langley's student, Elliott, showed that adrenaline, discovered approximately 20 years earlier by Bates, had the same general effect as stimulation of the sympathetic nerves.

The chemical nature of sympathetic neurotransmission had been assumed by Elliott and Dale, who showed the sympathetic-like effects of ergot alkaloids, and when Loewi monumentally demonstrated the chemical nature of neurotransmission in a frog's heart, later found to be due to acetylcholine, it seemed that adrenaline would be an attractive candidate neurochemical in the sympathetic nervous system. The isolation of 'sympathin' from sympathetic nerves by Cannon revealed that adrenaline was similar to, but chemically distinct from, the neurotransmitter released, and its identity remained elusive until von Euler revealed that the true neurotransmitter was the non-methylated derivative of adrenaline, noradrenaline.

Structure and Biosynthesis of Noradrenaline

Noradrenaline, a catecholamine, is derived from L-tyrosine, an aromatic amino acid present in the body fluids and taken up by noradrenaline-producing cells. Through various intermediate steps (Figure 1), L-tyrosine is converted to noradrenaline and, finally, to its methylated form, adrenaline, in phenylethanolamine *N*-methyltransferase-containing cells. The first cytosolic enzyme, tyrosine hydroxylase, is inhibited by excess production of noradrenaline and is the rate-limiting step in the regulation of noradrenaline synthesis. Tyrosine hydroxylase is found only in the cytosol in catecholamine-containing cells and is used as a marker for detection of adrenergic neurons. Dopamine β-hydroxylase is also used as a selective marker for catecholamine-containing cells, but it is located in the secretory vesicles, usually membrane bound; however, a small amount is soluble and released with the vesicle contents upon exocytosis.

Figure 1 Biosynthetic pathway of noradrenaline and adrenaline.

Where Is Noradrenaline Found?

Noradrenaline is released with adrenaline into the blood from the medullae of the adrenal glands where it can act as a circulating hormone, but it is classically thought of as the main neurotransmitter released from postganglionic sympathetic neurons. Sympathetic fibers project to the heart and along blood vessels, controlling cardiovascular responses to maintain blood pressure, and, with the aid of circulating adrenaline, regulate bronchodilation, glycogen and fat metabolism, thermogenesis, and secretions of hormones and mucus membranes (Table 1). There are also large networks of noradrenergic and adrenergic neurons originating in or close to the locus coeruleus and reticular formation in the brain stem, extensively projecting to the cortex, hippocampus, and cerebellum, and these neurons are involved in baroreceptor and blood pressure reflexes, and also in complex behaviors such as arousal and mood. Many of these tissues are being used to study noradrenaline release and reuptake, but the vas deferens offers the ideal system in which to study sympathetic neuronal release due to its ease of isolation, dense sympathetic innervation, high noradrenaline content, and exquisite sensitivity to pharmacological manipulation.

It is perhaps useful at this stage to remind the nonspecialist reader of the anatomy of the autonomic nervous system. As shown by Langley, autonomic nerves typically have both a preganglionic nerve traveling from the central nervous system and a postganglionic nerve traveling to the effector organ. Parasympathetic fibers either arise from specific cranial nuclei and travel in the occulomotor (III), facial (VII), glossopharyngeal (IX), and vagus (X) cranial nerves or leave the spinal cord at sacral levels S2–S4 before synapsing close to the tissues in collections of cell bodies known as ganglia, and continuing by way of short postganglionic fibers to the effector cells. Sympathetic neurons, however, are generally characterized by short preganglionic fibers, exiting the spinal cord at thoracolumbar levels T1–L3, synapsing in the paravertebral chains, and continuing to the effector organs as long postganglionic fibers (possibly more than 1 m long).

The innervation of the rodent vas deferens, a well-characterized model system, is unusual in that it is supplied by short postganglionic sympathetic neurons whose cell bodies lie within the hypogastric ganglia situated close to the prostatic end. These postganglionic nerves are mainly nonmyelinated axons (0.2–2 μm in diameter) embedded in Schwann cells, together with a small number of fine myelinated fibers (1 or 2 μm in diameter), which travel through the connective tissue and divide into numerous branches as they enter the prostatic end. Traversing the connective sheath, branches pass into the smooth muscle layers, splitting into smaller bundles of two to eight axons, and become varicose. The varicosities, which are approximately 1 or 2 μm in length and 1–1.5 μm in cross section,

Table 1 Summary of major adrenoceptor signaling and some drugs that can affect it

Adrenoceptor subtype	α_1	α_2	β_1	β_2	β_3
Primary signal transduction	Stimulation of phospholipase C ($G_{q/11}$) ↑IP_3, ↑DAG, and ↑Ca^{2+}	Inhibition of adenylyl cyclase ($G_{i/0}$) ↓cAMP	Stimulation of adenylyl cyclase (G_s) ↑cAMP	Stimulation of adenylyl cyclase (G_s) ↑cAMP	Stimulation of adenylyl cyclase (G_s) ↑cAMP
Secondary signal transduction	Stimulation of phospholipase D	Stimulation of adenylyl cyclase[a]	Stimulation of guanylyl cyclase	Stimulation of guanylyl cyclase	Stimulation of guanylyl cyclase
Major physiological effects	• Vasoconstriction • Relaxation of gastrointestinal tract smooth muscle • Contraction of seminal tract and uterus • Contraction of iris radial muscle • Glycogenolysis in liver • K^+ release from salivary glands	• Vasoconstriction • Relaxation of gastrointestinal tract smooth muscle • Decreased release of acetylcholine and noradrenaline from autonomic nerve terminals • Decreased insulin release • Platelet aggregation • Inhibition of sympathetic outflow in brain stem	(Actions mainly on heart) • Positive inotropy • Positive chronotropy • Positive dromotropy • Amylase secretion from salivary glands • Renin release from juxtaglomerular cells of the kidney	• Vasodilation • Bronchodilation • Relaxation of gastrointestinal tract smooth muscle • Relaxation of seminal tract and uterus • Relaxation of ciliary muscle • Glycogenolysis in liver and skeletal muscle • Increased release of noradrenaline from nerve terminals	• Lipolysis and thermogenesis in adipose tissue • Thermogenesis in skeletal muscle
Selective agonists	Phenylephrine Cirazoline	Clonidine Medetomidine	Dobutamine Xamoterol	Salbutamol Salmeterol	BRL 37344 ZD 7114
Selective antagonists	Prazosin Doxazosin	Yohimbine Idazoxan	Atenolol Metoprolol	Butoxamine ICI 118,551	SR 59230A

[a]The role of stimulating adenylyl cyclase in addition to its inhibition by α_2-adrenoceptor activation in some systems remains unknown. For simplicity, subtypes of receptors are not shown. IP_3, inositol-1,4,5-trisphosphate; DAG, diacylglycerol; cAMP, 3′-5′-cyclic adenosine monophosphate.

are packed with vesicles and mitochondria and are separated by intervaricose regions approximately 3–5 μm in length. The diameter of the axon spanning the intervaricose regions is only 0.1 μm, and each axon gives rise to between 10 000 and 30 000 varicosities (Figure 2). The conduction velocity in these nerves is less than 1 m s^{-1}. In the vas deferens, the varicosities traverse the smooth muscle cells in complex patterns, such that at least one varicosity makes close contact (approximately 20–50 nm) with each smooth muscle cell, with the varicosities being the sites where noradrenaline is synthesized and released.

How Can Noradrenaline Release Be Measured?

Early electrophysiological investigations into sympathetic nerves relied on intracellular recording. Basing the technique on the Nobel prize-winning work of Hodgkin, Huxley, and Katz, the nerve cell bodies in ganglia were impaled using glass microelectrodes and electrical changes across the membrane were measured. As at the neuromuscular junction, electrical signals could be detected in the absence of stimulation (excitatory postsynaptic potentials in nerves and end plate potentials in the motor end plate), as could the resulting action potentials on stimulation. Although this method gave fascinating insights into the release of acetylcholine, the primary neurotransmitter at these synapses, it could not reveal anything about the terminal release of noradrenaline from the postganglionic nerve. Electrophysiological measurements from nerve terminal varicosities proved difficult due to their small size and the large microelectrode diameters; progress remained slow.

In an effort to study and localize noradrenaline, a number of methods have been employed, including high-performance liquid chromatography, overflow, radiolabeling, and voltametry techniques. These approaches all indicated a neuronal release of noradrenaline, the most abundant neurotransmitter in sympathetic neurons, and that noradrenaline was stored in the vesicles in preparation for exocytosis. However, fractional release studies showed that

Figure 2 (a) Schematic diagram of a postganglionic sympathetic neuron showing the difference in size between cell body, axon, and varicosity. (b) A set of axon bundles loaded with the Ca^{2+} indicator Oregon Green 488 BAPTA-1 dextran. Note that only a single axon is represented in the corresponding box in (a). (c) Image of part of a sympathetic terminal loaded with the Ca^{2+} indicator Oregon Green 488 BAPTA-1 dextran. there was a disparity between the amount of noradrenaline released and the noradrenaline content of a vesicle.

Although these methods did not have the temporal or spatial resolution at the time to investigate the release characteristics of noradrenaline from a single varicosity, biochemical analysis of these studies provided two radically different hypotheses to explain the mechanism of noradrenaline release from the 'average' varicosity.

First, the 'fractional release' model suggested that the action potential only released a small fraction of the contents of one vesicle (1–3%) from each varicosity every time the nerve was stimulated, similar to the modern 'kiss-and-run' mechanism observed at some synapses in the central nervous system. In this scenario, on average 30–100 action potentials are required to release the equivalent of the neurotransmitter content of one vesicle from each varicosity, and this would mean that there is a constant release of neurotransmitter during neuronal activity providing an average 'biophase' concentration which bathes the smooth muscle and maintains a tonic contraction. With the assumption that the average varicosity has 1000 vesicles, this would mean that only approximately 300–400 molecules of transmitter would be released with each action potential, which should nonetheless be sufficient to reach maximal concentrations for receptor activation in a close contact neuroeffector junction.

Today, many textbooks still favor this explanation (as did the early investigators) because it appears to be a more efficient and economical way of transmitter turnover to achieve a given effector response while at the same time reusing the vesicles and allowing for efficient noradrenaline reuptake (approximately 90%). However, this would mean that sympathetic nerves would not behave like all other nerves, where quantal transmission was accepted.

An equally radical hypothesis is the 'intermittent release' model, which suggested that each action potential activates only 1–3% of all varicosities in the

tissue. When the release machinery was activated, an individual varicosity discharged a single packet of neurotransmitter equivalent to the neurotransmitter content of a single vesicle. In this case, neurotransmitter release would be highly intermittent at the level of the individual varicosity. This would cause approximately 50-fold higher noradrenaline concentrations in the junction, giving a larger 'margin of safety' for transmission, but would demand extreme efficiency of the local noradrenaline reuptake mechanisms to clear noradrenaline and terminate the response before it diffused away.

If this theory were true, it would raise more questions about why and how a varicosity would 'decide' to release neurotransmitter or not. It was understandable that the investigators favored the previous explanation. If this controversy was to be settled, then techniques with better resolution needed to be developed.

What Can We Learn About Sympathetic Neurotransmitter Release from Electrophysiology?

Burnstock and Holman, working in Melbourne, Australia, used one of the most densely innervated sympathetic tissues in the body, the vas deferens, to study neurotransmitter release. Sympathetic nerves in the body typically have low-frequency firing rates, and unlike the overflow studies, which require high frequencies to cause measurable overflow of transmitter, electrophysiology allowed the measurement of release on an impulse-to-impulse basis. Using microelectrode techniques similar to those used in ganglia, they impaled smooth muscle cells of the guinea pig vas deferens and recorded resting membrane potentials. In response to sympathetic nerve stimulation, transient depolarizations were recorded, termed excitatory junction potentials (EJPs). EJPs had a fairly slow time course (0.5–1 s), were graded with stimulus intensity, and increased in amplitude in response to the first few stimuli in a train (i.e., they exhibited facilitation). Perhaps more important, in the absence of stimulation, spontaneous EJPs (SEJPs) were recorded, which were reminiscent of miniature end plate potentials (MEPPs) at the skeletal neuromuscular junction that had famously been used to describe the phenomena surrounding quantal neurotransmission. SEJPs implied that neurotransmitter was released in multimolecular packets; however, unlike MEPPs and end plate potentials in skeletal muscle, EJPs and SEJPs had different time courses and could not be compared directly. The time course differences were probably a reflection of the tight electrical coupling between smooth muscle cells of the vas deferens, which caused rapid dissipation of charge from the point source, and also that the EJP represented the sum of electrical activity at several simultaneous release sites being activated throughout the muscle. Taken together with the overflow studies, and the difficulty in interpreting the results for a single release site, the electrical signal seemed to support the fractional release model.

High-Resolution Studies of EJPs

As the fractional release model enjoyed prime status, new methods were devised to break down EJPs into their component parts. Blakeley and Cunnane noted discontinuities between the rising phases of individual EJPs in the mouse and guinea pig vas deferens, and, on electronically differentiating the rising phases, these discontinuities were extracted as transient peaks in the rate of depolarization of the EJP, termed 'discrete events' (Figure 3). On comparing discrete events generated from SEJPs and EJPs, it was found that they matched almost perfectly, suggesting that release was intermittent and monoquantal. Various groups quickly verified the data, and so the fractional release model was moved aside for the intermittent model. Perhaps, in hindsight, it should not have come as a surprise that sympathetic nerves behave like all other nerves in the body and exhibit quantal or packeted neurotransmission.

Figure 3 Intracellular recordings of the membrane potential and its time derivative in single smooth muscle cells of the guinea pig vas deferens. The preparation was stimulated at 0.91 Hz and the transient peaks in the rate of depolarization (the 'discrete event') occur intermittently, showing that action potential evoked neurotransmitter release is intermittent. Reproduced from Blakeley AG and Cunnane TC (1979) The packeted release of transmitter from the sympathetic nerves of the guinea-pig vas deferens: An electrophysiological study: *Journal of Physiology* 296: 85–96; and Jackson VM and Cunnane TC (2001) Neurotransmitter release mechanisms in sympathetic neurons: Past, present, and future perspectives. *Neurochemical Research* 26: 875–889, with permission from Springer Science and Business Media.

Mechanisms of Intermittence

Sympathetic nerves proved to be difficult to comprehend. If they only released once in every 100 stimuli or so, then how could we use them to study release? We need to understand some of the mechanisms behind intermittence before we can investigate noradrenaline release further. There were two suggestions put forward to explain intermittence:

- Intermittent failure of the action potential to propagate throughout the complex nerve terminal network of branching axons and varicosities
- A very low probability of neurotransmitter release in the invaded varicosities

To resolve this conflict, focal extracellular measurement was developed by Brock and Cunnane. By moving an electrode close to the tissue and applying gentle suction, a small area could be 'isolated' from the tissue and drugs applied either inside or outside the electrode, which was perfused with physiological solution. It allowed the simultaneous measurement of the nerve terminal impulse (NTI) and also neurotransmitter release – the excitatory junction current (EJC). In the absence of stimulation, spontaneous EJCs were recorded, and following electrical nerve stimulation it was found that the action potential (NTI) arrived each time, whereas neurotransmitter release was highly intermittent (Figure 4). Application of tetrodotoxin, an inhibitor of voltage-gated Na^+ channels, abolished the NTI and evoked neurotransmitter release, but did not abolish spontaneous EJCs. Intermittence of neurotransmitter release was concluded to be due to some failure in depolarization–secretion coupling after the sympathetic nerve terminal is invaded by the action potential rather than action potential propagation failure in the complex terminal arborization of varicosities.

One of the more interesting observations occurred when pharmacological agents were used to manipulate neurotransmission. Following blockade of α-adrenoceptors, the major type of receptors for noradrenaline in the vas deferens, there was an increase in the overflow of noradrenaline and also an increase in the electrical signals recorded with microelectrodes in the smooth muscle cells. It transpired that there were receptors located on nerve terminals, α_2-adrenoceptors, that were distinct from postjunctional adrenoceptors (mainly α_1-adrenoceptors) and limited the release of noradrenaline. This led to the novel concept of α_2-adrenoceptor-mediated inhibition of neurotransmitter release in the great majority of sympathetically innervated tissues and added a new dimension to our understanding of the control of sympathetic nerve function. Previously, the centrally determined patterns of nerve firing were primarily thought to control neurotransmitter release, but now it was shown that neurotransmitter release could be controlled locally due to feedback inhibition of the action of released noradrenaline at distinct receptors on nerve terminals producing a brake on further neurotransmitter release. There was no doubt intermittence could be regulated by this local inhibition at the level of the varicosity, and although this idea was largely born in the peripheral nervous system, it is generally accepted that presynaptic receptors exist at every synapse. Indeed, we now know that many nerves have both inhibitory and excitatory receptors located on their nerve terminals, such as the prejunctional excitatory nicotinic receptors and the prejunctional inhibitory muscarinic receptors at the neuromuscular junction, which can increase or decrease acetylcholine release, respectively.

Figure 4 Frequency-dependent facilitation of neurotransmitter release in the guinea pig vas deferens. Simultaneous measurement of the nerve terminal impulse (NTI) and evoked excitatory junctional currents (EJCs) using focal extracellular recordings showed that although the impulses travel through the varicosities every time, EJCs are intermittent. Each panel shows 25 stimuli at 1, 2, and 4 Hz in the top, middle, and bottom panels, respectively. Reproduced from Jackson VM and Cunnane TC (2001) Neurotransmitter release mechanisms in sympathetic neurons: Past, present, and future perspectives. *Neurochemical Research* 26: 875–889, with permission from Springer Science and Business Media.

The importance of increases in intracellular Ca^{2+} concentrations as the trigger for exocytosis is well-known, and so perhaps intermittence was due to the failure of most varicosities to undergo appropriate changes in Ca^{2+} levels. Developments in confocal microscopy and Ca^{2+} indicators mean that we can now finally resolve Ca^{2+} dynamics in intact tissue preparations. By loading the nerve terminals through the cut end of the vas deferens, it has been shown that Ca^{2+} enters all varicosities when the action potential arrives.

Figure 5 Discreet and intermittent smooth muscle Ca^{2+} transients following nerve stimulation. The first six frames show selected images of the same smooth muscle cell taken during 2 Hz stimulation. There is no response to most stimuli (frame 1), whereas some stimuli evoke focal Ca^{2+} transients in the smooth muscle cell (frames 2–6). The final frame was obtained from a confocal section 3 μm above that of the preceding images, and it shows an overlying nerve terminal varicosity. The white dots denote the location (epicenter) of a single smooth muscle Ca^{2+} transient occurring at some time during eight sets of recordings. Reproduced from Brain KL, Jackson VM, Trout SJ, and Cunnane TC (2002) Intermittent ATP release from nerve terminals elicits focal smooth muscle Ca^{2+} transients in mouse vas deferens. *Journal of Physiology* 541: 849–862.

Through Ca^{2+} studies on neurons, it was questioned whether it would be possible to resolve neurotransmitter release optically. Occasionally, for indeterminate reasons, some smooth muscle cells were loaded with the Ca^{2+} indicator, and distinct changes in Ca^{2+} were noted following nerve stimulation both in the varicosity and directly below in the smooth muscle cell. The focal changes in Ca^{2+} recorded in the smooth muscle cells were termed neuroeffector Ca^{2+} transients (NCTs) (Figure 5). By simultaneously monitoring both pre- and postjunctional responses evoked by low-frequency nerve stimulation with cell-permeant Ca^{2+} indicators, Brain, Jackson, and Cunnane found that these NCTs correlated well with action potential-evoked Ca^{2+} transients in varicosities and with the release probability of individual varicosities on the same axon. Surprisingly, they found that some varicosities had an apparent release probability as high as 0.09, but there was a population of varicosities that never released and remained 'silent.' Finally, there is an optical method that provides a unique approach to detect neurotransmitter release at the level of the individual sympathetic neuroeffector junction (i.e., single varicosities on the same nerve terminal branch) at an unparalleled resolution.

Currently, we still do not know the reason for intermittence. However, the ability to demonstrate neurotransmitter release at high resolution surely holds the key to unraveling the mechanisms underlying release modulation at individual varicosities on an impulse-to-impulse basis in an intact organ. Autoinhibition, variation in secretory proteins, and discrete changes in Ca^{2+} in different varicosities are among some of the current hypotheses undergoing evaluation, but we are now in a better position to study neurotransmitter release from these nerves. However, what is the neurotransmitter? Surely it is noradrenaline.

The Identity Revealed

Although there was broad agreement across all techniques that noradrenaline is released on an impulse-to-impulse basis from sympathetic nerves, there were a number of observations that did not fit the noradrenergic theory. For example, when the rodent vas deferens was depleted of noradrenaline using reserpine, which irreversibly interferes with the Mg^{2+}- and adenosine-5′-triphosphate (ATP)-dependent uptake of biogenic amines into vesicles and thereby depletes noradrenaline from nerves, electrophysiological methods showed that the EJPs were still present and often larger in amplitude. This was due to a prejunctional action rather than a postjunctional sensitization because the size of the SEJPs remained unchanged. Similarly, when yohimbine was applied to block prejunctional autoinhibitory α_2-adrenoceptors, EJPs were no longer potentiated. In other words, we have a tissue devoid of noradrenaline, but EJPs, the electrical sign of neurotransmitter release, are still present – a strange paradox.

Further investigation using selective antagonists led to the rather revolutionary concept of noradrenaline–ATP co-transmission. Imagine the controversy when Burnstock, Westfall, and others suggested that ATP, Krooll's 'universal currency of bioenergy,' could also be released from sympathetic nerves and that it was ATP, and not noradrenaline, that was responsible for the generation of the EJP. This was not so surprising in retrospect because Douglas and Poisner had shown that ATP was co-stored and co-released

with adrenaline and noradrenaline in the adrenal medulla approximately 20 years previously. Some people called purinergic transmission the 'pure imagination' hypothesis on account of its radical and unbelievable concepts, but it is now generally accepted that ATP is released from almost all nerves and acts as a separate neurotransmitter. Indeed, moving away from Dale's principle, which states that each neuron can only secrete one type of neurotransmitter, we now know that neurotransmitter release can differ at different synapses of the same cell, both in the class of neurotransmitter and also in the quantities of the cocktails of neurotransmitters released. Yet again, an idea born in the peripheral nervous system is now accepted widely throughout the central nervous system.

Work on purinergic transmission spawned the discovery of G-protein-coupled P2Y purinoceptors and of a unique class of ligand-gated ion channels, P2X receptors, which do not follow the structure of any other family of ligand-gated channels. After activation by extracellular ATP, through nonselective cation entry, P2X receptors are responsible for the EJP and SEJP because P2X receptor antagonists and desensitizers abolish both EJPs and SEJPs. NCTs are a measure of the Ca^{2+} flowing through the nonselective cation pore together with amplification from the release of Ca^{2+} from intracellular stores, and similarly, these drugs abolish NCTs in the vas deferens, blood vessels, and bladder. In the vas deferens, the purinoceptor subtype $P2X_1$ is particularly important because knockout mice that do not have $P2X_1$ receptor expression lack EJPs, SEJPs, NCTs, and spontaneous NCTs.

It would seem that the electrophysiological and confocal investigations have not been monitoring the effects of released noradrenaline but, rather, measuring how sympathetic nerves release ATP. However, if noradrenaline and ATP are co-stored in sympathetic nerve vesicles, as the biochemical analysis would suggest, then ATP release will also reflect how noradrenaline is being released assuming exocytosis of the entire neurotransmitter content of a vesicle. Indeed, research using amperometry, a direct measurement of the oxidation current of noradrenaline, has shown that noradrenaline can be released intermittently on an impulse-to-impulse basis (Figure 6). Finally, overflow studies, optical studies, and electrophysiological methods appear to be converging in order to explain sympathetic neurotransmitter release, be it ATP or noradrenaline.

The Elusive Nature of Noradrenaline – The Paradox

Noradrenaline produces its effects through G-protein-coupled receptors (Table 1) and its action is terminated by reuptake into the prejunctional neuronal (uptake 1; inhibited by cocaine, desipramine, amphetamines, and tricyclic antidepressants) and postjunctional non-neuronal (uptake 2; inhibited by corticosterone) cells. Reuptake results in either the metabolism of noradrenaline by monoamine oxidases and catechol-*O*-methyl transferases within a reaction pathway that finally produces vanillylmandelic acid or 3-methoxy,4-hydroxyphenylglycol, which are excreted in the urine, or the noradrenaline can be recycled and released again from the prejunctional nerve terminal. In the smooth muscle

Figure 6 Intermittent release of noradrenaline from rat tail artery revealed by continuous amperometry. Five stimuli per panel at 0.1 Hz. Reproduced from Jackson VM and Cunnane TC (2001) Neurotransmitter release mechanisms in sympathetic neurons: Past, present, and future perspectives. *Neurochemical Research* 26: 875–889, with permission from Springer Science and Business Media; and Reproduced from Msghina M, Gonon F, and Stjärne L (1993) Intermittent release of noradrenaline by single pulses and release during short trains at high frequencies from sympathetic nerves in rat tail artery. *Neuroscience* 57: 887–890, with permission from Elsevier.

of the vas deferens, noradrenaline mediates most of its effects through α_1-adrenoceptors, which activate phospholipase C, and with increases in inositol-1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG), respectively, lead to increases in intracellular Ca^{2+} and contraction and should be independent of an electrical change. Of course, there are exceptions to this rule, the most notable example being the rat anococcygeus, in which increases in intracellular Ca^{2+} result in an electrical depolarization by opening a Cl^- channel, but generally under low-frequency stimulations, most tissues show little or no electrical changes on α_1-adrenoceptor activation.

It would be expected that IP_3-generated Ca^{2+} waves would be detected using Ca^{2+}-imaging confocal microscopy. Indeed, slow propagating waves in small arteries following nerve stimulation can be attributed to α_1-adrenoceptor stimulation because they are blocked by prazosin, an α_1-adrenoceptor antagonist. Similarly, cholinergic stimulation in the bladder results in waves that are blocked by cyclopentolate, a muscarinic receptor antagonist, which are thought to be generated secondary to muscarinic receptor-induced IP_3 synthesis. Such waves rarely occur within the longitudinal layer of the vas deferens upon nerve stimulation, but they can be induced by applying exogenous noradrenaline. We therefore have a paradox: exogenously applied noradrenaline causes Ca^{2+} waves, whereas neuronally released noradrenaline does not readily produce waves, and yet both cause a contraction that is mediated by α_1-adrenoceptors. Once again, the remarkable sympathetic nervous system confronts us with a paradox.

The knockout mouse for $P2X_1$ purinoceptors provided the ideal opportunity to study noradrenergic transmission in isolation because $P2X_1$ receptor effects were lost, and one of the compensatory mechanisms for the purinergic 'shortfall' was the supersensitivity of the tissue to noradrenaline. Using higher frequency nerve stimulation, which is known to favor the noradrenergic component of release, even in the presence of both yohimbine, to antagonize autoinhibitory α_2-adrenoceptors to maximize noradrenaline release, and desipramine, to inhibit the reuptake of noradrenaline and maximize its concentration within the neuroeffector cleft, there were still few Ca^{2+} transients due to neuronal noradrenaline release. The preparations still responded well to exogenously added noradrenaline and appeared to have a larger contraction mediated by α_1-adrenoceptors to both neuronal and exogenous noradrenaline.

Perhaps neuronally released noradrenaline activates a different population of receptors compared to exogenously applied noradrenaline and these receptors have different pathways. Indeed, prazosin is a non-subtype selective α_1-adrenoceptor antagonist, with α_{1A}-adrenoceptors favoring the IP_3-mediated increase in intracellular Ca^{2+}, whereas α_{1B}- and α_{1D}-adrenoceptors may favor the DAG and protein kinase C pathways of contraction (which do not require such large increases in intracellular Ca^{2+}); this might explain the apparent differences due to prazosin's nonselectivity. Of course, there are crossovers between the phospholipase C (IP_3 and DAG) and D (DAG only) pathways because the receptors are promiscuous and activate many different intracellular signaling cascades, including the Rho-kinase pathway, which allows contraction without any concomitant increase in Ca^{2+} within smooth muscle cells. How these results can be explained and how the various pathways and cotransmitters interact remain under investigation. Noradrenaline and its effects remain elusive despite the current sophisticated investigative techniques.

Conclusion

We began with noradrenaline being the only neurotransmitter released from postganglionic sympathetic nerves, but investigations into the nature of neurotransmitter release have revealed major new insights into the mechanism by which sympathetic nerves function – intermittent neurotransmitter release, autoinhibition through prejunctional/presynaptic receptors, facilitation of release through prejunctional nicotinic receptors, cotransmission, and perhaps the most startling finding of all, that some varicosities do not release neurotransmitter at all. There is a rich diversity of pre- and postjunctional receptors and interactions that remain to be investigated, and we look forward to the advances that studying the sympathetic nervous system will bring. It is fair to say that in the twenty-first century we remain surprisingly ignorant of how nerves release neurotransmitters and the effects that noradrenaline and its cotransmitters have on the innervated organs.

Norepinephrine: Adrenergic Receptors

D B Bylund, University of Nebraska Medical Center, Omaha, NE, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Norepinephrine (also called noradrenaline) is a neurotransmitter in both the peripheral and central nervous systems. Norepinephrine produces many effects in the body, the most notable being those associated with the 'fight-or-flight' response to perceived danger. The effects of norepinephrine and a related catecholamine, epinephrine (also called adrenaline), are mediated by the family of adrenergic receptors. The chemical structure of norepinephrine, as shown in Figure 1, indicates that it is a catecholamine, because it has both the catechol moiety consisting of a benzene ring (green) with two hydroxyl groups (red) and an amine (blue).

Adrenergic receptors (also called adrenoceptors) are widely distributed throughout the body. There are three major adrenergic receptor types: alpha-1, alpha-2, and beta. Each of these three receptor types is further divided into three subtypes. Adrenergic receptors are seven transmembrane receptors which consist of a single polypeptide chain with seven hydrophobic regions that form alpha-helical structures that span or transverse the membrane. Because the mechanism of action of adrenergic receptors includes the activation of guanine nucleotide regulatory binding proteins (G-proteins), they are also called G-protein-coupled receptors.

Stimulation of adrenergic receptors by endogenous catecholamines released in response to activation of the sympathetic autonomic nervous system (as well as by exogenous drugs called adrenergic agonists) results in a variety of effects such as increased heart rate, regulation of vascular tone, and bronchodilatation. In the central nervous system (CNS), adrenergic receptors are involved in many functions including memory, learning, alertness, and the response to stress.

History

In the late 1940s, Ulf von Euler in Sweden and Holtz in Germany identified norepinephrine as the neurotransmitter of the mammalian sympathetic nerves and soon thereafter also found it to be a normal constituent of mammalian brain. Norepinephrine was subsequently shown to also be a central neurotransmitter and was visualized in the brain by fluorescent and immunohistochemical techniques.

Adrenergic receptors were originally divided into two major types, alpha and beta, based on their pharmacological characteristics (i.e., rank order potency of agonists). Subsequently, the beta adrenergic receptors were subdivided into beta-1 and beta-2 subtypes, and more recently a beta-3 subtype was defined. The alpha adrenergic receptors were first subdivided into postsynaptic (alpha-1) and presynaptic (alpha-2) subtypes. After it was realized that not all alpha receptors with alpha-2 pharmacological characteristics were presynaptic, the pharmacological definition was used. The current classification scheme is based on three major types: alpha-1, alpha-2, and beta. Each of these three receptor types is further divided into three subtypes as shown in Figure 2: alpha-1A, alpha-1B, alpha-1D; alpha-2A, alpha-2B, alpha-2C; and beta-1, beta-2, beta-3.

Although adrenergic receptors are found throughout the body in tissues innervated by both the peripheral and CNSs, a few locations are of special interest. Alpha-1 adrenergic receptors are found peripherally in some blood vessels, whereas alpha-2 receptors are located on platelets and on nerve terminals in both the peripheral and CNSs. In the heart, beta-1 receptors predominate, where as in the smooth muscles of the lungs, some blood vessels, and the uterus, beta-2 receptors are relatively abundant.

Neurochemistry of Norepinephrine

Biosynthesis of Norepinephrine

Norepinephrine is synthesized in neurons starting with the amino acid tyrosine, which is obtained from the diet and can also be synthesized from phenylalanine. Tyrosine is converted to dihydroxyphenylalanine (DOPA) by the enzyme tyrosine hydroxylase, which is the rate-limiting enzyme for norepinephrine biosynthesis. DOPA, in turn, is converted to dopamine in the cytoplasm. Dopamine, which is also a neurotransmitter, is taken up into vesicles and converted to norepinephrine by the enzyme dopamine beta-hydroxylase. In the adrenal medulla and in a few brain regions, norepinephrine is converted to epinephrine by the enzyme phenylethanolamine *N*-methyltransferase.

Storage, Release, Reuptake, and Metabolism of Norepinephrine

Norepinephrine is stored in vesicles (also called storage granules) in the nerve terminals, which concentrates it and protects it from metabolism, until it is released following nerve stimulation. The major mechanism by which the effects of norepinephrine

are terminated is reuptake back into the nerve terminal by a high-affinity transporter. Norepinephrine can also be metabolized to inactive products. Inhibition of either of these processes results in an increase in the synaptic level of norepinephrine and a prolongation of its effects.

The reuptake of norepinephrine is mediated by the norepinephrine transporter (NET). Approximately 80% to 90% of the norepinephrine released into many synapses is cleared by this mechanism. NET belongs to the protein superfamily defined as Na^+/Cl^--dependent transporters and has 12 putative transmembrane domains. Some inhibitors of NET are antidepressants and are used in the treatment of clinical depression and other affective disorders. They are also sometimes used to treat anxiety disorders, obsessive–compulsive disorder, attention-deficit/hyperactivity disorder (ADHD), and chronic neuropathic pain. Several classes of antidepressant drugs inhibit NET, including the tricyclic antidepressants (e.g., imipramine, desipramine, doxepin), serotonin-norepinephrine reuptake inhibitors (SNRIs; e.g., venlafaxine, duloxetine), and the norepinephrine reuptake inhibitors (e.g., atomoxetine, reboxetine).

Norepinephrine is metabolized by the enzymes monoamine oxidase and catechol-O-methyltransferase to 3-methoxy-4-hydroxymandelic acid and 3-methoxy-4-hydroxyphenylglycol. These inactive degradation products can be quantitated in tissues, blood, and urine as a measure of norepinephrine turnover.

Figure 1 The structure of norepinephrine.

Ontogeny of Norepinephrine in the Brain

Cell bodies expressing tyrosine hydroxylase can be detected by 4 weeks of gestation in humans, and norepinephrine itself is detectable by 5–6 weeks. Norepinephrine levels in humans increase throughout the first trimester, especially from about 2 months of gestation forward. Following the initial increase in spinal norepinephrine, a decrease of 30–40% in concentration occurs between 6 months of gestation and early childhood. Noradrenergic neurons differentiate in rats between gestational day 10 and 13. From this point forward there is a steady differentiation and a nearly linear development of markers for noradrenergic neurons in the CNS, increasing approximately 100- to 1000-fold by adulthood. Thus, although the development of norepinephrine occurs fairly early and is reasonably rapid, it is slower than some of the other neurotransmitter systems, particularly the serotonin system.

Effects of Norepinephrine

Effects Mediated by the Autonomic Nervous System

The autonomic nervous system (also called the involuntary nervous system) is divided into two components, the sympathetic nervous system and the parasympathetic nervous system. The final nerves (postganglionic) in the sympathetic system are

Figure 2 The classification of the adrenergic receptors.

adrenergic and thus release norepinephrine in the various tissues (end organs). The adrenal medulla, which is part of the sympathetic system, releases epinephrine into the circulation. The activation of the sympathetic system, in response to perceived danger, results in the release of large quantities of norepinephrine and epinephrine. Norepinephrine acting at alpha-1 receptors causes vasoconstriction (contraction) of cutaneous blood vessels, whereas epinephrine acting at beta-2 receptors in the blood vessels of the skeletal muscles causes vasodilatation (relaxation), resulting in blood flow being increased in the muscles. Norepinephrine and epinephrine acting at beta-1 receptors increase the force and rate of contraction of the heart, whereas epinephrine acting at beta-2receptors causes bronchodilatation in the lungs and relaxation of the smooth muscle in the uterus.

Effects Mediated by the CNS

In the CNS, the cell bodies of noradrenergic neurons are found primarily in the locus coeruleus in the brain stem. These neurons, however, project widely throughout the brain and spinal cord. The locus coeruleus, and hence norepinephrine, is an important regulator of a variety of physiologic functions, including sleep/wake cycles, attention, orientation, mood, memory, and cardiovascular as well as other autonomic and endocrine functions. Although adrenergic receptors are found throughout the brain, the alpha-2 receptors in the CNS are of particular importance because they regulate the release of norepinephrine, as well as many other neurotransmitters.

Alpha-1 Adrenergic Receptors

Three genetic and four pharmacological alpha-1 adrenergic receptor subtypes have been defined. The alpha-1A and alpha-1B subtypes were initially defined based on their differential affinity for adrenergic agents such as WB4101 and phentolamine and their differential sensitivities to the site-directed alkylating agent chloroethylclonidine. The alpha-1B subtype was subsequently cloned from the hamster, and the alpha-1A was cloned from bovine brain, although it was originally called the alpha-1c adrenergic receptor. A third subtype, the alpha-1D adrenergic receptor, was subsequently cloned from the rat cerebral cortex, although this clone was originally called the alpha-1a subtype by some investigators. A fourth pharmacological subtype, the alpha-1L, has been identified in vascular tissues from several species but may represent a conformational state of the alpha-1A receptor. The current classification scheme includes the alpha-1A, the alpha-1B, and the alpha-1D, but there is no alpha-1C (Figure 2).

Pharmacological and Molecular Characteristics of Alpha-1 Adrenergic Receptors

In addition to norepinephrine and epinephrine, alpha-1 receptors are activated by agonists as phenylephrine and methoxamine. These agonists are relatively selective for alpha-1 receptors and have lower affinity for alpha-2 and beta receptors. By contrast, they have similar affinities for the three alpha-1 subtypes and are thus non-subtype-selective agonists. Similarly, antagonists including prazosin and tamsulosin are relatively selective for alpha-1 receptors and block alpha-2 and beta receptors only at high concentrations. Several other antagonists such as phentolamine and phenoxybenzamine block both alpha-1 and alpha-2 adrenergic receptors with similar affinities. Alpha-1A-selective antagonists include 5-methylurapidil and niguldipine, whereas cirazoline appears to be a selective alpha-1A agonist.

The alpha-1 adrenergic receptors are single polypeptide chains of 446–572-amino-acid residues that span the membrane seven times, with the N-terminus being extracellular and the C-terminus intracellular. Thus, there are three intracellular loops and three extracellular loops. In contrast to the alpha-2 receptors, but similar to the beta receptors, the alpha-1 receptors have a long C-terminal tail (137–179-amino-acid residues) and a short third intracellular loop (68–73-amino-acid residues) The C-terminal tails also have multiple sites of phosphorylation which are thought to be important in the desensitization, recycling, and downregulation of the receptor.

The human alpha-1 adrenergic receptor genes consist of two exons and a single large intron of at least 20 kbp in the region corresponding to the sixth transmembrane domain. No splice variants are known for the alpha-1B and alpha-1D subtypes. By contrast, at least ten splice variants of human alpha-1A subtype have been reported, but only four produce full-length receptors.

Alpha-2 Adrenergic Receptors

Three genetic and four pharmacological alpha-2 adrenergic receptor subtypes have also been defined (Figure 2). The alpha-2A and alpha-2B subtypes were initially defined based on their differential affinity for adrenergic agents such as prazosin and oxymetazoline. These subtypes were subsequently cloned from human, rat, and mouse. A third subtype, alpha-2C, was originally identified in an opossum kidney cell line and

has also been cloned from several species. A fourth pharmacological subtype, the alpha-2D, has been identified in the rat, mouse, and cow. This pharmacological subtype is a species ortholog of the human alpha-2A subtype and thus is not considered to be a separate genetic subtype.

Pharmacological and Molecular Characteristics of Alpha-2 Adrenergic Receptors

In addition to norepinephrine and epinephrine, alpha-2 receptors are activated by clonidine and brimonidine. These agonists are relatively selective for alpha-2 receptors and have lower affinity at alpha-1 and beta receptors. Similarly, the antagonist yohimibine is relatively selective for alpha-2 receptors and blocks alpha-1 and beta receptors only at higher concentrations. Antagonists that are at least somewhat selective for one of the alpha-2 subtypes include BRL44408 for the alpha-2A, prazosin and ARC-239 for the alpha-2B (note, however, that these two agents have much higher affinities for alpha-1 receptors), and rauwolscine for the alpha-2C subtype. Ozymetazoline is a partial agonist that has a higher affinity for the alpha-2A subtype as compared to the alpha-2B and alpha-2C subtypes.

The alpha-2 adrenergic receptors are single polypeptide chains of 450–462-amino-acid residues. In contrast to the alpha-1 and beta receptors, the alpha-2 receptors tend to have long third intracellular loops (148–179-amino-acid residues) and a short C-terminal tail (20–21-amino-acid residues). The third intracellular loops have multiple sites of phosphorylation which are thought to be important in the desensitization, recycling, and downregulation of the receptor. The alpha-2 adrenergic receptor genes do not contain introns, and thus there are no splice variants.

Beta Adrenergic Receptors

Three beta adrenergic receptor subtypes have been identified. The beta-1 adrenergic receptor, the dominant receptor in heart and adipose tissue, is equally sensitive to epinephrine and norepinephrine, whereas the beta-2 adrenergic receptor, responsible for relaxation of vascular, uterine, and airway smooth muscle, is less sensitive to norepinephrine than to epinephrine. The beta-3 receptor is insensitive to the commonly used beta adrenergic receptor antagonists and was previously referred to as the 'atypical' beta adrenergic receptor. A beta-4 receptor has been postulated; however, definitive evidence of its existence is lacking, and it is now thought to be a 'state' of the beta-1 adrenergic receptor.

Pharmacological and Molecular Characteristics of Beta Adrenergic Receptors

Isoproterenol is the prototypic non-subtype-selective beta agonist which has little effect at alpha-1 and alpha-2 receptors. Epinephrine is 10- to 100-fold more potent at the beta-2 receptor as compared to the beta-1 subtype, whereas norepinephrine is more potent than epinephrine at the beta-3 subtype. Many beta-2-selective agonists, such as terbutaline and salmeterol, have been developed for the treatment of asthma. Due to their subtype selectivity they have a lower incidence of side effects mediated by the beta-1 receptor. Propranolol is the prototypic non-subtype-selective beta antagonist which has equal affinities at the beta-1 and beta-2 subtypes. Other nonselective beta adrenergic antagonists include timolol, pindolol (which is actually a weak partial agonist), and carvedilol, which is also an alpha-1 antagonist. Several beta-1-selective antagonists have been developed, such as metoprolol and esmolol.

The beta adrenergic receptors are single polypeptide chains of 408–477-amino-acid residues. In contrast to the alpha-2 receptors, but similar to the alpha-1 receptors, the beta receptors tend to have longer C-terminal tails (61–97-amino-acid residues) and shorter third intracellular loops (54–80-amino-acid residues). The C-terminal tails have multiple sites of phosphorylation which are thought to be important in the desensitization, recycling, and downregulation of the receptor.

The beta-1 and beta-2 adrenergic receptor genes do not contain introns, and thus they have no splice variants. By contrast, the beta-3 receptor has one intron, resulting in two splice variants. However, no functional differences have been found between the two splice variants.

Regulation of Adrenergic Receptors

The processes involved in desensitization and downregulation have been extensively investigated for the beta-2 adrenergic receptor. The other adrenergic receptors, as well as many other G-protein-coupled receptors, appear to behave in a similar, although not identical, manner. Initial uncoupling of the beta-2 receptor from the G-protein after agonist binding is mediated by phosphorylation of specific residues in the carboxyl tail of the receptor. The phosphorylated beta-2 receptor serves as a substrate for the binding of β-arrestin, which not only uncouples the receptor from the signal transduction process but also serves as an adapter protein that mediates the binding of additional signaling proteins and entry into the internalization pathway. The mechanisms of beta-2 adrenergic receptor downregulation appear to involve both

an increase in the rate of degradation of the receptor and a decrease in the levels of beta receptor mRNA.

Adrenergic Receptor Signal Transduction Pathways

The alpha-1 adrenergic receptors activate the $G_{q/11}$ family of G-proteins, leading to the dissociation of the α and $\beta\gamma$ subunits and the subsequent stimulation of the enzyme phospholipase C. This enzyme hydrolyzes phosphatidylinositol in the membrane, producing inositol trisphosphate (IP_3) and diacylglycerol. These molecules act as second messengers mediating intracellular Ca^{2+} release via the IP_3 receptor and activating protein kinase C. Other signaling pathways that have also been shown to be activated by alpha-1 receptors include Ca^{2+} influx via voltage-dependent and independent calcium channels, arachidonic acid release, and activation of phospholipase A_2, phospholipase D activation, and mitogen-activated protein kinase.

The alpha-2 adrenergic receptors activate the $G_{i/o}$ family of G-proteins and alter (classically inhibit) the activity of the enzyme adenylate cyclase, which in turn, decreases the concentration of the second messenger cyclic AMP. In addition, the stimulation of alpha-2-receptors can regulate several other effector systems including the activation of K^+ channels, inhibition or activation of Ca^{2+} channels, and activation of phospholipase A_2, phospholipase C, and Na^+/H^+ exchange.

The beta adrenergic receptors activate the G_s family of G-proteins and activate adenylate cyclase, thus increasing in cyclic adenosine monophosphate (AMP) concentrations. Beta adrenergic receptors interact with many other signaling proteins, including the phosphoprotein EBP50 (ezrinradixin-moesin-binding phosphoprotein-50), the Na^+/H^+ exchanger regulatory factor, and cyclic nucleotide ras guanine-nucleotide exchange factor (CNrasGEF).

Traditionally it has been assumed that intrinsic efficacy of a ligand for the adrenergic receptors is a property of the ligand. However, recent evidence has shown that certain functionally selective ligands may act as either agonists or antagonists for different functions mediated by the same receptor. This functional selectivity likely involves differences in ligand-induced intermediate conformational states, the diversity of G-proteins, scaffolding and signaling partners, and receptor oligomers.

Adrenergic Receptor Polymorphisms

Polymorphisms have been identified in some of the alpha-2 and beta adrenergic receptor subtypes, which may have important clinical implications. A common polymorphism has been identified in the third intracellular loop of the alpha-2B receptor, which consists of a deletion of three glutamate residues (301–303) and is a risk factor for acute coronary events, but not hypertension. This deletion results in a loss of short-term agonist-induced desensitization. The most common polymorphism associated with the human alpha-2C receptor is the alpha-2C-del (residues 322 to 325 are missing), which occurs in 40% of Blacks and 4% of those from other ethnic backgrounds. As the alpha-2C-del receptor appears to be less efficiently coupled to G-proteins, it is less able to mediate a response to agonists. The consequence of this in humans is an impaired feedback inhibition of catecholamine release that is associated with elevated blood pressure and an increased risk of heart failure.

The gene encoding the human beta-1 adrenergic receptor is quite polymorphic, with 18 single nucleotide polymorphisms (SNPs), seven of which cause amino acid substitutions. A total of 13 polymorphisms in the beta-2 adrenergic receptor gene and its transcriptional regulator upstream peptide have been identified. Three closely linked polymorphisms, two coding regions at amino acid positions 16 and 27 and one in the upstream peptide, are common in the general Caucasian population. The glycine-16 receptor exhibits enhanced downregulation *in vitro* after agonist exposure. In contrast, arginine-16 receptors are more resistant to downregulation. Some studies have suggested a relationship among these polymorphisms, airway responsiveness (e.g., asthma), and the responsiveness to beta adrenergic agonists.

A tryptophan-64 to arginine polymorphism has been identified in the beta-3 adrenergic receptor. The allele frequency is approximately 30% in the Japanese population, higher in Pima Indians, and lower in Caucasians. Type 2 diabetic patients with this mutation showed a significantly younger age of onset of diabetes and an increased tendency to obesity, hyperinsulinemia, and hypertension.

Drugs Which Mimic or Block the Effects of Norepinephrine

Norepinephrine itself is rarely used as a drug due to its rapid metabolism and many sites of action. Drugs which evoke responses similar to sympathetic nerve stimulation are called sympathomimetic drugs. They produce their effects either directly by stimulating adrenergic receptors (adrenergic receptor agonists) or indirectly by promoting the release of norepinephrine or by blocking its reuptake. Table 1 gives examples of various sympathomimetic drugs with their mechanism of action, the effects they produce, and their therapeutic indications.

Table 1 Drugs which mimic the effects of norepinephrine

Receptor	*Examples of drugs*	*Effect*	*Therapeutic indication*
Alpha-1	Phenylephrine	Vasoconstriction	Hypotension, nasal congestion
Alpha-2	Clonidine, brimonidine	Lowers fluid pressure	Hypertension, glaucoma
Beta-1	Dobutamine	Increases heart rate	Cardiovascular shock
Beta-2	Albuterol, terbutaline, ritodrine	Relaxes smooth muscle in lung and uterus	Asthma, premature labor
(Indirect acting)	Amphetamine	CNS stimulant	Narcolepsy, hyperactivity
(Indirect acting)	Desipramine, tomoxetine	Blocks norepinephrine reuptake	Depression
(Indirect acting)	Phenelzine	Inhibits monoamine oxidase inhibitor (MAO)	Depression

Table 2 Drugs which block the effects of norepinephrine

Receptor	*Examples of drugs*	*Effect*	*Therapeutic indication*
Alpha-1	Prazosin, terazosin	Vasodilatation	Hypertension, benign prostatic hypertrophy
Alpha-2	Mirtazapine	Antidepressant	Depression
Beta	Propranolol, timolol	Decreases heart rate	Hypertension, angina, glaucoma
Beta-1	Atenolol, metoprolol	Decreases heart rate	Hypertension

Drugs which block the responses to sympathetic nerve stimulation and thus block the effects of norepinephrine are called adrenergic receptor antagonists. They have no direct effects of their own, but act by blocking the effects of either released norepinephrine or an administered adrenergic receptor agonist. Table 2 gives examples of adrenergic receptor antagonists (also called adrenergic blockers) with their receptor selectivity, the effects they produce, and their therapeutic indication.

Norepinephrine Cell Groups and Pathways

Locus Coeruleus

The nucleus locus coeruleus (LC) is a dense cluster of noradrenergic neurons in the dorsorostral pons. This nucleus gained prominence in the 1960s when new anatomical approaches revealed it to be the major source of norepinephrine (NE) in brain with projections throughout most central nervous system (CNS) regions. These findings stimulated a great deal of research into this system, resulting in a wealth of knowledge at the cellular, systems, and behavioral levels. Considerable evidence indicates that these neurons are important in a variety of cognitive, affective, arousal, and other behavioral functions, as well as associated clinical dysfunctions.

Locus coeruleus efferent projections As summarized in Table 1, LC NE neurons project throughout the neuraxis, including the cerebral cortex, thalamus, cerebellum, midbrain, and spinal cord. In this regard, it is different from other 'typical' brain systems that have very limited projection targets (e.g., thalamocortical projections). Despite this high degree of divergence, LC neurons exhibit substantial regional and laminar specificity in their efferent projections. Notably, brain areas in primates that are associated with attentional processing (e.g., parietal cortex, pulvinar nucleus, and superior colliculus) have particularly dense LC projections and NE receptors. Notable areas that receive little or no input from the LC include the caudate putamen and most of the hypothalamus. Ultrastructural evidence indicates that these neurons often make conventional synaptic appositions with postsynaptic targets, although the frequency of such synaptic contacts is controversial. Extrasynaptic (paracrine) release of NE from LC terminals also appears to be possible.

Locus coeruleus afferents A variety of evidence indicates that the LC receives a wealth of different neurotransmitter inputs. This nucleus is densely innervated by fibers that contain opiates, glutamate, γ-aminobutyric acid (GABA), serotonin, epinephrine, histamine, and the peptide orexin/hypocretin. The sources of these various inputs have not been fully elucidated, though some major inputs have been identified. The nucleus paragigantocellularis lateralis (PGi) in the ventrolateral rostral medulla, a major input that strongly excites LC neurons, is a source for glutamate, GABA, enkephalin, corticotropin-releasing hormone (CRH), and epinephrine. A strongly inhibitory GABA and enkephalin input originates from the dorsomedial rostral medulla. Excitatory orexin and histamine inputs originate in the hypothalamus.

The shell of dendrites surrounding the LC nucleus offers additional extensive targets for afferent termination, and indeed it appears that several areas target these extranuclear dendrites more so than the LC nucleus proper. Thus, projections from the periaqueductal gray matter, parabrachial region, preoptic area, amygdala, and medial prefrontal cortex, among other sites, project primarily to the peri-LC region, with relatively little input to the LC proper. Although some of these projections have been shown to contact LC dendrites, additional ultrastructural studies are needed to examine others.

A recent study has extended our understanding of LC afferents to the circuit level. Using transynaptic tracing, lesions, and electrophysiology, Aston-Jones and colleagues determined that the suprachiasmatic nucleus (SCN) indirectly innervates the LC, using the dorsomedial hypothalamus as a relay. Based upon the role of the SCN as the brain's major circadian pacemaker and the role of the LC in arousal and performance (see later), these findings reveal a possible circuit for circadian regulation of arousal and performance.

Recent work by Iba, Aston-Jones, and colleagues reveal that in monkey strong projections to LC originate in cingulate and orbital cortices (Figure 1). Given the roles of these prefrontal areas in conflict monitoring, decision making, and other cognitive functions, these projections may be responsible at least in part for the different modes of activity that occur in LC neurons during cognitive performance (described later). Interestingly, these prefrontal projections to LC appear to be stronger in primates than in rats, in concert with the more highly evolved prefrontal cortex and more prominent role of this structure in regulating behavior in primates.

Taken together, these observations indicate that LC is not a relay nucleus for primary sensory or motor information and that it receives highly processed information concerning internal and external sensory stimuli as well as behavioral and affective states. This suggests a highly integrative function for this system.

This table is based on the organization of LC versus non-LC systems as originally reviewed by Moore and Card in 1984 and published in the *Handbook of Chemical Neuroanatomy*, volume 2. The descriptions of fiber density were obtained from Moore and Card, whereas the information regarding efferent projections was updated based upon a comprehensive survey of research reports available in the literature. The information presented is meant to reflect major efferents of the adrenergic cell groups. Single asterisks indicate structures known to not receive LC afferents but for which the source of adrenergic innervation is unknown. The double asterisk indicates ventral horn innervation by LC, which is dependent upon rat strain.

Norepinephrine release Microdialysis methods have recently provided *in vivo* confirmation that certain drugs and behavioral conditions increase or decrease the release of norepinephrine from locus coeruleus axons. For example, reuptake blockers and stress both enhance extracellular NE levels in areas (such as the neocortex) that receive their only NE innervation from the LC. In addition, the

Figure 1 Plots of retrogradely labeled neurons in the nucleus accumbens and orbitofrontal cortex after injections of cholera toxin B into monkey locus coeruleus. (a) Accumbens neurons labeled from the monkey locus ceruleus. Lower sections are high-power views containing plotted cells; upper sections are low-power views to give orientation. (b) Orbitofrontal cortex neurons labeled from the monkey locus coeruleus. Sections on the right are high-power views containing plotted cells; sections on the left are low-power views to give orientation. For both panels, labels A22–A27 refer to distances (in millimeters) from the interaural line. CC, corpus callosum. From Aston-Jones G and Cohen JD (2005) Adaptive gain and the role of the locus coeruleus–norepinephrine system in optimal performance. *Journal of Comparative Neurology* 493: 99–110.

amount of NE release in cortex increases in proportion to activity within LC, even at low frequencies (2–4 Hz). Notably, burst stimulation elicits more NE release per impulse than evenly do spaced stimuli. This indicates that phasic LC responses (see later) may be particularly effective in releasing NE in target areas.

Locus coeruleus impulse activity *Sleep and waking*. Spontaneous LC activity in rats, cats, or monkeys varies with the stage of the sleep–wake cycle, with firing being most rapid during wakefulness, slower during slow-wave sleep, and virtually absent during paradoxical sleep. LC neurons are phasically activated by conspicuous unconditioned stimuli. Notably, stimuli that elicit large LC responses in either rats or monkeys also typically disrupt sleep or ongoing behavior, and evoke waking or a behavioral-orienting response. The same stimuli do not disrupt behavior if they elicit small LC responses.

Stress. Other studies have revealed strong activation of LC neurons by stressors. Stimuli such as sciatic nerve activation or other painful events strongly activate LC cells. Other stressors, such as a puff of air in the awake monkey or a variety of environmental or physiological stressors, also activate LC neurons. In addition, LC neurons are activated by corticotropin-releasing hormone, which mediates the response of LC cells to certain physiological stressors such as hypotension.

Locus coeruleus activity during cognitive performance. The preceding results suggest that, in addition to a role in sleep and waking, LC neurons may be involved in behavioral responses to sensory stimuli. Aston-Jones and colleagues tested this by recording impulse activity of LC neurons in monkeys performing a target detection task. These studies indicated that the LC exhibits two modes of impulse activity: a tonic mode in which tonic activity is high but phasic responses to targets are low or absent, and a phasic mode in which LC neurons fire tonically more slowly but exhibit consistent activation shortly following target stimuli. Behaviorally, the tonic mode corresponds to poor task performance with many false alarm errors, whereas the phasic mode is associated with nearly error-free performance. These results indicate that these different modes of LC activity may facilitate either selective, focused attention (phasic mode) or flexible behavior and scanning (tonic mode). Each of these LC and behavioral modes is adaptive, depending on the context.

LC activation at decision completion. Recent studies recording LC neural activity in monkeys performing a forced-choice task revealed that the aforementioned phasic responses described are neither purely sensory nor motor/premotor in nature. As shown in **Figure 2**, these LC responses are more closely linked to behavioral responses (lever releases) than to sensory stimuli that trigger the behavioral responses, but do not occur for lever releases elicited outside of the task context. Finally, the onset of these LC responses occurs at about 200 ms prior to the lever releases, at a time that the decision concerning lever release is being made. Aston-Jones and colleagues concluded from these results that these phasic LC responses reflected completion of a decision process, and that the modulatory gain-enhancing effects of the associated NE release (see later) facilitate brain processes and behaviors called upon by the decision just

Figure 2 Stimulus- and response-locked population perievent time histograms (PETHs) showing LC responses to cues for trials yielding correct and incorrect behavioral responses. (a) Stimulus-locked population PETHs showing LC response to cues (presented at time 0) for trials yielding correct or incorrect behavioral responses. Note that the LC response peaks sooner and is less prolonged on correct, compared to incorrect, trials in this analysis (17 533 and 1362 trials, respectively). No fluctuation in LC activity was detected on omission trials (dashed line, 1128 trials). Vertical lines indicate the mean behavioral RTs. Curves below PETHs represent the normalized RT distributions for correct and incorrect trials. (b) The difference in the phasic LC response between correct and incorrect trials is no longer evident on response-locked population PETHs. In addition, no LC response occurred prior to or following lever releases not associated with stimulus presentation (dashed line, 3381 trials). Vertical lines indicate the mean stimulus onset times. From Clayton EC, Rajkowski J, Cohen JD, et al. (2004) Phasic activation of monkey locus coeruleus neurons by simple decisions in a forced choice task. *Journal of Neuroscience* 24: 9914–9920.

made. In this way, the LC phasic response supports the current task/goal and facilitates focused performance in that task. The projections to LC from orbital and cingulate cortices (described previously) may mediate these phasic LC responses associated with decision processes.

Non-LC Norepinephrine and Epinephrine Cell Groups

Neurons in other brain nuclei aside from those in the LC constitute 55% of all CNS NE and epinephrine (E) cells. These neurons are clustered in two

rostrocaudally aligned columns within the brain stem. One column is located primarily in the ventral aspect of the pons and medulla and contains 44% of all NE/E neurons, whereas the second is situated in the dorsomedial medulla. The individual clusters of non-LC NE/E neurons within these cell columns are further subdivided on the basis of their specific anatomical location and the ability to synthesize E (Figure 3).

Non-LC NE/E projections An analysis of projection patterns of LC versus non-LC NE/E neurons reveals similarities and differences (Table 1). Non-LC NE neurons project exclusively subcortically and make a preponderance of connections onto motor nuclei in the medulla and spinal cord, and onto structures associated with visceral function. Within the brain stem, targets of non-LC NE/E neurons include cranial motor nuclei such as the dorsal motor vagus, motor trigeminal, motor facial, and the hypoglossal nucleus, as well as visceral–sensory nuclei such as the nucleus of the solitary tract, parabrachial complex, and periaqueductal gray. In the forebrain, non-LC cell clusters provide dense projections to visceral-related structures such as the bed nucleus of the stria terminalis (BNST), central nucleus of the amygdala, and paraventricular hypothalamus. Thalamic and epithalamic targets include the paraventricular nucleus, rhomboid nucleus, and habenula.

Within the different non-LC adrenergic nuclei, there is a preferential innervation of motor systems by A5 and A7 groups, whereas visceral–sensory areas are primarily innervated by medullary A1 and A2 nuclei. The E-containing fibers from C1 neurons

Figure 3 Localization of norepinephrine (red) and epinephrine (green) nuclei in the brain stem. The cell column in the ventral pons and medulla includes A1, C1, A5, and A7 cell groups, whereas the dorsal medulla column includes A2, C2, and C3 cell groups.

innervate both motor and visceral–sensory structures. C1 neurons send collaterals that innervate both spinal cord and brain stem targets. However, most C1 neurons that project to hypothalamus do not project to spinal cord or brain stem structures. In clear contrast to this pattern of organization, LC projections to the brain stem and spinal cord are directed almost exclusively to relay sites along ascending sensory pathways, including those associated with somatosensory, auditory, gustatory, and visual systems. This sensory-predominant bias of the LC efferent projection continues to the level of the thalamus and also includes the olfactory system. An overlap between LC and non-LC NE efferent projections to motor structures becomes evident in the cerebellar system, and the LC is the sole source of NE fibers to thalamic motor relay nuclei and motor (as well as sensory) processing regions of the cerebral cortex.

Non-LC impulse activity LC and non-LC neurons have similar electrophysiological signatures but exhibit differing responses to afferents and neurotransmitter systems. They are slow-firing neurons (<5 Hz) with wide action potentials (lasting more than 2 ms). Pharmacologically, both LC and non-LC neurons are inhibited by $\alpha 2$ adrenoceptor agonists, indicating the presence of a functional $\alpha 2$ autoreceptor. Conversely, sciatic nerve stimulation activates LC neurons, and also to a lesser extent A5 neurons, but not A2 neurons, indicating selectivity in the systems that activate the different adrenergic groups. Moreover, morphine strongly inhibits LC neurons but is reported to excite A5 neurons.

The organization of the non-LC adrenergic system and its connection to visceral-related areas prompted many studies of the non-LC adrenergic neurons; the findings indicate a diversity of roles in modulating cardiovascular, respiratory, renal, gastrointestinal, and endocrine functions. For example, the A1 area is involved in hemodynamic regulation by controlling the release of vasopressin, whereas C1 neurons are sensitive to blood pressure and are involved in regulating sodium and water balance. A5 neurons influence the respiratory rhythm generator of the rostral ventrolateral medulla, and A2 cells have a role in the regulation of food intake.

Stress Physiological (cardiovascular, osmotic, and immune challenges) as well as psychological (restraint and intermittent footshock) stressors activate both LC and non-LC NE/E neurons. These stressors also activate major targets of the non-LC system, such as the medial and central nuclei of the amygdala, BNST, and paraventricular hypothalamus, suggesting that non-LC adrenergic neurons are part of a functional stress

circuit. A significant difference between LC and non-LC cell groups may be habituation to stressors. Under chronic footshock regimens, LC neurons habituate whereas non-LC cells in A1, C1, A2, and C2 exhibit persistent stress responses. Thus, NE/E transmission in response to acute and persistent stressful conditions is differentially distributed across brain structures according to the unique efferent topographies of the LC and non-LC systems.

Drugs of abuse have profound effects on the activity of NE neurons throughout the brain. The aversiveness of opiate withdrawal is blocked by antagonizing β adrenoceptors in BNST; this NE input largely originates in A1/A2 neurons. A1/A2 neurons also appear to play a particularly prominent role in relapse to drug-seeking induced by stress. Several studies have shown that selective lesions of ascending A1/A2 NE projections, or antagonism of NE receptors in amygdala or BNST, attenuate relapse to drug-seeking induced by footshock stress.

Summary for non-LC systems In summary, several principles of organization emerge from examination of the efferent connections of the central NE/E cell groups. First, the distribution of adrenergic fibers is particularly dense in terminal fields innervated by non-LC adrenergic neurons (Table 1). Second, within the brain stem, the LC preferentially innervates primary sensory pathways while non-LC adrenergic nuclei innervate motor and visceral–sensory systems. Third, non-LC forebrain projections target visceral–sensory and autonomic circuits. Fourth, areas that subserve motor integrative functions such as the cerebellar circuit are mainly innervated by LC, with the exception of the inferior olive, which is mainly innervated by the A5 and A7 areas. Fifth, LC is the only source of NE innervation to the cortical mantle. Sixth, although all NE/E neurons have similar electrophysiological properties, LC and non-LC cells may respond differently to the same afferent inputs and neurotransmitter systems. This analysis leads to an appreciation of the complex anatomical relationships and physiological/behavioral properties of the different brain NE/E systems.

Postsynaptic Actions of Norepinephrine

Investigations in the 1960s and 1970s viewed NE as a putative conventional neurotransmitter and set out to determine its ability to increase or decrease the firing rate of target neurons. For the most part, local application of NE by microiontophoresis, or stimulation of LC, suppressed the spontaneous discharge of neurons in cerebellum, cerebral cortex, and elsewhere in the brain. These depressant responses were mimicked and blocked by adrenoceptor agonists and antagonists, respectively. Taken together, these findings support the idea that NE might function primarily as an inhibitory transmitter at central synapses.

Modulatory effects of NE on single neurons In the mid-1970s pioneering studies by Foote et al. in monkey auditory cortex demonstrated a differential depressant effect of microiontophoretically applied NE on single neurons, such that the spontaneous firing rate of recorded cells was suppressed to a greater extent than were stimulus-evoked discharges, thus yielding a net increase in the signal-to-noise ratio. This initial study prompted many other laboratories to investigate the actions of NE in a variety of sensory circuits within the mammalian brain, including olfactory bulb, sensory thalamus, visual, auditory, and somatosensory cortices. In many cases local application of NE was found to enhance extracellular responses of individual sensory neurons to synaptic stimuli; however, mixed effects were observed in other studies, with suppression of stimulus-evoked discharge predominating.

Later work by Waterhouse and colleagues examined NE actions at levels that had minimal or no effect on spontaneous discharge of target neurons. Under these conditions iontophoretic NE frequently produced absolute increases in stimulus-evoked discharge with minimal or no change in baseline firing. In other cases local administration of NE revealed robust cellular responses to otherwise subthreshold synaptic stimuli. The demonstration of NE-induced facilitation of cellular responses to direct iontophoretic application of GABA or glutamate under both normal and low-calcium/high-magnesium conditions argued that such effects were mediated postsynaptically. These findings in cerebral cortex and cerebellum of anesthetized and awake, behaving animals supported the general hypothesis that a prominent physiological function of central noradrenergic pathways is to enhance the efficacy of both excitatory and inhibitory synaptic transmission within target neuronal circuits, rather than to directly suppress cell firing.

Later work by Waterhouse et al. in cat and rat primary visual cortex showed that NE could alter specific receptive field properties (e.g., receptive field size, direction selectivity, velocity tuning) of visually responsive cells (Figure 4). Other studies showed that NE was capable of modifying the receptive field structure of cells in somatosensory and auditory cortices and cochlear nuclei. As such, these results go beyond the demonstration of simple monoamine-induced changes in the magnitude of synaptically evoked responses and begin to show that such actions can lead to selective alteration of the feature extraction properties

Figure 4 Effects of norepinephrine (NE) on responses of rat visual cortical neurons to visual field stimulation. (a, b) The raster and corresponding perievent histogram records show the extracellularly recorded responses of two single neurons in the rat visual cortex to movements of a vertically oriented (shown on the left) bar of light across the contralateral hemivisual field before, during, and after periods of microiontophoretic administration of NE. For each set of records, the uppermost line depicts the opening (step-up) and closing (step-down) of the shutter controlling the stimulus display. The trapezoid waveform indicates the position of the stimulus in visual space as it moves in the temporal (T) to nasal (N) direction and then back along the same path in the reverse direction. Time is indicated along the horizontal axis of the histogram, and discharge frequency of the cell is indicated along the vertical axis. Stimulus-bound excitatory or inhibitory components of the response were expressed as a percentage increase or decrease, respectively, of background firing rate (dotted line beneath histogram). (a) In the first cell the control response (top) consisted of an excitatory burst (solid bar) preceded by an inhibitory trough as the stimulus moved in the T to N direction, but no significant change in activity as the stimulus moved along the same path in the opposite direction (N to T). The visually evoked excitatory peak represented a 172% increase in firing over the basal level of discharge. Iontophoretic application of NE (5 nA) suppressed basal firing rate but produced an absolute increase in the visually evoked response (middle). Recovery to the control level of response was observed following cessation of NE administration (bottom). Each histogram sums unit activity during 13 trials; bin width = 15 ms. (b) In the second cell, there was no discernible response to the moving bar of light during the control period (top); however, during NE (5 nA) administration (middle) an obvious stimulus-evoked excitation (broken bar beneath histogram) and a stimulus-bound inhibition (dotted line beneath histogram) became evident. After cessation of NE iontophoresis (bottom), the cell gradually lost its sensitivity to the visual stimulus. Control and NE histograms, $n = 22$ trials; recovery histogram, $n = 31$ trials. Bin width = 15 ms.

of individual sensory neurons. More recent work by Arnsten, and colleagues indicates that NE and NE agonist drugs can modify the working-memory-related discharge of cells in prefrontal cortex of behaving monkeys. These latter findings suggest that the noradrenergic actions observed in sensory circuits may be generalized across brain regions that serve many different functions.

Additional studies in cortex and elsewhere have determined the pharmacologic specificity and dose dependency of NE-mediated modulatory effects. For example, the magnitude of cellular response to direct glutamate application can be maximally enhanced at a specific level of NE administration, and only moderately or minimally be affected by concentrations above and below this level (Figure 5(a)), thus revealing an inverted-U dose–response relationship for this effect of NE. Furthermore, noradrenergic enhancement of neuronal responses to excitatory synaptic stimuli are mimicked and blocked by α1-receptor agonists (Figure 5(b)) and antagonists, respectively, whereas the augmentation of inhibitory responses to GABA application (Figure 6) or afferent pathway stimulation involves activation of β receptors. Other studies, particularly those in hippocampus, provide data suggesting the opposite (i.e., NE enhancement of excitatory synaptic transmission is dependent upon β-receptor mechanisms and augmentation of synaptic inhibition is mediated by α1-receptor mechanisms). These disparate results have not been reconciled but may reflect unique receptor distributions or second-messenger linkages among neurons within different brain regions. Overall, these observations indicate that within a specified brain circuit

Figure 5 Modulatory actions of ionotphoretically applied norepinephrine and α1 agonist (phenylephrine) on glutamate-evoked discharges in rat barrel field cortical neurons. Responses of individual layer V neurons to iontophoretic pulses of suprathreshold levels of glutamate were quantified by analysis of perievent histograms (shown as insets) that were collected before, during, and after continuous microiontophoretic application of norepinephrine. Responses were then expressed as a percentage change from control (i.e., response to glutamate application alone = 100%) for different iontophoretic doses (nA) of norepinephrine. Each histogram and corresponding point on the graph represents the cell's response to six consecutive glutamate applications. (a) Example of a layer V cortical neuron: its excitatory response to glutamate (28 nA) was progressively increased with increasing levels of norepinephrine (peak at 5 nA) and then progressively suppressed from this optimal value with further increases in norepinephrine ejection current (6–20 nA). (b) Example of a second layer V cortical neuron: its excitatory response to glutamate (40 nA) was likewise progressively increased with increasing levels of phenylephrine (peak at 5 nA) and then progressively suppressed from this peak value with further increases in phenylephrine ejection current (10–30 nA).

Figure 6 Actions of norepinephrine (NE) and the β agonist isoproterenol (ISO) on γ-aminobutyric acid-induced inhibition of cortical neuron spontaneous discharge. Histogram records show responses of two somatosensory cortical cells (a and b) to regularly spaced, uniform iontophoretic pulses of γ-aminobutyric acid applied before, during, and after NE (a) or ISO (b) administration. Numbers above each histogram indicate the percentage of inhibition of spontaneous firing rate produced by γ-aminobutyric acid application. Each histogram sums unit activity for an equal number of γ-aminobutyric acid pulses, $n = 5$. Both NE (10 nA) and ISO (15 nA) produced a marked enhancement of the γ-aminobutyric acid response relative to a suppression of background firing. Recovery to the control level of response was observed in each case after termination of adrenergic drug application. Calibration: vertical, 5 counts per address; horizontal, 5 s.

an array of noradrenergic modulatory actions is possible, depending upon cellular expression of receptors and levels of NE available for interaction with those receptors.

Cellular mechanisms of NE action Intracellular experiments have demonstrated multiple actions of NE on properties of neuronal membranes. For example, NE-induced blockade of a calcium-activated potassium conductance leads to accommodation block and prolongation of evoked excitatory discharges. It is widely accepted that this effect, in conjunction with a membrane hyperpolarizing action of NE, can account for noradrenergic potentiation or signal-to-noise ratio enhancement of threshold level excitatory synaptic responses observed *in vivo*. McCormick and colleagues have found that NE's depolarizing action influences a complex interaction between intrinsic membrane currents in thalamic relay neurons. This interplay moves thalamic neurons back and forth between a non-signal-transmitting oscillatory mode during sleep and a single-spike transmission, or 'relay,' mode during waking.

Available evidence implicates the β-receptor-linked cyclic AMP system in NE-mediated augmentation of GABA-induced inhibition. For example, *in vivo*, local application of agents that elevate intracellular levels of cyclic AMP mimic or augment NE-mediated enhancement of GABA-induced inhibition of cerebellar Purkinje neurons. Subsequent studies in acutely dissociated cerebellar Purkinje neurons demonstrated augmentation of GABA membrane currents via intracellular diffusion of 8-bromo-cyclic AMP or the catalytic subunit of protein kinase A. And finally, additional investigations found that subunits of the GABA-A receptor can be phosphorylated by protein kinase A. The working hypothesis is that, upon release, NE initiates a cascade of events via postsynaptic β receptors that results in activation of protein kinase A and phosphorylation of GABA-A receptor subunits. In Purkinje neurons this phosphorylation of the receptor leads to enhanced GABA binding capacity or chloride conductance, thus providing for an overall increase in GABA response.

The intracellular events associated with NE-induced enhancement of stimulus-evoked excitatory discharges have not been identified with as much certainty, although work by several laboratories identifies protein kinase A and protein kinase C as candidates for mediating transmitter/modulator effects on synaptically evoked excitation. Elucidating the intracellular events and accompanying physiological actions that underlie NE-induced enhancement of responsiveness to synaptic inputs are major issues for future studies.

Effects of locus coeruleus output on neuronal and neural circuit response properties Studies in anesthetized animals show that stimulation of the LC efferent path elicits NE-like modulatory effects on target neurons in sensory circuits. These findings support the general hypothesis that a major function of the central LC–noradrenergic efferent system is to facilitate the transfer of information through sensory circuits following events that phasically activate the LC nucleus. More recent work in waking animals has shown that phasic and tonic activation of the LC efferent path can enhance the probability of stimulus-evoked spiking in both cortical and thalamic neurons according to an inverted-U function. Thus, as described for iontophoretically applied NE, neuronal responses to afferent stimulation are increased to a maximum at intermediate levels of LC stimulation, and to submaximal levels with LC activation levels above and below this level. As reported for iontophoretically applied NE, activation of the LC efferent pathway can also reveal or 'gate' cellular responses to otherwise subthreshold synaptic inputs. LC stimulation also decreases mean response latency and reduces

trial-to-trial variability of response latency for both sensory thalamic and cortical neuron responses to afferent input. Thus, increased output from the LC is capable of altering the magnitude and timing of cellular responses to sensory-driven synaptic input as well as recruiting (gating) additional cells into a response network. These results are important in that they extend observations of LC- and NE-mediated modulatory actions into the waking condition. Further, they show that LC output can simultaneously facilitate stimulus-evoked discharge patterns at multiple levels of an ascending sensory pathway.

The observed effects of LC stimulation on response threshold, response magnitude, and response latency in individual cells suggests that under certain behavioral conditions synaptically released NE can optimize information processing within sensory circuits and provide for a network-wide enhancement of sensory signal transmission. This idea is further supported by recent multineuron recording studies in which LC activation and NE release have been shown to modulate the representation of sensory information across ensembles of functionally related thalamic neurons.

Functional and Clinical Implications

The widespread NE system appears to be functionally multifaceted. On a 24 h timescale it modulates sleep and waking, permitting sleep with inactivity but promoting arousal by becoming active. Recent results for a circuit from the SCN to the LC indicate that this system may contribute to the circadian regulation of arousal and sleep–waking. However, on a much shorter timescale of seconds, this system appears to modulate attention and performance during the waking state. In this domain the LC system regulates behavioral flexibility by promoting either stable selective attention and focused behavioral performance or a scanning type of attention and more flexible behavior.

These findings have implications for the involvement of the LC system in clinical disorders. The role proposed for the LC in attention suggests that dysfunction of this system could contribute to the cognitive and sensory signal-processing deficits that are prominent in schizophrenia, attention-deficit/hyperactivity disorder, and dementia. In regard to dementia, LC neurons have been found to degenerate in both Alzheimer's and Parkinson's diseases.

Many clinical studies have also implicated this system in depression and anxiety. This is consistent with findings that there are substantial projections of NE neurons throughout the limbic system and that the LC system is engaged by novel and alarming stimuli. The high responsiveness of LC neurons to acute and chronic stressors is also consistent with a role for this system in depression. Moreover, many of the drugs used successfully to treat anxiety and depression target the noradrenergic system. There is, as well, a growing body of clinical evidence suggesting a role for the LC–NE system in posttraumatic stress disorder.

There have also been various proposals for a role of the LC in the etiology of sleep disorders. This is consistent with both the close association of activity of these cells with different stages of the sleep–wake cycle and the disrupted sleep patterns that are a hallmark of depression. Recent results indicate that the role of the LC extends to circadian disorders in sleep and performance as well.

The Notch Signaling Pathway

Briefly, at the core of the Notch signaling pathway is the Notch receptor, a single-pass transmembrane protein (Figure 1). The mature form of the receptor expressed at the cell surface is a heterodimer of an extracellular fragment ($Notch^{EC}$) and a membrane-spanning fragment ($Notch^{TM}$), generated during synthesis in the Golgi by proteolytic cleavage of the Notch protein at the S1 site by a furin convertase (Figure 1). Interaction of Notch with the Delta, Serrate, Lag-2 (DSL) family of ligands expressed on the surface of neighboring cells helps complete a sequence of three proteolytic cleavages that result in the release of the intracellular Notch domain ($Notch^{IC}$) from the plasma membrane (Figure 1). Activation of the Notch receptor requires that the ligands undergo endocytosis, an event that involves ubiquitination by RING E3 ligases such as Mindbomb and Neuralized (Figure 2). Internalization of the DSL ligand–$Notch^{EC}$ complex by the endocytic machinery is likely to provide a force that separates the $Notch^{EC}$ and $Notch^{TM}$ fragments, facilitating subsequent cleavage of Notch that releases the transcriptionally active $Notch^{IC}$ fragment into the cell (Figure 2). While interaction of Notch and a DSL ligand in a neighboring cell (in *trans*) facilitates activation of the Notch receptor, interaction of Notch with Delta in the same cell (in *cis*) prevents effective function of both Delta and Notch (Figure 1). The $Notch^{IC}$ fragment translocates to the nucleus, where, together with a member of the DNA-binding CBF1–RBP-Jk, Suppressor of Hairless, Lag-1 (CSL) family of transcription factors and cofactor Mastermind, it drives expression of target genes with regulatory DNA sequence recognized by the CSL protein DNA-binding domain (Figure 2). In the absence of $Notch^{IC}$, the CSL protein is part of a repressor complex that maintains basal repression of target genes recognized by this DNA-binding factor (Figure 2).

Lateral Inhibition and Selection of a Cell within a Proneural Cluster

Notch signaling is best known for its role in mediating interactions that ensure adjacent cells acquire distinct fates (Figure 2 and Figure 3). During lateral inhibition it ensures that only a single cell of a larger group of cells with the potential to adopt the same fate is selected to adopt a particular fate. This role is best illustrated by the function of Notch in neurogenesis.

During *Drosophila* neurogenesis, early patterning mechanisms initiate expression of 'proneural' genes in a small group of cells called a proneural cluster (PNC). These genes, including *achaete*, *scute*, *lethal* of *scute*, and *asense* in the Achaete–Scute complex or another family of genes related to *atonal*, encode basic helix–loop–helix (bHLH) transcription factors that give the cells in the PNC the potential to adopt a neural fate. The proneural factors can drive their own expression, and this positive autoregulation can drive progressively higher levels of proneural gene expression. If sufficiently high expression is achieved, it can become self-sustaining, independent of initiating factors, and the proneural factors are able to successfully initiate expression of additional genes that facilitate subsequent adoption of a neural fate. However, positive autoregulation can be regulated by additional factors that make it more or less effective, eventually determining whether critical levels of proneural factor expression can be established in a particular cell and hence whether that cell will actually adopt a particular neural fate.

The proneural factors drive expression or facilitate the function of the Notch ligand Delta (Figure 2). So as cells express higher levels of proneural factor, they become progressively better at activating Notch in neighboring cells. When Delta activates Notch in a neighboring cell within the PNC, it initiates the expression of genes in the Enhancer of Split (E(spl)) complex. These genes interfere with proneural factor expression, making it harder for the neighbor to acquire high levels of proneural expression. Like the proneural factors encoded by genes in the Achaete–Scute complex, some genes in the E(spl) complex encode bHLH transcriptional factors; however, they are part of a larger evolutionarily conserved family of Hairy E(spl)-related factors that are characterized by a C-terminal WRPW domain, which allows them to recruit corepressor Groucho and function as repressors to prevent expression of proneural genes. By promoting function of the Notch ligand Delta and activating Notch-mediated E(spl) transcription in neighboring cells, proneural factors indirectly inhibit proneural gene expression in neighboring cells, reducing their ability to adopt a neural fate. As a consequence of this process of lateral inhibition, only a single cell eventually acquires high enough levels of proneural gene expression to adopt a neural fate within a PNC. Adjacent cells in the PNC, characterized by relatively high levels of Notch activity, are prevented from adopting a neural fate, and they

Figure 1 Schematic of Notch and Delta showing functional domains and proteolytic cleavage. The mature Notch receptor is a heterodimer containing a Notch^{EC} fragment and a Notch^{TM} fragment made by furin-based cleavage of the full length Notch protein at the S1 site. The Notch–Lin12 Repeats (NLR) in the Notch^{EC} fragment prevent access to the S2 site in the Notch^{TM} fragment. Endocytosis of Delta following interaction with Notch^{EC} in an adjacent cell (in *trans)* facilitates removal of the Notch^{EC} fragment and allows an ADAM protease access to the S2 cleavage site. S2 cleavage is followed by γ secretase-dependent cleavage at an S3 site, which releases the Notch^{IC} fragment into the cell. The Notch^{IC} fragment contains a RAM domain, ankyrin (ANK) repeats, and a transactivation domain (TAD), which allows it to function in transcriptional activation complex with Mastermind and a CSL protein like Su(H) in the nucleus. The PEST sequence allows rapid degradation of the Notch^{IC} fragment in the nucleus. Interaction with Delta in the same cell (*cis*) interferes with function of Notch. Notch^{EC}, extracellular fragment of Notch receptor; Notch^{IC}, intracellular fragment; Notch^{TM}, membrane-spanning fragment.

acquire the ability to adopt an alternate fate that is dependent on relatively high levels of Notch signaling. Failure of lateral inhibition mediated by Notch signaling results in a 'neurogenic' fate as too many cells within the PNC adopt a neural fate. This is accompanied by a deficit in the number of cells with the alternate fate that is dependent on relatively high levels of Notch signaling. Based on the neurogenic phenotype produced by loss of Notch signaling, many of the genes originally identified in the Notch signaling pathway were referred to as 'neurogenic' genes.

The genetic regulatory network described above, first discovered in *Drosophila* and subsequently in many other metazoan animals, describes the manner in which Delta–Notch signaling mediates lateral inhibition in a PNC to select a single cell that will adopt a neural fate. Though the details differ, this is how cells are selected for differentiation with distinct fates during neurogenesis in a wide range of circumstances in the central nervous system (CNS) and peripheral nervous system (PNS). In *Drosophila* during early neurogenesis, cells from PNCs in the neuroectoderm are

Figure 2 The dual role of Su(H) in activation and repression ensures complementary expression of genes in the Achaete–Scute and Enhancer of Split (E(spl)) complexes in the sensory organ precursor (SOP) and non-SOP cells. Relatively low levels of Notch activation in the prospective SOP cell permits effective self-activation by genes in the Achaete–Scute complex, which results in high levels of *achaete* expression. Despite presence of achaete-binding sites in the E(spl)-C enhancers, high levels of achaete proteins do not drive *E(spl)* expression in the SOP cell because, in the absence of Notch^{IC}, Su(H) maintains basal repression of genes in E(spl)-C. Suppression of E (spl) bHLH genes prevents repression of genes in the Achaete–Scute complex, and repression of *Bearded* (*brd*) genes prevents inhibition of Neuralized function in the prospective SOP. Hence the prospective SOP effectively activates Notch in the surrounding non-SOP cells, where Notch^{IC} makes Su(H) function as part of an activator complex and drives expression of genes in the E(spl)-C. In these non-SOP cells, bHLH E(spl) proteins repress *achaete* expression, while *brd* proteins prevent effective Neuralized function. E(spl), Enhancer of Split; Neu, Neuralized; Notch^{IC}, intracellular fragment of Notch receptor.

selected to become neuroblasts during formation of the CNS. Cells selected to become neuroblasts delaminate deep to the neuroectoderm and aggregate to form the neural anlage, while cells that are not selected to become neuroblasts remain superficial and eventually contribute to the formation of the epidermis. In the PNS, sensory organ precursors (SOPs) are selected from PNCs in imaginal discs. Cells in the PNC that are not selected to become an SOP also contribute to the epidermis, while the SOP cell undergoes a sequence of stereotypical divisions to produce cells of the sensory organ. Lateral inhibition also selects the R8 photoreceptors within PNCs at the advancing edge of the morphogenetic wave in the developing eye. In this context the selected cell does not undergo additional divisions; however, specification of R8 cells is critical because the R8 cell initiates the specification of the surrounding photoreceptors, and they in turn help specify additional cells of the ommatidium.

Cis-Regulatory Logic of E(Spl) Expression in a PNC

E(spl) and proneural genes are eventually expressed in complementary patterns in the PNC, with proneural expression restricted to the SOP, and E(spl) gene expression restricted to surrounding non-SOP cells. Analysis of enhancer elements that direct expression of E(spl) genes in PNCs of the wing imaginal disc reveal how the dual role of the CSL protein Su (H) in either transcriptional repression or Notch-mediated transcriptional activation establishes complementary expression of E(spl) and proneural genes in the PNC (Figure 2). The enhancer that determines Notch-mediated expression of E(spl) genes in the

Figure 3 Lateral Inhibition selects only central cells when coupled with a central biasing mechanism. (a) In lateral inhibition, Notch signaling is part of negative feedback loop that amplifies differences in neural potential in adjacent cells. (b) If proneural genes were equally expressed in a proneural cluster (PNC), lateral inhibition would favor selection of cells at the edge of the cluster because edge cells do not receive inhibition from cells outside the PNC; in contrast, central cells receive inhibition from all surrounding neighbors. However, lateral inhibition could successfully select a central cell when coupled to a mechanism that ensures a central bias. Red bars represent lateral inhibition delivered to neighboring cells. (c) EGFR signaling promotes positive autoregulation by proneural genes. If each cell in the PNC were to be a source of a diffusible EGFR ligand, central cells would be exposed to the highest levels of the ligand and would have most efficient autoregulation of proneural genes. This defines a potential mechanism that facilitates self-organization of a central bias in proneural function that can then be amplified by Notch signaling leading to selection of a central cell. Ac-Sc, Achaete–Scute complex; EGF, epidermal growth factor; EGFR, epidermal growth factor receptor; E(spl), Enhancer of Split.

wing imaginal disc PNCs includes high-affinity sites for Su(H) binding, which allows E(spl) expression promoted by Notch^{IC}, Mastermind, and Su(H). However, the E(spl) enhancer also includes high-affinity sites for binding of proneural proteins Achaete and Scute. This seems paradoxical because the domain within the PNC where E(spl) genes are expressed is exactly where proneural expression is eventually

excluded; however, the combination of Su(H) and proneural binding sites in the enhancer ensures that Notch activation directs expression of E(spl) only within the PNC, where proneural expression has already been initiated. Though the E(spl) enhancer includes high-affinity proneural binding sites, high levels of proneural protein expression in the prospective SOP cannot independently drive E(spl) gene expression because in the absence of Notch^{IC}, Su(H) functions as part of a repressor complex that ensures genes in the E(spl) complex are not expressed. In surrounding non-SOP cells of the PNC, where Notch is activated by the SOP cell, Notch^{IC} makes Su(H) function as an activator to drive E(spl) gene expression.

The Complementary Role of Bearded Family Genes in the E(Spl) Complex

The E(spl) complex also includes non-bHLH genes of the *Bearded* (*Brd*) family. Their expression is also regulated by Notch activation; however, unlike the E(spl) bHLH genes, they do not inhibit proneural gene expression. Instead, they interfere with Delta function by inhibiting Neuralized mediated endocytosis of Delta, a step that is essential for effective activation of Notch in the neighboring cell (Figure 2). By inhibiting Neuralized function, *Brd* genes play a complementary role to bHLH E(spl) genes in making cells with Notch activation less likely to be selected as SOPs. Brd protein makes cells less effective at delivering Delta-mediated lateral inhibition to their neighbors and hence unlikely to win the competition to become an SOP. In the absence of Notch activation, Su(H) maintains repression of *Brd* genes in the prospective SOP cell, facilitating Neuralized function and making it more effective at delivering lateral inhibition to neighboring non-SOP cells.

Notch Signaling in the Progeny of Cells Selected by Lateral Inhibition

Though lateral inhibition typically refers to interactions between cells in the PNC that select a single cell, Notch signaling also has a critical role in determining distinct fates for the progeny of cells initially selected by lateral inhibition. For example, when a neuroblast divides, the daughter with less Notch activation becomes a ganglion mother cell (GMC), and the sibling with higher Notch activation becomes another neuroblast. When the GMC divides, the daughter with more Notch activity becomes a glial cell, and its sibling becomes a neuron. This lineage illustrates how the cell with less Notch activity is consistently permitted to adopt a fate that brings the cell closer to differentiating as a neuron, while the cell with greater Notch activity either remains as an undifferentiated progenitor or adopts a 'nonneural' fate. A similar pattern, discussed in more detail below, is seen in the lineage of the SOP.

Selecting a Central Cell within a PNC

The *Drosophila* epidermis develops more than 1000 bristles and other types sensory organs during development. Some of these bristles, called macrochaetes, are conspicuously large and located in stereotyped positions on the head and notum. Each macrochaete is derived from an SOP, previously also called a sense organ mother cell. In the wing imaginal disc, each SOP is, on average, selected from a cluster of 20–30 cells, called a PNC. All the cells in the PNC initially acquire the potential to become an SOP by their expression of proneural genes like *achaete* and *scute* that are part of the Achaete–Scute complex. However, competitive interactions mediated by Delta–Notch interactions eventually restrict high levels of proneural expression and SOP fate to a single cell or sometimes two cells within the PNC. High levels of proneural expression are first restricted to a smaller subset of cells within the PNC, called a proneural field. Then, within this field, the cell that attains the highest level of *achaete–scute* expression begins expressing *asense*, another proneural gene in the Achaete–Scute complex, and it acquires an SOP fate. The initial expression of proneural genes in stereotypical clusters is determined by the combinatorial function of heterogeneous 'prepattern' genes; however, the sustained high expression of proneural genes in a subset of cells depends on positive autoregulation by the proneural genes.

Biasing the Outcome of Notch Signaling

What determines which cell is eventually selected in a cluster and how is it reliably selected in a particular location within a large PNC? In the absence of additional biasing mechanisms, a central cell is least likely to be selected by lateral inhibition, and cells at the edge of a PNC are expected to have a competitive advantage (Figure 3). While cells at the edge do not receive lateral inhibition from neighbors outside the PNC, neighbors delivering lateral inhibition surround central cells.

Despite the inherent disadvantage of central cells with respect to lateral inhibition, it is often the case that they are the ones selected by lateral inhibition. Analysis of enhancer elements of the Achaete–Scute complex and epidermal growth factor receptor (EGFR) signaling suggests that interactions between EGFR and proneural factors might contribute to establishment of a central biasing mechanism during

selection of the SOP in the PNC for specific macrochaetes. The analysis of Achaete–Scute complex enhancers shows that one set of regulatory elements in a 'PNC enhancer' are responsible for initiating Achaete–Scute complex gene expression within a PNC in response to regulation by prepatterning genes, while another set of regulatory elements in a distinct 'SOP enhancer' mediate positive autoregulation by the proneural genes. The SOP autoregulatory enhancer is responsible for high levels of Achaete–Scute complex proneural expression in the cell that is eventually selected to become the SOP within the PNC. Proneural expression driven by proneural self-stimulation in the SOP enhancer is facilitated by EGFR signaling, and EGFR signaling is itself promoted by the proneural factors. As all the cells within the PNC secrete diffusible EGFR signals, central cells within a PNC are exposed to the highest levels of EGFR signaling. This results in particularly effective positive autoregulation of Achaete–Scute complex genes within central cells, biasing them for selection by lateral inhibition. Since diffusible EGFR ligands promote proneural expression by acting via the autoregulatory enhancer, their effect is limited to cells in the original PNC, where proneural expression was initiated by early patterning mechanisms, so EGFR signaling is unlikely to initiate ectopic proneural expression in cells outside the PNC.

Variations of the scheme described above play a role in biasing the outcome of lateral inhibition in various contexts. Selection of the progenitor for the *Drosophila* chordotonal organ, for example, is determined by the expression of another proneural gene, *atonal*, and it also involves an antagonistic relationship between EGFR and Notch signaling; however, in this context the initial progenitor selected by lateral inhibition continues to be the source of inductive EGFR signals, and it eventually recruits many more progenitors so that, unlike the SOP for external sensory bristles, the chordotonal organs are not isolated structures but organized to form small clusters.

Biasing Binary Cell Fate Decisions in the SOP Lineage

Competitive interactions mediated by Notch signaling continue to determine distinct cell fates in the progeny of cells initially selected by lateral inhibition. Here, the outcome of the competitive interactions is biased by the asymmetric inheritance of factors that can influence the efficacy of Notch signaling by progeny of the dividing cells. SOPs or the pI cells on the dorsal surface of the fly thorax (notum) undergo a series of stereotyped asymmetric divisions to generate cells that make cells of adult mechanosensory organs (Figure 4). The first of the asymmetric divisions is along the mediolateral axis and generates an anterior pIIb cell and a posterior pIIa cell. The pIIa cell divides once more to form a socket and a shaft cell, which are the external cells of mechanosensory organ. The pIIb cell divides twice to produce the internal cells of the sensory organ: the first division produces a glial cell and the pIIIb cell, and the pIIIb cell divides to form a sensory neuron and sheath cell. pIIa fate is dependent on high Notch activation, while pIIb fate is dependent on low Notch activation. Each sibling expresses both Delta and Notch and, in principle, could compete to acquire a dominant role in either delivering or receiving a Notch signal. However, asymmetric distribution of factors like Numb, Neuralized, and Sanpodo, determined by planar polarity signaling mechanisms, ensure that the anterior pIIb cell becomes more effective at delivering the Delta signal and the posterior pIIa cell more effective at having its Notch receptors activated. At pro-metaphase, planar polarity mechanisms segregate Partner of Inscrutable (Pins) to the anterior cortex of the pI cell, opposite to components of Par complex, including Bazooka (D-Par3), DaPKC, and DmPar6, which localize on the posterior cortex. Pins restricts localization of Baz to the posterior cortex of the dividing pI cell, and segregation of Baz along with DaPKC and DmPar6 at the posterior cortex restricts another factor, Lethal Giant Larvae, to the opposite anterior cortex. Lethal Giant Larvae in turn recruits Partner of Numb and Neuralized to the anterior cortex. As a consequence, following mitosis, Numb and Neuralized are segregated to the anterior pIIb cell. Numb prevents membrane localization of Sanpodo, a requirement for Notch function, and Numb also inhibits Notch in the pIIb cell by promoting its degradation. In addition, segregation of Neuralized to the pIIb cell allows this cell to internalize Delta in a manner that makes it effective in activating Notch in its neighbor. In contrast, absence of Numb and plasma membrane localization of Sanpodo make Notch effective in the pIIa cell, while absence of Neuralized prevents Delta in this cell from effectively activating Notch in its adjacent pIIb sibling. In this manner planar polarity mechanisms ensure that for the pII progeny of all the SOPs on the developing notum, the anterior sibling acquires a pIIb fate, and the posterior sibling acquires a pIIa fate. The coordinated fate of individual SOP progeny eventually ensures the coordinated orientation of all the sensory bristles in the notum.

A mechanism acting in parallel establishes an asymmetry in Delta recycling in the pIIa and pIIb cells (Figure 4). Shortly after division of the SOP, a Rab11-dependent recycling center is established around the centrosome in the pIIb cell. Establishment of this center is dependent on accumulation

Figure 4 Mechanisms linked to planar polarity bias the outcome of Notch signaling in the progeny of the sensory organ precursor (SOP). (a) The SOP (pI) divides to form an anterior pIIb and posterior pIIa cell. The pIIa cell divides to form the Shaft (Sh) and Socket (So) cells. The pIIb cell divides to form a Glial (Gli) cell and a pIIIb cell. The pIIIb cell divides to form a Neuron (N) and a Sheath (St) cell. Cells with relatively low Notch signaling adopt the fate represented by the dark cells in the lineage. (b) At pro-metaphase, planar polarity mechanisms segregate Pins (Partner of Inscrutable) to the anterior cortex of the pI cell. Pins restricts localization of Baz to the posterior cortex of the dividing pI cell, and segregation of Baz along with DaPKC and DmPar6 at the posterior cortex restricts another factor, Lethal Giant Larvae (Lgl), to the anterior cortex. Lgl in turn recruits Partner of Numb (Pon) and Neuralized (Neu) to the anterior cortex. (c) Numb and Neuralized are segregated to the anterior pIIb cell. In addition, the Rab11 binding protein, Nuclear Fallout (Nuf), is permitted to associate with the centrosome in the pIIb cell. Numb prevents membrane localization of Sanpodo, a requirement for Notch function, and Numb also inhibits Notch in the pIIb cell by promoting its degradation in the MVB. Nuf facilitates organization of a Rab11-dependent recycling center in the pIIb cell, which makes Delta available at the cell surface. Neuralized allows the pIIb cell to internalize Delta and activate Notch in its neighbor. In contrast, absence of Numb and plasma membrane localization of Sanpodo makes Notch effective in the pIIa cell, while inhibition of Nuf association with the centrosome and absence of Neuralized makes Delta less effective at delivering a signal to the adjacent pIIb cell. MVB, multivesicular body; $Notch^{IC}$, intracellular fragment of Notch receptor.

of the Rab11-binding protein Nuclear Fallout, the *Drosophila* homolog of vertebrate Arfophilin, on the centrosome. Association of Nuclear Fallout with the centrosome is inhibited in the pIIa but allowed in the pIIb cell. As a consequence, soon after division, the pIIb cell begins recycling Delta internalized before or during mitosis, quickly establishing itself as the dominant signaling cell.

The fate of siblings following asymmetric division of the neuroblasts in the *Drosophila* CNS is also biased by asymmetric segregation of cell fate determinants like Numb. In this context, however, the asymmetric localization of cell fate determinants is not determined by planar polarity mechanisms but by asymmetries associated with apical–basal polarity in an epithelial cell. Division of the neuroblast, perpendicular to the apical–basal axis, creates a smaller basal sibling that inherits Numb. Numb inhibits Notch function and permits this cell to adopt a GMC fate. In contrast, higher Notch activation in the larger apical sibling allows that cell to retain a neuroblast fate.

Notch Signaling in Vertebrate Neurogenesis

Homologs of genes involved in Notch signaling have now been identified in almost all metazoans, and analysis of their function in vertebrate model systems including chick, zebra fish, mouse, and rat has demonstrated that Notch has a conserved role in vertebrate neurogenesis. Similarities have been shown in many contexts; two examples, from *Xenopus* and zebra fish, illustrate some of the similarities.

Early differentiating neurons, also called primary neurons in *Xenopus* and zebra fish, are distributed in three bilateral longitudinal columns in the neuroepithelium of the caudal neural plate. Within each longitudinal column, only a subset of cells become early neurons. Exaggerated Notch signaling reduces the number of neurons. In contrast, loss of Notch signaling in this context results in too many early differentiating neurons, a loss of many of the late differentiating 'secondary' neurons, and loss of the progenitor population that would normally permit neurogenesis to continue during development. In the case of primary sensory neurons, called Rohon Beard cells, Notch signaling helps neuronal progenitors choose between a neuronal fate and a neural crest fate. Loss of Notch signaling allows too many cells to become sensory neurons and not enough progenitors adopt a neural crest fate. In homozygous zebra fish Mindbomb^{ta52b} alleles, severe loss of neural crest cells results in a loss of pigment cells in the tail, which is why this allele was originally called 'white tail.' These observations in *Xenopus* and zebra fish illustrate how Delta–Notch-mediated lateral inhibition drives selection of a subset of cells that become neurons. Like neuroblasts in *Drosophila* that delaminate from the neuroectoderm, cells that are selected to become neurons release their apical or ventricular attachments, delaminate from the neuroepithelium, and eventually differentiate under the pial surface of the neural tube. Subsequent studies have shown that expression of an *atonal*-related gene, *neurogenin* (*ngn1*), helps define the proneuronal domains and gives cells the potential to become neurons. Notch signaling drives expression of Hairy–E(spl)-related genes (called ESR genes in *Xenopus*, HER genes in zebra fish, and HES genes in most other vertebrates), and Ngn1 expression is prevented by Notch signaling. If cells express high enough levels of Ngn1, they can initiate the expression of additional genes that facilitate stable acquisition of neuronal fate. For example, Ngn1 drives expression of *neuroD*, a bHLH proneuronal gene whose function is not as easily inhibited by Notch signaling. Ngn1 also initiates MyT1 expression, a factor that makes selected cells less sensitive to Notch signaling. In addition, P27^{xic1} stabilizes Ngn1 and facilitates exit from the cell cycle. Despite the obvious similarities, there are important differences in the early roles described for Delta–Notch signaling in neurogenesis: In *Drosophila*, Notch signaling selects neuroblasts that delaminate and come together to form the neural anlage, whereas in *Xenopus* and zebra fish, Notch signaling plays a role in the selection of cells that become the earliest differentiating neurons within the neural anlage (neural plate).

There are four Delta homologs in zebra fish (*deltaA*, *deltaB*, *deltaC*, and *deltaD*). Of these, *deltaA* and *deltaD* are expressed in proneuronal domains during early neurogenesis. As cells are selected to become neurons, they express higher levels of *deltaA*, and expression becomes less in surrounding cells, reflecting dynamic regulation that is consistent with the process of lateral inhibition. Though Delta–Notch signaling is likely to play a role in lateral inhibition and cells are selected in a salt-and-pepper pattern from longitudinal columns of *ngn1*-expressing cells, it is not clear whether the cells form small contiguous *ngn1*-expressing clusters from which individual cells are selected or whether early patterning mechanisms simply define a long proneuronal domain from which cells are selected in salt-and-pepper pattern by lateral inhibition. Lineage analysis shows that Notch signaling clearly regulates binary cell fate decisions and that Notch signaling has a recurring role in regulating both early and late neurogenesis. However, the precise role of individual Delta and Notch homologs in lateral inhibition and binary cell fate decisions is only beginning to be defined, and it remains unclear what mechanisms bias selection by lateral inhibition.

In the zebra fish, Delta–Notch signaling also helps select sensory hair cells in the ear and in neuromasts. Neuromasts, initially deposited by the caudally migrating posterior lateral line promordium (pllp), contain a central hair cell that is surrounded by

supporting cells. Analysis of Notch–Delta function shows that it helps select a central hair cell within a proneural cluster defined by *atonal homolog1* expression. The migrating pllp contains three or four nascent neuromasts at various stages of maturation. The least mature are at the leading edge of the pllp, where *notch3* is diffusely expressed within a cluster of cells representing the future neuromast. As the neuromast matures, *atonal homolog1*and *deltaA* expression becomes prominent in a central cell, and *notch3* expression gets restricted to surrounding cells. Following deposition, neuromasts mature to produce a cluster of hair cells, following a pattern of development reminiscent of *Drosophila* chordotonal organs. Further analysis of neuromast development is likely to provide details about how the proneural cluster is defined, how biasing mechanisms lead to selection of a central cell in this context, and how additional hair cells are added to the cluster. It will be interesting to compare how a mechanism that operates in neuromasts compares with those defined for PNCs where SOPs are selected.

Additional Roles for Notch Signaling

Examples from *Drosophila* development illustrate how Notch signaling feeds into genetic networks that determine cell fate and how the location of a cell and interactions with additional signaling mechanisms can influence the outcome of lateral inhibition. These examples provide a useful framework for understanding how similar cell fate decisions are made during neurogenesis in other metazoan systems. Mechanisms that regulate protein trafficking and cell biology have a critical role in Notch signaling.

While the role of Notch signaling in lateral inhibition during neurogenesis has been emphasized, it should be kept in mind that Notch has diverse roles in all tissues. In addition to its role in lateral inhibition and in binary cell fate decisions, where it mediates competitive interactions and prevents adjacent cells from adopting the same fate, Notch signaling is also involved in inductive interactions where expression of Notch ligand in one cell is required to activate Notch and induce a specific fate in an adjacent cell. In ddition, instead of participating in a negative feedback loop, Notch activation can be part of a positive feedback loop in which mutual activation of Notch in adjacent cells helps maintain high Notch signaling and determines similar fate in adjacent cells. At the wing margin in *Drosophila* and at rhombomere boundaries in the zebra fish hindbrain, sustained Notch signaling is linked to expression of Wingless/Wnt and helps establish signaling centers at tissue compartment boundaries. During somitogenesis, delay between transcriptional regulation of gene expression and feedback inhibition by the encoded proteins results in oscillating gene expression; furthermore, since cell–cell communication contributes to the mechanism, the oscillations are synchronized between cells, and the synchronized oscillations are used to establish the periodic pattern of somites. Finally, while Notch can influence tissue patterning through its influence on cell fate at a transcriptional level, it may simultaneously influence the organization of factors that determine cell morphology. Understanding the diverse yet conserved roles of Notch in cell fate and tissue morphogenesis remains an important and exciting challenge for the future.

Pathway Overview

The Notch signaling pathway is one of a handful of signaling systems known to regulate the myriad of developmental decisions required for correct embryonic patterning and morphogenesis in metazoans. Consistent with this, Notch signaling affects the determination and differentiation of many different neural cell types in addition to regulating cell survival, adhesion, proliferation, and apoptosis. The activation of Notch by membrane-bound DSL (Delta, Serrate, LAG-2) ligands serves to limit signaling to cells in direct contact. Ligand binding leads to proteolytic release of the Notch intracellular domain (NICD) from the membrane, facilitating its role as a downstream signal transducer. The majority of signaling induced by Notch involves trafficking of NICD to the nucleus, where it interacts with a DNA-binding protein CSL (CBF1 in mammals, Su(H) in *Drosophila*, and LAG-1 in *Caenorhabditis elegans*) to recruit coactivators and turn on expression of target genes such as Hes-1 (hairy and enhancer of split-1) (Figure 1).

This mode of activation necessarily means that only one signal can be sent from each receptor molecule, and significantly, once a receptor is activated it cannot be reactivated. Given the direct nature of the signaling pathway, the core components are refreshingly few in number: ligand, receptor, and a DNA-binding downstream effector. However, this simplicity is balanced by a large, and still growing, number of requisite modulators that regulate this pathway.

Notch Receptors and DSL Ligands

The prototypic Notch receptor, *Drosophila* Notch (dNotch), is a type 1 transmembrane, cell surface protein with an ectodomain composed mainly of tandemly arrayed motifs related to epidermal growth factor (EGF-like repeats) (Figure 2(a)). Structure–function analyses indicate that the extracellular domain functions in ligand binding and repression of the signaling activity that is intrinsic to the intracellular domain. The Notch-related *Caenorhabditis elegans* proteins, GLP-1 and LIN-12, and the four mammalian Notch proteins, Notch1–4, all exhibit the same overall structure. Notch-related genes have been identified from a number of metazoans from sea urchin to human, but they are not present in plant genomes.

The DSL ligands that bind and activate the Notch/LIN-12/GLP-1 receptors comprise a family of proteins that are either Delta-like or Serrate-like (also known as Jagged) based on the structure of the two *Drosophila* ligands, Delta and Serrate (Figure 2(b)). In mammals, three Delta-like (Dll) genes have been identified (Dll-1, -3, and -4). Dll-2 has only been identified in *Xenopus* and four Dll genes have been reported for zebra fish, DeltaA–D, of which DeltaD is most similar to Dll-1. Only two Serrate-like subtypes (Serrate1/Jagged-1 and Serrate2/Jagged-2) have been isolated from humans, rats, mice, chickens, and frogs. There are three zebra fish Jagged genes (Jagged-1a, Jagged-1b, and Jagged-2).

Like the Notch receptors, the DSL ligands are single-pass cell surface proteins containing multiple EGF-like repeats; however, these ligands contain a signature motif dubbed DSL, which together with N-terminal (NT) sequences constitutes the ligand-binding domain. Although membrane attachment is thought to be important for activation of Notch, soluble DSL ligands have been found in worms, flies, and mammals. In fact, a search of the complete worm genome identified 10 DSL-containing ligands, with only five sequences predicting a transmembrane domain. In *Drosophila*, no soluble splice variants of Delta or Serrate have been reported; however, soluble forms of Delta, produced through cell surface proteolytic shedding, have been identified from embryos and cultured cells. The function of cleaved soluble DSL ligands in *Drosophila* is unclear, although when engineered soluble forms of Delta or Serrate are expressed in *Drosophila*, they produce phenotypes indicative of a loss in Notch signaling, suggesting that soluble ligands inhibit rather than activate Notch. Both Delta-like (Delta, Dll-1, and Dll-4) and Serrate-like (Jagged-1 and Jagged-2) ligands can be proteolytically processed by metalloproteases to effect extracellular domain shedding. The ability of soluble DSL ligands to either activate or inhibit signaling depends on their multimeric state; therefore, it is possible that the activity of soluble ligands may be regulated through interactions with the extracellular matrix as found for soluble growth factors. Alternatively, ligand shedding could represent a mechanism for downregulating activating ligand.

DSL ligands can also function outside of their role as activators of Notch signaling through interactions with the cytoskeleton via binding to PDZ-containing scaffolding proteins. PDZ-interaction motifs located in the C-terminus of DSL ligands can mediate interactions with MAGUK (membrane-associated guanylate

Figure 1 Notch signaling. In mammals (left), during trafficking to the cell surface mNotch is proteolytically processed by furin at the S1 site (1) and exists at the cell surface in a heterodimeric form (2). After ligand binding (3), DSL endocytosis of bound mNotch (4) is proposed to generate a 'pull' (arrow) that results in heterodimer dissociation (5) allowing removal of inhibitory sequences, including the LNR (red circles), that prevent ADAM cleavage. Following uptake of NECD$_s$ by the DSL cell, the remaining NICD$_s$ would then be exposed to activating proteolysis (6), first by ADAM to generate the S2 fragment that is subsequently cleaved by γ-secretase to produce the soluble NICD S3 fragment that translocates to the nucleus (7). Note that although mNotch S2 and S3 cleavages are shown here at the cell surface, it is also possible that either or both of these cleavages occur in an endosomal compartment. In the absence of Notch signaling, CSL recruits corepressors to inhibit gene transcription (8). When NICD is present, it displaces the corepressors and recruits coactivators to promote transcription of target genes such as Hes-1 or Hes-5 (9). In flies (right), there is evidence that cell surface dNotch is uncleaved (2). After ligand binding (3), the pull induced by DSL endocytosis (4 and 5) induces a conformational change that is thought to unmask the S2 site and allow for ADAM cleavage (6). This suggests that, unlike mammals, ligand-induced NECD release may be enzymatic, and not mechanical, in nature. Subsequent activating cleavage by γ-secretase (6) produces NICD that acts similarly to mammalian NICD in the nucleus to activate target genes such as Enhancer of split (E(spl)) (7–9).

kinase) family proteins. Mutation or deletion of the PDZ-binding domain in DeltaD, Dll-1, or Jagged-1 does not perturb Notch signaling, but rather produces phenotypes consistent with cytoskeletal involvement, such as aberrant cell migration or cell shape changes.

Regulation of Ligand-Induced Notch Signaling

Regulation of Ligand Expression

Cells take on distinct fates because Notch signaling is consistently activated in only one of the two interacting cells, highlighting the importance of establishing and maintaining signaling polarity. Studies in flies and worms have identified positive and negative transcriptional feedback mechanisms that amplify small differences in Notch and DSL ligand expression that bias which cells send or receive signals. Notch signaling can regulate gene expression of both the receptor and the ligand, and signaling from certain growth factor receptors (transforming growth factor-β (TGF-β) and vascular endothelial growth factor) also enhances DSL ligand expression. Other signaling pathways shown to potentiate DSL ligand expression include EGFR/MAP kinase, hormones, and NF-κB activation. Underscoring the importance of Notch and DSL ligand expression levels is the sensitivity to gene dosage reported for Notch-dependent processes, where both losses and gains in Notch activity produce mutant phenotypes. In humans, haploinsufficiency of either Jagged1 or Notch2 is associated with Alagille syndrome, whereas Notch1 haploinsufficiency is implicated in a subtype of inherited aortic disease.

Regulation of DSL Ligand Activity

The ability of cells to signal to Notch on adjacent cells is also regulated by endocytosis and membrane trafficking, consistent with the long-appreciated genetic interactions between Notch and shibire, which is the *Drosophila* homolog of dynamin, a key regulator of

Figure 2 Notch receptors and DSL ligands. (a) The schematic is based on the following protein sequences from GenBank: *Drosophila* Notch, P07207; human Notch1, P46531; human Notch2, Q04721; human Notch3, Q9UM47; human Notch4, Q99466; *C. elegans* LIN-12, P14585; *C. elegans* GLP-1, P13508. (b) Structures are based on the following protein sequences from GenBank: *Drosophila* Serrate, P18168; human Jagged1, XP056118; human Jagged2, Q9Y219; *Drosophila* Delta, P10041; human Delta1, O00548; *Xenopus* X-Delta-2, AAB37131; human Delta3, Q9NYJ7; human Delta4, Q9NR61; *C. elegans* LAG-2, P45442; *C. elegans* APX-1, P41990; *C. elegans* ARG-1, T16213; *C. elegans* DSL-1, AAC04450. The drawings are approximately to scale. ANK, ankyrin-like repeats; CR, cysteine-rich region; DSL, Delta/Serrate/LAG-2 domain; EGF, epidermal growth factor-like; HD, heterodimerization domain; LNR, LIN-12/Notch related repeat; NLS, nuclear localization sequence; NT, N-terminal domain; OPA, glutamine-rich region; PDZL; PDZ ligand motif; PEST, motif rich in proline, glutamine, serine, and threonine residues that is important in protein turnover; RAM, CSL interaction domain; SP, signal peptide; TAD, transactivation domain; TM, transmembrane domain.

endocytosis. Dynamin is required in both signal-sending and signal-receiving cells; however, the exact functions for endocytosis in productive DSL-induced Notch signaling are unclear. Identification of additional endocytosis and membrane trafficking proteins that function in Notch signaling (Table 1) has provided some insight.

DSL endocytosis is required for Notch activation Interestingly, DSL ligands defective in endocytosis accumulate at the cell surface yet are unable to activate Notch, suggesting that cell surface ligand alone is not sufficient to initiate signaling. This is consistent with the dynamin requirement in signal-sending cells, and other endocytic proteins are required for DSL

Table 1 Endocytosis and trafficking regulation of Notch signaling

Drosophila	*C. elegans*	*Mammals*	*Role in Notch signaling*
In the signal-sending cell			
E3 ubiquitin ligases			
Neuralized	F10D7.5[a]	NEURL, NEURL2	RING-type E3 ligase that binds and ubiquitinates DSL ligands and promotes endocytosis
Mind bomb (dMib)		MIB1, 2	RING-type E3 ligase that binds and ubiquitinates DSL ligands and promotes endocytosis
Clathrin-mediated endocytosis			
Liquid facets (lqf)	Epn-1	Epsin 1, 2	Clathrin-associated sorting protein required for Delta signaling activity
Shibire	dyn-1	Dynamin1, 2	Endocytosis of ligands from PM; required for NECD *trans*-endocytosis and possible recycling
Clathrin heavy	Chc-1	CLTC	Coat protein of endocytic pits and vesicles; enhances Lqf phenotype
Auxilin	Dnj-25	Auxilin,GAK	J-domain containing protein proposed to function in CCV formation and/or uncoating; enhances Lqf
Eps-15	Ehs-1	Eps15	Required for *trans*-endocytosis and Notch activation
RalA	Ral-1	RalA	GTPase functioning in endocytosis, recycling, and actin organization; enhances Lqf phenotype
Endosomal recycling			
Rab 11	Rab-11.1	Rab 11A	Asymmetrically distributed in signal-sending cell that may promote DSL recycling
Sec 15	C28G1.3[a]	Sec15	Component of the exocyst that may function in Delta recycling
In the signal-receiving cell			
E3 ubiquitin ligases			
Su(dx)	WWP1	Itch (Mm)/AIP4 (Hs), WWP 1, 2	Nedd-type E3 ligase that binds and ubiquitinates Notch; endosomal sorting and degradation of Notch, Deltex
Dnedd4	Y92H12A.2[a]	NEDD4-1,-2 (Nedd4l)	Nedd-type E3 ligase that binds and ubiquitinates Notch; endosomal sorting and degradation of Notch
D-Smurf	Ce33003[a]	hSmurf1,2	Nedd-type E3 ligase with partial genetic redundancy with Su(dx) in *Drosophila*
Cbl	sli-1	Cbl	E3 ligase that interacts with Notch; Notch lysosomal degradation
Deltex		DTX1-4	RING-type E3 ligase involved in endosomal sorting of Notch; ubiquitination(?) and proteosomal degradation of Notch involving Kurtz; effector of ligand- and CSL-independent signaling(?); positive modulator of Notch in *Drosophila*
Endocytosis/early endosome sorting			
Shibire	dyn-1	dynamin 1, 2	Endocytosis of Notch from the PM; required for S3 cleavage of Notch to produce NICD
Merlin/Expanded		NF2	FERM protein that clears Notch from the PM; negative modulator of Notch signaling
Avalanche		syntaxin7, 12	Early endosomal SNARE protein involved in Notch degradation and endocytosis; no genetic interaction with Notch
Rab5	rab-5	rab5A,C	Early endosome trafficking protein involved in Notch degradation and endocytosis; no genetic interaction with Notch
Hrs	hgrs-1	Hrs (HGS)	Directs ubiquitnylated cargo to ESCRT machinery; no genetic interaction with Notch except in ligand-independent Notch activity induced by LOF Lethal giant discs
Multivesicular body formation			
Erupted	C09G12.9[a]	tsg 101	ESCRT-I protein that restricts ligand-independent Notch activation; MVB sorting of Notch for degradation
Vps25	WO2A11.2[a]	Vps25	ESCRT-II protein that restricts ligand-independent Notch activation; MVB sorting of Notch for degradation
Lethal giant discs	Y37H9A.3[a]	CC2D1A,B	Restricts ligand-independent Notch activation; functions in endosomal sorting after Hrs
Other proteins with roles in endosomal sorting			
Kurtz	F53H8.2[a]	ARRB1, 2	Nonvisual β-arrestin that binds Deltex; proteosomal degradation of Notch that involves Deltex

[a]Homology by protein sequence only.

Where no gene is listed, no ortholog has been identified. CCV, clathrin-coated vesicle; CSL, CBF1/Suppressor of Hairless/LAG-1 Notch downstream effector; Eps, epidermal growth factor receptor pathway substrate; ESCRT, endosomal sorting complexes required for transport; FERM, 4.1 protein/ezrin/radixin/moesin; hrs, hepatocyte growth factor receptor tryosine kinase substrate; Hs, human; LOF, loss of function; Mm, mouse; MVB, multivesicular body; NECD, Notch extracellular domain; Nedd, neural precursor cell expressed, developmentally downregulated; NICD, Notch intracellular domain; PM, plasma membrane; RING, really interesting new gene; Su, Suppressor; tsg, tumor susceptibility gene; Vps, vascuolar protein sorting.

activity (Table 1). For example, the E3 ubiquitin ligases Neuralized and Mind bomb ubiquitinate the intracellular domains of invertebrate and vertebrate DSL ligands and promote their endocytosis. DSL ligands must be ubiquitinated to signal, and only ubiquitinated DSL ligands in the presence of Liquid facets, the sole *Drosophila* epsin-related clathrin-accessory protein, are competent to activate Notch on adjacent cells. Signal-sending cells also require additional proteins that function in clathrin-mediated endocytosis, such as clathrin, dynamin, auxilin, and Eps15, for DSL ligands to signal effectively. Together, these findings highlight the importance of DSL endocytosis in Notch activation, but the exact function is unclear and remains controversial.

DSL endocytosis functions in recycling The requirement for epsin-dependent endocytosis in the signal-sending cell has been suggested to reflect a role for epsin in promoting DSL recycling to produce an 'active' ligand through clustering, posttranslational modification, or maintaining high levels at the cell surface; however, direct demonstration that DSL ligands actually recycle is lacking.

DSL ligand recycling could produce strong signal-sending cells through asymmetric localization of Neuralized that potentiates ligand activity by promoting ubiquitin–epsin-dependent endocytosis and trafficking of DSL ligand. In addition, asymmetric partitioning of the recycling endosome has also been proposed to regulate Delta levels or activity by recycling Delta to the cell surface where it can activate Notch. The differential recycling of Delta has suggested a mechanism by which ligand could be concentrated in signal-sending cells. Consistent with a role for DSL recycling in Notch activation, losses in Sec15, which functions with Rab11 in trafficking proteins from the recycling endosome to the plasma membrane, also produce cell fate transformations indicative of defects in Notch signaling. Interestingly, the mechanism responsible for the apparent polarized distribution of recycling endosomes is different from that required for asymmetric segregation of Neuralized, indicating that there are multiple mechanisms operating to establish and maintain signal-sending potential.

That only some Notch-dependent processes require Sec15 activity is inconsistent with DSL recycling producing an 'active' ligand because all Notch signaling should require this. Nonetheless, Dll1 recycling defects in bone marrow stromal cells suppress Notch-dependent phenotypic changes in lymphoid progenitors, suggesting that DSL recycling is necessary to produce an active ligand. However, the reported accumulation of Dll1 to recycling endosomes could decrease Dll1 at the cell surface, thereby accounting for the losses in Notch signaling. In this case, the need for Dll1 to pass through the recycling endosome could reflect a mechanism to replenish cell surface ligand, especially given that Dll1 density determines the lymphoid fate generated from hematopoietic stem cells.

DSL endocytosis functions in proteolytic activation of Notch DSL endocytosis could function beyond presentation of cell surface ligand for Notch engagement, such as proteolytic activation of Notch to generate the NICD that functions as the downstream signal transducer (Figure 1). DSL binding induces a series of proteolytic cleavages in Notch, first at the extracellular ADAM site followed by γ-secretase cleavage within the membrane to release the NICD required for signaling. Although DSL is required to produce NICD from full-length Notch, it is unclear how ligand binding promotes ADAM cleavage, a necessary step in activating γ-secretase proteolysis. Studies of flies have suggested that endocytosis of DSL bound to Notch on adjacent cells (designated transendocytosis) might produce a molecular strain in Notch leading to conformational changes that facilitate ADAM cleavage. Since efficient γ-secretase cleavage depends on removal of the Notch extracellular domain (NECD), DSL endocytosis could also promote Notch signaling by clearing the ADAM-shed NECD through uptake by ligand cells.

DSL endocytosis promotes physical dissociation of Notch Findings with mammalian cells support a role for NECD transendocytosis by DSL ligand cells in Notch signaling but indicate that NECD is not proteolytically released. Rather, NECD transendocytosis by DSL ligand cells in the presence of ADAM inhibitors suggests that NECD is physically removed from Notch present on the surface of interacting cells. To understand this result, it is important to note that most of the mammalian Notch (mNotch) at the plasma membrane is an intramolecular heterodimer, formed through furin-proteolytic processing during transport to the cell surface (Figure 1). The NECD and membrane-bound NICD heterodimeric subunits remain associated following furin cleavage through noncovalent interactions that keep Notch intact and inactive. Although mNotch activation relies on heterodimeric formation, the significance of this processing event has remained controversial given that *Drosophila* Notch (dNotch) does not appear to require furin processing to signal. However, an unprocessed mNotch receptor is neither dissociated nor activated by DSL cells. Since DSL binding in the absence of endocytosis does not promote heterodimer dissociation, forces created during ligand endocytosis are proposed to remove

the NECD subunit ($NECD_s$) and expose the NICD subunit ($NICD_s$) to activating proteolysis (Figure 1). In support of this idea, a majority of activating Notch mutations in T cell acute lymphocytic leukemia are missense mutations that alter heterodimer stability and effect dissociation independent of ligand.

Interestingly, amino acid insertions near the ADAM cleavage site do not alter heterodimer stability but are nonetheless constitutively active. The inserted residues are proposed to expose the ADAM cleavage site within the intact heterodimer, which may be similar to how DSL binding activates dNotch. Specifically, there may be a requirement to remove or distance the inhibitory LNR domain of Notch, located just upstream of the HD (Figure 2), for S2 cleavage to occur. In fact, the LNR domain has been shown to be necessary for inhibiting S2 cleavage but not for maintaining the heterodimeric structure of Notch1. Together, these data suggest that DSL binding followed by endocytosis activates mNotch through heterodimer dissociation, whereas conformational changes that facilitate ADAM proteolysis of unprocessed dNotch may underlie its activation.

DSL epsin-dependent endocytosis generates a pulling force Since only ligands internalized by epsin appear competent to signal, what role could epsin play in Notch activation? It is possible that Notch binding to DSL could induce ligand clustering, which would amass ubiquitin binding sites for epsin via its ubiquitin interacting motif (UIM) repeats. By assembling multiple low-affinity UIM–mono-ubiquitin interactions, strong epsin–ubiquitinated DSL interactions could be generated, which may be necessary to overcome any resistance to DSL internalization when it is bound to Notch. In fact, replacement of the Delta intracellular domain with a single ubiquitin motif that can be further ubiquitinated allows internalization and signaling activity in zebra fish. However, a nonextendable ubiquitin only weakly signals in flies even though it promotes endocytosis, supporting the idea that multiple ubiquitin interaction sites are required for DSL to activate Notch.

Epsin is a multidomain protein that in addition to binding ubiquitinated cargo interacts with membrane phospholipids, clathrin, and other clathrin adaptors as well as Cdc42 GTPase-activating proteins that regulate actin dynamics. Together with reports that the actin cytoskeleton and dynamin produce membrane constriction and tension during the process of endocytosis, it is tempting to speculate that epsin is required for ligand activity to create an endocytic vesicle endowed with sufficient force to induce conformational changes that either physically pull the mNotch heterodimer apart or promote ADAM cleavage of intact dNotch. This may explain why ubiquitinated ligands internalized in cells lacking epsin are unable to signal and why only DSL ligands internalized in an epsin-dependent manner are competent to signal.

Mechanotransduction in DSL-Induced Notch Signaling

That endocytosis, rather than proteolysis, drives mNotch dissociation suggests a mechanism of activation that involves mechanotransduction to allow activating proteolysis to occur, rather than relying completely on proteolytic cleavage as proposed for dNotch. However, if an intact dNotch can be activated, why is heterodimeric formation required for activation of mNotch? Activation of a heterodimeric receptor through physical dissociation might allow for additional mechanisms of Notch activation. In fact, noncanonical ligands have been reported, and in particular the extracellular matrix proteins MAGP1 and-2 (microfibril-associated glycoprotein) dissociate mNotch independent of ADAM cleavage and DSL binding that leads to proteolytic activation of Notch. Since MAGP binds and dissociates Notch cells autonomously, it might allow Notch to function as a mechanosensor to detect changes in shear forces produced by blood flow, which, like Notch signaling, is implicated in arterial–venous fate determinations.

How do soluble DSL ligands activate Notch? If DSL endocytosis of Notch triggers proteolytic activation, how can soluble ligands activate signaling? Although soluble DSL ligands activate Notch signaling, they are less active than cell-associated ligands and require clustering or attachment to surfaces to efficiently activate signaling and induce biological responses. In fact, prefixed Delta-expressing cells that are presumably endocytosis defective activate Notch target genes. Perhaps soluble ligands attached to the extracellular matrix or cell surface bind to Notch, generating pulling forces through cell detachment and/or Notch endocytosis. This mechanism may account for the signaling activity of naturally occurring soluble DSL ligands identified for *C. elegans*, in which the Notch-related GLP-1 is also heterodimeric.

Endocytosis and Trafficking Regulate Notch Levels and Activity

Signal-receiving cells regulate basal levels and activity of cell surface Notch through ubiquitin-dependent endocytosis, sorting, and trafficking. Removal and replenishment of cell surface Notch independent of ligand might influence signaling through availability

of receptor for activation. However, the requirement for dynamin in signal-receiving cells suggests a role for Notch endocytosis, in concert with DSL endocytosis, to effect conformational changes and/or receptor dissociation through pulling forces exerted on ligand–receptor complexes. In addition, endocytosis and trafficking of Notch could promote interactions with activating proteases since both ADAMs and γ-secretase are integral membrane proteins. Alternatively, endocytosis could function to release NICD from the membrane following γ-secretase cleavage at the cell surface.

Where Does DSL-Induced Proteolytic Activation of Notch Occur in Cells?

Whereas S2 and S3 cleavages of Notch are usually depicted to occur at the cell surface, ADAMs are found at the plasma membrane, early endosomes, and lysosome, so theoretically, cleavage could occur at any of these sites. Although evidence for intracellular cleavage of mNotch by ADAMs is lacking, γ-secretase proteolysis may occur inside cells since both monoubiquitination and clathrin-mediated endocytosis of Notch are required for signaling. Ubiquitination could allow endocytosis and/or trafficking that directs the ADAM/S2 cleavage fragment to an intracellular γ-secretase-rich compartment for S3 cleavage. However, the cellular site for γ-secretase cleavage of Notch is controversial and data support cleavage at the cell surface as well as within the cell. Nonetheless, γ-secretase activity is present in lysosomes and is enhanced by low pH. Given reports that endocytosis is required for γ-secretase cleavage of proteins other than Notch, the endosome is an attractive site for Notch proteolytic activation.

DSL-Independent Endocytosis and Trafficking of Notch

In the absence of ligand, Notch is also removed from the cell surface and may be either recycled or targeted for degradation. Since ubiquitin signals endocytosis, sorting and trafficking of cell surface proteins, it is not surprising that a number of E3 ubiquitin ligases are associated with Notch (Table 1).

In mammalian cells, the E3 ubiquitin ligases Cbl and Itch/AIP4 have been reported to interact with or modify Notch, but the biological relevance of these findings is unclear. Genetic studies of flies have provided evidence that ubiquitination and endosomal trafficking of Notch are important regulators of Notch activity. The Nedd E3 ubiquitin ligases bind and ubiquitinate Notch, and they may regulate Notch cell surface expression by promoting endocytosis and targeting for lysosomal degradation. Dominant-negative Nedd proteins increase Notch localization to recycling endosomes and at the cell surface, suggesting that losses in Notch ubiquitination promote its return to the cell surface, perhaps for increased exposure to ligands. However, coexpression of dominant-negative Nedd proteins and Notch in *Drosophila* activates signaling independent of ligand. In this case, suppressing Nedd function could protect a positive Notch effector from degradation. In fact, both *Drosophila* and mammalian Nedd family members ubiquitinate Deltex, a positive effector of Notch signaling, marking it for lysosomal degradation. Deltex is a RING-finger E3 ubiquitin ligase that, when overexpressed in flies, results in aberrant accumulation of dNotch in late endosomes/lysosomes and ligand-independent signaling. However, Deltex has also been shown to ubiquitinate dNotch directly for proteosomal degradation that would limit signaling. This negative effect of Deltex on dNotch requires a third protein, Kurtz, the single *Drosophila* ortholog of β-arrestin. Interactions between β-arrestin and dNotch may mediate integration of Notch with other signaling pathways given that in mammalian cells β-arrestins act as scaffolds/adaptors for signaling effectors.

Membrane trafficking defects result in aberrant accumulation of Notch within endosomes and in some cases unliganded Notch is activated (Table 1). In the early endosome, Notch is localized by the Hrs protein to the ESCRT machinery that promotes trafficking for lysosomal degradation. Defects in either ESCRT or Hrs proteins promote endosomal accumulation of Notch, but ectopic signaling is only activated with loss of ESCRT components (vps23 (erupted)/tsg101 and vps25) or a novel cytoplasmic protein, Lethal giant discs (Lgd), which is epistatic to Hrs. This ligand-independent Notch activation requires γ-secretase and further indicates that Notch can be activated intracellularly.

The ability of some, but not all, endosomal trafficking defects to activate Notch inappropriately provides insight into the intracellular locale where Notch is activated. Differences in endosomal acidity could limit γ-secretase activity to a specific compartment where Notch accumulates and the pH is low enough to promote conformational changes and/or receptor dissociation for ligand-independent activation. Proteolysis is possible since Notch activating proteases are also transmembrane proteins that could be trapped with Notch in the same compartment when membrane trafficking is blocked. During normal membrane trafficking, Notch and its associated proteases would transit quickly though the endosome, thereby avoiding aberrant activation.

Regulation of Notch Target Gene Expression

Transcriptional Complexes

Structure–function analyses have identified several regions of the intracellular domain necessary for transcriptional activation (Figure 2(a)) in addition to two nuclear localization sites that function in transport of NICD to the nucleus. The RAM domain, juxtaposed to the cytoplasmic face of the membrane-spanning region, is responsible for strong interactions with CSL, the major effector of Notch signaling. In addition to the RAM domain, seven ankyrin (ANK) repeats also interact with CSL proteins and are both necessary and sufficient for Notch transcriptional activity. Downstream of the ANK repeats is a region of high homology required for transcriptional activation (TAD), and at the C-terminus PEST sequences regulate turnover of NICD protein in the nucleus. Although all four mammalian Notch proteins are proteolytically processed to generate active NICD-like fragments, the individual TADs vary in potency, which may reflect differences in target gene activation induced by the different Notch receptors.

Genetic studies indicate that the CSL genes Su(H) and LAG-1 are required for normal Notch/LIN-12/GLP-1 function but act downstream of the receptors to positively regulate signaling (Figure 1). Typically, the CSL proteins function as transcriptional repressors; however, activation of Notch signaling in cells converts these DNA-binding proteins into transcriptional activators. Complexes containing NICD and CSL physically associate with DNAs containing CSL binding sites, and these interactions correlate with transcriptional activation of Notch target genes such as Enhancer of split (E(spl)) and the homologous vertebrate genes of the Hes and HERP family (Figure 3). In fact, induced expression of E(spl) and its homologs has been a convenient marker to monitor and identify cells undergoing Notch signal transduction, although some interpretation is needed because these genes can be regulated independently of Notch.

A crucial component of the NICD/CSL activation complex is mastermind (MAM). There are three mastermind-like proteins in mammals, MAML1–3, that *in vitro* have differing abilities to potentiate the activity of NICD/CSL complexes. Structure studies indicate that MAM binds to a composite site that consists of both the ANK repeats of Notch and a portion of CSL (Figure 3). Only the NT 80 amino acids of MAM are necessary for binding to the CSL/NICD interface and on their own function as a dominant-negative pan-Notch inhibitor, presumably by forming inactive complexes with activated NICD. This implies that the bulk of MAM binds and recruits other proteins required for activated transcription. In fact, in response to ligand, NICD, MAM, p300, CBP, and SKIP (Ski-interacting protein) are found associated with the Hes1 promoter. Since CSL binds to its cognate binding sites in the absence of Notch protein, it is constantly present on the Hes1 promoter (Figure 3).

In the absence of activated Notch, CSL transcriptional repression has been linked to a number of corepressor proteins and their associated histone deacetylases (HDACs) (Figure 3). Mammalian CSL proteins physically interact with two different corepressor complexes, one containing SMRT (silencing mediator of retinoid and thyroid hormone receptors), HDAC-1, and SHARP/MINT (msx-interacting protein), and the other consisting of corepressors CIR (CBF1-interacting corepressor), SAP30, and HDAC-2. Notch can displace the corepressors bound to CSL to activate transcription, whereas SMRT or CIR can compete with NICD for binding to CSL that results in a suppression of NICD-mediated CSL activation. As might be expected for a protein that requires cofactors to actively repress transcription, 'de-repression' resulting in transcriptional activation can also occur either in the absence of corepressors or due to removal of CSL from its DNA-binding sites. KyoT2, a LIM-only protein, may act in this manner because it can block CSL binding to DNAT and compete with activated Notch1 for binding to CSL.

Notch Target Genes Regulated by CSL

The best genetically and biochemically characterized direct targets are the E(spl)/Hes/HERP genes. These genes encode basic helix–loop–helix (bHLH) transcription factors that in response to Notch signaling repress both the expression and the function of genes that encode activating bHLH transcription factors, such as the proneural achaete–scute complex (AS-C) in *Drosophila* and the vertebrate homologs of the AS-C genes, MASH, neuroD, neurogenin, and MATH.

The vertebrate homologs of E(spl), the Hes genes, also serve as Notch effectors downstream of NICD/CSL activation. Three of the Hes genes (Hes1, -5, and -7) and all three Hes-related genes (HERP1–3) have been shown to be direct transcriptional targets of Notch. As in the fly, genetic loss of Hes genes often, but not always, leads to Notch-like phenotypes. Although the Hes/HERP family of bHLH repressors represents a major subset of Notch target genes that lead to repression of downstream targets, it has become evident that CSL binding sites are present in a number of promoters and that NICD can lead to transcriptional

Figure 3 CSL transcriptional regulation. The DNA-binding CSL protein is common to both repression and activation complexes. In the absence of activated Notch, CSL interacts with known corepressor proteins (SMRT and SHARP(MINT)) that recruit histone deacetylases (HDAC1 or -2) to repress transcription (1). Upon Notch activation, NICD enters the nucleus and displaces the corepressor complex (2). NICD is thought to interact with CSL in a manner analogous to SMRT, although the Notch ICD and SMRT contain no identifiable sequence similarities. NICD binding to CSL creates a novel interaction site for the coactivator mastermind (MAM) that further recruits histone acetyltransferases (HAT), kinases, and elongation factors (not shown) to activate transcription (3). Loss of CSL DNA binding activity, either through interaction with KyoT2 or mutation of CSL, leads to 'de-repression' (4). In the absence of repression (and activation) complexes, some transcriptional activity is detected.

upregulation of these genes as well. The growing list includes Erbb2, glial fibrillary acidic protein, brain lipid-binding protein, GATA2, and IκBα.

Elaborations on Notch Signaling, Both Canonical and Noncanonical

The seemingly simple and direct mode of Notch signal transduction is at odds with the myriad of functions attributed to Notch, especially given the relatively small number of receptors and ligands identified for this signaling pathway. However, diversity in the output of canonical Notch signaling is most likely achieved by cross-interactions with other signaling pathways, and further diversity is achieved using noncanonical forms of Notch signaling. For example, in vascular development, the canonical Notch pathway involving NICD/CSL can cooperate with the hypoxia-inducible factors to promote blood vessel formation, perhaps by collaborating to drive expression of the Hey/HERP/Esr genes. The canonical Notch pathway can also interact with the TGF-β superfamily receptor signaling system through direct interactions between their downstream effectors. Smads activated following TGF-β binding to its cognate receptors can directly bind to NICD, leading to enhanced NICD–CSL activation of the target genes Hes/HERP. Finally, interactions have also been reported between canonical Notch signaling and the Wnt signaling pathway, but in this case the outcome is antagonistic. Cross-talk between Notch signaling and many of the major signaling pathways is likely to emerge in the future as more is learned about the global changes that occur in cells when they integrate multiple signals.

Diversity in Notch signal transduction is also achieved using pathways that diverge away from the

core one using CSL. For example, noncanonical ligands that lack DSL domains, such as DNER and F3/contactin/NB-3, have been reported to activate Notch and drive glial-specific genes such as myelin-associated glycoprotein through interactions with the downstream effector Deltex. Binding of these atypical Notch ligands leads to proteolytic activation of Notch and treatment with γ-secretase inhibitors blocks signaling. Although DNER and F3/contactin/NB-3 activation of Notch induces the translocation of NICD to the nucleus, transcriptional activation of glial-specific genes occurs independent of CSL and does not appear to involve Hes1. Diversity in Notch signaling may also be achieved using pathways that are activated independently of the transcriptional effects of NICD. In one report, for instance, DSL ligand-mediated Notch proteolysis has been proposed to induce rapid cytoplasmic responses, which involve a series of phosphorylation events on PI(3)K, Akt, and STAT3 that culminate with the translocation of phosphorylated STAT3 to the nucleus, where it stimulates Hes3 transcription. By an unknown mechanism, Hes3 leads to the production of sonic hedgehog to promote survival of neural stem cells, all independent of CSL transcriptional activation. Finally, diversity in Notch signaling may involve a pathway in which DSL ligand activates a nonheterodimeric form of Notch. Importantly, biochemical studies have documented that uncleaved, full-length Notch is endogenously expressed on the surface of a number of different mammalian cell types, and this form appears to be the major species found in *Drosophila* cells. This type of signaling has been reported to block myogenic differentiation in the absence of CSL. Notably, a full-length, furin-resistant, uncleaved Notch receptor can respond to ligand to suppress myogenesis but not activate a CSL reporter. These results indicate that an alternative form of the Notch receptor can mediate signaling which is both CSL independent and proteolysis independent.

Summary

In the past few years, there has been rapid growth in the understanding of Notch signaling mechanisms and functions. Genetically amenable model organisms that require Notch signaling have led to the identification and characterization of this essential signaling pathway. The growing number of interactions identified for Notch with other signaling pathways, as well as the isolation of additional Notch activators, likely account for the diverse and extensive nature of this highly conserved and ubiquitous signaling system. As additional components of endocytosis and membrane trafficking are linked to Notch signaling, requirement for endocytosis in Notch signaling should become clearer. What is becoming clear is that the more we investigate Notch signaling mechanisms, the more we realize just how pervasive its use is in both developmental and disease settings.

Background – NSF, SNAPs, and SNAREs

Classic work by George Palade and others in the 1960s established that secreted proteins follow a predetermined route from the endoplasmic reticulum (ER) through the various Golgi compartments to the plasma membrane. This route is known as the secretory pathway and comprises a series of transport steps, each requiring vesicle budding from the donor membrane followed by vesicle docking and fusion with the appropriate acceptor membrane. However, the molecular mechanisms underlying these budding and fusion processes were entirely unknown. In the late 1970s and early 1980s, genetic and biochemical approaches were used to shed light on this issue by studying the intracellular requirements for membrane trafficking in the secretory pathway. In the genetic approach, pioneered by Randy Schekman, yeast cells were mutagenized and then screened for mutants able to secrete at 25 °C (the permissive temperature) but not at 37 °C (the restrictive temperature). Further study revealed that these secretory (*sec*) mutants could be subdivided into 23 complementation groups, termed *sec1–23*, each representing a mutant allele of a gene required for vesicle formation or consumption at defined steps in the secretory pathway. In the biochemical approach, pioneered by James Rothman, membrane traffic through the mammalian Golgi was reconstituted *in vitro* using isolated Golgi complexes and cytosol. Subsequently, protein purification allowed the identification of several soluble proteins required for efficient intra-Golgi transport.

The first protein identified using the biochemical approach was *N*-ethylmaleimide-sensitive fusion protein (NSF), which was purified in 1988 based on its ability to reconstitute intra-Golgi transport after blockade by *N*-ethylmaleimide (NEM). NSF was soon found to be required for *in vitro* ER-to-Golgi transport and endocytic vesicle fusion, suggesting that NSF was required for multiple steps in the constitutive secretory and endocytic pathways. When the mammalian NSF gene was cloned in 1989, its coding sequence was found to be 48% identical to that of the yeast *sec18* gene. Like NSF, Sec18 is required for multiple steps in the secretory and endocytic pathways. Sec18 protein-containing yeast cytosol can substitute for NSF in mammalian *in vitro* assays of endosome fusion and intra-Golgi transport, thus emphasizing the functional conservation and near ubiquitous requirement for NSF/Sec18p in membrane traffic.

NSF exists in both cytosolic and membrane-associated forms, and the binding of NSF to membranes is mediated by soluble NSF attachment proteins (SNAPs; three isoforms – α, β, and γ). SNAPs are functional homologs of the yeast *SEC17* gene product required for ER-to-Golgi transport. NSF and SNAPs co-assemble into 20 *S* particles in the presence of detergent-solubilized membranes, indicating the presence of membrane-bound SNAP receptors (SNAREs). Using an immunoprecipitation approach with brain membranes, the Rothman lab identified the neuronal SNAREs as synaptobrevin (VAMP), syntaxin, and SNAP-25. These three proteins are proteolytic substrates for the botulinum neurotoxins, potent inhibitors of neurotransmission, thus implicating NSF and SNAPs in regulated exocytosis at the synapse. Furthermore, the neuronal SNARE proteins displayed sequence homology to various yeast proteins required for membrane traffic; for example, SNAP-25 is homologous to yeast Sec9. This discovery therefore had a tremendous impact on the field because it indicated that all membrane fusion events were mediated by NSF, SNAPs, and SNAREs.

The discovery of a complex of NSF/SNAP/SNARE proteins suggested that this might represent a single particle mediating vesicle docking and fusion. The SNARE hypothesis postulated that vesicle targeting/docking to the correct acceptor membrane was mediated by the selective interaction of specific SNAREs located on the vesicle (v-SNAREs) with appropriate SNAREs on the target membrane (t-SNAREs). Subsequent binding of SNAPs and NSF to this complex, followed by ATP hydrolysis by NSF, would disassemble the complex, leading to membrane fusion. Although appealing, this model was inconsistent with a variety of observations, not least that membrane fusion can be elicited in the absence of ATP during regulated exocytosis. Throughout the years, it has become accepted that the SNAREs execute the membrane fusion reaction, whereas NSF and SNAPs are not directly involved in fusion. Instead, NSF/SNAPs bind to dead-end SNARE complexes resident in the same membrane (*cis*-SNARE complexes) and use the energy of NSF ATPase activity to disassemble these complexes, thus freeing individual SNAREs to engage in future membrane fusion events.

SNAREs

Although originally defined biochemically as SNAP receptors, SNAREs are now defined structurally as

proteins containing a characteristic 60–70 residue domain known as the SNARE motif. Most SNAREs are integral membrane proteins with a single transmembrane domain at their C-terminus, although some lack transmembrane domains (e.g., SNAP-25 is targeted to membranes via palmitoylation). The classification of SNAREs as v- or t-, based on their localization to vesicle or target membranes, remains extremely useful conceptually. However, a rival classification system is also widely used based on the presence of a conserved glutamine (Q) or arginine (R) at the core of the SNARE motif. Most SNAREs contain a single motif, but some – notably the SNAP-25 homologs involved in exocytosis – contain two SNARE motifs. The interaction of individual SNAREs to form a complex is mediated by the formation of a helical bundle composed of four SNARE motifs (**Figure 1(a)**). In the case of the synaptic SNARE complex, one SNARE motif is provided by syntaxin (t-/Q-SNARE), two by SNAP-25 (t-/Q-SNARE), and one by VAMP (v-/R-SNARE). The formation of the three-helical t-/Q-SNARE heterodimer is the initial, rate-limiting step; upon formation, v-/R-SNARE binding can occur relatively quickly. The zippering together of the SNARE motifs to form the four-helical bundle occurs from the membrane distal N-termini toward the membrane proximal C-termini and is very energetically favorable. It is widely believed that this zippering process actively pulls the opposing membranes together to directly drive membrane fusion. This attractive idea is supported by experiments in which recombinant yeast and mammalian SNARE proteins incorporated into synthetic proteoliposomes have been shown to reconstitute membrane fusion *in vitro* in the absence of other proteins, albeit inefficiently. SNAREs, therefore, are the minimal machinery for membrane fusion.

SNAPs

NSF is a soluble protein whose function requires attachment to membranes. Biochemical approaches led to the purification of SNAPs as the adaptor proteins that linked NSF to membranes and also provided an essential function in the intra-Golgi transport assay. Three SNAP isoforms were purified from brain: α, β, and γ, all of which are 30–40 kDa monomeric soluble proteins. α-SNAP is ubiquitously expressed, whereas β-SNAP is a brain-specific isoform that has high sequence homology to α-SNAP. Intuitively, it seems that β-SNAP must serve some brain-specific function; however, in most assays, α- and β-SNAP are interchangeable and have similar activities. γ-SNAP displays much lower sequence homology, and despite its biochemical ability to bind NSF, there are relatively few examples in which a functional role for this isoform in membrane traffic has been demonstrated. The physiological role of γ-SNAP therefore remains unclear. In contrast, abundant functional evidence supports an evolutionarily conserved role for α-SNAP in membrane traffic. Genetic evidence comes from the *in vivo* block in membrane fusion caused by mutations in the yeast homolog of α-SNAP, Sec17. Furthermore, Sec17 protein can provide SNAP activity in mammalian assays of both NSF binding and *in vitro* reconstitution of membrane traffic. α-SNAP has been shown to be involved in various membrane traffic steps, including regulated exocytosis in neuronal and endocrine cells. A mouse mutant, hydrocephalus with hop gait (*hyh*), has been found to be due to a single missense mutation in α-SNAP. These mutants are characterized by postnatal death induced by aberrant ventricular fluid regulation, suggesting an important physiological role for SNAPs in normal brain function.

The defining characteristic of SNAPs is their ability to bind NSF. However, this does not occur in solution: NSF will only bind to SNAPs that are prebound to SNAREs (or to a plastic surface, which suffices *in vitro*). Therefore, the binding site on SNAPs for NSF must normally be occluded in the cytosol, only becoming exposed upon SNARE binding. It appears that three SNAP molecules are needed to link each SNARE complex to one NSF molecule. The only available crystal structure for a SNAP is that of the yeast Sec17 protein. This reveals a highly α-helical structure comprising an N-terminal domain composed of a

series of helical hairpins capped by a C-terminal helical bundle (Figure 1(b)). Because this structure is of the protein in isolation, the residues that contact NSF and the SNAREs cannot be deduced. Nevertheless, based on biochemical analysis using mutant proteins, it seems likely that the helical hairpin domain lies along the length of the SNARE complex, with its N-terminus at the membrane-proximal region and its C-terminus in contact with NSF at the membrane-distal end of the SNARE complex. It should be noted that α-SNAP is capable of binding to syntaxin alone and also to the syntaxin/SNAP-25 t-/Q-SNARE heterodimer. In both cases, NSF can be recruited to these complexes and mediate their ATP-dependent disassembly, although whether such subcomplexes are formed *in vivo* and their functional relevance remain unknown.

Thus far, we have only considered SNAPs as adaptor proteins, linking NSF to membrane-bound *cis*-SNARE complexes. However, SNAPs also have an essential catalytic function in stimulating the ATPase activity of NSF. These two actions of SNAPs can be uncoupled by mutations in the extreme C-terminus of α-SNAP, which do not affect binding to SNARE complexes or recruitment of NSF to these complexes but abolish the SNAP-mediated stimulation of NSF ATPase activity. This results in the formation of stable NSF-SNAP-SNARE complexes that do not disassemble in the presence of hydrolyzable ATP. This demonstrates that the weak intrinsic ATPase activity of NSF is insufficient to drive SNARE complex disassembly and that stimulation of ATPase activity by SNAPs is essential for this critical function of NSF. Indeed, mutation of the highly conserved penultimate leucine 294 residue to alanine in α-SNAP produces a dominant-negative mutant that inhibits membrane traffic in both the exocytic and the endocytic pathway.

NSF

As discussed previously, abundant functional evidence from yeast and mammalian systems supports an essential physiological role for NSF in all constitutive membrane traffic steps. The general requirement for NSF in membrane trafficking extends to regulated exocytosis, as illustrated by the *Drosophila comatose* mutants. These flies appear normal at 23 °C but exhibit paralysis at 38 °C due to a block in synaptic transmission. The *D. comatose* phenotype is due to missense mutations in the *dNSF1* gene, which encodes the majority of NSF protein in adult flies. Another gene, *dNSF2*, is expressed earlier in development; mutations in this gene lead to developmental defects and overgrowth of the neuromuscular junction.

NSF is a member of the AAA+ family of ATPases associated with a variety of cellular activities. Structural and biochemical studies have shown NSF to be a homohexamer of 76 kDa subunits arranged in a ring, forming a barrel-like structure containing a central cavity. Each individual subunit comprises three domains: an N-terminal domain and two AAA+ ATPase domains, D1 and D2 (Figure 2(a)). The approximately 200-amino acid N domain is composed of two subdomains, N_A and N_B, joined by a linker (Figure 2(b)). The N domain mediates binding to the SNAP/SNARE complex, as point mutations in this region of both NSF and Sec18 inhibit SNAP/Sec17 binding. The N domain also appears to be involved in transducing the SNAP stimulation of ATPase activity, as antibodies directed at this domain result in increased ATPase activity. It is the D1 domain that is the source of this ATPase activity, although in the absence of SNAPs the intrinsic ATPase

Figure 2 Domain structure and posttranslational modification of NSF. activity of NSF is extremely low. SNAP binding to NSF stimulates D1 domain ATP hydrolysis severalfold and is essential for NSF to disassemble SNARE complexes. ATP binding and hydrolysis is coordinated by Walker A and B box motifs present in the D1 domain. Mutants in the D1 Walker A motif are unable to bind ATP and are also unable to interact with SNAP/SNARE complexes. In contrast, mutants in the D1 Walker B motif can bind ATP and interact with SNAP/SNARE complexes normally but are unable to hydrolyze the bound ATP and hence cannot disassemble these complexes. Thus, NSF binding to SNAP/SNARE complexes is dependent on the D1 ATP-bound conformation; hydrolysis of this ATP in response to SNAP stimulation both disassembles the SNAREs and releases NSF, as the ADP-bound conformation is unable to bind to SNAPs. Indeed, electron microscopy studies have revealed distinct conformations of NSF depending on its nucleotide-bound state. In the ATP-bound state, NSF's N domains extend out from the central ring, but these are withdrawn in the ADP-bound state. Mutation of residues in the D1 Walker B motif creates dominant negative mutants of NSF and Sec18, presumably because this results in the accumulation of dead-end SNAP/SNARE/NSF complexes that cannot be disassembled (just like the dominant negative SNAP L294A mutant). Although ATPase defective mutants of NSF and Sec18 are generally nonfunctional in membrane traffic, these are apparently functional in the NSF-dependent reconstitution of Golgi reassembly *in vitro*. The reason for this exception is not clear. The D2 domain is homologous to the D1 domain and also contains Walker A and B boxes (**Figure 2(c)**). However, mutations in these domains have minimal effect on NSF ATPase activity, either intrinsic or SNAP stimulated, indicating that this AAA+ ATPase domain is catalytically inactive. Instead, the D2 domain has an essential structural role in forming the hexameric structure that is required for NSF function. Indeed, truncation mutants lacking the D2 domain are not functional in membrane traffic.

Classical Functions of SNAPs and NSF

Overwhelming evidence suggests that the major, evolutionarily conserved function of SNAPs and NSF is their cooperative action in disassembling *cis*-SNARE complexes. NSF and SNAP can be thought of as chaperone and co-chaperone proteins whose job is to mediate the unfolding of such complexes wherever and whenever they form in the cell. This conclusion is supported by analysis of the temperature-sensitive yeast *sec18-1* and *D. comatose st17* and *st53* NSF mutants, which accumulate SNARE complexes upon shift to the restrictive temperature. These mutant proteins exhibit defects in SNAP binding, intrinsic ATPase activity, and SNAP-stimulated ATPase activity, respectively. It therefore seems that the *in vivo* function of SNAPs/NSF involves several sequential events: (1) SNAPs bind to *cis*-SNARE complexes; (2) NSF is recruited to form the SNARE/SNAP/NSF complex; and (3) SNAPs stimulate the intrinsic ATPase activity of NSF, triggering disassembly of the complex.

Although the requirement for SNAPs/NSF in SNARE complex disassembly is not in doubt, the precise stage at which this acts in the membrane traffic process has been controversial. Although, by definition, t-SNAREs should not reside on vesicles, it has been shown that this is in fact the case for a variety of regulated secretory vesicles. Furthermore, *cis*-SNARE complexes are present on synaptic vesicles and these can be disassembled by NSF/SNAPs. Studies of *in vitro* reconstitution of yeast vacuolar fusion indicated a predocking, priming role for Sec17/Sec18 because the function of these proteins was completed even before donor and acceptor vacuoles were mixed. One caveat of this conclusion, however, is that in such homotypic fusion systems, it is difficult to distinguish predocking from postfusion because all vacuoles presumably contain *cis*-SNARE complexes leftover from previous fusion events. Analysis of heterotypic membrane fusion in regulated exocytosis does not suffer from this problem; however, results from these studies have yielded opposite conclusions. For example, recombinant α-SNAP causes a large increase in calcium-triggered exocytosis of dense-cored granules in chromaffin cells; 99% of these granules are undocked, and there is no contribution from postfusion recycling in this assay, strongly suggesting a predocking role. Similarly, analysis of sperm exocytosis, in which the fusion of a single giant undocked vesicle, the acrosome, is triggered by calcium, reveals a stimulatory action of α-SNAP and NSF. It is difficult to see how the action of SNAPs/NSF could be anything other than predocking in these systems. In contrast, analysis of synaptic exocytosis in *D. comatose* mutants has resulted in the opposite conclusion, namely that NSF/SNAPs execute a strictly postfusion role. This is based on the observation that the entire synaptic vesicle pool at the neuromuscular junction can be exocytosed despite the inactivation of NSF, and that SNARE complexes accumulate only as a result of membrane fusion. It may be that the special requirements of the synapse for rapid exocytosis under high-frequency stimulation require a significant reserve capacity of free SNAREs. Indeed, there are approximately 70 copies of VAMP/synaptobrevin on a single synaptic vesicle. Perhaps in other regulated exocytotic events,

Figure 3 Role of NSF and SNAPs in membrane traffic. NSF/SNAPs associate with *cis*-SNARE complexes either on the vesicle (stage 1, predocking) or on target membranes (stage 2, postfusion). SNAP-stimulated NSF ATPase activity then disassembles the complex, releasing SNAREs to engage in further rounds of membrane fusion.

a large reserve capacity is not available, resulting in the observed acute requirement for NSF/SNAPs. It may be relevant in this regard that the initial rapid burst of exocytosis in chromaffin cells is not stimulated by SNAPs and is unaffected by NEM. Thus, it may be that in these cells, a small pool of preprimed, rapidly released vesicles can fuse without the need for acute NSF/SNAP action, whereas the bulk of release that occurs later actively requires SNAP/NSF-mediated disassembly of *cis*-SNARE complexes on the vesicle (Figure 3, stage 1) and/or plasma membranes (Figure 3, stage 2) to free up the SNAREs for subsequent fusion events.

Novel, SNARE-Independent Functions of SNAPs and NSF

In addition to its well-characterized interaction with the SNAP/SNARE complex, NSF has been reported to bind to a large number of other proteins. In most cases, this has been reported using yeast two-hybrid or coimmunoprecipitation/pull-down approaches. Note that NSF requires ATP or ADP for stability, so putative interactions observed in nucleotide-free solutions, which cause NSF aggregation, should be viewed with caution. Nevertheless, it is interesting to note that the various NSF binding proteins mainly fit into two categories. The first comprises proteins that function in various membrane trafficking steps, such as Rab protein complexes and the small, ubiquitin-like LMA1/GATE-16 proteins. These interactions may contribute to NSF's classical function in membrane traffic, albeit in a SNARE-independent manner. However, the second category of NSF binding proteins comprises plasma membrane receptors and appears unconnected with the classical function of NSF. This includes the GluR2 subunit of AMPA-type glutamate receptors, $GABA_A$ and $GABA_B$ receptor subunits, dopamine D1 and D2 receptors, adrenomedullin receptors, and several muscarinic receptor subtypes. Interestingly, the interactions generally occur on the C-terminal cytoplasmic tails of these receptors. By far the best characterized interaction is that of the GluR2 C-terminus with NSF. Originally identified by yeast two-hybrid screens, this interaction is ATP dependent but does not require SNAPs. Abrogation of the NSF–GluR2 interaction inhibits AMPA receptor-mediated synaptic transmission and affects synaptic plasticity, demonstrating the physiological importance of this interaction. The GluR2 C-terminus is a hotspot for protein interactions, with PICK1 also binding to this site. Binding to PICK1 facilitates endocytosis, and hence functional removal, of AMPA receptors. NSF can bind to this GluR2–PICK1 complex in the absence of SNAPs, but it can only disassemble the complex upon addition of SNAPs. This bears a striking resemblance to the classical SNARE disassembly function of NSF, but in this case the GluR2/PICK1/SNAP complex is the substrate for disassembly and SNAPs play a purely catalytic role in stimulating NSF ATPase activity. It is thought that disassembly of PICK1 both antagonizes endocytosis and frees up the GluR2 C-terminus to interact with other synaptic proteins such as ABP/GRIP, thus stabilizing AMPA receptor surface expression. Interestingly, overexpression of α- and β-SNAPs has distinct effects on AMPA receptor endocytosis, providing a rare example of a functional difference between these two isoforms and suggesting that the brain-specific nature of β-SNAP may be related to such nonclassical, SNARE-independent functions. It is tempting to speculate that the interaction of NSF with other receptors may also be concerned with disassembling multiprotein complexes containing these receptors. In this way, the classical role of NSF as a chaperone acting to unwind SNARE protein complexes would simply have been adapted for the unfolding of other structurally similar protein complexes.

Regulation of NSF by Posttranslational Modifications

NSF could be thought of as a housekeeping protein whose job is to continually recycle protein complexes throughout the cell. However, cellular NSF activity is not uniform and is in fact regulated by posttranslational modifications. Secretion of Weibel–Palade bodies from endothelial cells, which mediates vascular

thrombosis and inflammation, is inhibited by nitric oxide (NO) and hydrogen peroxide (H_2O_2) due to inactivation of the exocytosis machinery. Treatment of NSF with NO or H_2O_2 was found to block its ability to disassemble SNARE complexes. Cysteine 91 in the N domain and cysteine 264 in the D1 domain are the likely sites of S-nitrosylation and oxidation, respectively (**Figures 2(a) and 2(b)**). Treatment of NSF with H_2O_2 inhibits intrinsic ATPase activity, explaining the block in SNARE complex disassembly induced by this agent. This is consistent with the position of cysteine 264 in the D1 domain Walker A ATP-binding motif. Furthermore, the inhibition of exocytosis by H_2O_2 in permeabilized endothelial cells is prevented by expression of a C264T mutant NSF. In contrast, the mechanism by which NO prevents NSF-mediated SNARE complex disassembly remains unclear because NO has no effect on SNAP binding or on NSF's intrinsic ATPase activity. It may be that NO blocks ATPase activation by SNAPs, although this speculation remains to be tested experimentally. Interestingly, nitrosylation of NSF not only affects its classical function in SNARE complex disassembly in endothelial cell exocytosis but also impacts on its novel function in regulating AMPA receptors. NO treatment of NSF in this case increased binding to the GluR2 subunit, an effect that was mimicked by a C91A mutant NSF. Activation of NMDA receptors leads to both NSF nitrosylation and an NO-dependent increase in GluR2 incorporation into the plasma membrane. This suggests a model in which activation of postsynaptic NMDA receptors leads to generation of NO, which in turns nitrosylates NSF, facilitating binding to GluR2 to promote surface expression of the receptor. Such a model would be consistent with the involvement of both NO and NSF in synaptic plasticity. Whether postsynaptically liberated NO acts as a retrograde messenger to modulate NSF's classical function in SNARE complex disassembly in the presynaptic terminal is unknown.

NSF has also been shown to be regulated by phosphorylation. Phosphorylation of NSF *in vitro* on tyrosine 83 by the tyrosine kinase Fes results in two effects: an increase in intrinsic ATPase activity and a decrease in affinity for α-SNAP. Tyr83 is located at the junction between NSF's two N-terminal subdomains, and phosphorylation of this residue would likely disrupt the interface between the subdomains and hence affect SNAP binding (**Figures 2(a) and 2(b)**). Expression of a nonphosphorylatable NSF mutant, Y83F, induces the formation of large vesicles, the same phenotype seen upon expression of the tyrosine phosphatase PTP-MEG2. These results suggest that homotypic fusion of secretory vesicles is regulated by phosphorylation of NSF on Tyr83. Presumably, inhibition of NSF by tyrosine kinases causes an accumulation of dead-end *cis*-SNARE complexes and thereby inhibits homotypic fusion, whereas local dephosphorylation via vesicular PTP-MEG2 antagonizes this effect. In addition, it appears that the same phosphorylation event also affects heterotypic fusion in exocytosis because expression of phosphomimetic NSF-Y83E in Jurkat cells partially inhibited interleukin-2 secretion. Interestingly, earlier work demonstrated depolarization-induced NSF phosphorylation in brain synaptosomes, suggesting that such regulation of NSF may also occur in neurons. In this case, phosphorylation of Ser237 by protein kinase C inhibited NSF binding to the SNAP/SNARE complex – the same biochemical effect as Tyr83 phosphorylation. NSF has also been shown to be phosphorylated by the serine/threonine kinase Pctaire1. In this case, phosphorylation occurs on Ser569 in the D2 domain (**Figures 2(a) and 2(c)**) and results in destabilization of the hexamer. Phosphorylation on this residue would therefore inhibit NSF function, and indeed a nonphosphorylatable S569A mutant NSF enhances exocytosis in PC12 cells.

Conclusions

Much has been learned during the past 20 years since the discovery of NSF. We now have considerable structural, biochemical, and functional insight into NSF and SNAPs. The picture that emerges is of NSF as a molecular chaperone that acts to disassemble protein complexes in concert with its cochaperones, SNAPs (**Figure 3**). The fact that NSF/SNAPs can disassemble all the different SNARE complexes formed as a result of membrane fusion indicates that this chaperone machine recognizes a general tertiary structure rather than a specific sequence motif. This flexibility probably facilitated the adoption of different, non-SNARE complexes as substrates for disassembly later in evolution, such as the GluR2–PICK1 complex. Much remains unknown, however. For example, does this general principle hold for the other proteins that NSF has been found to bind, and what is the physiological relevance of these interactions? The physiological functions of β- and γ-SNAPs also remain unclear. It seems likely that despite being the first proteins identified in membrane fusion, the future will hold surprising discoveries regarding these key molecules.

Nuclear Movements in Neurons

Y-H Youn and A Wynshaw-Boris, University of California at San Diego, La Jolla, CA, USA

Types of Nuclear Movements during Neuronal Development

Two basic types of nuclear migration occur during early brain development: (1) interkinetic nuclear migration of mitotically dividing neural stem cells and radial glial progenitor cells and (2) nuclear translocation during migration of postmitotic neurons. During the development of the mammalian brain, the self-renewal of neural progenitor cells can generate two daughter progenitor cells with the same cell fate by symmetric (proliferative) cell divisions, or one daughter progenitor cell and a second, different cell type (neuron or glial cell) by asymmetric (neurogenic or gliogenic) cell divisions. Prior to the onset of neurogenesis, neuroepithelial stem cells (NSCs) in the neuroepithelium, which consist of a pseudostratified single-cell layer of NSCs, display interkinetic nuclear migration whereby nuclei migrate up and down the entire apical–basal axis during the cell cycle. At the onset of neurogenesis, neuroepithelial stem cells give rise to a distinct cell type, radial glial cells. Radial glial cells represent more fate-restricted progenitors, and most neurons in the central nervous system are derived from radial glial cells. In these progenitors, interkinetic nuclear migration also occurs but it is limited to the ventricular, or proliferative, zone and is excluded from the developing intermediate zone and cortical plate. Although the exact mechanism of interkinetic nuclear migration in neuroepithelial and radial glial cells is unknown, it is known that the apical direction of nuclear migration (G2) is faster than that occurring in the basal direction (G1).

A second type of nuclear migration occurs in postmitotic neurons. The leading process of migrating neurons is in front of the soma, which contains the nucleus, and is directed toward the pial surface. The trailing process is behind the nucleus. The position of the nucleus advances into the leading process as the neuron migrates toward the pial surface during radial migration. This nuclear translocation is mediated by a microtubule-based nuclear cage that is linked to the centrosome (Figure 1), and the entire process of nuclear migration is controlled by cytoplasmic dynein.

Apical–Basal Polarity and Interkinetic Nuclear Migration during Neurogenesis

The neuroepithelium in the proliferating neural tube and the radial glial progenitors during neurogenesis display characteristic apical–basal polarity. This is manifested by strict apical localization of proteins and cellular components such as the centrosomes, prominin-1, adherens junctions, apical protein kinase C (PKC), Par3, and Par6. Apical–basal polarity is crucial to allow symmetric and/or asymmetric distribution of cellular components during mitosis and to orient the plane of cell division. Additionally, apical–basal polarity of these components results in the exposure of the migrating nucleus to different concentrations of these components during progression through the cell cycle. For example, the nucleus of proliferating neuroepithelial cells moves from the apical to the basal side of the cell during G1 phase of the cell cycle, where DNA synthesis occurs during S phase, before the nucleus moves back to the apical side during G2 to finally divide at the apical side. Although apical–basal polarity is somewhat relaxed once neurogenesis commences, it is still present in radial glial cells. These cells also display interkinetic nuclear migration that only spans the ventricular zone rather than the entire length of the cell.

Cytoskeletal–Centrosome Coordination during Neuronal Migration

The migration of progenitor neurons to their final destination within the brain requires major cytoarchitectural changes of the actin and microtubule (MT) cytoskeletons. MTs are essential to maintain the extended processes of forward-moving neurons, and actin filaments play a key role in axonal outgrowth and cell motility. Nucleokinesis mainly depends on the microtubule network in migrating neurons. The site of MT emanation just in front of the nucleus has been recognized as the centrosome – the microtubule organizing center (MTOC), a structure found in all plant and animal cells from which microtubules radiate – of the cell. A microtubule-based nuclear cage complex couples the centrosome and nucleus (Figure 1). Disturbance of this coupling complex results in migration defects. Following the advance of the centrosome into the leading process of the migrating neuron, the nucleus translocates forward in a saltatory fashion, with myosin II-based contraction at the rear of the neuron. Myosin II seems to accumulate periodically behind the nucleus, forming a short tail at the rear of the cell, suggesting that myosin II has an important role in maintaining the nucleus on the same axis as the MTOC and the extending growth cone.

In mammalian cell polarity, postsynaptic density/disc/zonula occludens-1 (PDZ)-containing proteins Par3/Par6 are required to regulate the orientation of the mitotic spindle during cell division. Cell polarity is

Figure 1 A model of nuclear migration in neuronal cells. A centrosome (C) is controlled by the cell polarity and guides the direction of movement during the migration. The centrosome localizes in front of the nucleus (N) and toward the leading process (LP). At the stage depicted in the middle figure, a cytoplasmic dilation forms ahead of the nucleus, and the forces generated from the centrosome and microtubule (MT) pull on the microtubule cage (red lines) surrounding the nucleus. The nucleus thus moves forward toward the centrosome, and the process can then repeat, enabling migration.

determined by spatially localized Par3/Par6 via phosphatidylinositol 3-kinase (PI3K) phosphorylation of glycogen synthase kinase-3 (GSK-3). This pathway is crucial for cell polarity, centrosome reorientation, and wound healing (cell migration) in a cultured astrocytes/wound model system. The integrin signaling pathway is also involved in cell polarity and activation of the cytoplasmic mammalian Par6 (mPar6) complex associated with PKC-ζ. During neuronal migration, the role of Par genes has been reported. Par6α is localized to the neuronal centrosome along with PKC-ζ. Deficiency of Par6α results in the scattered distribution of PKC-ζ and mislocalized perinuclear microtubule cytoskeleton.

Besides microtubules, actin filaments are also involved in the interkinetic nuclear migration of neuroepithelial cells. Cytochalasin B interferes with actin polymerization and induces defects of nuclear migration in neuroepithelial cells through the disruption of nonmuscle myosin heavy chain II-B. However, this drug does not stop the cell cycle phase, which leads to mitosis when the nucleus is localized anywhere in the ventricular zone, rather than the apical zone. On the other hand, hydroxyurea inhibits S phase progression but does not interfere with interkinetic nuclear migration (see later). These studies indicate that the two different cellular events, interkinetic nuclear migration and the cell cycle of neuroepithelial cells, are coordinated with each other during development but have different underlying regulatory mechanisms.

Dynein and Lis1/Ndel1 in the Regulation of Nucleokinesis

Type I lissencephaly is a human neuronal migration disorder that results from a disorganization of both pyramidal neurons (radial migration) and interneurons (tangential migration). It is characterized by generalized agyria/pachygyria (reduction or complete lack of gyri and sulci), four abnormal cortical layers, enlarged ventricles, and generalized neuronal heterotopias. Miller–Dieker syndrome (MDS) consists of severe classical lissencephaly, characteristic facial anomalies, and occasionally other malformations. Children with MDS are severely retarded and suffer from epilepsy. Craniofacial dysmorphisms (characteristic of abnormal development) include microcephaly with bitemporal narrowing, a high forehead, a small nose with upturned nares, thin vermilion border, and micrognathia (small lower jaw). The disorder is invariably fatal in early childhood. Isolated lissencephaly sequence (ILS) is a heterogeneous disorder consisting of variably severe lissencephaly with no other major malformations, such as the craniofacial dysmorphism seen in MDS. Children with ILS are also severely retarded and typically have epilepsy. MDS (100%) and some cases of ILS (40%) are the result of haploinsufficiency at human chromosome 17p13.3, with visible or submicroscopic deletions detectable by fluorescent *in situ* hybridization (FISH). The *LIS1* (*PAFAH1B1*) gene was cloned from this region in several MDS patients. Point mutations and an intragenic deletion in *LIS1* were identified in ILS patients; no gross structural chromosomal rearrangements were found, confirming that mutations or deletions of the *LIS1* gene are responsible for classical lissencephaly in ILS and MDS patients. The more severe neuronal migration phenotype and facial dysmorphisms displayed by MDS patients suggest that genes other than *LIS1*, such as *14-3-3e* (see later), are responsible for these phenotypes.

The Lis1 protein was first reported to be a stoichiometric component of purified platelet-activating factor acetylhydrolase 1b (PAFAH-1b). However, it was also found that Lis1 is a component of a highly conserved pathway that regulates nuclear migration in fungi. The Lis1 homolog in the slime mold *Aspergillus nidulans,* NudF, is part of a signaling pathway that regulates nuclear migration along microtubules via the regulation of dynein motor function. In this slime mold, nuclei migrate toward the growing tip of

hyphae to establish regular spacing, a process termed nucleokinesis. Several nuclear distribution mutants (*nud* mutants) have been generated in this organism. One of these, *nudF*, is the fungal homolog of *LIS1*. The identification of other *nud* mutants directly implicates cytoplasmic dynein and dynactin (a regulator of the microtubule motor protein dynein) in this process. The *nudA* and *nudG* genes code for the heavy chain and the 8-kDa light chain of cytoplasmic dynein, respectively. A mutant allele of *nudF*, *nudF6*, is suppressed by mutations in *nudA*, the cytoplasmic dynein heavy chain, providing genetic evidence that NudA and NudF are in the same genetic pathway, and suggesting that Lis1 might directly interact with cytoplasmic dynein. *NudK* codes for Arp1, which is part of the dynactin complex, and dynactin is required for dynein-mediated vesicle transport. A screen for multicopy suppressors of the *nudF* phenotype identified *nudE*, demonstrating that overexpression of NudE can rescue the *nudF* (*LIS1*) phenotype. NudE is a homolog of the nuclear distribution protein RO11 in *Neurospora crassa,* the mitotic protein MP43 in *Xenopus laevis*, and two murine homologs of NudE named NUDEL (for NudE-like) and NudE (see later). Thus, several genes responsible for nuclear movement have been isolated from *Aspergillus*. The Nud pathway is remarkably conserved in eukaryotes.

The mouse gene, *Lis1* (*Pafah1b1*), has been disrupted to examine the consequences of dosage reduction and complete deficiency of *Lis1 in vivo*. Mice with decreased levels of *Lis1* exhibit dose-dependent disorganized cortical layers, hippocampus, cerebellum, and olfactory bulb due to cell-autonomous neuronal migration defects, and are a good model for the human disorder. Complete loss of Lis1 results in peri-implantation lethality, demonstrating that *Lis1* is an essential gene. Several lines of evidence support the conclusion that there are *in vivo* migrational defects in mice with reduction of Lis1 dosage. These include histological analysis during development, bromodeoxyuridine (BrdU) birthdating experiments (a method to examine whether there are abnormalities in cortical layering by labeling postmitotic neurons with a pulse of BrdU; those neurons born just after BrdU injection are intensely labeled with BrdU, since they do not dilute the label as would occur if they divide further) and *in vitro* migration of granule cells from cerebellar cell reaggregates. For example, Lis1 is required for nuclear movement during neuronal migration by coupling the nucleus to the centrosome. Cerebellar granule cells from $Lis1^{+/-}$ mice display slowed migration and a lengthening of the distance between the centrosome and the nucleus. Lis1 is localized to the centrosome with some extension toward the nucleus. Consistent with an important role in dynein function, inhibition of dynein by overexpression of dynamitin results in a similar phenotype. Finally, studies show that interference RNA (RNAi) knockdown of *Ndel1*, *Lis1*, or *dynein* by *in utero* electroporation into the developing neocortex results in impaired neuronal positioning and causes the uncoupling of the centrosome and nucleus. These studies suggest that nuclear movement during neuronal migration is mediated by a Lis1 complex regulating cytoplasmic dynein function, a function that is conserved through evolution from *Aspergillus* to mammals.

Lis1 directly interacts with three distinct sites in the cytoplasmic dynein heavy chain, in regions that contain the basal stem or tail portion of the heavy chain molecule responsible for cargo binding and the motor domain. Lis1 also interacts with the dynamitin subunit of dynactin, which is a dynein supplemental complex that binds to dynein and regulates its binding to several cytoplasmic structures. Lis1 is colocalized with cytoplasmic dynein at the mitotic kinetochores, indicating a role of Lis1 in chromosomal behavior. For example, microinjection of anti-Lis1 antibody results in a delay of mitotic progression accompanied with chromosomal defects at the metaphase plate. Lis1 is also expressed at the cortical (marginal) area of proliferating epithelial cells, and its overexpression results in disruption of the mitotic spindle organization as a result of reductions in cortical distribution of dynein. Thus, the dynein/Lis1 complex plays an important role in the regulation of spindle orientation. These findings suggest that the mitotic spindle cleavage plane plays an important role during neurogenesis of neuroepithelial cells in the ventricular zone.

Mammalian Lis1 is in a complex associated with mNudC and with two NudE orthologs (discussed earlier), mNudE (Nde1) and its isoform NudEL (Ndel1). These three Nud homologs bind to dynein motor proteins, and these proteins also play important roles in neuronal migration via nucleokinesis. Nde1-deleted mice are viable and have been reported to have migrational defects but normal cortical lamination, though the mutant cortex has fewer neuronal cells and significantly thinner superficial cortical layer compared to wild type. Ndel1 is required for neuronal migration via interaction with Lis1. Complete loss of Ndel1 results in embryonic lethality at the peri-implantation stage and a deficiency of cell proliferation. Disruption of Ndel1 results in defective nuclear/centrosomal coupling and wider average distances between centrosome and nucleus. Ndel1 may also play an important role in MT organization, since it also interacts with katanin p60 for remodeling of MTOC. Thus, Ndel1 and Lis1, probably as well as

Nde1, have common roles for dynein regulation, the MTOC, and neuronal migration.

Ndel1 is phosphorylated and regulated by Cdk5 (Cdc2 in fibroblasts) and aurora A kinase. Cdk5 is a brain-specific kinase central for axonal guidance/growth and neuronal migration in the developing cerebral cortex. It is activated by interaction with p35 or p39, required co-activators. Ndel1 has five proline-dependent serine/threonine phosphorylation motifs and is phosphorylated by Cdk5/p35. Phospho-Ndel1 (P-Ndel1) can bind to the 14-3-3 protein epsilon subunit directly, which protects P-Ndel1 from phosphatase attack. Loss of 14-3-3e in mice results in neuronal migration defects, disruption of dynein motor function, and decreased steady-state levels of Cdk5-phosphorylated P-Ndel1. In addition, 14-3-3e is deleted in human patients with MDS, and may be responsible for some of the more severe defects displayed by MDS patients. Thus, the activity of Ndel1 and the Lis1/dynein complex appears to be tightly regulated by a typical signal transduction pathway.

DCX in the Regulation of Nucleokinesis

The major cause of X-linked lissencephaly is mutation of the *doublecortin* (*DCX*) gene. Mutations in the *DCX* gene cause gross neocortical disorganization and lissencephaly in hemizygous males, while heterozygous females show a mosaic phenotype with a normal cortex as well as a second band of misplaced (heterotopic) neurons beneath the cortex ('double cortex syndrome'). Little is known of the nature of involvement of the protein doublecortin in neuronal migration. This is partly because doublecortin appears to be present only in mammals, and so it has not been possible to study its function in fungi or *Drosophila*. However, both Lis1 and doublecortin are known to associate with microtubules in mammalian cells. Lis1 appears to increase microtubule polymerization and to decrease microtubule depolymerization rates *in vitro* and doublecortin appears to bind to and polymerize microtubules both *in vitro* and in heterologous cells. It seems then that Lis1 and doublecortin are both working in concert to maintain microtubule polymerization, and might function together to increase the pool of polymerized microtubules to promote neuronal migration, although how microtubule polymerization might facilitate successful neuronal migration remains to be elucidated.

As the nuclei move into the leading process, the network of perinuclear MTs continuously sustains the tight centrosome–nucleus coupling complex. Doublecortin plays an important role in control of the formation of the MT network and centrosome–nucleus coupling. In growing axons and dendrites, doublecortin is particularly expressed, indicating that this protein is responsible for the development of the leading process. Doublecortin may be involved in the stabilization of MTs and may be localized to the MTs bridging the nucleus and centrosome in moving cells. Overexpression of doublecortin in neurons promotes locomotion and increases the angle of nuclear–centrosome coupling, while *DCX* small interfering RNA (siRNA) leads to defects of radial migration and cortical development. However, the exact role of doublecortin in MT stabilization of moving neurons is unknown.

Concluding Remarks

Several core mechanisms regulating interkinetic nuclear migration, including cell polarity and signaling, have been shown over the past several years to reorganize cytoskeletal architecture in migrating and dividing cells. However, many important questions remain. The roles of extracellular cues in nucleokinesis need further study. Recent reports of vertebrate neurogenesis provide hints to the importance of asymmetric cell division in cell fate and migration, but the signaling molecules and cascades that regulate nucleokinesis and link it to the centrosomal positioning in the leading edge have yet to be described. Discovery of pathways that determine the architectural remodeling of cytoskeletal dynamics in the leading and trailing edges of migrating cells will undoubtedly provide a more advanced framework for understanding nucleokinesis.

Nucleic Acid Introduction into Primary Neurons and Glia

J-Y Sul*, A Sharma*, J Eberwine, and P G Haydon, University of Pennsylvania School of Medicine, Philadelphia, PA, USA

© 2009 Published by Elsevier Ltd.

By modifying gene expression within the nervous system and following its impact on brain function, neuroscientists have gained insight into brain functionality in a variety of different contexts. Exogenous expression in a system lacking a gene of interest has been utilized to recapitulate a lost cellular function or reverse a behavioral phenotype implicating the gene's involvement in a certain pathway or function. Overexpression of genes has allowed for improved detection of protein-binding partners and for the unmasking of putative cellular functions. Expression of mutated forms of genes has helped establish disease models in both cell lines and organisms. The expression of exogenous nucleic acids with affinity tags and fluorescent markers has allowed for improved detection and noninvasive tracking of gene expression. The ultimate goal of gene transfection is to understand brain function from the level of single cells to that of entire organisms. Within the past couple of decades, several different methodologies have been developed for gene delivery and modified for efficient gene transfer into postmitotic neurons and mitotic glial cells. Exogenous genes can now be expressed in single cells, large population of cultured cells, cultured slices, and organisms. In this article, we discuss these methodologies and also highlight novel methods of gene delivery.

Gene delivery methods can be categorized as chemical, viral, or physical based on the mechanism of entry of the gene into the cytosol. Chemical methods are the most commonly utilized approach in which genes are delivered through lipid–nucleic acid complexes, cationic polymer–nucleic acid complexes, and calcium phosphate–nucleic acid coprecipitates. Viral gene delivery involves the engineering of viral genomes to infect target cells with a specific gene(s) of interest. Physical methods include the direct transfer of naked nucleic acids into cells. These methods include electroporation, biolistic methodologies (gene gun), microinjection, and the recently developed technique phototransfection.

Chemical and viral mechanisms of gene delivery are similar in that they first require that the nucleic acid be packaged into proper delivery vectors. For chemical methods, nucleic acids are packaged into chemical vectors that have the ability to penetrate the plasma membrane. This packaging is directed by both electrostatic interactions and the hydrophobic effect. For example, lipid chemical vectors are macromolecules containing both lengthy, hydrophobic tails and hydrophilic cationic head groups. The amphipathic nature of these molecules allows them to interact with both the nucleic acid and the lipid membrane. The hydrophobic tails, in the presence of an aqueous environment and at the proper concentration, condense into energetically favorable, spherical vesicles called liposomes that can interact with the plasma membrane. The cationic head group forms complexes with the negatively charged nucleic acids largely through electrostatic interactions. Thus, the nucleic acid is packaged on the surface of the liposome in a manner that neutralizes the negative charge and that can protect it from intracellular nuclease activity. A similar process guides the formation of polymer–nucleic acid complexes as well as calcium–phosphate–nucleic acid complexes. Viral methods of gene delivery involve directly engineering a foreign gene(s) of interest into a viral genome. This modified viral genome is then incorporated into the genome of packaging cells through a molecular recombination event. These packaging cells have the ability to assemble intracellular viral particles containing the viral genome and the gene(s) of interest.

Following nucleic acid packaging, the genes have to be transferred and expressed in target cells. For chemical and viral transfection, target cell entry is believed to occur following vector fusion with the cell membrane and internalization via an endocytosis-like process. Viral particles or chemical complexes containing nucleic acids are trapped within small membranous vesicles derived from the plasma membrane called endosomes. Viral particles have the ability to dissociate from cytosolic endosomes and can be transported to the nucleus. Some viruses require active mitosis to enter the nucleus, while others have direct nuclear membrane entry mechanisms. Following nuclear entry, viral particles dissociate in the nucleus, exposing the viral genome containing the gene(s) of interest. The nucleic acid can be expressed directly or following incorporation into the target cell genome. Chemical complexes can also be found in endosomes but do not have efficient endosomal dissociation mechanisms. Consequently, following endosome fusion with lysosomes, the nucleic acid can be degraded through the action of lysosomal enzymes. However, the inclusion of endosomal and lysosomal escape agents such as chloroquine and the modification of lipid vectors with pH buffering head groups have protected against lysosomal enzyme degradation.

*Both authors contributed equally to this work.

In addition, the use of nuclear targeting peptides has assisted in nuclear entry via chemical methods. These developments have improved transfection efficiency through chemical transfection methodologies.

Chemical transfection methods have lower transfection efficiencies (10–25%) and are generally not utilized for *in vivo* gene expression. However, they have a number of benefits and are heavily utilized in the field of neuroscience. These benefits include their ease of use, lower levels of cytotoxicity, capability for large insert expression, and minimal lag time for gene expression. A variety of parameters should be considered when optimizing these methods to maximize expression efficiency and to minimize cellular toxicity. For lipid-mediated transfection as well as other chemical transfection methods, important parameters include the ratio of nucleic acid concentration to vector concentration, the ratio of nucleic acid concentration to cell number, the vector–nucleic acid association time, the cell culture conditions, and the gene expression time.

Viral transfection systems provide significantly higher transfection efficiencies for both nonmitotic neurons and mitotic astrocytes. Viruses can have up to 95% infection efficiencies with high levels of expression in target cells whether in dissociated culture, in brain slices, or *in vivo*. However, there are also major drawbacks to consider with this method of gene delivery, including the limitations on insert size, toxicity to cells, and the time and effort needed to construct recombinant viral vectors. Furthermore, a number of different viral vectors are utilized to transfect cells of the nervous system. Hence, it is important to choose the appropriate one based on the properties of the virus and the goals of the experiment. Adenovirus (AdV) has been the most commonly used viral vector and has the ability to transfect neurons and glia both *in vivo* and *ex vivo*. Expression of transgenes can occur days after infection but lasts for weeks to months. There are limitations on insert size that should be noted as well as the finding of cytotoxicity at high titers. Lentivirus systems also can target expression to both neurons and glia but have the added advantage of stable expression for months to years. Adeno-associated virus (AAV) can provide robust gene expression selectively for neurons *in vivo* and *ex vivo* and is much less toxic than other viral vectors. However, its use is limited to inserts that are smaller than 5 kb with expression delayed 2 weeks following infection. Other viral vectors used for gene delivery include herpes simplex virus (HSV), vaccinia virus, Sindbis virus, and Semliki Forest virus (SFV) (Table 1).

Physical transfection methods employ completely different mechanisms to penetrate the cellular membrane with nucleic acid. Electroporation systems utilize cell type optimized electrical currents to make transient pores in the membranes of cells allowing for surrounding nucleic acid to enter the cell. Because the electrical current can severely reduce cell viability, millions of neurons are required for a single transfection. However, despite this drawback, the transfection rate of surviving cells can be greater than 50%. In addition, methods have been developed for single cell electroporation of dissociated neurons in culture as well as for transfection in organisms. Biolistic systems use gas pressure as a means to penetrate cells in culture or in slices with genes prepackaged onto metal bids. Careful optimization of the number of bids and gas pressure is required to minimize cell damage. Microinjection involves utilizing a sharp, micron-tipped micropipette to directly puncture and inject nucleic acid into a single cell under a microscope. With mammalian cells, this procedure is labor intensive and requires a great deal of skill compared to other transfection methods.

Because of demands for noninvasive, spatiotemporal control of gene expression in the nervous system, many of the preceding methods have been investigated for their ability to transfect certain cell

Table 1 Comparison of different viral vector systems

types in a controlled manner. Viral transfection methodologies have especially been developed to better meet these demands. Currently, the natural tropism of viruses largely determines which cells are targeted for expression with the gene(s) of interest. However, the recent discovery and characterization of neuron- and glial-specific promoters have helped improve upon the spatial control of gene expression, especially *in vivo*. Inducible expression systems have complemented these approaches to allow for the temporal control of transgene expression. In addition to viral methods, chemical methods have also been investigated for targeted gene expression. The *in vivo* delivery of liposomes that are targeted to certain cell types may become an option for the spatial control of gene expression. Here, antibody-coupled liposomes have been shown to penetrate the blood–brain barrier and enter the central nervous system. This may allow for targeted gene expression based upon the unique expression of surface markers by different cells types within the nervous system.

Figure 1 Two-photon laser poration successfully introduces an exogenous dye into neurons. Live hippocampal neurons are incubated with membrane-impermeable Lucifer Yellow and imaged prior to photoporation (lower left panel). A 2 μm × 2 μm area from part of the cell body of the central neuron is selected for photoporation (box, schematic upper left panel). A two-photon laser is briefly targeted to this area (red arrow, schematic upper right panel) allowing the Lucifer Yellow to enter the cell at the site of poration (schematic upper right panel). After poration, the neuron has taken up the Lucifer Yellow and become fluorescent near the site of photoporation (lower right panel). Scale bar = 20 μm.

Recently, a few research groups have developed a novel, single-cell transfection methodology called phototransfection or photoporation. This physical transfection methodology utilizes a microscope equipped with a femtosecond, pulsatile laser to form small poration sites within the plasma membrane of target cells (Figure 1). This allows bath-applied DNA or RNA to transiently enter the poration sites without detrimental affects on cell viability. By controlling the concentration of nucleic acid in the bath, the amount of nucleic acid that enters the cell can be approximated and modulated. Using this approach, astrocytes and neurons derived from diverse regions of the nervous system can be targeted. Different cellular regions, including the nucleus, cytoplasm, axon, and dendrites, can be uniquely selected for the localized expression of nucleic acid. Furthermore, subcellular regions including proximal and distal dendrites can be also be targeted. Multiple genes can be simultaneously expressed within a single cell or can be differentially expressed within different regions of the cell. In addition to the spatial control of gene expression, genes can be expressed at different time points within the same cell, either at the same region or at a different region

Figure 2 Phototransfection allows for the introduction of exogenous nucleic acid into neurons. Neurons are phototransfected in the presence of bath-applied capped green fluorescent protein (GFP) mRNA. The arrow represents the site of phototransfection. Differential interference contrast (DIC) images show the neuron prior to phototransfection and at indicated times after phototransfection. These images are overlaid with the GFP fluorescent signal. Scale bar = 20 μm.

of the cell. Currently, this method of gene transfection has been utilized to target gene expression within cultured primary cells of the nervous system. Efforts are under way to utilize this approach for the transfection of brain slices and for the transfection of single cells within organisms (Figure 2).

Many different gene delivery methodologies have been successfully used to study the nervous system. Currently, there is no single method that can allow for efficient, specific expression in all experimental preparations. Consequently, investigators must be aware of the advantages and drawbacks of each method and choose a method based on the experimental question and system being utilized. As the field of neuronal gene delivery moves forward, methodologies will be developed to restrict exogenous gene expression to specific cell types or pathways. This will better allow for the study of the nervous system.

Numerical Intelligence: Neural Substrates

A Nieder, University of Tübingen, Tübingen, Germany

© 2009 Elsevier Ltd. All rights reserved.

Numbers can be used most flexibly to quantify, rank, and identify virtually everything that is imaginable. Although true counting and mathematics are cultural achievements that are bound to language, it has become evident during the past few decades that basic numerical skills are independent from language. Human adults, infants, and animals are able to nonverbally and approximately grasp the numerical properties of objects or events. Such nonverbal numerical systems are the precursors on which verbal numerical representations build up, and their neural foundation can be studied in animal models.

This article reviews the progress that has been made in our understanding of the neural underpinnings of numerical competence in human and nonhuman primates. It is structured according to the basic concepts numerical quantity, which refers to the empirical property cardinality (the size of a set, also termed 'numerosity'), and numerical rank, which refers to the property serial order.

Numerical Quantity (Cardinality)

Behavior

Animals can discriminate the cardinality of sets. During the past six decades, roughly half a dozen bird and mammal species have successfully been trained to perform several numerical tasks in different modalities. Importantly, animals can transfer their numerical knowledge to numerosities they have not been trained on, which indicates a true understanding of the concept of cardinalities and their sequential arrangement. Moreover, numerical intelligence is not induced by extensive training in the laboratory but can be demonstrated spontaneously in the wild. The data collected for different species indicate that quantity information is indeed exploited by animals in their natural habitat to draw informed choices, for example, in foraging situations or social interactions.

Also, preverbal human infants of several months of age have the capacity to represent cardinality, both in the visual and in the auditory domain. Infants can also engage in rudimentary arithmetic, which was first shown in experiments in which 5-month-old infants were shown basic addition and subtraction operations on small sets of objects.

Human adults can reliably compare the cardinality of sets under conditions that prevent or discourage verbal counting. In contrast to precise verbal counting, however, nonverbal discrimination performance is only inaccurate, or approximate. Some indigenous human cultures that lack number words or have a very restricted concept of verbal counting rely completely on nonverbal cardinality assessment (so-called 'one–two–many' system of 'counting'). Thus, humans without a linguistic number concept can only estimate the number of items by means of a nonverbal quantification system. Together, these studies provide evidence for an evolutionary ancient quantification system which operates independent from language and can thus be studied in animal models.

Numerosity-Selective Neurons

Recordings in monkeys demonstrated the capacity of single neurons to encode numerical quantity. In monkeys performing a visual delayed match-to-numerosity task (Figure 1(a)), the highest proportion of numerosity-selective neurons (Figure 1(c)) was found in the lateral prefrontal cortex (PFC), irrespective of co-varying nonnumerical parameters. In the posterior parietal cortex (PPC), numerosity-selective neurons were most abundant in the fundus of the intraparietal sulcus (IPS); they were few in other PPC areas or the anterior inferior temporal cortex (aITC) (Figure 1(b)). Neurons in a somatosensory-responsive region of the superior parietal lobule (part of area 5) have been reported to keep track of the number of movements, but in a movement-type-dependent manner (i.e., the neurons responded differently whether the monkey's movement was 'push' or 'turn'). Area 5 neurons were not encoding numerosity in visual displays.

Numerosity-selective neurons in the PFC and IPS were tuned for the number of items on a visual display; that is, they showed maximum activity to one of the five presented quantities – a neuron's 'preferred numerosity' (Figure 1(c)). All numerosity-selective neurons together formed a bank of overlapping numerosity filters (Figure 1(e)), thus mirroring the animals' behavioral performance (Figure 1(d)). Interestingly, the neurons' sequentially arranged overlapping tuning curves preserved an inherent order of cardinalities. This is important because numerosities are not isolated categories but, rather, exist in relation to one another (e.g., '3' is greater than '2' and less than '4'); they need to be sequentially ordered to allow meaningful quantity assignments.

The fact that IPS neurons require shorter latencies to become numerosity selective than PFC neurons suggests that the IPS might be the first cortical stage that extracts visual numerical information. Because PPC and PFC are functionally interconnected, that

Figure 1 Representation of visual cardinality in rhesus monkeys. (a) Behavioral task. Monkeys performed a delayed match-to-numerosity task. They were required to extract the numerosity in a visual array, memorize it briefly, and match it to the one of two alternative test displays that showed the same numerosity (but with a different visual pattern). (b) Lateral view of the brain of a monkey shows the recording sites in lateral prefrontal cortex (LPFC), posterior parietal cortex (PPC), and anterior inferior temporal cortex (aITC). The proportions of numerosity-selective neurons in each area are color coded according to the color scale. As, arcuate sulcus; Cs, central sulcus; IPS, intraparietal sulcus; LF, lateral fissure; LS, lunate sulcus; PS, principal sulcus; STS, superior temporal sulcus. (c) Responses of a single neuron recorded from the PFC. The neuron showed graded discharge during sample presentation (interval shaded in gray, 500–1300 ms) as a function of numerosities 1 to 5 (color coded average discharge functions). The inset shows the tuning of the neuron and its response to different control stimuli. The preferred numerosity was '4' for this PFC neuron. (d) Behavioral numerosity discrimination functions of two monkeys. The curves indicate whether they judged the first test stimulus (after the delay) as containing the same number of items as the sample display. The function peaks (and the color legend) indicate the sample numerosity at which each curve was derived. Behavioral filter functions are skewed on a linear scale (not shown) but symmetric on a logarithmic scale. (e) The averaged single-cell numerosity tuning functions (from PFC) are also asymmetric on a linear scale (not shown) but symmetric after logarithmic transformation.

information might be conveyed directly or indirectly to the PFC, where it is amplified and maintained to gain control over behavior.

The response properties of numerosity-selective cortical cells can explain basic psychophysical phenomena in monkeys, such as the numerical distance and size effect (Figure 1(d)). The numerical distance effect states that it is easier to discriminate quantities that are numerically remote from each other (e.g., 2 vs. 6 is easier than 5 vs. 6), whereas the numerical size effect captures the finding that pairs of numerosities of a constant numerical distance are easier to discriminate if the quantities are small (e.g., 2 vs. 3 is easier than 5 vs. 6). The numerical distance effect results from the fact that the neural filter functions that are engaged in the discrimination of adjacent numerosities heavily overlap. As a result, the signal-to-noise ratio of the neural signal detection process is low, and the monkeys

would make many errors. On the other hand, the filter functions of neurons that are tuned to remote numerosities barely overlap, which results in a high signal-to-noise ratio and, therefore, good performance in cases in which the animal has to discriminate sets by a larger numerical distance.

The numerical size effect is based on the finding that neuronal tuning obeys Weber's law: the widths of the tuning curves (or neuronal numerical representations) increase linearly with preferred numerosities (i.e., on average, neurons become less precisely tuned as the preferred quantity increases). Hence, selective neural filters that do not overlap much are engaged if a monkey has to discriminate small numerosities (e.g., 1 and 2), which results in high signal-to-noise ratios and few errors for the discrimination. Conversely, if a monkey has to discriminate large numerosities (e.g., 4 and 5), the filter functions would overlap considerably. Therefore, the discrimination would show a low signal-to-noise ratio, which leads to poor performance.

The Scaling of Numerical Representations

As mentioned previously, the neurons' overlapping tuning curves are orderly arranged along a 'number line' (Figure 1(e)). However, what is the scaling scheme of such a number line and are neuronal numerical representations best described on a linear, or a nonlinear, possibly logarithmically compressed scale? The latter would be predicted if Fechner's law holds. Fechner's law states that the perceived magnitude (S) is a logarithmic function of stimulus intensity (I) multiplied by a modality- and dimension-specific constant (k). Since the behavioral discrimination and single-unit tuning functions might be regarded as the monkeys' behavioral and neural numerical representations (Figures 1(d) and 1(e)), the crucial question then concerns which scaling scheme would provide symmetric (i.e., Gaussian) probability density distributions. Both the performance and the single-unit data for numerosity judgments are better described by a compressed scale (Figures 1(d) and 1(e)) as opposed to a linear scale. Therefore, single-neuron representations of numerical quantity in monkeys obey Fechner's law.

Functional Imaging in Humans

In humans, the PFC and the parietal lobe, in particular the IPS, have long been regarded as the prime source for numerical competence. This view, however, was almost exclusively based on verbal and symbolic number tasks, which are only vaguely comparable to numerical magnitude estimation. If anatomical and functional similarities between the brains of monkeys and humans do exist, nonverbal cardinality should be processed in the human brain in equivalent areas as seen in monkeys. Indeed, such a corresponding blood oxygenation level-dependent (BOLD) activation in the IPS of humans has been found using functional magnetic resonance imaging (fMRI) adaptation with numerosities (Figure 2). Subjects were repeatedly presented with several visual displays of a fixed numerosity (e.g., 16 dots), without the requirement to discriminate them. The rationale of this protocol is the following: if any region of the brain contains a population of numerosity-selective neurons that are tuned to a specific number of dots and automatically detect numerical information, such a population of detectors should habituate (i.e., decrease its discharge) to numerosities that are repeatedly presented, whereas neurons tuned to other numerosities should not be affected. Such a habituation effect was then 'read out' by recording the event-related fMRI activation to a single deviating numerosity (e.g., 32 dots) that was presented at the end of a display sequence. In fact, the only region in the brain that was significantly habituated to numerosity was the horizontal segment of the IPS (Figure 2(a)). With this fMRI adaptation protocol, the average numerosity tuning curve of the underlying neural population could be traced indirectly in humans (Figure 2(b)). Similar to single neuron responses in monkeys, fMRI tuning curves in humans seem to be well described on a logarithmic scale, which suggests that the nonverbal number line in all primates is nonlinearly compressed.

Language allows humans to use symbolic representations, and numbers are the symbols that are employed when dealing with numerical information. Interestingly, numerical values that are cued by number symbols and set size have been shown to activate corresponding structures in the brain in humans. The IPS, which has been suggested to play a central role in basic quantity representations, is sometimes the only area specifically activated in simple number detection or comparison tasks. Eger et al. performed fMRI measurements on subjects who were asked to merely detect numerals, letters, or colors which were presented visually (written words and symbols) or acoustically (spoken words). To avoid confounds by response selection and associated cognitive states (e.g., attention), the authors analyzed the presentation of nontarget numerals (numerals that were not required to be detected) and compared it to nontarget letters or colors. The IPS was the only region that exhibited higher activation for numerals, both visually and acoustically (Figure 3(a)). Therefore, numerical activation in the IPS seems to be automatic (task independent), supramodal (visual and auditory), and notation independent (irrespective of whether numerals are spoken or written, presented in Arabic notation or spelled-out form). The IPS, however, is

Figure 2 Functional MRI adaptation with numerosities in humans. (a) Regions in the human brain that responded to numerosity changes (i.e., exhibited numerosity selectivity). Colored areas in the axial (top left) and coronal (top right) sections and on the surface image indicate the IPS. (b) Activation difference between the habituation and deviant numerosities resulted in (inverted) numerosity tuning curves that were more symmetrically fitted on a logarithmic (right) than on a linear (left) scale. Adapted from Piazza M, Izard V, Pinel P, Le Bihan D, and Dehaene S (2004) Tuning curves for approximate numerosity in the human intraparietal sulcus. *Neuron* 44: 547–555.

also engaged in more general magnitude judgments. Pinel et al. scanned subjects with fMRI while they compared Arabic numerals for luminance, font size, and numerical value. The authors observed strong overlap in the neural substrates in the three tasks. Number and size, but not luminance, activated a common parietal region, indicating toward an intimate relationship between spatial and numerical representations. This might mean that number-coding neurons are intermingled with other magnitude-coding neurons along the IPS.

Beyond mere encoding of quantity information *per se*, verbal numerical competence requires additional cognitive components. Dehaene and co-workers suggested that verbal counting and calculation engages two more parietal regions: a posterior dorsal parietal area, which is activated by shifts in spatial attention whenever subjects count, and a left angular gyrus area, which is related to linguistic processing. Moreover, simple calculation tasks (e.g., subtraction) typically activate a distributed network that involves parietal, prefrontal, and premotor cortices (Figure 3(b)).

Developmental studies confirm that impairments of arithmetical abilities correlate with abnormalities in the organization of parietofrontal networks, and the IPS in particular. Using voxel-based morphometry, Isaacs et al. compared the density of gray matter in adolescents who were born at equally severe grades of prematurity. Half of these subjects (with otherwise normal IQ) suffered from dyscalculia, and the

Figure 3 BOLD activation in humans to number symbols and arithmetics. (a) Cortical localization of supramodal responses to numbers (e.g., to both Arabic numerals and spoken number words). Compared to letters and colors, significant bilateral activation was only found deep in the horizontal IPS. (b) Activation pattern observed during subtraction. A covert subtraction task was contrasted with covert naming of the next number in the number line. It resulted in a distributed response pattern involving parietal, premotor, and prefrontal cortices. Adapted from Eger E, Sterzer P, Russ MO, Giraud AL, and Kleinschmidt A (2003) A supramodal number representation in human intraparietal cortex. *Neuron* 37: 719–725.

only region in the brain that showed reduced gray matter associated with arithmetical deficits was the left IPS. Therefore, dyscalculia in children might be the result of specific disabilities in basic numerical processing rather than the consequence of deficits in other cognitive abilities. Arithmetic deficits are also found in certain genetic conditions, such as the Turner syndrome (X monosomy), fragile X syndrome, and velocardiofacial syndrome. In these conditions, fMRI hypoactivation (decreased BOLD activation) was found in the IPS and wider parietofrontal networks.

Neuropsychological Studies

Brain damages in humans can cause relatively selective impairments in dealing with numbers, called acalculia. The most frequent lesions yielding acalculia involve the left inferior parietal area or the left parieto-occipito-temporal junction. In cases of left inferior parietal lesion, acalculia is frequently associated with agraphia, finger agnosia, and left–right confusion in a tetrad of deficits called Gerstmann's syndrome. In addition, calculation deficits have also been observed following left medial frontal, left and right frontal, and temporo-occipital lesions. A major issue in neuropsychological studies is the dissociation between deficits in language and numerical functions, particularly when the left hemisphere is affected. One study has indicated that syntactical mathematical operations (e.g., calculation rules such as solving equations according to brackets) are largely independently represented from linguistic syntax, at least in an adult brain.

Numerical Rank (Serial Order)

Behavior

Numerical rank is the second major numerical concept that shows biological precursors. List learning – the ability to encode and then retrieve an arbitrary list of items in their correct order – opened a window to study how the ordinal rank of objects is learned and stored by animals. Rhesus monkeys learned the serial order of items in several lists with up to seven items. Controlled manipulations of such learned lists showed that the monkeys acquired knowledge of each item's ordinal position.

Single-Unit Studies of Serial Order

Ordinal categorization of visual items requires both information about the rank of an item (e.g., based on temporal order) and its identity. The single-neuron correlate of temporal rank order information in visual lists has been studied in monkeys trained to observe and remember the order in which three visual objects appeared so that the animals could plan a subsequent triple-reaching movement in the same order (Figure 4(a)). Neurons in the ventrolateral PFC were selective for visual object properties, whereas neurons in the dorsolateral PFC were selectively tuned to the rank order of the objects irrespective of the visual properties of objects; for example, a rank-order selective neuron would be active whenever the second item of the shuffled lists appears (Figure 4(b)). A third class of neurons, found in the ventrolateral PFC, showed the most complex response that was characterized by integrating the objects' sensory and order information; such a neuron would only discharge whenever a certain object appeared at a given position in the sequence.

Figure 4 Temporal ordering task and single cell responses from the PFC. (a) Monkeys were required to observe and remember the order in which three visual objects appeared so that the animals could plan a subsequent triple-reaching movement in the same order. (b) Two single neurons encoding the first (cell 1) and the second rank (cell 2), irrespective of the order in which the three items (symbolized by letters ABC) appeared. Neural responses are shown in a dot-raster histogram (top; each dot represents an action potential) and averaged as peri-stimulus time histograms (bottom). Adapted from Ninokura Y, Mushiake H, and Tanji J (2004) Integration of temporal order and object information in the monkey lateral prefrontal cortex. *Journal of Neurophysiology* 91: 555–560.

The lateral PFC is an ideal region in the brain to encode both sensory object properties and rank-order information because it receives massive sensory input from the temporal and parietal lobes, and it projects to premotor and motor areas of the frontal lobe. As a result, neurons that encode the ordinal position of task-related hand or eye movements have been found frequently in prefrontal and a variety of motor-related cortical areas in trained monkeys, such as the frontal eye field (FEF), the presupplementary motor areas (pre-SMAs), the supplementary motor area (SMA), the caudate nucleus, the anterior cingulate cortex (CGa), and even the primary motor cortex (M1). Motor-related areas such as M1, SMA, pre-SMA, and FEF may receive numerical information that has been computed on earlier stages of the cortical hierarchy to perform appropriate serial-order actions.

Human Studies

Based on patient studies, the lateral PFC has been implicated in maintaining temporal order information, which is an integral aspect of episodic memory. It is well-known that damage to the human frontal cortex causes impairment in tasks that require recall of the temporal order of stimuli. A similar ordering impairment has resulted from lesioning the dorsolateral frontal cortex in monkeys, which supports the view that the dorsolateral PFC in primates is important in maintaining information about the order of events. Functional MRI studies of humans show that prefrontal and parietal cortices are more strongly activated for order information (e.g., the order of words in a list) than for item information (the presence of words in a list). In addition, the lateral frontoparietal areas, the basal ganglia, and the cerebellum are preferentially involved in ordinal control of hand movements.

Nutrient Sensing: Carbohydrates

B E Levin, Veterans Affairs Medical Center, East Orange, NJ, USA

Published by Elsevier Ltd.

Introduction

Carbohydrates in the body exist largely either as glucose in the fluid compartments, including the blood, cerebrospinal fluid, and interstitial fluid, or as glucose complexed in the form of glycogen. The regulation of these circulating levels and stores is an integral part of the overall regulation of energy homeostasis in the body – that is, the balance between intake, expenditure, and storage of calories. Where intake exceeds expenditure, excess calories are stored as glycogen in liver, muscle, and brain and as fat in adipose depots. In addition to these basic functions, ingested nutrients must transit the gastrointestinal tract where they are digested, absorbed, and then assimilated into various tissues. Many of these functions are mediated by the autonomic nervous system, the function of which is modulated by an integrated network of specialized glucose sensors in the brain and periphery. The term 'glucose sensing' is used here to define the way in which these sensors utilize glucose as a signaling molecule to control their activity and output as monitors of the status of glucose in the body. In fact, glucose-sensing elements throughout the body contribute to virtually all aspects of energy homeostasis. Very low plasma and brain glucose levels stimulate, whereas high levels inhibit, energy intake. Glucose sensing is also involved in various aspects of assimilation and storage of energy, as well as its expenditure as heat (thermogenesis). In the brain, most neurons utilize glucose primarily to fuel metabolic requirements associated with changes in their activity. Glucose-sensing neurons represent a specialized class of neurons which have evolved to use glucose as a signaling molecule to control their firing rate and transmitter release. However, glucose rarely acts alone on glucose-sensing neurons. Many glucose-sensing neurons also integrate the inputs of a variety of hormones such as leptin and insulin, and of metabolic substrates such as lactate, ketone bodies, and fatty acids; they also integrate the neural inputs from peripheral sensors to control their membrane potential, neuronal activity, and gene transcription (Figure 1). Thus, although glucose sensing is the primary subject of this article, since these neurons respond to a host of other inputs from the periphery it is virtually impossible to consider their ability to sense glucose in isolation.

Glucose and the Components of Energy Homeostasis

Energy Intake

In 1953, Jean Mayer proposed the 'glucostatic hypothesis' whereby arteriovenous differences and/or glucose oxidation were monitored by specialized hypothalamic neurons as a means of controlling food intake. He believed that the hypothalamus was the site of such sensors because prior studies had shown that damage to the ventromedial hypothalamus caused both humans and animals to eat voraciously, while damage to the lateral hypothalamus caused animals to cease eating. To date, it is still unclear whether changes in blood glucose levels within the physiological range actually play a primary role in the regulation of ingestion. On the other hand, there is no question that rapid lowering of blood glucose levels (hypoglycemia) or administration of drugs which block intracellular glucose utilization (glucopenia) can and do produce feelings of hunger which drive the individual into a behavioral sequence required to seek and ingest food. However, acute drops in blood glucose rarely occur in nature and are mainly caused by inadvertent overdoses of insulin in diabetic individuals. A more physiological role for reduced glucose levels in the control of ingestion is suggested by studies showing that small (~10%) dips in blood glucose levels precede the onset of some individual meals. But, it is uncertain whether such dips are a physiological stimulant of intake or simply an epiphenomenon of underlying circadian rhythms of hormones and neural functions. On the other hand, infusions of glucose into the brain or portal vein of the liver have variably been reported to reduce food intake. Yet it is unclear whether the levels of glucose required to produce satiety are either physiologically relevant or simply act by providing a sufficient caloric load to produce satiety. Ingestion is a complicated process which requires behavioral arousal, the development of hunger, increased motor activity to seek and procure food, behavioral feedback relating to the rewarding properties of food, and finally satiety. Regardless of whether glucose can act alone to alter these various aspects of ingestive behavior, changes in ambient glucose concentrations within the physiological range clearly can alter the activity of brain glucose-sensing neurons that are known to be involved in all of these aspects of feeding (Figure 2).

Energy Assimilation

Ingested macronutrients must be absorbed and assimilated to generate energy to fuel the body's

Figure 1 Location of peripheral and central glucose sensors and their connections. Vagal, glossopharyngeal, and sympathetic afferents from metabolic sensors (four-pointed stars) in the portal vein, carotid body (note Hering's nerve), and intestines converge on nucleus tractus solitarius (NTS) glucose-sensing neurons (five-pointed stars) in the medulla. These afferent inputs are integrated by NTS neurons along with metabolic and hormonal signals, which are transported across the blood–brain barrier or cross through fenestrated capillaries in the area postrema (AP) adjacent to the NTS. In addition to the NTS, glucose-sensing neurons in the dorsal motor nucleus of the vagus (DMNX) and the caudal and rostral ventrolateral medulla (CVLM, RVLM) also integrate these incoming signals and project to various hypothalamic nuclei – the arcuate (ARC), ventromedial (VMN), dorsomedial (DMN), paraventricular (PVN) – and to the lateral hypothalamic area (LHA) and the amygdala. Metabolic-sensing serotonin neurons in the raphe pallidus and obscurus (RPa/Ob) project to sympathetic preganglionic neurons in the intermediolateral cell column of the spinal cord. Metabolites and hormones also interact with glucose-sensing neurons in the hypothalamus and with dopamine neurons in the substantia nigra (SN) and ventral tegmental area (VTA). Neurons in the ARC project to additional sensing neurons in the PVN. SN neurons project to the striatum for control of motor activity and VTA neurons project to limbic areas involved in reward and motivation. ME, median eminence. Green stars are glucose-excited glucose sensors and red stars are glucose-inhibited glucose sensors.

metabolic needs. Glucose is a major source of such energy but requires insulin for uptake and incorporation into peripheral tissues. Glucose alters its own uptake and utilization by directly stimulating the release of insulin from the pancreatic β cell, the prototypic glucose-sensing cell in the body. Insulin release occurs when adenosine triphosphate (ATP) is generated by the sequential glycolysis and oxidation of glucose. An increased ratio of ATP/ADP leads to the inactivation of an ATP-sensitive K^+ (K_{ATP}) channel which depolarizes the cell membrane, leading to calcium influx and insulin release. This process is enhanced by vagal, and inhibited by sympathetic, inputs to the β cell. Both of these neural inputs are regulated by glucose acting on central glucose-sensing neurons in brain areas such as the lateral hypothalamic area (LHA), the arcuate (ARC), paraventricular (PVN), dorsomedial (DMN), and ventromedial (VMN) nuclei of the hypothalamus and the nucleus tractus solitarius (NTS), rostral ventrolateral medulla (RVLM), raphe pallidus (RPa) and raphe obscurus (ROb), and dorsal motor nucleus of the vagus (DMNX) in the medulla (Figures 1 and 2). Insulin is an anabolic hormone in the periphery in that it promotes the uptake of glucose into muscle and other organs. Insulin also inhibits breakdown of glycogen (glycogenolysis) in the liver and the release of fatty acids (lipolysis) from adipose depots. Thus, insulin is the intermediary through which glucose controls its own peripheral metabolism.

Energy Expenditure

Assimilation of nutrients also leads to the generation of heat, a process known as diet-induced thermogenesis. In humans, this occurs primarily in muscle. Rodents

Figure 2 Efferent connections of glucose-sensing neurons involved in the regulation of energy homeostasis. Glucose-sensing neurons (green stars, glucose-excited neurons; red stars, glucose-inhibited neurons) are localized throughout the forebrain, hypothalamus, and brain stem. Arcuate (ARC) neuropeptide Y (NPY) neurons and proopiomelanocortin (POMC) neurons (which produce α-melanocyte-stimulating hormone (α-MSH)) are prototypic glucose-sensing neurons having the primary function of regulation of energy homeostasis. They project to the paraventricular nuclei (PVN) and to metabolic-sensing neurons (heavy dotted lines) orexin and melanin-concentrating hormone (MCH) in the lateral hypothalamic area (LHA). Some ARC POMC neurons also project to intermediolateral (IML) cell column preganglionic sympathetic nervous system (SNS) neurons in the spinal cord. PVN neurons project to the median eminence (ME) and pituitary to modulate neuroendocrine outputs and to sympathetic and parasympathetic output neurons in the medulla for control of visceral functions involved in energy homeostasis. In contrast to the relatively limited targets of ARC NPY and POMC neurons, the orexin and MCH LHA neurons project widely to brain areas involved in a large variety of behavioral and physiological functions, some of which are involved in the regulation of various aspects of energy homeostasis (VMN, ventromedial nucleus; NTS, nucleus tractus solitarius; RPa/Ob, raphe pallidus and obscurus; RVLM, rostral ventrolateral medulla; DMNX, dorsal motor nucleus of the vagus). Some of these targets also contain glucose-sensing neurons (VTA, ventral tegmentum area; n. Acc, nucleus accumbens; LC, locus coeruleus; DRa, dorsal raphe nucleus; CG, central gray; DVC, dorsal vagal complex).

also use brown adipose tissue, a specialized form of adipose tissue in which mitochondrial production of ATP is uncoupled from the oxidation of fatty acids leading to the generation of heat. Exercise is an additional source of thermogenesis. Glucose acts as a major stimulant of diet-induced thermogenesis and as a substrate to fuel exercise-induced heat production. This glucose-induced thermogenesis is mediated in part by direct effects of glucose on glucose-sensing neurons in the PVN, ARC, RPa/ROb, and RVLM which lead to activation of sympathetic efferents to thermogenic organs (Figure 2).

Peripheral Glucose Sensors

Aside from the pancreatic β cell, peripheral glucose sensors reside in the portal vein, the small intestines, and the glomus cells of the carotid body. While we know a great deal about the mechanisms by which β cells and glucose-sensing neurons monitor glucose levels, less is known about the mechanisms utilized by other peripheral sensors. It is known that glucose-activated signals are transmitted via vagal, glossopharyngeal, and sympathetic afferents which terminate on glucose-sensing NTS neurons, which integrate these neural signals with the effects of glucose acting directly on these same neurons (Figure 1). Portal vein sensors appear to transmit their signals via different sets of afferents, depending upon the levels of glucose. Raising portal vein glucose levels leads to a decrease in vagal afferent discharges that impinge upon NTS neurons, and these same NTS neurons are directly inhibited by glucose. On the other hand, lowering portal vein glucose levels by producing systemic hypoglycemia activates sympathetic (but not vagal) afferents. These afferents are required for the initiation of the

counterregulatory release of epinephrine from the adrenal medulla, norepinephrine from sympathetic nerves, and glucagon from the pancreatic α cells. Collectively these act in concert to raise blood glucose levels by stimulating glycogenolysis and promoting hepatic glucose production. The glomus cells of the carotid body are activated by both low glucose and low oxygen levels, and they communicate with the brain via glossopharyngeal parasympathetic afferents in Hering's nerve. Much like pancreatic β cells, intestinal glucose-sensing neurons and cells appear to utilize the K_{ATP} channel to sense glucose and they presumably communicate with the brain via vagal afferents (Figure 1). The L cells of the gut are an example of glucose-sensing cells which release peptides such as glucagon-like peptide-1 (GLP-1) in response to rising glucose levels. Such peptides may act on local gut vagal afferent receptors directly or may be released into the bloodstream to alter glucose homeostasis by acting on organs such as the pancreas, or by stimulating receptors on hepatic portal sensors.

How Do Neurons Sense Glucose?

Glucose Enters the Brain by Several Routes

Glucose enters most peripheral organs by diffusion through fenestrations between vascular endothelial cells. In the brain, endothelial cells in microvessels have tight junctions which prevent such diffusion. Thus, glucose enters the brain by facilitated transport across this blood–brain barrier via the GLUT1 glucose transporter (Figure 3). As a result, a gradient is maintained whereby brain interstitial glucose levels are held at ~20–30% of blood levels during normal or euglycemic conditions. This ratio falls to as low as 10–15% during systemic hypoglycemia. Brain glucose levels take 2–5 min to equilibrate after changes in blood glucose levels. Glucose is also transported across the choroid plexus into the cerebrospinal fluid with a delay of about 15 min. From there it can diffuse across the ependymal lining of the ventricles into the adjacent interstitial space of the brain. Glucose may also diffuse directly from the blood into the brain

Figure 3 Hypothetical model of the mechanism of neuronal glucose sensing in a glucose-excited (GE) neuron. Glucose is transported across the endothelial cells of brain microvessels by GLUT1 transporters into the interstitial space, which maintains glucose levels at ~20–30% of blood levels. All neurons transport glucose by GLUT3 transporters. Hexokinase I (HKI) initiates glycolysis and glucose oxidation, which generates ATP for the ongoing metabolic demands of the cell. Glucose-sensing neurons also express glucokinase (GK), which is co-localized with mitochondria adjacent to K_{ATP} channels in the cell membrane. The GK-mediated generation of ATP occurs by oxidation of glucose in a concentration-dependent manner, which raises the ATP:ADP ratio and binding of ATP to the K_{ATP} channel. This binding inactivates (closes) the channel, leading to membrane depolarization and entry of extracellular calcium through a voltage-dependent calcium channel (VDCC) and propagation of an action potential. Glucose uptake and GK-mediated production of ATP and K_{ATP} channel inactivation can occur independently at axon terminals, leading to release of transmitters such as glutamate and γ-aminobutyric acid (GABA). Astrocytes have their foot processes adjacent to microvessels and they transport glucose via GLUT1 or GLUT2 transporters from the blood into the astrocytes where it is stored as glycogen. Glycogenolysis produces lactate, which is exported via monocarboxylate transporters (MCT) to the extracellular space, where it can be taken up by neurons through MCTs and converted to pyruvate by lactate dehydrogenase (LDH). Pyruvate can then be oxidized to produce an alternate source of ATP to fuel the metabolic needs of the cell.

at circumventricular organs such as the area postrema, which contains fenestrated capillaries (Figures 1 and 2). Diffusion from the area postrema can influence glucose-sensing neurons in the adjacent NTS. On the other hand, while the median eminence also contains fenestrated capillaries, glucose probably does not diffuse to the adjacent ARC because of barriers imposed by specialized glia and tanycytes, which functionally separate the two structures. Thus, depending upon the proximity of neurons to the ventricles or circumventricular organs and the rate of local glucose transport (which varies in different brain regions), glucose-sensing neurons can be exposed to glucose from up to three separate sources, each with its own temporal- and concentration-dependent patterns. Since such neurons also receive indirect neural inputs from peripheral glucose sensors, they act as comparators, integrating the arriving glucose-related signals having differing strengths and temporal patterns. The resulting effect on their membrane potential determines their firing rate and level of transmitter and neuropeptide release.

Direct Effects of Glucose on Glucose-Sensing Neurons

Glucose is transported into most neurons by the high-affinity, high-capacity GLUT3 transporter. Because of these kinetic properties, glucose transport into the neuron remains relatively constant across the physiological range of glucose levels experienced by the brain. Intraneuronal glucose is phosphorylated by hexokinase I, a high-affinity hexokinase which is saturated under physiological conditions and is also inhibited by its end product, glucose-6-phosphate. Thus, because of their kinetics, neither GLUT3 nor hexokinase I is rate limiting in the control of glucose metabolism or glucose sensing. For this purpose, glucose-sensing neurons have evolved an alternate pathway by which glucose acts in a concentration-dependent manner to generate ATP and regulate membrane potential and firing rate. There are two broad categories of glucose-sensing neurons; glucose-excited (GE) neurons increase, while glucose-inhibited (GI) neurons decrease, their activity as ambient glucose levels rise. They reverse this pattern as glucose levels fall. GE and GI neurons are located throughout the neuraxis and different areas contain differing percentages of each type of glucose sensor (Figures 1 and 2).

As with all other neurons, GE and GI neurons utilize GLUT3 and hexokinase I to provide for their ongoing metabolic needs. However, many glucose-sensing neurons also utilize glucokinase (GK; hexokinase IV) as the rate-limiting step in glucose sensing. The affinity of GK for glucose in the brain, as in the pancreas, is approximately 6–11 mM. Also, GK is not subject to end-product inhibition as is hexokinase I. At least 65% of GE and 45% of GI neurons express GK mRNA. In those GK-expressing neurons, pharmacological inhibition of GK activity decreases activity in GE neurons and increases activity in GI neurons held at glucose concentrations comparable to those seen in the brain (2.5 mM) under slightly hyperglycemic conditions in the periphery (~8 mM). On the other hand, pharmacological activation of GK inhibits the activity of GI neurons and enhances the activity of GE neurons held at glucose concentrations comparable to those seen in the brain (0.5 mM) under systemic hypoglycemic conditions (~3.5 mM). Interestingly, although GK mRNA cannot be demonstrated in all glucose-sensing neurons, an 80% reduction in GK mRNA in primary cultures of ventromedial hypothalamic neurons almost completely eliminates the ability of both GE and GI neurons to sense and respond to glucose. These data strongly suggest that GK is a critical regulator of neuronal activity in many GE and GI neurons.

Glucose-excited neurons Because of their similarity to pancreatic β cells, we know a great deal about the way in which GE neurons sense glucose (Figure 3). The K_{ATP} channel is the final common pathway for glucose sensing in both. It is an octomeric protein composed of four Kir6.2 pore-forming units for potassium and four sulfonylurea receptor subunits. Oxidation of glucose increases the ratio of ATP/ADP, causing ATP to bind to the channel. Binding of either ATP or sulfonylureas inactivates (closes) the channel and depolarizes the cell membrane. Depolarization is followed by influx of extracellular calcium through a voltage-dependent calcium channel, which in turn is often (but not always) followed by an increase in action potential frequency. Importantly, glucose-induced closure of the K_{ATP} channel at nerve terminals on some GE neurons can also release neurotransmitters independently of action potentials propagated from the cell body (Figure 3). While GK is probably the primary regulatory step in GE (and GI) neuronal glucose sensing, it is much less abundant than hexokinase I and is unlikely to contribute significantly to the overall, well-buffered pool of intracellular ATP which regulates K_{ATP} channel activity. Thus, GK may be compartmentalized in a microenvironment with mitochondria close to the K_{ATP} channels in the plasma membrane where ATP generated through the GK pathway can control channel activity (Figure 3).

Glucose-inhibited neurons While the K_{ATP} channel appears to be the final common pathway involved in GE neuron glucose sensing, much less is known about the way in which GI neurons sense glucose. In many ways, GI neurons are similar to pancreatic glucagon-secreting α cells. Both express GK and both are also inhibited as glucose levels rise and are activated as glucose levels fall. A Cl^- channel, the Na^+–K^+ ATP pump, and an ATP-responsive K^+ channel have all been proposed as possible final common pathways, but the actual effector of GI glucose sensing is unknown.

Alternate mechanisms of neuronal glucose sensing It is likely that all neurons do not depend upon GK as the regulator of glucose sensing. As with the rat pancreatic β cell, GLUT2 has been proposed as a rate-limiting step in neuronal glucose sensing. However, GLUT2 is in very low abundance in the brain and less than 30% of GE or GI neurons express GLUT2 mRNA. On the other hand, almost 70% of VMN glucose-sensing neurons co-express insulin receptor and GLUT4 mRNA. In peripheral tissues, occupation of the insulin receptor causes translocation of GLUT4 to the cell membrane, where it binds and transports glucose into the cell. This mechanism is required for glucose utilization in peripheral tissues. On the other hand, there is little convincing evidence that the brain requires insulin for glucose uptake and metabolism. However, the co-expression of insulin receptor and GLUT4 on glucose-sensing neurons suggests that insulin can act to enhance their glucose uptake under certain circumstances. For example, insulin may facilitate glucose transport during systemic hypoglycemia when brain glucose levels are lowered. Thus, insulin has little effect on the activity of ARC GE neurons at physiological glucose concentrations (2.5 mM) but causes increased neuronal activity when ambient glucose levels are lowered to those seen in the brain (0.5 mM) during hypoglycemia. In addition to this mechanism, adenosine monophosphate (AMP)-activated kinase (AMPK) is a well-described energy sensor in peripheral organs and is also localized in hypothalamic areas containing glucose-sensing neurons. Pharmacological activation of AMPK during systemic hypoglycemia enhances the systemic counterregulatory responses which normally mobilize glucose from peripheral tissues. Conversely, hypothalamic AMPK activity is regulated by ambient glucose levels. Thus, AMPK may function as an alternate emergency glucose sensor in some neurons. Finally, the sodium–glucose cotransporter may function as an alternate regulator of glucose sensing (as it appears to do in some intestinal glucose-sensing L cells); drugs which inhibit its activity decrease the responsiveness of GE neurons to glucose. However, the mRNA for this transporter is expressed in only a very few of such neurons. Thus, while the majority of glucose-sensing neurons utilize GK as their primary regulator, there are likely to be alternative mechanisms which function in these and other non-GK-expressing neurons, to allow neurons to sense and respond to glucose, particularly when glucose supply is limited.

Indirect Effects of Glucose on Glucose-Sensing Neurons

Glucose-sensing neurons do not function in isolation. They are surrounded by and provided with metabolic support by astrocytes, which readily take up and store glucose as glycogen (Figure 3). Glycogen is hydrolyzed to release lactate into the extracellular space from which it is taken up by neurons via monocarboxylate transporters (MCTs), converted to pyruvate by lactate dehydrogenase, and then oxidized to provide ATP. By this mechanism, lactate can reverse the inhibition of GE neuronal activity which occurs at low ambient glucose levels. To date, it remains unresolved what role astrocyte-derived lactate production plays in the support of non-glucose-sensing neurons and signaling in glucose-sensing neurons under physiological conditions.

Glucose-Sensing Neurons as Metabolic Sensors

GE and GI neurons have differing properties with regard to their sensitivity to glucose and to other hormones and metabolic substrates. GE neurons are more sensitive to glucose than are GI neurons, but the range over which both respond to glucose is also a function of their anatomic location. For example, GE neurons in the VMN are maximally activated over a range of 0.1–2.5 mM glucose, while ARC GE neurons continue to increase their activity up to 5 mM glucose. These differences in sensitivity may reflect inputs from surrounding astrocytes or neurons but might also be due to the fact that the K_{ATP} channel has different proportions of sulfonylurea-binding subunits, which could alter their sensitivity to glucose. Also, because the K_{ATP} channel is subject to modulatory effects of G-protein-coupled receptors, phosphoinositol 3-kinase (as modulated by both leptin and insulin), and levels of intracellular long-chain CoA molecules derived from fatty acids, the milieu in which a given neuron finds itself combines with its intrinsic metabolic and physiological characteristics to determine how it will respond to glucose. Thus, glucose-sensing neurons are really metabolic sensors in which the combined input of metabolites, peptides, transmitters, and hormones can affect both their short-term and long-term ability to sense and respond to glucose.

Role of Glucose-Sensing Neurons in the Regulation of Energy Homeostasis

The processes of ingestion, assimilation, expenditure, and storage of calories involved in the control of energy homeostasis are all ultimately controlled by the dialogue between the brain and the periphery. As with most neural functions, control of energy homeostasis resides within a distributed network of neural centers distributed throughout the brain (Figures 1 and 2). Because early studies showed a huge impact of hypothalamic lesions on the regulation of energy homeostasis, a great deal of emphasis and study has focused on the hypothalamus as a primary site of such regulation. In areas such as the ARC and VMN, 10–30% of the neurons are glucose sensing. These include neurons expressing the anabolic ARC neuropeptide Y (NPY)/agouti-related peptide (AgRP) and LHA orexin and melanin-concentrating hormone (MCH), and the catabolic ARC proopiomelanocortin (POMC) neurons. NPY/AgRP and orexin neurons are GI in type, and POMC and MCH neurons are GE in type. The ARC NPY/AgRP and POMC neurons have overlapping projections primarily to the PVN, LHA, and sympathetic preganglionic spinal cord neurons, and their major function appears to be the regulation of energy homeostasis. On the other hand, small populations of MCH and orexin neurons localized in the LHA project widely throughout the neuraxis to areas involved in cognition, emotion, motivation, reward, motor activity, arousal, autonomic, and neuroendocrine activation (Figure 2). Thus, the ARC neurons are primarily dedicated to the control of energy homeostasis while MCH and orexin neurons are effectors through which the ARC neurons modulate the complex sets of behaviors and physiological functions, of which the regulation of energy homeostasis is only a small part. Many of the ARC and LHA neurons are both glucose sensors and metabolic sensors. They also receive direct or indirect afferents from the NTS and other brain stem nuclei which are also integrators of peripheral neural, metabolic, and hormonal signals (Figure 1). Thus, no one site or set of neurons functions alone. Instead the combined input of this distributed network of metabolic-sensing neurons acts collectively to regulate energy homeostasis.

Glucose-Sensing Neurons and Obesity

Since glucose-sensing neurons are so important in the control of energy homeostasis, it is not surprising that alterations in their function might affect the long-term regulation of body weight and adiposity. In fact, rats selectively bred to develop diet-induced obesity when the caloric density and fat content of their diet are increased manifest a number of abnormalities of both glucose sensing and hypothalamic neuronal responsiveness to leptin and insulin. These abnormalities include a reduced number of hypothalamic GE neurons, reduced sensitivity of the K_{ATP} channel to both ATP and sulfonylureas in GE neurons, reduced binding of sulfonylureas to the sulfonylurea binding site on the K_{ATP} channel, aberrant activation of the sympathetic nervous system to glucose infused either systemically or directly into the forebrain via the carotid artery, and increased expression of GK mRNA in the ventromedial hypothalamus associated with a blunted response to insulin-induced hypoglycemia. All of these abnormalities antedate the development of obesity, as does a reduced sensitivity to the anorectic effects of both leptin and centrally administered insulin. Such data suggest that there may be a genetic predisposition toward reduced sensitivity of glucose-sensing neurons to catabolic feedback signals which would ordinarily limit the amount of food ingested. Such a raised threshold would provide a competitive advantage where cycles of feast and famine were common, since it would allow such individuals to eat beyond their metabolic needs, to store as many calories as fat as possible when food was readily available. This would serve as a buffer during times of food shortage. However, in our modern society, where food is abundant and can be obtained with little expenditure of energy, such a trait would predispose such individuals to become obese. Thus, a reduced sensitivity of glucose-sensing neurons to metabolic and hormonal feedback cues may be one of the factors which underlie the current worldwide epidemic of obesity.

Summary and Conclusions

Glucose is a critical substrate for neuronal function. Mammals have evolved specialized peripheral glucose sensors and central neurons which utilize glucose as a signaling molecule, as a means of sensing and regulating glucose and carbohydrate metabolism. The peripheral sensors communicate with the central glucose-sensing neurons via autonomic visceral afferents, whereas glucose is monitored directly by brain glucose-sensing neurons, many of which use GK as a rate-limiting step in the signaling pathway. These neurons also respond to a variety of hormones such as leptin and insulin and metabolic substrates such as fatty acids, lactate, and ketone bodies, which provide direct or indirect indices of the status of energy storage depots and the metabolic state of the body. All of these signals are integrated in a time- and concentration-dependent manner at the level of the cell's membrane potential, to regulate neuronal activity,

metabolism, and transmitter release. These metabolic-sensing neurons are spread throughout the brain in a distributed network which controls the regulation of energy homeostasis. Some obesity-prone individuals inherit a raised threshold for sensing metabolic and hormonal signals from the periphery. While this raised threshold would allow them to survive periods of scarce food availability, it may predispose them to become obese when food is readily available at low energetic cost.

Introduction

The regulation of energy balance is the result of an accurate match between energy intake and energy expenditure. This is critical to the survival of any organism, and consequently humans have evolved a number of redundant mechanisms to ensure that the energy balance equation is maintained. To accomplish this regulation of energy balance, the central nervous system (CNS) must be able to monitor two separate variables. The first of these is the amount of stored fuel in the body. Most of this stored fuel is in the form of adipose tissue deposited in depots throughout the body (Figure 1). A wide range of evidence indicates that adipose tissue is a major endocrine organ, secreting factors that control a number of key metabolic processes. At least some of these factors appear to provide afferent information back to the CNS about the status of these stored calories. In particular, a large body of evidence indicates that the hormone leptin circulates in proportion to the amount of calories in adipose tissue. Leptin appears to cross the blood–brain barrier, where it acts upon a number of key receptor populations. One key receptor population is within the arcuate nucleus of the hypothalamus.

The second key variable is the amount of energy currently available to power necessary biological functions. Monitoring this available fuel is a key function for metabolic circuits within the CNS, since a failure to keep adequate fuel available is rapidly catastrophic. The need to monitor cellular fuel availability is not unique to cells in the CNS. Rather, this is a necessary component of every cell to ensure that key cellular processes are scaled back when the required energy is not available. Individual cells accomplish this by the complex networks of biochemical reactions that ensure that the proper amount and type of fuel is available for cellular processes. To regulate this network of biochemical reactions, cells have developed signaling pathways that act as 'fuel sensors.' These fuel sensors serve to read out the availability of key aspects of fuel to regulate broad aspects of cellular activity.

Fuel Sensors

One key energy form that cells must carefully monitor is adenosine triphosphate (ATP), since it provides the basic source of energy for most cellular processes. Because of ATP's central importance, cells have enzymes with activities that are regulated by the ratio of ATP to adenosine monophosphate (AMP). Two examples of such fuel sensors are AMP kinase (AMPK) and the mammalian Target of Rapamycin (mTOR) protein. AMPK is a highly conserved serine/threonine kinase. AMPK is activated when cellular fuel availability is low, and its activation leads to a number of cellar changes that conserve energy. This regulation is achieved because the tumor suppressor serine/threonine kinase LKB1 (now named STK11), which is itself activated by AMP, and the Ca^{2+}/calmodulin-dependent protein kinase kinase-β (CaMKKβ) regulate phosphorylation and activation of AMPK. Moreover, AMP simultaneously inhibits AMPK dephosphorylation by inhibiting protein phosphatase-2C. These effects are antagonized in the presence of high concentrations of ATP, allowing AMPK activity to precisely monitor changes in the cellular ratio of ATP:AMP.

While AMPK is activated in low-fuel situations, mTOR is activated when cellular energy is in abundance. mTOR (also known as FRAP, RAFT, RAPT, or SEP) is a ~280 kDa protein member of the phosphatidylinositol kinase-related protein kinase family that regulates critical aspects of cell growth, including transcription, translation initiation, and elongation, and cell-cycle progression. mTOR exists in two distinct multiprotein complexes: one containing a protein called raptor (mTORC1) and another containing a protein called rictor (mTORC2). The mTORC1 is the best studied and understood of the two complexes, since it appears to be the major mediator of rapamycin's potent actions. During nutrient deprivation, mTORC1 is stabilized in a manner that inhibits mTOR kinase activity, whereas it changes conformation and serves as a positive regulator of its activity in the presence of nutrients. Raptor also serves as an adaptor protein that recruits mTOR substrates, such as the 40S ribosomal proteins S6 kinase-1 and S6 kinase-2 (S6K1 and S6K2), and is necessary for their phosphorylation by mTOR. Given that the mTOR pathway is crucial for regulating rates of new protein synthesis, mTOR responds not to just fuel availability but also to those hormones and amino acids which regulate growth.

CNS Fuel Sensing

While individual cells must monitor their fuel levels to regulate specific intracellular functions, the CNS has a different problem. Individual neurons may monitor fuel levels but they must also coordinate the fuel availability they detect locally across the different

Figure 1 Regulation of energy balance.

tissues of the organism, and then direct behavior to act on critical needs. In many ways, the CNS is not an ideal organ for this function. Most neurons are heavily protected from the changing levels of fuels that peripheral cells must navigate. This protection is largely the result of glial cells, which are capable of providing needed fuel to neurons even when such fuel is in short supply. Second, neurons typically use glucose or related substitutes, such as lactate, as their primary source of fuel. While good evidence links glucose-sensing to the regulation of metabolism, many peripheral cell types, including the major energy-burning cells in muscle, can use either fatty acids or glucose to provide energy. Thus, for the CNS to regulate the organism's overall metabolic milieu it would seem necessary for neurons to be able to monitor lipid availability.

Despite some of these obvious drawbacks, growing evidence implicates specialized neuronal populations as being capable of sensing not just glucose availability but also energy more generally. The first piece of this new appreciation came from work using inhibitors of fatty acid synthase (FAS). It has long been established that FAS and fatty acid metabolism are regulated by the nutritional status of animals via lipogenic tissues, such as adipose and liver. Because the brain is not lipogenic, there was little reason to think that the *de novo* fatty acid synthesis pathway played an important role in the CNS. However, lipogenic enzymes are found in hypothalamic nuclei known to be critical for regulating both food intake and other metabolic parameters. Moreover, evidence from studies using FAS inhibitors, and using other pharmacological or genetic tools to modulate different enzymes of the FAS pathway in the CNS, suggests that this system senses and integrates signals from nutrients and nutrient-derived hormones. Administration of the natural FAS inhibitor cerulenin or a synthetic analog (C75) causes profound, dose-dependent anorexia and weight loss in rats and mice. These

effects are also observed with intracerebroventricular (icv) administration of much lower doses of C75, suggesting that the brain is the key site of action. In addition to the effects of C75, direct administration of oleic acid into the CNS results in reduced food intake and reduced hepatic glucose output. Collectively, these data point to an important ability of the CNS to monitor fuel in the form of fatty acids, rather than just the traditional fuel of neurons in the form of glucose.

CNS Fuel Sensors in the Regulation of Energy Balance

Given that at least some neuronal populations within the CNS appear to be able to respond to both lipids and glucose, one reasonable hypothesis is that these specialized populations of neurons have adapted to use the activity of cellular fuel sensors to assess the availability of fuel in the organism and to direct behavior and physiology. Solid evidence now links both AMPK and mTOR activity in the hypothalamus to the regulation of energy balance.

A number of manipulations of available energy appear to regulate AMPK activity within discrete nuclei of the hypothalamus. For instance, fasting, glucose deprivation, and administration of the melanocortin receptor antagonist/inverse agonist agouti-related protein (AgRP) increase AMPK activity in the same hypothalamic regions where refeeding, glucose, and a melanocortin receptor agonist reduce AMPK activity. Furthermore, the potent orexigen ghrelin increases hypothalamic AMPK activity, while anorexigenic treatments such as α-lipoic acid decrease hypothalamic AMPK levels. Because AMPK is activated in conditions of negative energy balance, it would be predicted to activate efferent pathways that promote the entry of fuels into the organism, in order to reestablish energy homeostasis. Increased activation of AMPK in the ventromedial hypothalamus has been found to stimulate feeding behavior and weight gain in rodents and to reduce the anorexigenic and weightreducing effects of α-lipoic acid. These data collectively support the hypothesis that AMPK activity detects changes in cellular energy to influence subsequent food ingestion.

Recent evidence also supports an important role for mTOR. By immunohistochemistry, mTOR activity is not widespread within the CNS but rather is localized to key circuits that regulate food intake and metabolism. mTOR activity is found in the arcuate nucleus of the hypothalamus and can be localized to both AgRP and proopiomelanocortin (POMC)-producing cells. The amount of mTOR activity in the arcuate also appears to be regulated by energy status, with fasting reducing mTOR activity. mTOR activity can be potently increased by specific branched-chain amino acids such as leucine. This is also true in the CNS, where leucine, but not valine, increases mTOR activity and can also reduce food intake. Collectively, these data point to an important role for mTOR as a cellular fuel sensor that is used by key populations of neurons to regulate food intake.

One important aspect of both AMPK and mTOR is that they are regulated by hormonal signals in addition to their fuel-sensing capacity. As a consequence, they are ideally suited to not only be important for regulating the CNS response to fluctuations in available fuel, but also could be a key part of the response to stored fuel. Leptin is one such key signal and it appears to regulate activity of both AMPK and mTOR in the hypothalamus. Leptin administration decreases AMPK activity in the hypothalamus, and increased constitutive AMPK activity blunts the anorexic effects of leptin. Similarly, mTOR is an important target of the phosphatidylinositol 3-kinase (PI3K) and Akt signaling cascade, and leptin has been shown to activate PI3K in the hypothalamus. CNS administration of leptin results in increased mTOR activity in the hypothalamus, and when mTOR is inhibited by CNS administration of rapamycin, it reduces the ability of leptin to reduce food intake. Thus, another role for these fuel sensors in the hypothalamus is to integrate signals concerning available metabolic fuels and signals of stored fuel, to guide ingestion and metabolism.

Conclusions

Our understanding of how CNS circuits regulate food intake and body weight has expanded rapidly in the past 15 years. An important part of that new understanding is the result of applying advances in our understanding of cellular metabolic pathways back to the CNS. Evolving multicellular organisms developed specialized metabolic organs for storing and exchanging different types of metabolic fuels. While such organs give an organism an enormous advantage, the need to coordinate across these organs is critical for survival. The CNS clearly plays a large role in this process and has developed a number of ways both to sense metabolic perturbations and to respond to them. Given this central role, however, it also means that the CNS may be an important part of the etiology of diseases of metabolic disruption, such as obesity and type 2 diabetes. A wide range of evidence points to the same circuits that regulate food intake as being crucial to the regulation of blood

glucose. While the prevailing view of how obesity leads to greatly increased incidence of type 2 diabetes is that increased fat stores lead to insulin resistance in muscle and greater strain on the β-cell, the new data suggest a more radical hypothesis. Given that such insulin resistance and β-cell failure is linked to alterations in key fuel-sensing metabolic pathways, it may be that the primary lesion is alterations in the fuelsensing capabilities in the CNS. Such a disruption would simultaneously lead to the inability to accurately match caloric intake and caloric expenditure, while limiting the ability to coordinate metabolic activity across different organs. Thus, it may be that the CNS will provide a single underlying etiology that links obesity to type 2 diabetes. Future work will need to focus on understanding how environmental and genetic factors can influence the function of these fuel-sensing pathways to increase or decrease the incidence of metabolic disease.

Synaptic Plasticity and Neurogenesis

Energy restriction has been shown to increase the average and maximum life span of rats and mice by up to 50% and retard age-related deficits in motor function and learning and memory (Table 1). For example, lifelong caloric restriction (CR; 30–40% reduction below *ad libitum* levels) and intermittent fasting (IF; every-other-day fasting), starting after puberty, improved the performance of mice on tests of motor coordination and complex learning. Conversely, long-term overfeeding, particularly with diets high in fats and carbohydrates, can impair learning and memory and motor function in rodents. Electrophysiological recordings of synaptic transmission in hippocampi from aged rats that had been maintained on control and CR diets showed that long-term potentiation (LTP), believed to be a cellular correlate of learning and memory, is enhanced by low-energy diets (Figure 1). In addition, data from studies of obese and untreated diabetic humans suggest a detrimental effect of high-energy diets on cognitive function which may result from chronic elevations of circulating glucose and lipids.

The adult brain contains populations of neural stem cells that divide and are capable of differentiating into new neurons; these cells are located primarily in the dentate gyrus of the hippocampus and the subventricular zone of the cerebral cortex. However, many newly generated neurons undergo a form of programmed cell death called apoptosis and therefore never become functional. Hippocampal neurogenesis is increased in rats and mice maintained on an IF energy restriction regimen, apparently as the result of increased survival of newly generated neurons (Figure 1). On the other hand, controlled CR results in increased survival of newly generated glial cells without affecting neurogenesis. Interestingly, increased energy expenditure (regular exercise) and ischemia also enhance hippocampal neurogenesis, demonstrating a high level of sensitivity of neural stem cells to changes in energy metabolism. Excessive energy intake and diabetes suppress neurogenesis in rodent models. Because recent findings suggest that neurogenesis plays an important role in the adaptive responses of the brain to changing environments, energy intake is likely to influence those responses.

Neuronal Vulnerability to Injury and Disease

Although it is well established that moderate energy restriction can reduce the incidence of type 2 diabetes, cardiovascular disease, and many types of cancer, only recently has the influence of energy intake on neurological disorders been elucidated. Epidemiological studies in human populations have revealed associations between overeating, type 2 diabetes, and increased risk of Alzheimer's disease (AD), Parkinson's disease (PD), and stroke. Individuals with low caloric intakes are at reduced risk of these disorders. Experiments in both rodent and monkey models have directly demonstrated that CR and IF diets suppress or delay brain disease processes and are neuroprotective. IF protects hippocampal neurons of rats and mice against seizure-induced damage and also reduces brain damage and improves functional outcome in a rat model of focal ischemic stroke. An IF regime also has been shown to protect dopaminergic neurons in a mouse model of PD and protect striatal neurons in a mouse model of Huntington's disease (HD). Additionally, CR has been shown to suppress the amyloid pathology and improve cognitive function in mouse models of AD, and monkeys maintained on a CR diet exhibited improved motor function and higher striatal dopamine levels compared to monkeys on a control diet in a PD model. CR can also protect the retina against ischemic injury and auditory neural cells against age-related degeneration.

While the amount of calories consumed can affect the vulnerability of neurons to injury and disease, the specific source of the energy supply may also be important. Dietary fats that promote cardiovascular disease, including saturated fats and trans fatty acids, may also render neurons vulnerable to neurodegenerative disease. On the other hand, omega-3 fatty acids such as docosahexanoic acid may protect neural cells against disease. The ways in which the body and its cells metabolize energy may be altered in neurodegenerative disorders. For example, both HD patients and some strains of huntingtin mutant mice develop a hypermetabolic state and lose body weight progressively beginning early in the disease process. In addition, deficits in glucose utilization may occur prior to neuronal degeneration in brain regions most severely affected in AD and PD. Moreover, mitochondrial toxins can cause PD-like (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridire (MPTP) and rotenone) or HD-like (3-nitropropionic acid) pathologies and symptoms in rodents, monkeys, and humans. The ability of

Table 1 Summary of the effects of energy intake (low-energy: CR and IF; high-energy: high-fat/high-glucose diet) on brain plasticity and neuronal vulnerability

Dietary manipulation	*Plasticity*	*Neuronal vulnerability*
Caloric restriction (CR)	Enhance	Decrease
Intermittent fasting (IF)	Enhance	Decrease
High-fat/high-glucose	Decrease	Enhance

Figure 1 Hormesis model of the mechanism by which dietary energy restriction enhances neural plasticity and disease resistance. Energy restriction imposes a mild stress on neural cells, resulting in the activation of signaling pathways that upregulate the expression of proteins that promote neuronal survival, synaptic plasticity, and neurogenesis. These proteins include neurotrophic factors such as BDNF, protein chaperones, antioxidants, mitochondrial uncoupling proteins, and plasma membrane redox enzymes. Insulin and IGF-1 signaling pathways are responsive to energy restriction and may contribute to the adaptive stress responses of neural cells.

CR and IF diets to protect neurons against the latter toxins suggests an important role for energy intake in modifying key mechanisms involved in the pathogenesis of neurodegenerative disorders. However, reduced energy diets are not uniformly beneficial. Epidemiological findings and recent data from studies of mouse models of amyotrophic lateral sclerosis (ALS) suggest that motor neurons may not respond adaptively to energy restriction. Instead, high-fat diets may benefit motor neurons and protect them against ALS.

Neuroendocrine Responses to Variable Energy Availability

Highly complex integrated neuroendocrine systems control the balance between energy intake and expenditure in the context of food availability. The hypothalamus is a critical regulator of energy balance; it responds to hormones involved in energy intake (leptin and ghrelin, for example) and to higher cognitive processes in brain regions such as the hippocampus. Importantly, the hypothalamus also controls behavioral and metabolic responses to stress. Accordingly, the hypothalamic–pituitary–adrenal (HPA) axis is activated in response to energy restriction, resulting in increases of circulating glucocorticoid levels (cortisol in humans and other primates, and corticosterone in rodents). Accompanying the latter changes are increased arousal and physical activity. The state of mild stress imposed by CR and IF is part of an adaptive response that motivates the animal or human to actively seek food. Conversely, constant access to food results in satiety and reduced cognitive and physical activity. Numerous changes in neuroendocrine signaling systems occur in response to moderate energy restriction, including decreased levels of insulin and leptin (associated with increased sensitivity of insulin and leptin target cells), growth hormone, and prolactin. Such neuroendocrine changes are adaptive, orchestrating the reallocation of energy reserves among organ systems (i.e., reducing body fat and shifting reserves from reproductive processes to those necessary for survival). Severe energy restriction results in drastic changes in neuroendocrine systems that can be considered emergency measures. In females these include complete shutdown of the reproductive system and an incessant increase in physical and cognitive activities.

Fundamental aspects of cardiovascular physiology are sensitive to energy intake, including blood pressure, heart rate, and heart rate variability. Obesity and a sedentary lifestyle are associated with increased blood pressure and decreased heart rate variability in humans. When rats are maintained on CR or IF diets, their blood pressure (both systolic and diastolic) and resting heart rate decrease. In addition, cardiovascular stress adaptation is enhanced as indicated by a more rapid recovery of blood pressure and heart rate following exposure to physiological stressors. CR and IF diets result in an increase in heart rate variability, suggesting a relative increase in parasympathetic (acetylcholine-mediated) regulation of the heart. The latter changes, as well as increased insulin sensitivity, occur despite hyperactivation of the HPA axis. The hyperactivation of the HPA axis in response to energy restriction is of considerable interest because other types of stress that activate the HPA, including chronic uncontrollable psychosocial stress, are detrimental. Apparently, there are pivotal differences in how cells and organ systems respond to different types of stress; they respond adaptively to energy restriction and exercise, but maladaptively to excessive energy intake and unrelieved stress.

Cellular and Molecular Mechanisms: Hormesis and Insulin Signaling

The available data support two general mechanisms by which energy restriction extends life span in many organisms and increases disease resistance. One potential mechanism involves a decrease in oxidative stress as the result of lower amounts of glucose availability to cells and, accordingly, decreased production of mitochondrial reactive oxygen species (ROS). Accordingly, overeating enhances cellular ROS production, which can damage proteins and lipids in neurons, resulting in impaired synaptic plasticity and even cell death. ROS that are increased in response to energy intake include superoxide anion radical, hydrogen peroxide, hydroxyl radical, and nitric oxide. Such ROS damage cell membranes, DNA, and proteins, which can lead to cell dysfunction and death. There is considerable evidence that ROS contribute to the demise of neurons in essentially all neurodegenerative conditions including stroke, AD, PD, HD, and ALS. Prolonged energy restriction that occurs during IF may also protect neurons by shifting energy substrates from glucose to ketone bodies such as β-hydroxybutyrate, resulting in less ROS production.

A second mechanism by which energy restriction could be neuroprotective is by hormesis, a process in which cells subjected to a mild stress become resistant to more severe stress (Figure 1). Studies of rats and mice maintained on energy restriction diets have documented increases in levels of several stress resistance proteins, including heat-shock proteins and other protein chaperones, mitochondrial uncoupling proteins, plasma membrane redox enzymes, and sirtuins (histone deacetylases believed to play important roles in energy metabolism and aging). Interestingly, manipulations of dietary energy intake and exercise can also affect the production of several neurotrophic factors in certain brain regions such as brain-derived neurotrophic factor (BDNF) and glial cell line-derived neurotrophic factor (GDNF), which may contribute to the effects of changes in energy intake and expenditure on neuronal plasticity and vulnerability to disease. Although moderate energy restriction may protect neurons against injury and disease through decreased ROS and activation of hormesis mechanisms, the effects of severe energy restriction on these pathways are currently poorly understood.

Some of the effects of dietary energy restriction and overeating on peripheral organ systems may be mediated by neurotransmitter and neurotrophic factor signaling in the brain. Energy restriction has been reported to affect the levels of several neurotransmitters in the brains of rodents, including dopamine, norepinephrine, serotonin, and glutamate. Type 2 diabetes is associated with reductions in levels of serotonin and norepinephrine in different brain regions, and patients with clinical depression are prone to diabetes, further supporting relationships between neurotransmitter signaling in the brain and peripheral energy metabolism. Other studies have documented effects of pharmacological manipulations of such neurotransmitter signaling pathways on peripheral glucose metabolism. Energy restriction enhances insulin sensitivity peripherally, and findings from studies of BDNF-deficient mice and mice in which BDNF is infused into the brain suggest a role for BDNF signaling in the antidiabetic effects of energy restriction. Although the specific neural circuits and signaling pathways by which the nervous system mediates effects of energy intake on other organ systems remain to be established, both dietary energy restriction and excess affect blood pressure and heart rate variability by mechanisms which involve changes in the autonomic nervous system.

Finally, in light of the important roles of insulin and insulin-like growth factor (IGF) signaling pathways in the regulation of aging, the involvement of these factors in the effects of energy intake on neural plasticity is likely. Studies of the nematode *Caenorhabditis elegans* and the fly *Drosophila melanogaster* have clearly established a major role for insulin signaling in aging and life span determination. In *C. elegans,* activation of the insulin receptor homolog Daf-2 stimulates a PI_3 kinase (Age-1) which phosphorylates and activates Akt kinase; Akt phosphorylates and inhibits the forkhead transcription factor Daf16. Mutations in the insulin signaling pathway extend life span in worms, in part by derepressing daf-16, resulting in the expression of 'longevity genes' including those involved in cellular stress resistance. In mammals, insulin and IGF-1 activate receptors coupled to PI_3 kinase and Akt (Figure 2). Mammalian homologs of Daf-16 that are targets of Akt comprise the FOXO transcription factor family. FOXOs are sensitive to metabolic and oxidative stress and control the expression of genes involved in glucose metabolism, antioxidant defenses, and DNA repair. Insulin and IGF-1 have been shown to protect neurons against oxidative and metabolic insults and may also play important roles in neurogenesis and synaptic plasticity.

Dietary energy restriction increases the sensitivity of muscle and liver cells to insulin, resulting in improved glucose tolerance and resistance to diabetes and cardiovascular disease, two major causes of death in humans. Circulating levels of both insulin and IGF-1 decrease in response to energy restriction; however, levels of IGF-1 in the brain may increase. IGF-1 has been shown to act directly on neurons

Figure 2 Insulin, IGF-1, and BDNF each activate receptors (IR, IGFR, and TrkB, respectively) coupled to the PI3 kinase–Akt pathway. Akt phosphorylates and inhibits FOXO transcription factors such as FOXO3. FOXO3 activity may be modified by oxidative and metabolic stress and by the histone deacetylase SIRT1. Akt and cellular stress also activate the transcription factor Nrf2 by causing the dissociation of Keap from Nrf2. Nrf2 translocates to the nucleus and binds to the antioxidant response element (ARE) in genes that encode cytoprotective proteins such as antioxidant enzymes (AOE) and phase 2 proteins. Calcium influx through ionotropic glutamate receptors or voltage-dependent Ca^{2+} channels activates the transcription factor CREB (cyclic AMP response element binding protein) which binds the CBP (CREB binding protein) to regulate transcription of genes encoding proteins involved in neuronal plasticity and survival, including brain-derived neurotrophic factor (BDNF) and Bcl-2.

and neural stem cells to promote plasticity and resistance to degeneration, emphasizing the importance of insulin-like signaling in brain plasticity and disease susceptibility.

Although not fully understood, there is evidence that the activities of FOXOs and sirtuins are modified by insulin/IGF-1 and in response to energy restriction, and these changes may contribute to the life span-extending and neuroprotective effects of energy restriction.

Implications for Improving Brain Health Span

As with other major organ systems, the brain is adversely affected by excessive dietary energy intake and so benefits from spartan diets. Studies of the effects of CR and regular exercise on life span in rodents suggest that energy restriction has a major impact on longevity (both the mean and maximum life span can be increased 30–40%), whereas lifelong exercise regimens are less effective (5–10% increase in mean life span). Cutting back on energy intake is therefore likely to extend the disease-free period of life for most individuals. For the many who are unable to curtail their food intake, other approaches are being developed to either promote a reduction in food intake or modulate the cellular and molecular pathways that mediate beneficial effects of energy restriction on the nervous system. To treat obesity, agents that suppress appetite are being developed, including those acting on melanocortin and cannabinoid signaling pathways; such agents would be expected to promote healthy brain aging. Attempts to develop dietary supplements that mimic the effects of CR are in progress, but their effectiveness to date has been limited by unanticipated adverse effects on some organ systems. Finally, it may be possible to activate neuronal stress resistance pathways; examples would include agents that stimulate neurotrophic factor signaling, induce protein chaperone expression, and/or enhance antioxidant systems.

Nystagmus

M J Shelhamer, The Johns Hopkins University School of Medicine, Baltimore, MD, USA

© 2009 Elsevier Ltd. All rights reserved.

Vestibular Nystagmus

An oscillatory pattern of eye movements characterized by alternating fast and slow phases. Nystagmus can be either the normal compensatory response to head/world motion, or a pathologic response to peripheral vestibular or central neural injury.

Example

When an animal rotates about a vertical axis, an eye movement is generated that attempts to keep the eyes stable in space. If the motion is prolonged for more than a few seconds and then abruptly halted, the same eye movement is generated in the opposite direction in an attempt to compensate for illusory motion in the opposite direction. This reflexive compensatory eye movement is known as nystagmus, vestibular nystagmus in this case since it is generated by the vestibular system and is manifest as the vestibulo-ocular reflex (VOR). The associated perception of spinning is known as vertigo.

Definition

The word nystagmus is derived from 'nustagmos,' Greek for 'drowsiness,' which refers to the nodding motion made by the head of a sleepy individual: slow leaning forward punctuated by rapid adjustments to the upright. Nystagmus was recognized hundreds of years ago, while systematic studies began in the late 1790s and early 1800s by Wells, Mach, Purkinje, and Crum Brown. Early controversy as to whether or not the eyes moved during the vertigo associated with body rotation was resolved in part by observing a retinal after-image during the nystagmus generated after self-rotation; its apparent motion against a stationary background demonstrated that the eyes indeed move and in this case generate postrotatory vestibular nystagmus.

Description

The most prominent feature of nystagmus is the characteristic alternating fast and slow phases (Figure 1). (An exception is pendular nystagmus, where the waveform is more sinusoidal.) The slow phases are intended to stabilize vision by matching the velocity of the visual field relative to the head, thereby keeping retinal image motion (retinal slip) at a low level in order to enhance visual acuity. The fast phases reset the eyes to select and begin tracking a new point. Nystagmus is most often labeled in terms of the direction of the fast phases, since they are so easily seen upon visual examination of a person's eyes; hence 'right-beating nystagmus' has slow phases to the left, and would be compensatory for rightward head movements. During sustained nystagmus, the eyes are on average deviated in the fast-phase direction; this is the so-called beating field.

This description alludes to the function of nystagmus as helping to maintain visual acuity during head motion. A separate but closely related eye movement pattern is optokinetic nystagmus (OKN), which is evoked by the homogeneous motion of a wide-field visual stimulus about a stationary subject.

Although nystagmus is almost always involuntary (reflexive), some normal subjects can produce a form of voluntary nystagmus (saccadic oscillations) at will.

Main Characteristics

Nystagmus can usually be suppressed by fixating on a visual target. High-performance aircraft pilots must suppress the nystagmus that would result from rapid maneuvers in order to maintain gaze on cockpit instruments. Repeated exposures to head/body rotation will habituate the response, so that it decreases in intensity. This is one way in which ice skaters can perform fast multiple spins without adverse effects. During slower turns by dancers, for example, spotting is a helpful strategy to avoid nystagmus and vertigo: the head and eyes maintain gaze on a fixed position while the body turns, then the head and eyes make a rapid movement in the direction of body rotation in order to fixate a new position. This eliminates the prolonged vestibular stimulation (head rotation) which would lead to perrotatory nystagmus.

The apparent motion of the visual world during nystagmus slow phases (the perception of the world spinning) indicates that there is no efference copy (internal monitoring) of the slow phases. It is such an efference copy that allows, for example, smooth pursuit eye movements to be made without the perception that the world is moving in the opposite direction.

Nystagmus fast phases have the same kinematic properties as saccades, and are generated by the same neural structures. The slow phases of vestibular nystagmus are a manifestation of the VOR, in which head rotation transduced by the semicircular canals of the vestibular system drives the eyes in the opposite direction so as to stabilize gaze on a fixed point in space.

Figure 1 Example of optokinetic nystagmus (OKN), stimulated with a wide-field visual stimulus moving at 60° s^{-1}.

Figure 2 Examples of vestibular nystagmus. Eye position (top) and velocity (bottom) waveforms are shown. Fast phases appear as large-amplitude spikes in the velocity signal; plot scale has been set to show characteristic exponential decay of the slow-phase velocity. Perrotatory nystagmus begins at start of head rotation, near beginning of each graph. Postrotatory nystagmus begins when rotation stops, near center of each graph. Note initial rise in slow-phase velocity, followed by exponential decay, in each case. Courtesy of Mark Walker.

Vestibular nystagmus is often induced in the lab and clinic by prolonged rotation at a constant velocity, followed by a rapid halt; this results in perrotatory nystagmus and postrotatory nystagmus. In each case, the nystagmus slow-phase velocity starts at a value approximately equal to that of the rotational stimulus (a gain near 1.0). The velocity of successive slow phases decreases approximately as a decaying exponential, characterized by a dominant time constant. The time constant (highly variable but typically about 10–15 s) is much longer than the mechanical time constant of the semicircular canals; the central perseveration of activity is known as velocity storage (see Figure 2).

OKN (Figure 1) has an almost immediate rise to a near-constant velocity slow phase. It can be generated by moving a large OKN drum with a patterned visual field around the stationary subject. OKN is also generated more naturally during prolonged head turns (more than a second or so): when the VOR slow phases begin to decay in velocity they are augmented by an optokinetic response. Thus, there is a strong synergy between vestibular and optokinetic responses and the associated forms of nystagmus.

Although horizontal nystagmus is most often studied, at least in the laboratory, the appropriate natural stimuli, and some pathological conditions, can produce nystagmus with vertical or torsional

components. Rotation of the head toward one shoulder, for example, will produce torsional nystagmus.

Neural Basis

As is true for a great many types of eye movements, the neural pathways for nystagmus include two neural pools that implement the mathematical operation of integration with respect to time. The first of these is the velocity-storage integrator, which as noted above acts to perseverate vestibular activity from the semicircular canals. The other integrator converts neural eye-velocity commands to eye-position commands, both of which are needed to drive the extraocular muscles correctly. In particular, this second integrator confers the ability to maintain eccentric gaze. Deficits in the velocity-storage integrator affect the long time constant of the VOR. Deficits in the velocity-position integrator can lead to changes in the shape of the nystagmus slow phase. Normally the slow phase is straight (constant velocity), in accord with its role in stabilization of the line of sight during a prolonged head movement. If the integrator is abnormally leaky, it cannot maintain its output level, and each slow phase will decrease in velocity, leading to a scalloped shape. If the integrator is unstable, its output increases out of proportion to the input, and each slow phase will exhibit an exponential increase in velocity.

Vestibular Pathology

Nystagmus can be a reliable indicator of vestibular pathology. This discussion will be presented in terms of horizontal nystagmus, although similar reasoning applies to vertical and torsional movements, with some modifications.

If an acute peripheral lesion upsets the normal balance of tonic activity from the two sets of vestibular apparatus on either side of midline, the resulting imbalance is interpreted centrally as a prolonged rotation away from the lesioned side. This results in a strong and persistent spontaneous nystagmus, with fast phases directed away from the affected canal. Subsequent reduction in spontaneous nystagmus is one indicator of central compensation for this pathology.

The three semicircular canals are approximately aligned with the movement directions of the extraocular muscles. Thus, nystagmus that follows a specific canal plane often results from a peripheral lesion of that canal, while nystagmus in other directions is of central origin. Pure vertical or torsional nystagmus, for example, will not be of peripheral vestibular origin, but rather has a central cause. A peripheral cause also leaves fixation suppression largely intact, since central fixation mechanisms are spared. Cross-coupling (e.g., vertical nystagmus after horizontal head motions) also indicates a central cause.

Types of Nystagmus

Many specific types of nystagmus have been identified. Some are named for the particular eye motion that is involved, while others draw on the mode of stimulation for their naming.

Various types of physiologic nystagmus can be considered as the normal response to actual or perceived motion. These include perrotatory and postrotatory vestibular nystagmus, which manifest the VOR. Caloric nystagmus is generated by warm or cold stimulation of the horizontal semicircular canal, through water or air introduced into the external auditory meatus. Ideally the head is tilted back to place the horizontal canals in a vertical orientation. The resulting temperature gradient induces convection currents in the canal endolymph, mimicking a head turn. (There is also a small direct thermal effect on the nerve.)

Since nystagmus very often expresses an intent to compensate for real or illusory head motion, stimuli that mimic the sensory or motor circumstances that occur during actual head or body motion can also produce a ‘compensatory’ nystagmus. Such stimuli include movement of the outstretched arm with the hand following a surrounding drum that rotates in darkness (arthrokinetic nystagmus), and the proprioceptive input that results from apparent walking in a tight circle while actually stationary with the floor moving. Rotating sound fields can also induce nystagmus in a similar fashion.

Many specific types of pathologic nystagmus have been cataloged; in some cases the underlying neurophysiology is known and so these eye movements can serve as useful diagnostic tools. Many types of pathologic nystagmus are acquired through trauma or disease, but there also exists congenital nystagmus, which is often associated with visual deficits during development. Congenital nystagmus is most often characterized by a foveation period in each cycle, when the eyes are still or nearly so, allowing for, in some cases, normal visual acuity.

Periodic alternating nystagmus (PAN) is a spontaneous horizontal nystagmus that reverses direction approximately every two minutes; it is due to cerebellar deficit that renders the time constant of velocity storage unusually long and creates interactions with mechanisms that attempt to readjust the time constant.

Acute alcohol intoxication can change the density of the vestibular endolymph relative to that of the

cupula, and so render the semicircular canals sensitive to gravity, resulting in positional alcoholic nystagmus. Heavy water has the same effect in the opposite direction. Benign paroxysmal positional vertigo (BPPV), where debris in the canal renders it sensitive to gravity, is another cause of positional nystagmus.

Loud sounds can induce nystagmus through pathologic stimulation of the peripheral vestibular system (Tullio phenomenon, semicircular canal dehiscence syndrome).

Otolithic stimulation through linear acceleration (including changing orientation with respect to gravity) can also produce a form of vestibular nystagmus, a manifestation of the translational VOR (TVOR). Since TVOR slow-phase velocity depends strongly on viewing distance, such otolith-dependent nystagmus typically becomes stronger upon convergence. Normal subjects sometimes exhibit vertical nystagmus, probably of otolithic origin, when supine in darkness.

Gaze-evoked nystagmus occurs when a person attempts to hold the eyes in an eccentric position, such as far to the right. Here, the velocity-position integrator is leaky and does not generate a steady position signal to hold the eyes in the desired position. The eyes then drift back toward center, under the influence of elastic forces in the orbit, until corrected by a saccade back to the desired eccentric position. After extended eccentric gaze holding, a rebound nystagmus may be present upon straight-ahead gaze. Less intense forms of gaze-evoked and rebound nystagmus are not unusual in normal subjects.

Dynamics and Models of Nystagmus

It is apparent that in nystagmus, the slow phases do not take the eyes as far as they can go in one direction before being interrupted by a fast phase, and the fast phases do not occur at a regular rate. The rules – whether deterministic or random – that determine these properties are not completely understood.

One model for vestibular nystagmus is based on a 'center of interest,' a point to which the fast phases take the eyes in anticipation of seeing something interesting on which to then maintain gaze. Fast phases are generated when an internal neural copy of eye position, minus the center of interest, reaches a (variable) threshold. Another suggestion is that fast phases extend the linear range of the VOR, by triggering a fast phase when the eyes move far enough that neural responses on either side of the midline start to approach inhibitory cut-off.

Given a set of consecutive values, it is possible to predict, to a limited extent, the future values of fast-phase beginning and ending positions. However, randomized versions of these sequences, which retain linear autocorrelations, are as predictable. This indicates that each of these sequences is a temporally correlated random process (a random walk). On the other hand, fast-phase intervals are essentially unpredictable, as is characteristic of an uncorrelated random process. Although this has been demonstrated strictly for OKN, the interpretation in terms of a visual 'center of interest' as in vestibular nystagmus is evident.

Introduction

Obsessive–compulsive disorder (OCD) is a complex and heterogeneous psychiatric disorder characterized by obsessions and compulsions (also known as 'rituals'). Obsessions are unwanted ideas, images, or impulses which repeatedly enter an individual's mind. Although recognized to be self-generated, they are experienced as 'egodystonic' (out of character and distressing). Compulsions are repetitive behaviors or mental acts which are often intended to neutralize anxiety provoked by the obsessions (Figure 1). These rituals are often driven by rules that must be applied rigidly. In order to qualify for the diagnosis, the symptoms must be disabling.

Although the core features of obsessions and compulsions appear to be remarkably consistent throughout the life span, in both sexes and in different cultures and races, the detailed content of these symptoms is varied. Two patients with OCD may present with completely nonoverlapping symptom profiles. However, more commonly, patients experience multiple types of obsessions and compulsions. The most common types of obsessions and compulsions are listed in Table 1. These symptoms tend to group in predictable ways. Indeed, multiple factor and cluster-analytical studies have identified at least four relatively independent and temporally stable symptom dimensions: (1) contamination obsessions and washing/cleaning compulsions; (2) aggressive, sexual and religious obsessions and related compulsions (often checking); (3) obsessions concerning a need for symmetry or exactness, ordering/arranging, repeating, and counting compulsions; and (4) hoarding and collecting obsessions and compulsions (Figure 2).

Aggressive and sexual obsessions in OCD must be differentiated from violent thoughts occurring in other disorders, such as urges to hurt people in psychopathy or to abuse children in pedophilia. People with OCD fear that they might commit an offense but do not carry out the feared act, and spend an excessive amount of time and energy resisting and controlling their behavior to avoid the risk of harm.

OCD often occurs together with other complicating conditions, such as depression. Screening for and treating these comorbidities is an important part of the management of the disorder (see Table 2). A majority of people with OCD of all ages understand the senseless nature of their repetitive, unwanted behaviors and intrusive, recurrent thoughts. This may lead to shame, reluctance to seek help, and poor recognition by health professionals. People with OCD have long delays in accessing effective treatments. A recent study found that the mean duration from onset of symptoms to receiving treatment was 14 years, although younger patients had access to treatment sooner.

Individuals with OCD frequently present to nonpsychiatrists for treatment (Table 3) and their symptoms often go undetected. There is a need for greater awareness of OCD in a range of nonpsychiatric health care settings, and clinicians need to be confident about recognizing it. OCD can occur throughout the life span, with children as young as 6 or 7 years of age presenting with the characteristic impairing symptoms. At the other end of the age range, cases may present for the first time in old age. A majority of adults report the onset in childhood or adolescence. OCD can result in significant disability, and the World Health Organization rates it as one of the top 20 most disabling diseases. If untreated, OCD generally persists, yet there are effective, evidence-based psychological and pharmacological treatments.

Recent epidemiological studies report prevalence rates of 0.8% in adults and in 0.25% of 5- to 15-year-old children, although earlier studies have suggested rates as high as 1–3% in adults and 1–2% in children and adolescents. The causes of OCD are unknown but, like in most complex psychiatric disorders, are likely to stem from a combination of genetic, neurobiological, cognitive-behavioral, and environmental factors.

Genetics of OCD

The influence of genetic factors in OCD has been suggested since the earliest descriptions of the disorder, and a number of study designs have been employed to determine to what extent OCD is heritable. First, family studies have convincingly shown that OCD runs in families – that is, first-degree relatives of OCD patients have an elevated risk of having OCD or subclinical obsessive–compulsive symptoms. These studies, however, do not allow disentangling whether this familiarity is due to genetic or environmental factors. For this purpose adoption or twin

Figure 1 The obsessive–compulsive disorder cycle. Obsessions are intrusive thoughts (ideas, images, or impulses) which repeatedly enter an individual's mind against his/her will. These generate significant levels of anxiety and are difficult to dismiss. Compulsions, or rituals, are repetitive acts that are performed in an attempt to reduce the anxiety caused by the obsessions, but the relief is only temporary. Later in the course of obsessive–compulsive disorder, rituals can become more automatic and can increase, rather than reduce, the anxiety. Adapted from Heyman I, Mataix-Cols D, and Fineberg NA (2006) Obsessive–compulsive disorder. *British Medical Journal* 333: 424–429.

studies are needed. Adoption studies are generally rare, and to our knowledge no such studies have been published concerning OCD. Twin studies, which compare the concordance of OCD in monozygotic versus dizygotic twins, have been conducted using either a categorical approach (presence or absence of OCD), or a dimensional approach (using the whole distribution of OC symptoms in a population). Published twin studies using a categorical approach usually suffer from several methodological problems. However, more statistically sound twin studies with a dimensional approach have clearly demonstrated the importance of genetic factors for OC symptoms, with heritabilities ranging from 45% to 65% in children and 27% to 47% in adults.

Genetic linkage analysis provides a powerful approach to elucidate the underlying genetic factors in inherited disorders. Linkage studies are designed to determine whether a behavioral phenotype, such as psychiatric disorder or a dimensional trait, is physically linked to a genetic marker, a segment of DNA with a known physical location on a chromosome. Linkage studies on OCD are rare and have been performed in relatively small clinical samples. Two independent genome scans identified a region of chromosome 9p24 that had a suggestive linkage to early-onset OCD. Recently, a large affected sib-pair sample from 219 families from the OCD Collaborative Genetics Study showed suggestive evidence for linkage in several regions, including 1q, 3q, 6q, 7p, and 15q. The same group also found significant linkage to compulsive hoarding on chromosome 14. These findings strengthen the notion that OCD is a complex and heterogeneous disorder.

Association studies offer an alternative strategy for studying genetic factors, and the aim is to demonstrate

Figure 2 Schematic representation of the major symptom dimensions of obsessive–compulsive disorder. Most studies consistently identify four symptom dimensions (continuous lines); some others identify a fifth dimension consisting of sexual and religious obsessions (dashed line), but more research is needed to determine the validity of this dimension. Note the overlap between the dimensions: monosymptomatic patients are very rare.

a significantly different distribution of candidate gene variants in affected (OCD) and unaffected (non-OCD) individuals. A large number of genetic association studies on OCD have been conducted in various populations, mainly investigating the possible contribution of genes to both the serotonergic system and the dopaminergic system. Unfortunately, the results of most association studies in OCD are inconsistent and inconclusive, possibly due to a number of reasons, including small sample sizes, the use of mixed populations, failure to account for multiple testing, and the clinical heterogeneity of OCD. Recently, more statistically sound association studies have been conducted focusing on glutamatergic transmission.

Table 2 Conditions commonly occurring with OCD

Condition	*Frequency (%)*
Depression	50–60
Specific phobia	22
Social phobia	18
Eating disorder	17
Alcohol dependence	14
Panic disorder	12
Tourette's disorder	7
Schizophrenia	14

Two independent studies found an association of glutamate transporter gene *SLC1A1*, particularly in males. The encoding region for *SLC1A1* lies on chromosome 9p24, a region where suggestive linkage was reported earlier. A meta-analysis of all published case-control data on catechol-*O*-methyltranferase (COMT) found evidence of an association between the Met158 allele of COMT and OCD. The association was present in men but not in women. COMT has a role in cortical dopamine signaling and information processing. Another study reported an association between oligodendrocyte lineage transcription factor 2 (OLIG2) and OCD, especially when Tourette's disorder was absent. OLIG2 has an essential regulation role in the development of cells that produce white matter (myelin). The *OLIG2* gene is also highly expressed in the brain regions implicated in OCD.

In sum, it is clear from family and twin studies that genetic factors play a role in the etiology of OCD. As statistically sound linkage and association studies have just started to be published, it is too early to predict which specific genes are clearly implicated in OCD etiology. Furthermore, it seems essential for genetic research on OCD to take into account the heterogeneity of the disorder. For example, the use of OCD dimensions as quantitative phenotypes could be a promising approach for future genetic studies.

Functional Neuroanatomy of OCD

Current neurobiological theories of OCD suggest that specific frontal–subcortical circuits are involved in the symptoms and cognitive deficits associated with the disorder. These theories arose from various sources of evidence: the presence of OCD symptoms in some neurological conditions (Tourette's syndrome, Huntington's disease, Sydenham's chorea, and other basal ganglia disorders), the emergence of OCD-like behaviors in patients with focal brain injury, and the fact that surgical interventions that interrupt these frontal–subcortical circuits improve both mood and OCD symptoms. However, the strongest support for these models derives from the advent of modern neuroimaging techniques, which have provided a direct window into the OCD brain *in vivo*. Currently, the most widely accepted neuroanatomical model of OCD proposes the involvement of a direct and an indirect cortico–striato–thalamic pathway. In the direct pathway, an excitatory glutamatergic signal projects to the striatum, sending an inhibitory γ-aminobutyric acid (GABA)ergic signal to the internal part of the globus pallidus. This results in a decreased inhibition (disinhibition) of the thalamus and thus an increased excitatory effect on the prefrontal cortex (Figure 3). In the indirect pathway, the striatum projects an inhibitory signal to the external part of the globus pallidus and the subthalamic nucleus, sending an excitatory signal to the internal part of the globus pallidus. The net effect is an increased inhibition of the thalamus and decreased excitation on the prefrontal cortex. It is hypothesized that the direct pathway functions as a self-reinforcing positive feedback loop and contributes to the initiation and continuation of behaviors, whereas the indirect pathway provides a mechanism of negative feedback which is important in the inhibition of behaviors and in switching between behaviors. Thus, an imbalance between these frontal–striatal circuits might mediate the symptoms of OCD: an excess tone in the direct, relative to the indirect, frontal–striatal circuit is hypothesized to result in enhanced activation of the orbitofrontal cortex, ventral striatum, and medial dorsal thalamus. Based on the positive therapeutic effects of selective serotonergic reuptake inhibitors on OCD symptomatology and the inhibitory effect of serotonin on dopamine, it is suggested that failure

Figure 3 A widely accepted frontal–striatal model of obsessive–compulsive disorder. PFC, prefrontal cortex; NC d, dorsal part of caudate nucleus; NC v, ventral part of caudate nucleus; GP ext, external part of globus pallidus; GP int, internal part of globus pallidus; NST, subthalamic nucleus; D_1, dopamine type 1; D_2, dopamine type 2; broken lines indicate inhibitory γ-aminobutyric acid (GABA)ergic projections; solid lines indicate excitatory glutamatergic projections. From Mataix-Cols D and van den Heuvel O (2006) Common and distinct neural correlates of obsessive–compulsive and related disorders. *Psychiatric Clinics of North America* 29(2): 391–410, with permission.

of the serotonergic system results in decreased compensation of the dopaminergic influence on the frontal–striatal circuits. Dopamine (D) has a dual role on the balance between the direct and indirect frontal–striatal pathways. In the human brain, D_1 receptor expression is prominent in the ventromedial (relative to dorsolateral) prefrontal cortex and ventral (relative to dorsal) striatum. Functionally, this dopaminergic differentiation implies a stronger D_1 influence on the direct pathway of the ventromedial frontal–striatal circuit and a stronger D_2 influence on the *indirect* pathway of the *dorsolateral* frontal–striatal circuit, resulting in a hyperactivated ventral and an inhibited dorsal frontal–striatal system (see Figures 3 and 4). This corresponds with the results of functional neuroimaging studies in OCD, showing increased activation of limbic and ventral frontal–striatal regions at rest and in response to disease-relevant information and decreased responsiveness of dorsal frontal–striatal regions during executive performance.

Appealing as it may be, this model is likely to be overly simplistic, as it is based on several assumptions about the OCD brain and OCD:

- These brain structures mediate all types of OCD symptoms (i.e., OCD is a unitary nosological entity):

Psychiatric classification systems – *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) and *International Classification of Diseases* (ICD-10) – view OCD as a unitary nosological entity, but researchers are currently disputing this view. OCD may be a compendium of multiple potentially overlapping syndromes rather than a unitary entity. Each of the major symptom dimensions of OCD (i.e., contamination/washing, harm/checking, symmetry/order, and hoarding) is associated with specific patterns of comorbidity, genetic transmission, neuropsychological function, and treatment response. Several preliminary neuroimaging studies from different laboratories strongly suggest that discrete neural systems may mediate the expression of different symptom dimensions in OCD. Therefore, any revised neurobiological model of OCD will need to take into account this heterogeneity.

- These circuits represent the unique neural signature of OCD, i.e., they are not implicated in other disorders:

The picture is further complicated by the fact that OCD (currently classified as an anxiety disorder) often co-occurs with other anxiety disorders and depression. OCD has also been associated with other nonanxiety disorders that share phenomenological features, family aggregation, and (some of them) treatment response with OCD, the so-called OCD spectrum disorders. This elevated comorbidity is also reflected in a substantial degree of overlap in their neural substrates.

- There are qualitative differences between the OCD and the healthy brain:

Another assumption that remains untested is that there are qualitative differences between the OCD and healthy brains. However, the few symptom provocation studies that included healthy control groups

Figure 4 Schematic representation of interconnected brain regions which are part of the ventral prefrontal–striatal circuit (left) and the dorsal prefrontal–striatal circuit (right). The images are sagittal brain slices of a T_1-weighted magnetic resonance image scan, arranged from a medial view (leftmost image) to a lateral view (rightmost image). OFC, orbitofrontal cortex; ACC, anterior cingulate cortex; DLPFC, dorsolateral prefrontal cortex; GP, globus pallidus; A, orbitofrontal cortex; B, nucleus accumbens (ventral striatum); C, thalamus (medial part of mediodorsal nucleus); D, dorsolateral prefrontal cortex; E, nucleus caudatus (dorsal striatum); F, thalamus (lateral part of mediodorsal nucleus).

seem to suggest that the differences could be more quantitative than qualitative. Indeed, these studies revealed similar patterns of brain activation in both groups, although the degree of activation was, for the most part, significantly higher in the patient group. Clearly more research on this topic is needed but, if confirmed, the neuroimaging findings could reflect exaggerations of normal emotional responses to biologically relevant stimuli, rather than fundamentally abnormal neuronal responses. Furthermore, several studies have shown that the brain abnormalities seen in OCD tend to normalize after successful treatment, suggesting that these may be state dependent.

- Dysfunction in these brain regions causes OCD:

Finally, it must be emphasized that differences in brain function between patients and controls do not necessarily indicate that dysfunction in these regions causes OCD. Neuroimaging tools should be regarded as correlational techniques that allow researchers to understand the neurophysiological bases of the behaviors under study, but not necessarily their cause. At least three possible interpretations of the neuroimaging data are possible: (1) dysfunction in certain brain regions causes OCD, (2) dysfunction in certain brain regions is a consequence of OCD, and (3) another spurious variable causes both phenomena.

Immunology of OCD

In the past decade there is been renewed interest in the relationship between infections, psychiatric symptoms, and movement disorders. In particular, it was noted that some children develop OCD and/or tics in the weeks after *Streptococcus* infection. These children were categorized as suffering from pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS) and have been carefully investigated in a range of research studies. The most widely accepted mechanistic explanation is that antibodies, generated as part of the immune response to the streptococcal infection, cross the blood-brain barrier and interact with neuronal antigens, resulting in neurological and psychiatric symptoms. This remains a controversial area of

research, with many questions yet to be answered, such as the specificity of the psychiatric symptoms in relation to streptococcal infection, the characterization of the autoantibodies and their binding sites in human brain, and the degree of relevance to clinical practice.

Evidence for the proposed neuroimmunological mechanism includes the finding of identical antibasal ganglia antibodies in Sydenham's chorea, an autoimmune poststreptococcal illness which is characterized by a subcortical movement disorder, but also frequently incorporates psychiatric features, including obsessive–compulsive symptoms. Immunomodulatory treatments used in Sydenham's chorea have led to a trial of immunological therapy for children with PANDAS. Although this has only been attempted in a single clinical trial, one study of therapeutic plasma exchange and intravenous immunglobulin demonstrated improvement in both tic and OCD symptoms in these children. This suggested a direct pathogenic relationship between the circulating autoantibodies and the central nervous system symptoms.

There have been further attempts to characterize the autoantibodies, and it has been shown in a range of poststreptococcal illness that these antibodies recognize basal ganglia proteins of specific molecular weights. The autoantigens have been identified in some studies to be glycolytic enzymes, which also act as neuronal cell surface receptors. Other studies have proposed a mammalian lysoganglioside GM1 to be the human epitope. More research is needed to further establish the molecular mechanisms of this proposed autoimmune risk for OCD; however, all of the implicated brain binding proteins have protein homologs in streptococci, thus making them potential 'molecular mimics.'

It is unknown what proportion of childhood OCD or tics might be PANDAS; one study reported that 11% of children with tic disorders experienced worsening of tics in the 6 months following streptococcal infection. Another study has shown that patients with Tourette's syndrome or OCD were more likely than control children to have had a streptococcal infection in the 3 months before onset. The children with PANDAS had a somewhat atypical course to their OCD, with an 'on–off' trajectory to their symptoms, relapse being associated with presumed reinfection with streptococcus. Consideration has been given to whether more usually presenting OCD in children might be associated with earlier streptococcal infection. One study showed that in 50 consecutive child or adolescent patients seen in an OCD clinic, 42% had circulating antibodies to streptococcal antigens (antistreptolysin O; ASO), in contrast to 20% of healthy school children. Furthermore, 48% of these children had antibasal ganglia antibodies (ABGAs), which are only found at a rate of 3% in normal populations. This raises tantalizing questions about whether exposure to streptococcal infection could be one of the environmental factors that predispose a subgroup of children to OCD, and whether there is a specific subtype of OCD has an autoimmune cause.

There are many unanswered questions. For example, infections with streptococcus are common, yet relatively few people develop autoimmune complications. It has been proposed that genetic factors predispose vulnerable individuals to a risk of developing central nervous system complications mediated by autoreactive antibodies, following streptococcal infection. Recent work has revealed that obsessive–compulsive spectrum disorders are more common in patients with rheumatic fever, another autoimmune streptococcal illness, compared to the general population. The risk of developing OCD or a related disorder is also comparatively greater in first-degree relatives of those with rheumatic fever, demonstrating a familial relationship between these disorders, which may be genetic, although further work is required to establish this.

Currently, the clinical implications, in terms of assessment and treatment of this emerging relationship between streptococcus and OCD, remain unclear. If children present with sudden-onset OCD or tics, it is good practice to inquire about pharyngitis or other sites of infection, and if current infection is established, to treat with antibiotics as usual. Studies in which PANDAS patients have been treated prophylactically with antibiotics in the hope of preventing relapses of symptoms have given equivocal results. Similarly, immunomodulatory treatments remain experimental, and should be considered only in the context of research trials in specialist centers. Best clinical practice for children and young people with OCD, even if a streptococcal origin is suspected, is to offer the current evidence-based treatments (see later). It remains to be seen whether a subgroup of OCD with an immunological trigger has characteristics that differ from other forms of OCD, or differing treatment responsiveness.

Management of OCD

Multiple randomized controlled trials (RCTs) have established the efficacy of both a form of psychotherapy called cognitive behavior therapy (CBT) and certain medications; the medications, which inhibit the synaptic reuptake of serotonin, are the tricyclic antidepressant clomipramine and the more highly selective serotonin reuptake inhibitors (SSRIs). There is no evidence to support the efficacy of psychodynamic psychotherapy in OCD and its use is therefore not recommended.

In both adults and children, the specific CBT technique most strongly associated with good outcome in CBT studies is exposure and response prevention (E/RP). Briefly, the patient is encouraged to progressively face his/her feared situations (exposure), while refraining from performing his/her rituals (response prevention). Engaging the patients with OCD by helping them design a graded program of E/RP, and working collaboratively on easiest challenges first, are essential. Careful education about mechanisms of anxiety, understanding that repeated exposure leads to reduced anxiety, as well as reduction in obsessions, is important for success. Practice is needed, as patients with OCD will have been reinforcing their behaviors by avoiding feared situations or carrying out rituals to deal with their fears for some time. It is often needed to involve the patient's family members in this process, as many participate in (and thus help maintain) the patient's rituals.

Because many patients do not have access to specialist CBT clinics, and waiting lists for treatment are often long, there is currently much interest in developing effective tele-care and self-help programs for OCD. These have the potential to save much clinician time and to reach many more patients that would otherwise remain untreated. Indeed, recent RCTs have shown that E/RP can be successfully delivered by a therapist over the telephone and even by an interactive computer program with minimal therapist contact and without impairing efficacy.

All the SSRIs have been subject to large-scale clinical trials and have been found to be superior to placebo in both adults and children with OCD. Dose-finding studies have only been carried out in adults. Higher doses of SSRIs are needed to effectively treat OCD, compared with depression. SSRIs have largely superseded clomipramine for treating OCD because of their lesser toxicity in overdose and more favorable side-effect profile. This is especially important for children, for whom cardiac toxicity may be a risk. Head-to-head studies show equivalent efficacy and better tolerability for SSRIs relative to clomipramine. Clomipramine remains a useful option, but is usually reserved for cases in which trials of SSRIs have been ineffective.

There is some evidence supporting various medication strategies in resistant cases, including increasing the dose of the SSRI to the maximum tolerated, and switching to an alternative, as there may be idiosyncrasy in response. OCD does not respond to antipsychotics given as monotherapy. There is evidence from children and adults that adding low doses of first- and second-generation antipsychotics to SSRIs may benefit cases of resistant OCD and OCD with comorbid tics. Several studies have shown that people with OCD continue to benefit from long-term medication but that many patients relapse if medication is discontinued. For at least some cases, therefore, treatment may need to be continued indefinitely. This is not the case with E/RP, and therapeutic gains are usually maintained long-term, although some boosting sessions may be required.

Despite the demonstrated efficacy of both CBT and SSRIs, up to 40% of cases fail to respond adequately to these treatments. Recent studies suggest that patients with hoarding symptoms may be particularly treatment resistant, and new treatment approaches are being developed and tested for these patients. Some centers offer neurosurgery (cingulotomy or anterior capsulotomy) for severe, treatment-resistant OCD but, for obvious reasons, these treatments have not been evaluated in controlled trials and remain controversial. More recently a reversible form of neurosurgery consisting of deep-brain stimulation of the anterior capsule/ventral striatum has been developed and tested in OCD with promising results, but more large-scale controlled studies are needed.

Octopamine and Other Monoamines in Invertebrates

T D Sotnikova and R R Gainetdinov, Duke University Medical Center, Durham, NC, USA

Introduction

In both vertebrates and invertebrates, biogenic monoamines are important neuroactive molecules involved in neuronal communications. In invertebrates, octopamine and other monoamines can act physiologically as neurotransmitters, neuromodulators, or neurohormones. Biogenic monoamines such as octopamine, tyramine, dopamine, serotonin, and histamine regulate numerous vital functions, including cardiovascular control, movement, endocrine regulation, circadian rhythms, emotional behaviors, learning, and memory. Although the adrenergic transmitters norepinephrine and epinephrine are found at low concentrations in some invertebrate species, it is believed that their physiological roles in invertebrates are limited. Monoamines exert a large part of their effects by binding to specific receptors that primarily belong to the superfamily of G-protein-coupled receptors (GPCRs). Considerable progress has been achieved during the past few decades toward the understanding of the functional role of these monoamines in invertebrate physiology. Here, we summarize current knowledge on the biochemistry of monoaminergic pathways, regulatory mechanisms of monoaminergic transmission, receptors and signaling pathways involved in their actions, and physiological functions mediated by monoaminergic mediators in invertebrates.

Octopamine

Since its discovery more than 50 years ago in the salivary glands of *Octopus*, octopamine has been the subject of intense investigation. Although octopamine-containing neurons present only in a small subset of neurons (40–100 in insects) within the nervous system, the role of octapamine in invertebrate physiology cannot be underestimated. It is believed that octopamine and, to a lesser degree, tyramine play a pleiotropic role in invertebrate physiology that is mediated in vertebrates by adrenaline and noradrenaline. Octopamine is synthesized from the amino acid tyrosine in two steps. Decarboxylation of tyrosine by tyrosine decarboxylase (TDC) results in the production of tyramine (Figure 1). Two forms of this enzyme are known, one of which is expressed in nonneuronal cells (TDC1) and the other one (TDC2) is expressed in neurons. The second step involves the enzyme tyramine-β-hydroxylase (TβH), which converts tyramine to octopamine by the addition of a hydroxyl group in the β-position. Enzymatic inactivation of octopamine is believed to occur predominantly by N-acetylation or N-methylation. In contrast to vertebrates, monoamine oxidase (MAO) plays only a minor role in the inactivation of monoamines in invertebrates. Additional mechanisms of octopamine inactivation may involve sulfate and γ-glutamyl conjugation.

Several critical presynaptic processes governing monoaminergic transmission in mammals play a similar role in invertebrates. They include processes involved in packaging of monoamines into synaptic vesicles for subsequent storage and release, release-related events, and reuptake of released monoamines via plasma membrane transporters. Released monoamines elicit their transmitter functions by activating corresponding postsynaptic receptors, which in most cases belong to the GPCR family. All the functional elements necessary for these processes have been identified for octopaminergic transmission.

In *Drosophila*, newly synthesized octopamine is packaged into synaptic vesicles by the *Drosophila* homolog of the vesicular monoamine transporter (dVMAT). Two mRNA splice variants (dVMAT-A and-B) that differ at their C-terminus have been identified. dVMAT-A recognizes octopamine, tyramine, as well as other monoamines, including dopamine, serotonin, and histamine, as preferential substrates. Importantly, this transporter is similar to mammalian VMAT homologs with regard to pharmacological properties and can be potently inhibited by reserpine and some environmental toxins. Octopamine can be released in response to various stimuli in a calcium-dependent manner. After release and generation of corresponding signaling events at the postsynaptic cells via activation of receptors, octopamine undergoes rapid reuptake into presynaptic terminals by specific plasma membrane transporters. Reuptake is the major route of inactivation for octopamine but, at the same time, it provides recycled transmitter for subsequent release. Generally, invertebrate plasma membrane transporters share structural and pharmacological features with transporters found in vertebrates. In several insect species, such as the cabbage looper and cockroach, but not *Drosophila*, a specific phenolamine transporter that can transport octopamine with high affinity has been identified. Interestingly, since cocaine was found to interact with octopamine reuptake, the ability of cocaine to induce hyperactivity and leaf walk-off in the insects has

Figure 1 Synthesis of tyramine, octopamine, and dopamine in invertebrates. In the first step, tyrosine is decarboxylated by tyrosine decarboxylase to tyramine. Tyramine, in turn, is hydroxylated by enzyme tyramine β-hydroxylase to octopamine. Alternatively, as in vertebrates, tyrosine can be hydroxylated by tyrosine hydroxylase to L-DOPA. Decarboxylation of L-DOPA by DOPA decarboxylase (also known as L-aromatic amino acid decarboxylase) results in production of dopamine.

been related to octopaminergic transmission. It is believed that alkaloid of the coca plant, cocaine, has an insecticide function that prevents insects from eating the leaves via modulation of octopaminergic neurotransmission.

When octopamine is released in the synapse, it binds to corresponding GPCRs and elicits a physiological response. Octopamine receptors (OARs) share significant structural features with the corresponding adrenergic receptors. OARs have been detected in almost every peripheral organ in a large number of different insect species. Based on similarities in structure and signaling properties with vertebrate adrenergic receptors, OARs were classified as alpha-adrenergic-like octopamine receptors, beta-adrenergic-like octopamine receptors, and octopamine/tyramine or tyraminergic receptors. The most prominent subtype, alpha-adrenergic-like octopamine receptors, which is homologous to the *Drosophila* OAMB (OAR primarily expressed in the mushroom bodies), is ubiquitously expressed throughout the body and is believed to be responsible for most functions mediated by octopamine. Three splice variants of *Drosophila* OAMB have been found, and these variants may have different pharmacological properties.

Many high-affinity agonists and very few antagonists of OARs are known. They have been identified mostly in an attempt to develop insecticides that would not be effective in mammals. In fact, some OAR agonists were used as effective insecticides. Among high-affinity OAR agonists, synephrine and chlordimeform are best known. Some phenyliminoimidazolidine and aminooxazoline derivatives also display extremely high activity at OARs with K_D values in the subnanomolar range. Octopaminergic agonists that induce insecticide action typically at low doses induce hyperactivity, which is followed by the leaf walk-off syndrome, with tremor and lethality at higher concentrations. OAR antagonists do not exert insecticide actions and, in fact, very few of these compounds can inhibit octopamine action in various physiological preparations. Some OAR antagonists, such as phentolamine and mianserin, also show potent antagonistic activity at other monoaminergic receptors in invertebrates and vertebrates. Only one antagonist, epinastine, is considered to be relatively selective and is used as a tool for the dissection of the role of octopaminergic neurotransmission *in vivo* in invertebrates. Second-messenger coupling of OARs is believed to be primarily mediated by the activation of cAMP synthesis and the elevation of Ca^{2+} concentrations via involvement of G_s and G_q.

Octopamine plays a major role in essentially every organ and every function of invertebrates. Historically, the investigation of the functional roles of octopamine began with the demonstration of its action on
