peripheral functions, such as muscle tension and relaxation rate. It should be noted, however, that the modulatory effects of octopamine in peripheral tissues are generally quite minor. Octopamine enhances muscle performance of the locust flight muscle, which is critical for fight-or-flight response. Stress-related enhancement of motor activity requires the change of primary energy source between rest and the onset of fight or long-term flight. Elevated octopamine levels in the hemolymph during stress induce the release of adipokinetic hormone from the corpora cardiaca. At the same time, octopamine has a direct effect on body fat, leading to the release of fatty acids into the hemolymph, that enhances the adipokinetic effect of the adipokinetic hormone. This complex adaptation to high-energy demands also involves the concomitant modulation of other organs, especially those required for transportation of metabolites and oxygen, namely the heart and the trachea/air sacs, which are in part modulated by octopamine. As a result, octopamine is involved in modulation of multiple organs to orchestrate the fight-or-flight response in times of high-energy demands.

One of the best characterized peripheral targets of octopamine action is the firefly light organ, in which octopamine functions as a true transmitter in a very straightforward paradigm. It is well established that octopamine is released from unpaired neurons located in the abdominal ganglion that innervate the light organ of the firefly. Electrical stimulation of the corresponding nerve, as well as octopamine application, induces light emission from the organ, thereby providing a simple physiological output that is easily quantifiable. Importantly, OARs are the only monoaminergic receptors expressed in this tissue, making it an excellent model in the assessment of OAR pharmacology.

Octopaminergic transmission is also critical for essentially all sensory inputs. Acoustic, visual, olfactory, gustatory, tactile, and proprioceptive functions can be modulated by octopamine. Involvement of octopamine in the modulation of the olfactory pathway in the brain may contribute to its role in learning and memory. In addition, octopamine modulation can be involved in the pheromone sensing pathway.

Octopamine has the highest concentration and plays a prominent role within the nervous system. It is well-known that octopamine injected into different parts of the insect nervous system can elicit different behaviors. Generally, octopamine controls the initiation and maintenance of various rhythmic behaviors in the central nervous system of insects. Among other important functions, octopamine is involved in the control of sensitization toward novel stimuli. The most impressive demonstration of such action was performed using the kicking reflex in locust that normally undergoes habituation and then can be completely restored by octopamine application. The role of octopamine in learning and memory can be demonstrated in the honeybee, in which injection of octopaminergic agonists can facilitate both memory formation and retrieval of memory. Octopamine also plays an important role in social behaviors. Octopamine enhances kin recognition in bees and modulates the behavior toward foreign bees. Furthermore, octopamine appears to be involved in the control of division of labor in a honeybee colony. Another related behavior that may also be controlled by octopamine is a hygienic behavior. In arthropods, octopamine is also involved in regulation of aggressive behaviors. Whereas serotonin induces aggressive behavior, octopamine seems to be involved in a submissive behavior in crustaceans. Thus, the role of this compound in the fight-or-flight reaction in insects might be related not only to modulation of peripheral targets, such as motor output or energy supply, but also to the direct influence of octopamine on the central nervous system-mediated functions.

Tyramine

The first step in the biosynthesis of octopamine, tyrosine decarboxylation by TDC, results in the formation of tyramine (Figure 1). In addition to conversion to octopamine, N-acetylation, N-methylation, potential MAO-mediated inactivation, and β-alanine conjugation seem to be important pathways for tyramine degradation. Since tyramine serves as a precursor of octopamine, demonstration of the role of tyramine as a neurotransmitter has been difficult. For example, TDC deletion mutants would result in elimination of both octopaminergic and tyraminergic neurotransmission, thereby complicating delineation of tyramine functions. However, accumulating evidence strongly indicates a neurotransmitter role of tyramine. Although it is not clearly established if both tyramine and octopamine act as transmitters in the same neurons and may be co-released, immunohistochemical studies have identified a set of larval neurons that contain tyramine but not octopamine, suggesting the existence of specific tyraminergic neurons capable of exclusive tyramine release. Tyramine can be accumulated in vesicles via vesicular monoamine transporters, such as dVMAT-A in *Drosophila*. Rapid reuptake of released tyramine by plasma membrane transporters has also been described. It has been shown that both the cocaine-sensitive *Drosophila* dopamine transporter (dDAT) and the specific phenolamine transporter discovered in the cabbage looper can transport tyramine with high affinity.

Actions of tyramine are mediated via GPCR tyraminergic receptors (TARs), which may also be involved, in part, in octopamine transmission. These receptors share structural features with the α-adrenergic receptors but have little similarity with mammalian trace amine receptors that can also be activated by tyramine. Only one TAR has been found in *Drosophila*, and thus all tyraminergic neurotransmission seems to be mediated exclusively through this receptor. In the *honoka* mutant (a *Drosophila* strain) that has a significantly lower level of TAR expression, a slight hyperactivity, impairment in some olfactory tasks, and reduced tyramine-induced muscle contraction were observed. In addition, an impairment of responses to repellents such as ethyl acetate was found, and the inhibitory effects of tyramine on the excitatory junction potential of the larval body wall muscle were significantly affected.

TAR pharmacology is quite limited, and no selective agonists (other than tyramine) are currently available. Nevertheless, some compounds among 5-phenyloxazoles show relatively high activity at TARs. Furthermore, a high-affinity antagonist of the TAR has been identified. Yohimbine, an indol alkaloid of the yohimbe tree, is mostly known for its antagonistic action on vertebrate α_2-adrenergic receptors. In invertebrates, yohimbine is a potent antagonist of TAR, and in *Drosophila* it can induce physiological effects similar to those observed in *honoka* mutants. It is believed that invertebrate TARs are coupled to the G_i protein, thereby inducing inhibition of the adenylate cyclase. Thus, regarding adenylate cyclase activity, tyramine signaling is inhibitory, whereas octopamine signaling is mostly stimulatory.

In contrast to octopamine, which induces an increase in insect activity, tyramine induces a decrease in activity. It is believed, in fact, that the balance between tyramine and octopamine activity is critical for normal locomotion in *Drosophila* and similar regulation may be important also for other functions and behaviors. Although few specific functions for tyramine have been identified, like OARs, TARs are ubiquitously distributed within the nervous system. Interestingly, tyramine has been shown to contribute to cocaine sensitization and the regulation of locomotor response to ethanol in *Drosophila*. Tyramine may also be involved in gustatory and visual sensitivity. Finally, tyramine is found in nonneuronal cells. In fact, it may act as a paracrine signal in the *Drosophila* renal system.

Dopamine

In invertebrates, dopamine synthesis processes are similar to those in mammalian neurons (**Figure 1**). It begins with the conversion of the amino acid tyrosine to L-dihydroxyphenylalanine (L-DOPA), the immediate dopamine precursor, by rate limiting in dopamine synthesis enzyme tyrosine hydroxylase (TH). This process requires the coenzyme tetrahydrobiopterin, which in turn is dependent on GTP cyclohydrolase activity. Subsequently, L-DOPA is decarboxylated to dopamine by the enzyme DOPA decarboxylase (DDC), which is also known as aromatic amino acid decarboxylase (AADC). Major metabolites of dopamine, such as dihydroxyphenylacetic acid, 3-methoxytyramine, and homovanillic acid, are found at low levels in invertebrates. Although several MAO and catechol-*O*-methyltransferase homologues exist in the *Caenorhabditis elegans* genome, these enzymes that are critical for the catabolism of dopamine in vertebrates have not been identified yet in invertebrates. In *Drosophila*, a large part of dopamine is inactivated by the enzyme *β*-alanyl-dopamine-synthetase to generate *β*-alanyl-dopamine. Degradation of dopamine also occurs via *N*-acetyltransferase-mediated conversion of dopamine to *N*-acetyl-dopamine.

Most of the studies aimed at the identification and analysis of molecules orchestrating dopamine signaling in invertebrates have been performed in the nematode *C. elegans*. Dopamine signaling in *C. elegans*, as in vertebrates, arises from a small number of cells that exert modulatory control over a larger network involved in various physiological functions. The experimental model was instrumental in the isolation and characterization of molecules important for dopamine synthesis, packaging, reuptake, and signaling that are essential for dopamine-supported behaviors. Among 302 neurons found in *C. elegans*, 8 dopamine neurons in the hermaphrodite with an additional set of 6 dopamine neurons specific to males were identified. Dopamine neurons make extensive connections that are annotated in WormBase.

A forward genetic approach involving screening for mutations that induce a loss of dopaminergic phenotype revealed that essentially all critical proteins required for dopaminergic transmission in mammals are present in invertebrates. Synthesized dopamine is rapidly packaged into synaptic vesicles by a VMAT, in which dopamine is stored available for release following neuronal depolarization. The first dopamine-related mutant identified (*cat-1*) displayed a loss of dopamine accumulation in vesicles. CAT-1 protein shows relatively high homology to human VMAT1 and VMAT2 and can support uptake of both dopamine and serotonin, which is sensitive to reserpine. Thus, it is believed that CAT-1 plays the same role as mammalian VMATs by packaging dopamine and other monoamines into synaptic vesicles. *Cat-2* has been identified as a TH homolog based on structural

similarity. Importantly, *cat-2* mutants display strikingly reduced dopamine levels, recapitulating the effect of TH deletion in mice. CAT-4 is believed to be a GTP cyclohydrolase enzyme responsible for production of the TH cofactor tetrahydrobiopterin. Similarly, AADC (*bas-1*) and the DAT (*dat-1*) homologues have been identified in *C. elegans*. It should be noted that homologues of some of these regulatory proteins were also identified in other invertebrate species. For example, *Drosophila* homologues of VMAT (dVMAT) and DAT (dDAT) are known.

Actions of dopamine in *C. elegans* are mediated by four dopamine receptors that are classified as dop-1 through dop-4. Several splice variants of these receptors have been identified (four for dop-1, two for dop-2, and four for dop-3). Although pharmacological properties of many dopamine agonists and antagonists are different at these receptors from their mammalian counterparts, dop-1 and dop-4 might be considered as analogous to mammalian D1 dopamine receptors with the major signaling pathway involving stimulation of adenylate cyclase, with dop-2 and dop-3 displaying signaling properties of mammalian D2 class dopamine receptors that induce inhibition of adenylate cyclase. By using knock-out animals, specific functions mediated by dopamine via these receptors have been delineated. Dop-1 was implicated in habituation to nose tap response, suggesting that this receptor is important for maintenance of the avoidance response. Whereas no clear function has been identified for dop-2, dop-3 was implicated in dopamine-induced paralysis and basal slowing mechanisms. Dop-4 receptor may be involved in the regulation of pharyngeal pumping, chemosensation, defecation, oxygen sensing, and male mating behavior. In general, dopamine-mediated functions in *C. elegans* include egg-laying behaviors, defecation, basal motor activity, sensation/response to food sources, and habitutation to touch.

Serotonin

Identical biochemical pathways exist in both vertebrates and invertebrates to synthesize the indolamine 5-hydroxytryptamine (5-HT; serotonin) (Figure 2). The first and rate-limiting reaction involves hydroxylation of tryptophan at the indole ring in the 5′ position by tryptophan hydroxylase. Then, 5-hydroxytryptophan is decarboxylated by DDC to serotonin. Since DDC plays a similar role in the decarboxylation of L-DOPA to dopamine (Figure 1), a defect of this enzyme simultaneously affects synthesis of both dopamine and serotonin. Once synthesized, serotonin is transported into synaptic vesicles by the vesicular transporters, and it has been shown that CAT-1 can effectively uptake serotonin into vesicles in *C. elegans*,

Figure 2 Synthesis of serotonin (5-hydroxytryptamine (5-HT)) in invertebrates. L-Tryptophan is hydroxylated by tryptophan hydroxylase to 5-hydroxytryptophan, which is in turn decarboxylated by DOPA decarboxylase to generate serotonin.

whereas dVMAT may have a similar function in *Drosophila*. Selective reuptake of released serotonin occurs via specific serotonin transporters, and in *Drosophila* the serotonin transporter (dSERT) has been cloned.

Most serotonergic neurons in insects are interneurons in the brain and the ventral cord with multiple projections to most parts of the nervous system. Both in mammals and in invertebrates, serotonin acts through multiple receptor subtypes and mediates a variety of functions. Altogether, 12 serotonin GPCR receptor genes have been cloned from *Drosophila*, mollusks (*Lymnaea* and *Aplysia*), and nematodes (*C. elegans* and *Ascaris*). Initial attempts to classify these receptors by using pharmacological tools developed for vertebrate receptors were largely unsuccessful. Gene structure and amino acid sequence seem to provide a more definitive way to classify invertebrate 5-HT receptors. Serotonin-mediated functions in invertebrates include aggression in lobsters, feeding and learning in snails and nematodes, and locomotion in nematodes and *Drosophila*. Serotonin is also critically involved in basic developmental processes, such as cell proliferation, migration, differentiation, and morphogenesis, both in invertebrates and in mammals.

Figure 3 Synthesis of histamine in invertebrates. One-step synthesis involves decarboxylation of L-histidine by histidine decarboxylase to histamine.

Histamine

As in vertebrates, a single enzymatic step converts L-histidine to histamine in invertebrates (Figure 3). The decarboxylation reaction is mediated by histidine decarboxylase (HDC). In invertebrates, histamine has been shown to be a major neurotransmitter released from photoreceptors in response to illumination. Histamine is synthesized only in a small population of neurons in the insect brain. For example, the brain of the honeybee contains only approximately 150 histaminergic neurons. Histaminergic neurons project to many cerebral areas and may play a role in hormonal secretion, thermoregulation, cardiovascular control, and memory functions. Like other monoamines, histamine is packaged in synaptic vesicles by vesicular monoamine transporters, such as dVMAT in *Drosophila*, and can be released in response to various stimuli. Whereas four GPCRs mediate histamine functions in vertebrates, no histaminergic GPCRs have been identified in invertebrates. Two histamine-gated chloride channels were identified as putative histamine receptors. One of them is localized in the lamina of the eye, where histamine functions as a neurotransmitter released from photoreceptors. Interestingly, mutation in the gene encoding HDC results in elimination of histamine but does not cause lethality, suggesting a limited role of histamine during development or in the regulation of vital functions in adults. At the same time, HDC mutants are blind, indicating disrupted synaptic transmission between photoreceptor terminals and postsynaptic monopolar cells in the lamina or medulla. In addition, these mutants demonstrate deficits in mechanosensory transduction. In crickets, histamine plays an important role in the inhibition of an auditory interneuron within the prothoracic ganglion, indicating that histamine is involved not only in sensory transmission but also in the inhibitory modulation of interneurons in insects.

Summary

Biogenic amines are important mediators of neuronal signaling in the central and peripheral nervous systems in many invertebrate species. In general, the organization of the monoaminergic system in invertebrates shows remarkable similarity to that in vertebrates, with the most notable difference reflecting a limited role of adrenergic transmission. It is believed that the role of norepinephrine and epinephrine in invertebrates is generally played by octopamine and tyramine. Although a relatively small number of neurons contain monoaminergic transmitters in invertebrates, they nevertheless supply most of the nervous system with a fine network of projections. This organization is similar to that of mammalian adrenergic transmission, in which a relatively small number of noradrenergic neurons are able to innervate all major parts of the brain. Essentially all major proteins involved in synthesis, vesicular storage, and release, reuptake, and metabolism of monoamines have been identified in invertebrates, showing that the universal nature of molecular mechanisms of monoaminergic transmission is preserved from invertebrates to mammals. As in vertebrates, multiple receptor subtypes (mostly GPCRs) mediate the physiological actions of biogenic amines in invertebrates. It is believed that further characterization of monoaminergic transmission in invertebrates could provide important novel clues for understanding the nature of monoaminergic transmission in more complex organisms such as mammals.

In humans and other primates, the central retina includes a small region, the fovea, in which the receptors and related neural circuitry are highly specialized to provide a level of visual analysis many times more detailed than is possible in the more peripheral portions of the retina. This foveal region of high-acuity vision is smaller than one might imagine, subtending only a few degrees of visual angle, about the size of a 3 cm diameter coin held at arm's length. It is only within this foveal region that our vision is sharp enough for us to recognize a friend's face from a distance of 15 ft or to read normal size type. Consequently, humans and other primates make frequent eye movements as they visually scan their surroundings. These eye movements bring the retinal images of objects of interest into the region of sharpest vision, the fovea, and maintain such images on the fovea if either the visual object or the observer should move.

Most eye movements fall into one of five categories: (1) saccadic eye movements, which quickly shift the center of gaze (i.e., the fovea) from one visual object to another; (2) pursuit, or tracking, movements, which maintain the image of a moving object on the fovea so it can be seen clearly while it is followed with the eyes; (3) vergence movements, which maintain binocular fusion when a visual target moves closer to or farther away from the observer; (4) vestibulo-ocular movements, which compensate for movements of the head when the gaze is fixed on a target of interest; and (5) optokinetic movements, which compensate for slow movements of the entire visual field (as when watching the scenery from a moving car). In addition, saccades can be made voluntarily in total darkness, and numerous neurological conditions can result in abnormal spontaneous eye movements. Some eye movements are voluntary in nature; others are purely reflexive. The goal of the present article is to describe the major neuroanatomical structures and pathways that are involved in the control of two classes of voluntary eye movements: voluntary saccadic eye movements and smooth pursuit eye movements.

Cerebral Cortex and the Control of Eye Movements

Both saccadic and smooth pursuit eye movements are executed primarily with respect to visual stimuli in an individual's environment (although sometimes auditory or somatosensory stimuli can also serve to guide saccadic eye movements). It is reasonable, therefore, that the signals that initiate and control these eye movements originate in regions of the cerebral cortex that have dense connections with the visual system and, in particular, with visual association areas. Current evidence indicates that control signals from the cortex to the brain stem oculomotor centers originate not in a single cortical region but in a group of cortical regions that act together, in concert, to guide voluntary eye movements. These regions, termed cortical eye fields, are illustrated in **Figure 1(a)** and include the frontal eye field (FEF), the supplementary eye field (SEF), the prefrontal eye field (PFEF), the parietal eye field (PEF), the medial superior temporal region (MST), and the precuneus region (designated area 7m in monkeys). In each of these regions: (1) electrical stimulation evokes eye movements; (2) neural activity increases prior to the initiation of an eye movement; and (3) cortical damage or inactivation produces measurable impairment of eye movements. In addition, (4) each of these regions has direct projections to neural centers in the brain stem that are known to be concerned with eye movement control (**Figure 1(a)**); and (5) each of these regions is connected reciprocally with other cortical regions that are concerned with eye movements (**Figure 1(b)**). Finally, (6) functional magnetic resonance imaging (fMRI) studies in humans have confirmed that each of these cortical regions becomes more active during the performance of oculomotor tasks. On the basis of this evidence, these regions are referred to as eye fields. Anatomical, neurophysiological, and fMRI studies provide evidence that each eye field is composed of two distinct subregions, one devoted to the control of saccadic eye movements and the other to pursuit eye movements (**Figure 2**). Several other cortical areas, including regions in the cingulate cortex and in the temporal polysensory area, play some role in the control of voluntary eye movement, but have not yet been studied in sufficient depth to determine whether they are also eye fields in the same sense as the areas already described.

Most evidence available today supports the proposal that the several cortical eye fields comprise nodes in a distributed cortical network, with each node making distinct contributions to the whole but with some overlap in functional capability among the various nodes. For example, the several eye fields are densely and preferentially interconnected with one another and share many functional characteristics. Furthermore, although the disturbances of eye movements that are

produced by damage or inactivation in a single cortical eye field may be significant for a few hours or days, the disturbances recover very quickly. Eye movements are typically back to near normal within a few days after damage to a single cortical eye field. In contrast, damage to two cortical eye fields together produces a much more profound and long-lasting deficit of oculomotor control, suggesting that, when a single eye field is damaged, the other eye fields are able to somehow substitute for the missing functions.

Saccadic Eye Movement Pathways

The neural pathways that control saccadic eye movements are, with a few exceptions, distinct from the pathways that control pursuit eye movements. Two of the most important saccade-related pathways from the cerebral cortex to the brain stem oculomotor system are illustrated in a simplified diagram in Figure 3. The first pathway involves the superior colliculus (SC). Most of the eye fields already described, including the FEF, PEF, SEF, and PFEF, send substantial projections to the intermediate and deep layers of the SC. Neurons in these layers become active before saccadic eye movements, and electrical stimulation in these layers evokes eye movements. In contrast, neurons in the more superficial layers of the SC have visual sensory receptive fields. A major feature of the SC is that it contains a precise map of visual space, both in the superficial sensory layers and in the deeper motor layers.

The visual receptive fields of neurons in the superficial layers are arranged so that (1) neurons in the anterior part of the SC have receptive fields in the central portion of the contralateral visual hemifield, (2) neurons in the posterior SC have receptive fields in the periphery of the contralateral visual field, (3) neurons in the lateral part of the colliculus have receptive fields in the lower half of the contralateral hemifield, and (4) neurons in the medial part of the SC have visual fields in the upper half of the contralateral hemifield.

In the intermediate and deep layers, there is a motor map that is in register with the visual map in the superficial layers. For example, in the anterior part

of the intermediate and deep layers of the SC, neurons are active before saccades that bring the center of gaze to the central portion of the contralateral hemifield (as in 1 above). Similarly, neurons in the intermediate and deep layers of the lateral portion of the posterior SC become active prior to saccades that bring the center of gaze into the lower half of the peripheral portion of the contralateral visual hemifield (as in 3 above).

Neurons in the intermediate layers of the SC project to the paramedian pontine reticular formation (PPRF), a region concerned with horizontal saccades, and to the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF), a structure that is concerned with vertical saccades. Neurons within the PPRF generate a step increase in activity that initiates a saccadic movement. Some of these neurons project to the nucleus prepositus hypoglossi (PH), where the step activity is integrated to produce the tonic increase in activity that is necessary to maintain the eyes in the new, postsaccade position. This tonic activity is then relayed to the abducens nucleus, where it is combined with the step activity from excitatory burst neurons in the PPRF to yield the burst-tonic activity necessary to produce an accurate saccade (Figure 3).

The axons of the excitatory burst neurons (PPRF) and tonic neurons (PH) terminate on both motor neurons and interneurons in the abducens nucleus, as diagramed in Figure 4. In this illustration, the motor neurons in the left abducens nucleus innervate the lateral rectus muscle on the left side. The axons of the interneurons in the left abducens nucleus cross the midline, ascend in the medial longitudinal fasciculus, and terminate on motor neurons in the right oculomotor nucleus. These neurons, in turn, innervate the medial rectus muscle on right side. Thus, the identical signal reaches the lateral rectus muscle on the left side and the medial rectus muscle on the right side, and a conjugate saccadic eye movement to the left is produced.

Vertical saccades are controlled by brain stem circuitry that is generally analogous to the neural circuitry previously described for horizontal saccades. This circuitry includes connections from the SC to the riMLF and the interstitial nucleus of Cajal (iC), nuclei which lie within the central mesencephalic reticular formation. The role of the riMLF in vertical saccades is analogous to that of the PPRF for horizontal saccades, and the function of the iC is analogous to that of the PH.

Paradoxically, in spite of the obvious central location of the SC in the brain stem oculomotor system, the destruction of the SC is quickly compensated by other systems and saccadic eye movements return to almost normal within a very short time. One candidate system that may mediate this rapid recovery is a projection from the FEF, PEF, SEF, and PFEF to the pontine nuclei and nucleus reticularis tegmenti pontis

(NRTP). The FEF, SEF, PFEF, and 7 m project predominantly to the NRTP and to the dorsomedial pontine nuclei (DMPN). Neurons in the NRTP and DMPN project to the oculomotor vermis (primarily lobule VII). From the vermis, signals leave the cerebellum via the oculomotor region of the fastigial nucleus (FOR) and thence to the premotor areas of the brain stem for the control of horizontal and vertical saccades, the PPRF and riMLF, respectively.

Some neurons in the NRTP and DMPN also project to the paraflocculus. This portion of the cerebellar hemisphere is particularly implicated in the control of pursuit eye movements, although there is evidence that it may also participate in the control of saccades. The pathway from the paraflocculus exits the cerebellum via the dentate nucleus and returns to the cerebral cortex by way of the ventral lateral nucleus of the thalamus.

The posterior eye field (PEF) also projects to the pontine nuclei, but, in contrast to the FEF, it projects primarily to the dorsolateral pontine nuclei (DLPN) and the lateral pontine nuclei (LPN). Neurons in the DLPN have been particularly implicated in pursuit eye movements, but activity related to saccadic eye movements has also been observed there. The DLPN projects to the oculomotor vermis and the paraflocculus, as do the DMPN and NRTP. From the vermis, signals leave the cerebellum via the fastigial nucleus, which projects to the PPRF and riMLF, the premotor areas for the control of horizontal and vertical saccades, respectively.

An additional neural circuit important for saccadic eye movements originates in the FEF, SEF, and PFEF and projects to the caudate nucleus. From there, the pathway goes to the substantia nigra, pars reticularis, and then to the intermediate layers of the SC. This pathway exerts an inhibitory influence on neurons in the SC. This inhibition reduces the probability that neural activity in the SC will cause an unintended saccade during the fixation of a stationary target. The inhibition is suspended just before an intended saccadic eye movement is initiated.

The major neural pathways involved in the control of saccadic eye movements are diagramed in Figure 5. This diagram shows only cortigofugal pathways. The cortical–subcortical–cortical feedback loops from the basal ganglia, SC, and cerebellum are addressed later in the article.

Pursuit Eye Movement Pathways

The neural pathways that control visual pursuit eye movements are not understood as completely as the saccadic eye movement pathways. The pursuit pathways involve the cerebellum and vestibular nuclei more directly than do the pathways for saccadic eye movements, and they avoid the SC to a large extent. The major neural pathways involved in the control of pursuit eye movements are diagramed in Figure 6. From the cortex of the posterior hemisphere, pursuit-related areas, including the middle temporal area (MT), MST, lateral intraparietal area (LIP), and 7 m, project to the DLPN. The DLPN contains neurons with activity directly related to pursuit eye movements, and lesion or inactivation of the DLPN produces disruption of pursuit movements. The pursuit subregion of the FEF (FEFsem) and the SEF project to regions of the NRTP and the DMPN that are known to participate in the control of pursuit eye movements. The DLPN projects to both the dorsal paraflocculus and to the oculomotor vermis of the cerebellum (lobules VI and VII). The projection to the dorsal paraflocculus (solid line in Figure 6) is stronger than the one to the vermis (dashed line).

The NRTP and DMPN also project to the oculomotor vermis and the dorsal paraflocculus, but in contrast to the DLPN projection, the connections of the NRTP and DMPN to the vermis (solid line) are stronger than those to the paraflocculus (dashed line). The paraflocculus then projects to the vestibular

nuclei (medial vestibular nucleus (MVN) for horizontal movements; Y-group cells for vertical movements). Finally, the vestibular nuclei send the pursuit-related signals directly to the motor nuclei of the oculomotor system. In contrast to the connections of the paraflocculus (a component of the cerebellar hemisphere, a phylogenetically newer structure than the vermis), the vermis projects primarily to the FOR, which, in turn, projects to the oculomotor nuclei.

The Thalamus and Eye Movement Control

In addition to the direct control exerted by the network of cortical eye fields on the oculomotor system in the brain stem, there are a number of nuclei in the thalamus that also contribute to the control of voluntary saccadic and pursuit eye movements. There are two ways in which the thalamus influences eye movements. The first is via connections between the anterior intralaminar nuclei, particularly the paracentral and central lateral nuclei, with other oculomotor structures. Some neurons in these nuclei (or immediately adjacent to them) have activity that begins prior to saccadic eye movements; some are active during the fixation of visual targets; and some neurons carry signals related to the location of saccadic targets, even in the absence of a visible target stimulus. Yet other neurons in these nuclei have activity that is related to the parameters of visual pursuit movements. The neural connections of the anterior intralaminar nuclei include the saccade subregion of FEF (FEFsac), the FEFsem, and the PEF, in addition to the basal ganglia, cerebellum, and some oculomotor structures in the brain stem. Currently available evidence therefore indicates that the paracentral and central lateral nuclei of the thalamus play a relatively direct role in the initiation and control of saccadic and pursuit eye movements.

The second mode in which thalamic nuclei participate in oculomotor control is that of relay (and processing) structures in the cortical–subcortical–cortical feedback loops. Numerous such feedback loops have been described in motor and higher function circuitry. The most important of the oculomotor loops involve feedback to the cortex from the SC, basal ganglia, and cerebellum. Two representative loops are diagramed in Figure 7. The first (A) is depicted by thick blue dashed lines. This circuit originates in the FEFsem and projects to the caudate nucleus (and, to a lesser extent, to the putamen); it goes from there to the globus pallidus. The globus pallidus, in turn, projects to the VLcr and VApc nuclei of the thalamus, which project back to the FEFsem. The function of this circuit is not yet understood, but probably is concerned with the high degree of feedback that is necessary to maintain an image of a smoothly moving visual target on the fovea.

A second feedback circuit (B in Figure 7) is more completely understood. This circuit originates in the FEFsac and projects to the oculomotor layers of the SC. Neurons in those layers project to the dorsomedial nucleus of the thalamus, where they synapse on neurons that project back to the FEFsac. This circuit serves to carry a corollary discharge signal from the SC back to the FEFsac that is proportional to an actual saccadic eye movement that has just been made. The FEFsac can then compare the magnitude and direction of the intended saccade with the saccade that actually occurred. If this circuit is inactivated at the dorsomedial nucleus, the accuracy of successive saccades is dramatically reduced because the animal is not aware of the eye position at the end of the first saccade when the second saccade is initiated. Similar feedback loops through the cerebellum have also been described, but are not illustrated here.

Figure 7 Diagram of representative cortical–subcortical–cortical feedback circuits. Heavy blue dashed lines indicate a feedback loop (A) related to the control of pursuit eye movements that runs from FEFsem to the striatum, globus pallidus, and thalamus and then returns to the FEFsem. Heavy red dashed lines indicate a feedback loop (B) that runs from the FEFsac to the SC, then back to the thalamus, and finally back to the FEFsac. The gray boxes on the right illustrate the primary smooth pursuit pathway and a secondary saccade pathway through the cerebellum. Feedback loops similar to A and B also exist in the cerebellar pathways, but they are not illustrated here. Interactions between the Saccadic and Pursuit Pathways

Saccadic and pursuit eye movements are fundamentally different in their modes of interaction with the visual environment. Saccades are essentially preprogrammed movements that can be made at will, even in the absence of visual targets. In contrast, a smooth pursuit movement can be made only in the presence of a moving target and, by its nature, must be continuously modified in speed and direction to match the velocity of its target. These differences in the basic characteristics of saccadic and pursuit eye movements dictate that the neural circuitry controlling the two will be largely distinct from one another. Nevertheless, the saccadic system and the pursuit system must frequently interact with one another, for example, when making a saccadic eye movement to a moving target in order to initiate a pursuit movement. There is an increasing body of anatomical and physiological evidence that the two relatively independent basic pathways that have been described here come together at a number of sites in the brain stem and are, in fact, not as completely independent of one another as was formerly believed. Among the structures in the oculomotor system in which there seems to be some degree of interaction between the saccadic and pursuit systems are the DLPN and DMPN; the cerebellar vermis; the SC; the riMLF and PPRF; and the anterior intralaminar nuclei of the thalamus.

Summary and Conclusions

In summary, voluntary eye movements are used to shift the center of gaze from one point of interest to another in an individual's surroundings (saccadic eye movements) or to maintain the image of a moving object on the fovea so it can be tracked accurately with the eyes (pursuit eye movements). These two types of eye movements are controlled by largely separate neural circuits. Both classes of eye movements are controlled at the highest level by cortico-cortical networks consisting of at least six cortical eye fields acting in concert. Neural pathways concerned with saccadic eye movements originate in distinct

subregions of most of these eye fields and project to the SC, the basal ganglia, and (via brain stem relay centers) the cerebellum. Signals from the SC, in turn, engage oculomotor centers in the pontine and mesencephalic reticular formation.

Neural pathways concerned with pursuit eye movements also originate in the cortical eye fields, in subregions that are distinct from the saccadic subregions. In contrast to the saccadic pathways, the pursuit pathways project predominantly to the cerebellum (via brain stem relay centers). From the cerebellum, pursuit signals go to the vestibular nuclei and then to the ocular motor neurons. Both the pursuit and saccadic subregions of the cortical eye fields project to the basal ganglia and the cerebellum, and it is likely that some interaction between the two eye movement systems occurs in these structures. Both the basal ganglia and the cerebellum participate in cortico-subcortico-thalamo-cortical feedback loops that help to fine-tune the eye movements.

Oculomotor System: Models

L M Optican, Laboratory of Sensorimotor Research, NEI, NIH, DHHS, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

The oculomotor system comprises the contents of the orbits (the globe; six extraocular eye muscles; and many fatty, fibrous, and elastic tissues) and parts of the brain. The globe undergoes a very limited amount of translation during movements, about 2 mm along the anterior–posterior axis and 0.5 mm in the frontal plane. Thus, the globe can be considered to be a spherical joint with its center fixed in the orbit. There are three main properties of the orbit that the brain must deal with. The first is the orbital mechanics created by the three-dimensional (3-D) geometry of the eye muscles and the surrounding orbital tissues. These determine the pulling action of each muscle, that is, how a contraction of a muscle is converted to a torque applied to the globe. The second is the dynamics of the orbital tissues. If the time course of the innervation sent to the muscles is not appropriate for the orbital dynamics, the eye will drift when the movement is over. The third is that 3-D rotations are not commutative. If the axis of the applied torque is not correct for the orientation of the eye, plant dynamics will cause unintended drifts or blips around other axes.

Oculomotor Plant

The oculomotor plant is very complicated, nonlinear, and still only poorly understood. Thus, many models of the plant are in use today, with linear models being used when the details can be safely lumped together to give average dynamics.

Lumped Plant Models

Early models of the plant were simplified by considering only rotations of the eye around a single (e.g., vertical) axis. Control theory models of the plant date from the suggestion by Westheimer in 1954 that rapid eye movements (called saccades) were the step response of the plant. This idea suggests a very simple saccadic system because the visual input for a saccade (a jump of the target of interest) evokes a step change in the site of innervation on the retina and, hence, in other brain areas containing maps of retinal activity. If these inputs were added together with appropriate weights (stronger for more distant targets), they would create a steplike change in the firing rate of the neurons, which could be sent directly to the plant. Westheimer proposed that the plant was a critically damped linear system, which would foveate the target as quickly as possible without overshooting it.

In 1964, Robinson measured the mechanical properties of the plant and found that its dynamics were dominated by the viscosity of the muscles and, thus, was not critically damped but instead overdamped. The dominant time constant of the plant was ~285 ms. Thus, if the innervation to the plant were changed in a steplike fashion, the eyes would drift exponentially toward the target and would only arrive after about three time constants. Because we make 3–4 saccades s^{-1}, the innervation must be able to compensate for the viscosity in the plant or our eyes would never stop drifting.

Robinson derived a fourth-order linear model of the plant's mechanics and showed that the innervation needed to drive the plant to make a saccade consisted of at least three parts: a pulse, a slide, and a step. The step determines the final orientation of the eye, the pulse generates extra force to overcome the viscous drag of the orbital tissues, and the slide compensates for some of the viscosity and the relaxation in slow orbital tissues after the rapid part of the movement is over.

The ratio of the output (eye position) to the input (innervation) in Robinson's model of the plant was represented as a transfer function (a linear input–output relationship expressed as the ratio of two complex polynomials). Robinson's plant consisted of one real zero (the value at which the numerator polynomial becomes zero), two real poles (values at which the denominator polynomial of the transfer function becomes zero), and a complex-pole pair. The complex-pole pair contributes an oscillation to the output of a movement that is very small because of the large viscosity. Thus, the plant can be usefully approximated with just two real poles and one zero. Figure 1(a) shows the corresponding mechanical model with three viscoelastic (or Voigt) elements, with the transfer function:

$$E/R = c \times ([sT_z + 1]/[sT_1 + 1][sT_2 + 1])$$

where s is the complex Laplace transform variable, T_1 and T_2 are the viscoelastic time constants, or plant poles, and T_z is the plant's zero (Figure 1(b); Table 1). The scale factor, c, is set by the net compliance of

Figure 1 Second-order linear approximation to the oculomotor plant and its neural compensation: (a) mechanical model of the active and passive tissues in the plant, with the viscosity and elasticity represented by Voigt elements (parallel spring, *K*, and dashpot, *R*); (b) simplified transfer function of the model in (a) (Plant) and the circuit needed to compensate its dynamics. In (a), the force of the muscle's contractile elements is represented by *F*; the eyeball is represented by E, and the time constant of each Voigt element is *R*/*K*. In (b), the innervation (*R*) for an eye position (*E*) requires a pulse, slide, and step. For one-dimensional rotations, the slide and step can be obtained by integrating the pulse. Green traces show velocity command (*V*), step, pulse and slide of innervation, combined pulse-slide-step (*R*), and eye position (*E*). The plant has two poles (T_1 and T_2) and one zero (T_z). *A*, *B*, and *C* are weights and T_s is a time constant needed to build the slide of innervation (see **Table 1**). The transfer functions are shown in Laplace transform notation, so $1/s$ represents a perfect integrator, and $1/(sT+1)$ represents a leaky integrator (or low-pass filter).

Table 1 Lumped two-pole, one-zero plant model and its compensator

Model transfer function		
T_1	Dominant pole's time constant	0.136 s
T_2	Second pole's time constant	0.726 s
T_z	Plant's zero time constant	0.615 s
τ	Excitation–contraction coupling delay	0.008 s
Compensator (final common path)		
A	Step gain	1
B	Pulse gain	0.1605
C	Slide gain	0.0865
T_s	Slide time constant	0.615 s

the springs in the model $(K_1+K_2)/(K_1K_2)$ and the innervation–contraction coupling ratio, but it is conventionally set to 1 so that the gain of the plant is 1 for very low frequency movements. In terms of the viscosity and elasticity, the time constants are $T_i = R_i/K_i$, and the zero is given by $T_z = (R_1+R_2)/(K_1+K_2)$.

Numerically, the stiffnesses of the two passive elements are approximately 0.79 and 1.22 g/°, with viscosities of 0.0158 and 1.22 gs/°. (Note: Ophthalmologists measure muscle force during surgery with a spring scale calibrated in grams; 1g force is 9.8×10^{-3} N.) Thus, the time constants for the poles in the passive tissues are 0.020 and 1.000 s, and the zero is at 0.615 s. The viscoelasticity and active-force generation of the muscle is represented by another Voigt element (*F*, K_m, R_m). Its stiffness is about 1.58 g/° and the viscosity is about 0.316 gs/°, which gives a lumped time constant for both muscles of approximately 0.200 s. Combining the passive and active tissues, we can approximate the total plant model with two poles ($T_1 = 0.136$ s, $T_2 = 0.726$ s) and one zero ($T_z = 0.615$ s). The zero approximately cancels the second pole, making the dominant time constant about 0.150 s. Thus, in models in which the details of rapid eye movements are not important, the plant model can be reduced to just a single pole: $1/(0.150s+1)$. When time delays are taken into account, a delay of about 8 ms is added to the plant by putting the factor $e^{-0.008s}$ in the numerator of the transfer function.

Note that these values are all approximations of a more complex, nonlinear system. As such, their values can change in different species or under different experimental conditions. For example, the dominant time constant in monkeys ranges from 0.090 to 0.200 s and in humans from approximately 0.100 to 0.200 s.

One Dimension

In one dimension, the compensatory innervation (*R*) needed to drive this plant can be easily determined if the pulse command (*V*) is known (**Figure 1(b)**). Integrating the pulse with a gain (*A*) gives the step, and low-pass filtering the pulse (with gain *C* and time constant T_s) gives the slide. With perfect plant compensation, the ratio of eye movement to innervation would simply be $1/s$ (a pure integrator). Hence, for normal saccades, the gain of the step should be 1, which fixes $A=1$. The gain of the pulse must then be $B = T_1T_2/T_s$, which is about 0.1605. To compensate for the zero in the plant, $T_s = T_z$, or 0.615. The gain of the slide must be $C = T_1 + T_2 - T_s - (T_1T_2/T_s)$, which is 0.0865. **Figure 2** shows an implementation of the plant and its compensator and the output from a simulation run (cf. **Table 1**).

Figure 2 Simulation of the simple plant model and its neural compensator from **Figure 1**: (a) implementation of the model in MATLAB/SIMULINK visual programming environment; (b) output of a simulation run. In (a) The generator on the left puts out a pulse 500°/s high for 0.020 s (which should make an eye movement of 10°). The compensator consists of three parallel operators: an integrator (yellow), an amplifier (purple), and a low-pass filter (blue). The plant model (red) is made by combining a low-pass filter block (for T_1) with a lead–lag block (for T_z and T_2). Other blocks (white background) allow Simulink to plot the simulation output in real time (scope) and send it to the MATLAB workspace (output). In (b), the left panel shows the step, pulse (divided by 5 to scale it to fit with the others), and slide; the right panel shows the pulse–slide–step drive (green) and the output of the plant (eye). Note that the pulse part of the drive signal is about eight times bigger than the step part. Most of the energy in this pulse is eaten up by the muscles to overcome their own viscosity, and only a small part is passed to the tendon. Mux, multiplexer.

A major simplification for determining the innervation occurs in one-dimensional (1-D) models because in 1-D orientation is the integral of angular velocity, just as position is the integral of velocity. Thus, in 1-D the torque vector determined by the pulse of innervation and the torque determined by the slide and step are collinear (necessarily, because there is only one axis). Thus, if the pulse of innervation were already computed, obtaining the step of innervation would require simply the mathematical integration of

that pulse. Similarly, the slide could be obtained as the response of a leaky integrator to the pulse.

Three Dimensions

Three-dimensional rotations are more complicated than 1-D rotations because 3-D orientation is not the integral of angular velocity (i.e., rotations are not commutative). However, three dimensional muscle torques are commutative vectors, and the final eye orientation is thus determined by the balance of torques between active and passive tissues. However, during a 3-D movement, the eye deviates from a straight trajectory (e.g., with torsional blips) because of the lack of commutativity, unless the torque is modified by the current eye orientation. Torque could be modified by changing the innervation or changing the mechanics of the orbit.

Muscle Pulleys

Originally it was assumed that the muscle always went straight from its origin to its insertion, even as the eye looked into eccentric orientations. Thus, the pulling direction of the muscles would not change much as the eye moved (Figure 3(a)), and the brain would have to compute a new torque axis for each ocular orientation. However, in 1989 Miller used magnetic resonance imaging (MRI) of human orbits to show that the belly of the muscle did not move as the eye turned, thus creating an inflection point in the eye muscle path. Further research by Demer and colleagues found that this point corresponded to fibromuscular pulleys, which encircle the belly of each muscle (except the superior oblique, which goes through the bony trochlear pulley). Quaia and Optican showed in 1998 that, if the pulleys are in the right place (approximately halfway between the equator and the posterior pole of the eye), the amount by which the axis of action tips for the pulse will be just enough to compensate for the noncommutativity of 3-D rotations (Figure 3(b)), without affecting the final orientation set by the step. This makes the 3-D angular velocity vector approximately equal to the derivative of the 3-D orientation vector. That means the brain could calculate innervation in 3-D as if it were in 1-D: the pulse can simply be the derivative of the desired change in eye orientation, and the slide and step can be obtained from the pulse through (leaky) integration.

As the eye turns, the position of the pulleys must also change, so as to keep the geometrical relationship between the pulley and muscle insertion constant. If the pulley did not move, as the eye rotated the muscle insertion would run into the pulley. Fortunately, all that this requires is that the pulleys move back as much as the globe rotates in its direction. This may be facilitated by the fact that the orbital layers of the extraocular muscles insert on the pulley itself. Thus, as the muscle contracts, it moves both the eye and the pulley.

Figure 3 Effect of eye orientation on the axis of action of extraocular muscle: (a) without pulleys; (b) with pulleys. In (a), if there were no impediments the muscle would slip as the eye turned, so that the muscle always took the shortest path to the insertion. In this case, even for a 45° elevation, the axis of action (green dotted line) tips very little (~6°). In (b), a specialized structure in the orbital tissues, called a pulley (blue), holds the muscle in place as the eye turns. In this case, for a 45° elevation, the pulley redirects the axis of action of the muscle (green dotted line) by tilting it in the same direction as the globe has moved, but by only half as much (22.5°). Adapted from Quaia C and Optican LM (2003) Three-dimensional rotations of the eye. In: Kaufman PL and Alm A (eds.) *Adler's Physiology of the Eye: Clinical Application*, pp. 818–829. New York: Mosby.

Eye Movement Models

Eye movements can be divided up into subtypes by their speed, latency, and whether they are voluntary

or reflexive. These include vestibular, optokinetic, smooth pursuit, saccadic, vergence, and short-latency ocular following movements. Many parts of the brain respond to several eye movement types, so the brain does not necessarily process these types independently. Saccades are the most demanding movements to model from the point of view of dynamics, and they are used as an oculomotor model prototype next.

Final Common Integrator

The task of computing oculomotor innervations comes down to generating an appropriate pulse of innervation and then integrating that to obtain a slide and a step for plant compensation. Skavenski and Robinson showed that the phase lag introduced by the brain from the head-velocity signal on the vestibular afferents to the oculomotor neurons was ~90°. This indicated that the brain must be performing an integration of desired eye velocity to get the eye position signal needed by the motor neurons. This observation gave rise to the concept of a final common path, which includes the motor neurons and the neural integrator. Any eye movement command (e.g., vestibular, pursuit, or saccade) need only generate an eye velocity command and feed it into the final common path. All the other mechanisms from there to the orbit are shared by all systems. This sharing makes the neural integrator a key element of all oculomotor movements. Lesion and single-unit recording studies have localized the neural integrator to the vestibular nuclei, midbrain interstitial nucleus of Cajal (NIC; for vertical and torsional components), the brain stem nucleus prepositus hypoglossi (NPH; for horizontal components), and corresponding parts of the cerebellum.

Figure 4 The saccadic system must consist of two functional subdivisions: a context-dependent sensory-to-motor transformation that changes the input signals into a desired eye orientation signal, E_d, and an inverse of the plant model that converts desired eye orientation into the innervation needed to drive the eye until $E = E_d$.

Figure 5 Local feedback loop, proposed by Robinson, that corresponds to the inverse plant model in Figure 4. The feedback loop contains a forward model of the plant that takes innervation as an input and puts out eye orientation. (The forward plant model is represented by a resettable leaky integrator.) The forward plant model's output, $\Delta\hat{E}$, is called the efference copy of the change in eye orientation, ΔE. The comparator subtracts efference copy from desired change in orientation to calculate dynamic (i.e., changing during the movement) motor error, m_e.

Saccadic System Functions

The saccadic system (Figure 4) takes target location in retinotopic coordinates and additional information about the movement's context (such as the orientation of the eyes and motion of the target) and produces the innervation required to get the eye (E) on target (T). In essence, the saccadic system must consist of two functional subdivisions, a sensory-to-motor transformation that changes the input signals into a desired eye orientation signal, E_d, and an inverse model of the plant that can convert an eye orientation into the corresponding innervation needed to drive the eye until $E = E_d$.

Robinson realized that an inverse plant model can be made simply by placing a forward model of the plant in a feedback loop around a high-gain amplifier (Figure 5). This loop defines a new signal, the instantaneous, or dynamic, motor error (m_e). It is the difference between the desired eye orientation change and the current estimate of the eye orientation change ($\Delta E_d - \Delta\hat{E}$) obtained by feeding a copy of the innervation that goes to the plant into the forward model (the forward model can be well approximated by an integrator that resets to zero before every saccade). The summing junction that subtracts $\Delta\hat{E}$ from ΔE_d is called a comparator. If the gain of the controller is high enough, the negative feedback loop drives the output of the comparator (motor error) to zero and the eye's orientation becomes equal to the desired orientation. The sensory-to-motor transformation is much more complicated because it must take into account the current orientation of the eyes, whether the target is moving or stationary, what behavior is desired, and so on. How this transformation is carried out is not well understood, but by moving from a lumped to a distributed model various mechanisms can be proposed.

Brain Areas and the Lumped Model

The brain can calculate the needed innervation if it knows the change in eye orientation that is desired. There are two obvious areas in the brain that could provide this signal: the superior colliculus (SC) and the cerebellum (CB).

Superior colliculus It is not easy to incorporate the SC into a lumped model of the saccadic system as the source of the desired eye movement for three reasons. First, the SC contains a spatially coded map. However, the feedback signal that comes back to the comparator (Figure 5) is temporally coded. Thus, the SC output must be converted into a temporal code before it can feed into the comparator. The second problem is that the locus of activity on the SC encodes the desired target in retinotopic coordinates, not the movement necessary to acquire it. The third problem is that the SC cannot be the only input to the saccadic system because, after SC lesions, saccades are accurate, although they start with a longer latency and have a lower peak speed than normal. This suggests that another area must cooperate with the SC to make a movement.

Oculomotor cerebellum The CB is the area most concerned with making accurate eye movements. The oculomotor vermis (OV) and the caudal part of the fastigial nucleus (cFN) are involved in controlling saccades.

Just as SC-receptive fields form a map of visual space, the cells in the CB form a map of movement space. This map is not as well defined as the SC map, and many cells participate in almost every movement. To aid in interpretation more than to be descriptive, the midline CB can be represented as two maps (Figure 6). The vermis is the only cortical structure in the brain that is continuous across the midline. When unfolded, it is actually much longer than it is wide, but this conceptual map simply represents small saccades toward the center of the vermis and larger saccades toward the edges. The only output from the cerebellar cortex is the inhibitory axon of the Purkinje cell. It projects directly to the ipsilateral cFN.

The cFN in primates is a very small structure. Although it is near the midline, the left and right nuclei are not interconnected. There are inhibitory cells that project out of the cFN, but they go only to the inferior olive and are not discussed here. The outputs from the excitatory cells in the cFN cross over the midline and go to the brain stem. In particular, they project to the contralateral medium lead burst neurons (inhibitory burst neurons (IBNs) and excitatory burst neurons (EBNs)) in the brain stem.

Figure 6 Conceptual maps in the cerebellum. For modeling, the cerebellum can be regarded as having two areas: the cortex and the deep cerebellar nuclei. The areas related to horizontal movements are the midline structures (posterior vermis and caudal fastigial nucleus, cFN). The vermis has a coarse map of saccade size and direction (purple arrows). The cFN is quite small, and the cells receive convergent input from many Purkinje cells. Thus, it is unlikely that they contain any kind of topographical map. Nonetheless, it is convenient to think of the cFN as repeating the map in the vermis but with the sign reversed. The output of the fastigial nucleus crosses over and goes to the brain stem on the other side. Thus, activity in the left nucleus corresponds to rightward saccades. The output of the vermis goes to the ipsilateral fastigial nucleus, but the output comes only from the Purkinje cells, which are inhibitory. Thus, a rightward saccade requires a pause in the left vermis. Correspondingly, an increase in activity in the right vermis inhibits the right fastigial nucleus, unbalancing the fastigial output to the brain stem. This results in a rightward movement.

The direction associated with activation of Purkinje cells on the left is thus a movement to the left because it inhibits the left cFN which projects to rightward premotor burst neurons (MLBNs), thus tipping the balance toward a leftward movement. In contrast, activation of the left cFN causes a rightward eye movement. It thus makes sense to extend our conceptual map of the CB to include vertical movements by placing up and down cells at the top and bottom of the vermis and down and up cells at the top and bottom of the cFN, respectively (Figure 6).

As more data on the role of cells in the midline CB, and related areas such as the interpositus deep cerebellar nucleus, become available, these conceptual maps will need to be updated to maintain a closer isomorphism with the brain. However, the concept of a map, at least in the cerebellar cortex, will probably still be useful.

Neuromimetic Model of the Saccadic System

A lumped model simplifies the description of a system by using simple connections of physically meaningful signals (e.g., target position and eye velocity) among complex elements (e.g., a resettable integrator). Unfortunately, the signals flowing through the brain often do not correspond to physical signals, and individual neurons are not very complex information processors. Instead, the complexity of the brain comes from the massive interconnection of many simple neurons. Thus, to build a model of the saccadic system that incorporates some of this complexity while maintaining its physiological isomorphisms with the brain requires a distributed model. If the distributed model contains elements with anatomical correspondences with the brain and if the elements carry signals observed in neurophysiological recordings, the model can be called neuromimetic.

Now that the conceptual visual (SC) and motor (CB) maps have been presented, they can be combined into a distributed neuromimetic model of the saccadic system (Figure 7). The cerebral cortex is the source of visual information, cognitive choices about what the eyes should look at and the context of the movement. The drive for the eye comes from two parallel pathways, the SC and the CB. These project down to the brain stem areas for controlling the eye muscles. The cerebrum and the SC cooperate to select the target. No specific signal to start the movement is needed. Once the SC determines the target, it stops sending a veto signal to the omnipause neurons (OPNs), which inhibit the saccade generator. The SC also sends a fixed-direction drive signal (in retinotopic coordinates) to the brain stem. The information about the selected target and the movement's context (e.g., target is moving) are sent to the CB. The CB sends a variable-direction drive (or pilot) signal to the brain stem. The sum of the drive from the CB and the SC form the velocity command that moves the eye. This command is also fed back to the CB. The velocity signal can be used to update the current state of the CB. If necessary, the CB can then change the direction of the pilot signal to bring the eyes to the target. When the CB decides that the movement is over, it sends a choke signal to the brain stem (presumably to contralateral IBNs) that cuts off the input to the motor neurons, stopping the saccade.

Figure 7 Distributed model of the saccadic system. The cerebral cortex and the superior colliculus (SC) determine what target to look at. The SC stops its input signal to the omnipause neurons (OPNs), shutting them off and disinhibiting the saccade generator. The SC also sends a drive command to the brain stem premotor burst neurons (MLBNs) to get the eye moving. The cerebellum sends a variable-direction drive (pilot) signal to the brain stem. The sum of the drive from the cerebellum and the SC form the velocity command that moves the eye. If the cerebellum decides that the movement is over, it sends a choke signal to the brain stem (via the contralateral inhibitory burst neurons) that cuts off the input to the motor neurons (MNs), stopping the saccade. The output of the SC is directionally fixed, and so it is called a directional, or retinal, drive. The cerebellum receives a feedback signal (efference copy of eye position and/or velocity) during the movement and, thus, can adjust its output to steer the saccade, so its output is called a pilot drive. When we compare this feedback loop with the one in **Figure 5**, it clear that the key element of Robinson's model, the local feedback loop, goes from the MLBN to the cerebellum (green arrow). Thus, the role of the forward plant model in **Figure 5** is played here by the cerebellum.

The neurons in the left SC fire for rightward targets, and the neurons in the right SC fire for leftward targets. However, cFN neurons fire for both ipsi- and contralateral saccades. How can the same neuron fire for both directions of movement and accomplish anything? One possible interpretation is suggested by the observation that cFN neurons fire with a shorter latency for contra- than for ipsilateral saccades. The contralateral burst is time-locked to the start of the movement, but the ipsilateral burst occurs with a high degree of variability, usually near the end of the movement. This timing difference of cFN activity can be exploited. In the brain stem, there is some evidence that IBNs are stronger than EBNs. This breaks the anatomical symmetry and allows the early contralateral output to be a drive signal, whereas the later ipsilateral output acts as a choke.

Thus, for a rightward saccade, the left OV must pause and the left cFN must fire, which drives the right IBNs and EBNs. The right EBNs drive the right lateral rectus and left medial rectus. The right IBNs cross over and inhibit the EBNs, IBNs, and motor neurons on the left side. Near the end of the saccade, the right vermis pauses and the right cFN fires. The output from the right cFN crosses over and drives the left IBNs and EBNs. At this time, the left IBNs and EBNs are being inhibited by the right IBNs. However, if we assume that the excitation from the right cFN is more powerful than the inhibition from the right IBNs on the left IBNs, it will begin firing. The left IBNs cross over to the right side and inhibit the right IBNs, right EBNs, and right motor neurons (probably presynaptically). This crossed inhibition chokes off the drive to the motor neurons and stops the movement.

During the movement, the CB is also sending a signal to the SC that inhibits the SC more and more toward the end of the movement (squelch). Thus, the SC is inside a feedback loop, but it is not a classic error control feedback loop. It simply causes the SC output to decay somewhat during the movement, which may make it easier to start a new saccade after the current one is completed.

A diagram of how the system works is shown in Figure 8(a). On the left side, the bullet-shape represents the retinotopic map on the SC. On the right side, the upper rectangle represents the vermis (continuous across the midline), and the two squares represent the left and right cFN oculomotor regions (FOR). The appearance of the target causes a locus of activity somewhere in the SC (blue disk). This is communicated to the CB, but the projection diverges widely and, thus. cells in most of the vermis become active, which shuts down the FOR (red arrows). The innervation for the movement is the sum of the outputs from the SC and the CB (with the sign reversed for the ipsilateral FOR, making it a choke signal). This sum drives the brain stem burst neurons, which in turn provide feedback to the vermis. During the saccade, the feedback must cause some kind of updating in the CB, which causes different parts of it to pause as the movement progresses. This can be thought of as a spreading wave across the CB cortex. However, it is important to keep in mind that the mechanism underlying this apparent spread is unknown. Other mechanisms (such as a population of neurons with different thresholds) could also cause the activity in the ipsilateral vermis to pause at the right time. Nonetheless, it is important to realize that the spread of the pause in the vermis cannot be generated simply by some kind of diffusion process within the CB or by transport delay (along the parallel fibers that cross the midline). If that were the case, the movement would be unable to compensate for motor noise in the system. The only way the CB can steer the movement to the target is by processing instantaneous feedback information.

An example of how movement context is incorporated into the model is shown in Figure 8(b). Suppose that the target appears on the horizontal meridian, at the same eccentricity as in Figure 8(a). Then, the locus of activity in the SC would be same in both cases (blue disk). However, the CB also receives information that the target is moving. Based on its previous experience, the CB has learned that to acquire this target the initial locus of activity must be moved a bit down and to

Figure 8 Interaction of drive signals from superior colliculus (SC) and cerebellum determine the saccade (two-dimensional maps of the SC and cerebellum show where activity must be for the desired eye movement): (a) under normal circumstances; (b) when contextual information (e.g., target velocity, behavioral commands, or initial eye position) indicate that a different movement is called for. In (a), the output of the SC and the corresponding output of the cerebellum are simply summed (with the sign of the choke reversed, red arrow). Feedback (green arrows) causes the activity at different places in the vermis to pause at the right time (as if a wave of inhibition were spreading across the vermis, gray arrow). In (b), the initial locus of the pause in the vermis is displaced, creating a new drive signal from the fastigial oculomotor region (FOR), as shown by the magenta disk. During the eye movement, feedback drives the spread of the Purkinje cell (PC) pause along the magenta arrow. Thus, the total output (sum of SC and cerebellar drives) gets the eye on target. $\sum_w$, weighted sum.

the right (magenta disk). The sum of the SC and CB outputs now causes the eye to move up and to the right. Feedback causes the pause in the vermis (or burst in the FOR) to move up and to the right (magenta arrow). The eye is thus successfully steered to it rendezvous with the moving target.

The Brain Does Not Have a Desired Eye Movement Signal

The division of the drive signal across different areas in the distributed model has profound consequences. The most important question is: where in the brain is the desired eye movement represented? Let us consider in more detail a saccade to a moving target. Figure 9(a) shows the target configurations and the corresponding eye movements. Blue symbols and traces show a saccade to a stationary target at 20° eccentricity. Green symbols and traces show a saccade to a stationary target at 15°. Orange symbols and traces show a saccade to a target (*) appearing at 20° and moving toward the fixation point (+) at 50° s^{-1}. If the delay between target appearance and the saccade is 100 ms, then the target will be 5° closer to the fixation point at the time of the saccade than when it appeared. Thus, to rendezvous with the moving target the eye needs to make only a 15° saccade (and then pursue the target).

Figure 9 The brain's representation of the desired target is distributed: (a) the target configurations and the corresponding eye movements; (b) diagrams of the superior colliculus (SC; retinotopic) and cerebellum (CB; motorotopic). In (a), suppose the saccade is made from the fixation point (blue plus) to a stationary target at 20° (blue asterisk). The representation of the target in the (SC) is at the 20° locus (blue disk). The representation of the target in the CB is also at the 20° locus (dashed blue circle). The resultant saccade goes to the target (blue trace). If the saccade is made to a stationary target at 15° (green), the locus of activity in the SC is more rostral and the locus of activity in the CB is more medial (green disk and dotted circle). However, when the saccade is made to a moving target that appears at 20° and moves toward the fixation point at 50° s^{-1}, the loci of activity in the SC and CB differ (b). If the saccade occurs in 100 ms, the target will have moved closer, so only a 15° saccade needs to be made. In this case, the locus of activity in the SC is still at the 20° site (orange ring) because the SC encodes the location of the appearance of the target. The CB receives the location of the original appearance, but it also receives information about the velocity of the target (Context). Based on previous experience, the CB has learned that it needs to make only a 10° contribution for this movement. Thus, activity starts at that site (orange ring). The total outputs of the SC and the CB are now correct to make a 15° movement. However, neither area alone encoded the actual size of the movement. The most fundamental signal of the lumped model, the desired eye movement, thus does not exist in the distributed model. $\sum_w$, weighted sum.

Figure 9(b) shows a diagram of the SC (retinotopic) and CB (motorotopic) maps. From the results just described, we know where the activity in the SC and CB must be localized during saccades to stationary targets. For the 20° stationary target, the locus of activity in the SC is at the appropriate caudal site (blue disk), and in the CB the pause is at the 20° site (blue dashed circle). If the effective drive is the average of the retinal and pilot signals, then a 20° saccade results. The same argument reveals that the loci in the SC and the CB must be at the 15° sites for the shorter saccade to a closer target (green disk and green dotted circle).

Now, consider the orange target. The target appears at 20° eccentricity. Thus, the locus of activity in the SC, which knows only which target was selected in retinotopic coordinates, must be at the 20° site (orange circle). Where is the locus of the pause in the CB? If it were also at the 20° site (blue dashed circle), a 20° saccade would result, which would be too large. If the locus in the CB were at the 15° site (green dotted circle), which is the calculated size of the desired movement based on the target's motion, then the saccade would still be too big because the SC is still putting out a command for a 20° saccade. Instead, the pause in the CB must be at the 10° site (orange circle) because, if the SC puts out too much drive, the CB must put out a smaller drive and/or choke sooner. The average of those two drives gets the eye on target. Thus, neither the SC nor the CB encodes the size of the movement. Desired movement size is distributed across several brain structures and is an emergent property of the neuronal circuit.

The distributed model does not contain a signal encoding the desired eye movement. Why is this so important? Because all classical models based on control theory or optimization theory work by driving a motor error signal to zero. However, the existence of an instantaneous motor error signal depends on a comparator to calculate the difference between desired and accomplished eye movements (Figure 10(b)). Since Robinson's original proposal of the local feedback loop in 1975, no neurophysiological evidence

Figure 10 Comparison of models of the saccadic system: (a) distributed; (b) lumped. In (b), the lumped model, the signals all encode physical values. The input to the pulse generator is the desired eye orientation (E_d). It is compared to the efference copy of eye orientation, producing motor error (m_e). However, the distributed model of the saccadic system (a) has no signal corresponding to the desired eye movement. Thus, no comparator is present in the distributed model and there is no motor error signal. In the distributed model, the information processed in the cerebellum is spatially coded (red), but in the downstream areas information is temporally coded (blue). Note that the two types of signals never mix (i.e., there is no comparator). Instead, the temporal activity of the feedback signal causes an updating of the spatial locus of activity in the cerebellum. $\hat{E}$, estimate of eye orientation; STM, sensory-to-motor transform.

of a neuronal population encoding the desired eye movement, let alone dynamic motor error, has ever been found. The neuromimetic, distributed model does not use a desired eye movement signal, and thus it cannot compute a motor error; hence, it does not need a comparator. Instead, the model uses a desired target signal in retinotopic coordinates and knowledge of the current context of the movement, and it works because, after repeated saccades, the CB learns to make the correct contribution, on average, in that situation. Instantaneous feedback of an efference copy signal allows the CB to compensate for motor noise on an individual saccade by updating the locus of activity in the CB. Thus, the brain does not appear to have, and does not need, either a motor error or a desired movement signal.

Drosophila as a Genetic Model

Ever since Thomas Hunt Morgan's groundbreaking work in the 1920s, *Drosophila* has been recognized as a powerful genetic model system. The genome of *Drosophila* consists of three major chromosomes (the X chromosome and second and third chromosomes) and a small, mostly heterochromatic fourth chromosome, which contains few genes. The genome encoded by the major chromosomes is divided into 100 cytological bands, of which 1–20 are located on the X chromosome, 21–40 and 41–60 are on the left and right arms of the second chromosome, respectively, and 61–80 and 81–100 are on the left and right arms of the third chromosome, respectively. Each cytological band is subdivided into six regions, indicated by the letters A–F. Recombination occurs only in females. Mutations can be readily generated and stably propagated through the use of balancer chromosomes, which contain large inversions and suppress recombination. Gene disruption by transposon mobilization has become the preferred way to introduce mutations. Transposons can also be used as vectors to drive transgenes in specific cells. Such transgenes can either be used to rescue mutant phenotypes or to drive fluorescent reporter genes as neuroanatomical markers; for toxic or apoptotic proteins that can ablate cells or render neurons dysfunctional; and for RNAi constructs that can suppress expression of specific genes. Large numbers of mutant stocks in controlled genetic backgrounds are available to *Drosophila* researchers from national stock centers. In addition, fly stocks with overlapping deficiencies, in which parts of chromosomes are missing, that cover about 70% of the genome are also available and can be used for high-resolution gene mapping.

The genome of *Drosophila melanogaster* was sequenced in 2000 and has been extensively annotated. In addition, genomes of several other *Drosophila* species have also been sequenced, enabling comparative and evolutionary analyses. In addition to its advantages as a genetic model, *Drosophila* is also readily amenable to electrophysiological, behavioral, and neuroanatomical experimentation. These experimental advantages and the relative simplicity of its olfactory system have made *Drosophila* an attractive model for studies on chemosensation.

Anatomy of the *Drosophila* Olfactory System

The olfactory system of *Drosophila* shows remarkable similarities in its functional organization to the mammalian olfactory system and, because of its reduced numerical simplicity, has become one of the best characterized chemosensory systems. It consists of ~1200 olfactory neurons compartmentalized in three morphologically distinct sensilla – the basiconic, coeloconic, and trichoid sensilla, in the third antennal segments – and ~120 olfactory neurons in basiconic sensilla in the maxillary palps. Basiconic sensilla are further subdivided into large and small basiconic sensilla. The sensilla are fluid-filled porous structures that comprise dendrites from one to four olfactory neurons. The axons of olfactory sensory neurons project via the antennal nerve to the antennal lobes, where multiple axons from primary olfactory neurons converge to form synapses with a single or few projection neurons in complex spherical structures, 'named glomeruli,' of the neuropil. The glomeruli also contain synaptic contacts with local interneurons which are intrinsic to the antennal lobe and are primarily inhibitory. Each antennal lobe contains ~43 individually identifiable glomeruli. Axons from olfactory sensory neurons project ipsilaterally, but bifurcate in the vicinity of the antennal lobe to form an additional projection to the contralateral antennal lobe via a commissure that connects the two antennal lobes. Output neurons from the antennal lobes project ipsilaterally to Kenyon cells of the mushroom bodies and the lateral horn of the proto cerebrum in the central brain. Cell bodies of output neurons are organized as three distinct clusters in the antennal lobes – the dorsal, ventral, and lateral clusters. The primary olfactory projection in larvae is similar to that in the adult brain in that olfactory sensory neurons project to glomeruli in the larval antennal lobe, but the larval olfactory system is even simpler, consisting of only 21 olfactory sensory neurons, contained bilaterally in two symmetrically located dorsal organs.

Development of the Olfactory System in *Drosophila*

Early development of the olfactory system in *Drosophila* is regulated by basic helix–loop–helix transcription factors, including atonal, achaete-scute, and amos, and by the transcriptional regulator lozenge. The pattern of atonal expression in the antennal imaginal disc is influenced in turn by hedgehog, wingless, and epidermal growth factor patterning genes. Atonal specifies the development of peripheral glial cells which wrap around growing olfactory sensory axons early during

development as they segregate into three fascicles that exit the antennae toward the antennal lobes. There are at least two subclasses of glia, designated Mz317 and GH146 glial cells. The latter arise in the brain and migrate to the antennae along the developing olfactory axons. Overexpression or misexpression of atonal in all sensory precursor neurons in the imaginal antennal disc results in the conversion of all sensillar classes into coeloconic sensilla, indicating that atonal specifies the formation of this particular sensillar type. Axon collaterals that project to the contralateral antennal lobes are guided by slit-dependent robo2 signaling.

The first adult olfactory sensory neurons arise from the eye-antennal disc at around 16 h after puparium formation, and well-defined glomeruli are observed at around 48 h after puparium formation. The projection sites of axons of olfactory sensory neurons appear to be predetermined. Since the first odorant receptors are expressed 60 h after puparium formation, well after the formation of glomerular connections, odorant receptors appear not to be involved with axonal convergence and targeting during development of the *Drosophila* olfactory system, in contrast to the vertebrate olfactory system. The mosaic analysis using a repressible cell marker (MARCM) method, a genetic technique that uses mitotic recombination to drive expression of a reporter gene in progeny of neuronal precursor cells, has shown that antennal lobe projection neurons form dendritic arborizations at predetermined glomerular locations prior to the arrival of axons of olfactory sensory neurons. The maintenance of the projection neuron map, either at the dendritic sites in the glomeruli or at the axonal projection sites in the protocerebrum, is independent of sensory input. Thus, the *Drosophila* olfactory system is hardwired, and development of the functional adult olfactory pathway at the level of glomeruli requires the precise alignment and integration of the olfactory sensory neuron map with the projection neuron map.

The p21-activated serine–threonine kinase (PAK) and the SH2/SH3 adapter protein Dock have been implicated in precise targeting of axons to their appropriate glomerular destinations. In addition, multiple forms of the cell surface protein Dscam (Down syndrome cell adhesion molecule) are expressed in axons of developing olfactory sensory neurons, and the expression of Dscam is essential for correct wiring between axons and their glomerular targets. Thus, specific adhesion molecules that interact with the extracellular environment and regulate intracellular signaling pathways form a framework within which the axons of olfactory sensory neurons that will express a particular odorant receptor are sorted and guided toward their appropriate glomerular targets.

Odorant-Binding Proteins

When odorants diffuse into the porous sensilla they partition into the aqueous fluid that surrounds the chemosensory dendrites of olfactory neurons (the perilymph) and contains odorant-binding proteins (Obps). Obps are secreted by support cells and comprise a family of about 50 proteins of 18–20 kDa. Although the sequences of these rapidly evolving proteins are divergent, Obps are characterized by six conserved cysteine residues that are thought to be important for maintaining their three-dimensional structures.

Genes encoding Obps are located on all three major *Drosophila* chromosomes and occur both as single genes and in clusters. The recommended nomenclature for these genes is the prefix *Obp* followed by the cytological band location and a lower case identifying letter; for example, *Obp56d* is located at cytological location 56, where it is the fourth member of this family at this chromosomal location (indicated by the letter d).

The functions of Obps remain poorly defined. It has been postulated that they bind hydrophobic odorants to facilitate their partitioning in the aqueous sensillar perilymph and their transport to odorant receptors at the chemosensory membrane. A role for protecting odorants from degradation or a role in the removal of odorants has also been postulated. However, a different protein, named Pinocchio (also designated smell impaired 21F, or smi21F), which is widely and abundantly expressed in the third antennal segment and which is only distantly related to the Obp family, has been implicated in the removal of xenobiotics from the perilymph.

There is good evidence that Obps are important for transporting odorants in the perilymph to their receptors. First, functional and structural studies on the pheromone-binding protein of the silk moth, *Bombyx mori*, reveal a pH-dependent mechanism by which this protein binds and releases bombykol. Second, flies in which one Obp gene had been deleted were attracted to high concentrations of ethanol and short-chain alcohols that were repellant to wild-type flies.The gene encoding this Obp was, therefore, called *lush*, and is synonymous with *Obp76*a. Subsequent electrophysiological and behavioral experiments showed that *lush* mutants did not respond to the pheromone 11-*cis*-vaccenyl acetate, suggesting that Lush may function both in general odorant recognition of short-chain alcohols and pheromone recognition. Normal electrophysiological and behavioral responses could be restored either by delivering recombinant Lush protein along with the pheromone via a recording pipette to trichoid sensilla, where *Obp76a* is normally expressed,

or by introducing an *Obp76a* transgene into the mutant background. The crystal structure of the alcohol-binding site of this Obp has also been reported.

Despite the absolute requirement of Lush for responses to 11-*cis*-vaccenyl acetate, the importance of other Obps in olfaction remains to be determined. Heterologous expression of the *Drosophila* Or43a receptor in *Xenopus* oocytes in the absence of Obps resulted in odorant-induced current responses. Similarly, response profiles of odorant receptors expressed under an *Or22a* promoter in an *Or22a* deletion mutant resembled the response profiles of the same receptors in their native sensilla. It should be noted, however, that high concentrations of odorants were applied to obtain electrophysiological responses in the heterologously expressed Or43a receptor, and it is possible that response profiles of odorant receptors would shift to lower odorant concentrations in the presence of the appropriate Obps.

Some Obps show sexually dimorphic expression. For example, *Obp99a* and *Obp99b* show profound sex-biased expression in females and males, respectively, suggesting that these genes have evolved through gene duplication of an ancestral gene with subsequent sex-specific functional diversification. Altered regulation of expression of some Obps has been observed following mating, during exposure to starvation stress, during the development of alcohol tolerance after exposure to alcohol, and as a correlated response to artificial selection for divergent levels of copulation latency and aggression. These observations suggest that this multigene family of proteins serves important functions that broadly affect the organism's physiology and behavior.

Odorant Receptors

Drosophila olfactory neurons express a unique odorant receptor from a repertoire of 56 odorant receptor (*Or*) genes together with a common odorant receptor, Or83b. These receptors belong to the superfamily of seven-transmembrane domain G-protein-coupled receptors. Their sequences are divergent and they are unrelated to vertebrate odorant receptors. The common Or83b receptor forms a heterodimer with the unique odorant receptor, and this dimerization is essential for transport and insertion of the specific odorant receptors in the chemosensory dendritic membrane. Evidence suggests that *Drosophila* odorant receptors have a unique membrane topology among G-protein-coupled receptors, with their N-termini located on the cytoplasmic side of the cell and the C-termini extracellularly.

Neurons that express the same receptor project bilaterally to one, or rarely two, of about 43 individually identifiable symmetrically located glomeruli in the antennal lobes, where olfactory information is encoded in a spatial and temporal pattern of glomerular activation. Four cases have been identified in which olfactory sensory neurons co-express two receptors together with Or83b, and one case has been observed in which a glomerulus receives input from two populations of olfactory sensory neurons expressing different receptors. Sexually dimorphic glomeruli, which may be involved in courtship and mating behavior, receive input from three groups of olfactory sensory neurons expressing unique odorant receptors.

Organization and Response Properties of Odorant Receptors

Elegant extracellular recordings from sensilla in the maxillary palps and third antennal segments of *D. melanogaster* have characterized the response properties of olfactory sensory neurons and shown that sensilla can be classified as specific types that contain invariant combinations of neurons with defined molecular receptive fields. Each maxillary palp contains only 120 olfactory neurons housed in 60 basiconic sensilla with two neurons per sensillum. Based on their odorant response profiles, olfactory sensory neurons in the maxillary palp can be classified into six functional classes, which follow a strict pairing rule such that two neurons with particular response profiles always occur together. Thus, sensilla in the maxillary palps can be classified into three groups, designated pb1, pb2, and pb3 (pb indicates palp basiconic), and responses from individual neurons within these sensilla can be distinguished based on their spike amplitudes. A similar organization is found in the antennae, where two olfactory sensory neurons are housed together within the basiconic sensilla, with one sensillar type containing four olfactory sensory neurons. Again, neurons with defined odorant response profiles are housed within these sensilla according to strict pairing rules. Based on a diagnostic panel of 12 odorants, there are 16 classes of olfactory sensory neurons housed in seven different types of sensilla in the antennae, designated ab1–ab3 for the large basiconic sensilla and ab4–ab7 for the small basiconic sensilla (ab indicates 'antenna basiconic'; see Figure 1). The distribution of the different sensilla varies across the antennae. In addition, the response kinetics to different odorants will vary among olfactory sensory neurons, and both excitatory and inhibitory responses to odorants have been observed.

A deletion mutant lacking the *Or22a* and *Or22b* gene enables ectopic expression of receptors under

Figure 1 Functional characterization of *Drosophila* olfactory receptor neurons. (a) Characterization of olfactory receptor neuron (ORN) response profiles for three types of large basiconic sensilla (ab1, ab2, and ab3) and four types of small basiconic sensilla (ab4, ab5, ab6, and ab7) with 11 diagnostic stimuli and the solvent control, paraffin oil (po). Responses are measured as the increase (or decrease) in spikes per second compared to the spontaneous firing frequency. Sixteen classes of olfactory sensory neurons occur in characteristic combinations in the seven basiconic sensilla types. (b) Schematic representation of the seven functionally characterized basiconic sensilla types in the antenna. (c) Distribution of morphological subtypes of sensilla across the third antennal segment. The arista (ar) is a mechanosensory structure that extends from the antenna. (d) The distribution of functional types of basiconic sensilla described in (a and b). Each circle represents a recording from one sensillum (question marks represent recordings that could not be classified).The dotted lines represent boundaries between morphological categories of sensilla. Dorsal is at the top; medial is along the center of the diagram. the *Or22a* promoter in otherwise silent mutant neurons and establishes an elegant *in vivo* assay system for a comprehensive characterization of odorant receptor specificities, including larval odorant receptors, odorant receptors from other species (such as the female-specific AgOr1 receptor from the malaria vector, *Anopheles gambiae*, that recognizes the human host odorant 4-methylphenol), and odorant receptors expressed in the maxillary palps and antennae of adult flies. This analysis was subsequently extended to a comprehensive characterization of the molecular receptive fields and response characteristics of 24 odorant receptors with a panel of more than 100 odorants.

Central Processing of Olfactory Information

The glomerular map is decoded in central brain structures – the lateral horn of the protocerebrum and the mushroom bodies. Axons from projection neurons with dendritic arbors in specific glomeruli in the antennal lobes course through the antennal cerebral tract, form branches in the mushroom body, and terminal axonal arborizations in the lateral horn of the protocerebrum. The axonal arborization patterns in the lateral horn are highly stereotyped and invariant among individuals (Figure 2). Furthermore, projection neurons with similar terminal axon fields receive input

Figure 2 Neural projections in the *Drosophila* olfactory system, illustrating the stereotypic labeled line projection pathway of neurons that express the Or47b receptor. (a) Schematic representation of the *Drosophila* olfactory pathway. The diagram shows a frontal view of the *Drosophila* head, with the compound eyes shaded in red, the antennae in gray, and the antennal lobes in blue. Olfactory sensory neurons that express the Or47b receptor are shown as blue dots, and their axons converge on the VA1l/m glomerulus (green). Axons of output neurons (green) project to the calices of the mushroom bodies and the lateral horn of the protocerebrum. (b) *In situ* hybridization shows stereotypical expression of Or47b in olfactory sensory neurons located in a restricted lateral dorsal region of the third antennal segment. (c) The left-hand panels show that axons from olfactory sensory neurons, in which the Or47b promoter drives expression of green fluorescent protein, converge upon the VA1l/m glomerulus in the antennal lobes. The right-hand panels show stereotypical axonal arborizations of a single projection neuron from the VA1l/m glomerulus in the ventral region of the lateral horn of the protocerebrum. Reproduced from Keller A and Vosshall LB (2003) Decoding olfaction in *Drosophila*. *Current Opinion in Neurobiology* 13: 103–110, with permission.

from adjacent glomeruli. In this aspect the organization of the insect olfactory system is reminiscent of the vertebrate system, where adjacent glomeruli in the olfactory bulb tend to respond to structurally related odorants. The stereotypical projection pattern from the antennal lobe to the lateral horn suggests positional preservation of the glomerular chemotopic map onto the axonal projection map in the lateral horn. The projection to the lateral horn, however, is more diffuse than is the primary olfactory sensory projection to the antennal lobe glomeruli, with substantial interdigitation among axonal innervation fields. The innervation patterns of axons of projection neurons onto the dendrites of Kenyon cells in the calyx of the mushroom body are more variable than is the strict stereotypy found in the lateral horn, suggesting greater synaptic plasticity in the mushroom bodies, which have been implicated with learning and memory. It has been suggested that odor recognition may be a primary function of the lateral horn, whereas the mushroom bodies may be the principal sites for odorant-associated memory formation.

High-resolution calcium imaging with calcium-sensitive fluorescent reporter transgenes enables real-time monitoring of odorant-induced glomerular activation. Such experiments have shown that glomeruli are functional units that are either activated or not, but never show partial activation. Different odorants elicit distinct glomerular activation patterns that are invariant among different individuals and are faithfully transmitted to projection neurons in the activated glomeruli. At low odorant concentrations few glomeruli are activated, but as odorant concentrations increase they elicit activity in a larger segment of the glomerular field, which most likely reflects recruitment of odorant receptors with lower affinity. To what extent temporal characteristics of the glomerular activation map are essential for odorant recognition and olfactory discrimination in *Drosophila* still remains an unresolved issue.

Genetic Architecture of Olfactory Behavior

Odorant Recognition and Behavior

Electrophysiological and behavioral studies have shown that, as in mammalian olfaction, odorant recognition in

Drosophila is combinatorial. A given odorant can interact with multiple receptors and, although receptors differ in the scope of their response profiles, odorant receptors can interact with multiple ligands. In the larval olfactory system systematic ablation of any one of the 21 olfactory sensory neurons results in disruption of chemotactic responses to small subsets of odorants, but when only a single neuron remains intact (i.e., functional redundancy in odorant recognition is removed), larvae can still exhibit chemotaxis. Nevertheless, olfactory sensory neurons acting in concert in this system facilitate odorant recognition. Behavioral assays that can quantify both attractant and avoidance responses of adult flies to odorants have been developed, including Y-maze assays, olfactory trap assays, computer-assisted video-monitoring systems, and simple dipstick assays, in which repellent responses are monitored away from a cotton-wool swab dipped in an odorant solution. Most larval responses to odorants are attractant, whereas both attractant and repellant responses are common in adult flies. However, the direction of a behavioral response to an odorant is often concentration dependent, with attractant responses at low and intermediate concentrations giving way to repellent responses at high odorant concentrations. The response to carbon dioxide has been especially well characterized. Carbon dioxide is a potent repellent, which elicits avoidance behavior by activating olfactory sensory neurons that project to a single glomerulus in the antennal lobe, the V glomerulus.

Gene Networks That Mediate Olfactory Behavior

The behavioral response to external chemical signals requires not only odorant recognition, but also signal transduction, signal propagation, signal processing and interpretation, and generating an appropriate behavioral output. A vast proportion of the genome is required to enable behavioral responses to chemical stimuli. Genes that are essential for olfactory behavior can be readily identified by *P*-element insertional mutagenesis, whereby a transposable element, a genetically engineered DNA construct, inserts in or near a gene that contributes to the behavior, thereby disrupting its function and generating a mutant phenotype. Quantitative genetic studies and whole-genome transcriptional profiling of *P*-element insertional olfactory mutants in controlled genetic backgrounds have shown that the genetic architecture of olfactory behavior consists of interactive networks of multifunctional (pleiotropic) genes characterized by nonadditive (epistatic) effects on the phenotype. These networks are plastic and adjust dynamically to environmental changes. They encompass, among others, genes implicated in development of the nervous system. Hypomorphic mutations in these genes, which show no overt or only subtle neuroanatomical effects, can have profound effects on adult olfactory behavior. A complete understanding of the neurogenetic underpinnings of olfactory behavior will ultimately require linking genetic networks to neural circuitry, a central challenge for future investigations.

Olfactory Receptor Neurons and Glomeruli

The honeybee's strong points as a model system for olfaction research are the facts that odor processing can be studied through learning tests, with odor as an appetitive stimulus, and that odor-induced neural excitation can be monitored both at the single-neuron level and at the neural network level. A total of 60 000 olfactory receptor neurons (ORNs) on each antenna project their axons to the antennal lobes (ALs), which are subdivided into approximately 160 identified glomeruli. Most of the ORNs are in groups of 25–20 in pore plates (sensilla placodea). The number and distribution of receptor molecules are unknown, but in analogy with the findings in *Drosophila* and the mouse – for which a correspondence between the number of olfactory receptor genes and the number of glomeruli has been found – it is assumed that approximately 160 different ORNs may exist on the bee antennae.

Extracellular recordings from ORNs in pore plates showed that the respective chemoprofiles are broad and overlapping. Furthermore, the temporal response characteristic of single ORNs can be complex, including both excitatory and inhibitory components to particular odors, indicating antagonistic processing either at the level of intracellular cellular pathways initiated by more than one receptor protein in each ORN, or by neural processing between ORNs within one pore plate.

Each ORN innervates only one glomerulus, and axons from ORNs within one pore plate reach different glomeruli. The glomeruli are interconnected by about 4000 local interneurons, and about 800 projection neurons (PNs) lead from the glomeruli to higher order brain centers, such as the mushroom bodies and the lateral protocerebrum. Using calcium imaging, it is possible to measure odor-evoked glomerular activity patterns in about 40 of the 160 glomeruli. Using a computerized morphological atlas of AL glomeruli, it was possible to map the identity of glomerular units onto the physiological recordings done with calcium imaging. With this procedure, it was possible to compare the response profiles of individual glomeruli among specimens (Figure 1).

Glomerular Activity Pattern and Odor Identity

Two main issues were addressed with the imaging technique: first, whether odor representation is conserved within the species, and second, whether the activity pattern elicited by an odor is sufficient to predict the odor stimulus. The combinatorial pattern of glomerular activity is indeed highly conserved between individuals, indicating a tight developmental control of ORN input processing in the AL. Furthermore, statistical analysis carried out on 18 of the 160 glomeruli of the bee (11%) using a discriminant analysis showed that odor representations of each given odor form a coherent 'cloud' in the multidimensional space where axes are defined by each of the identified glomeruli. In 86% of these cases the odor could be identified from the glomerular activity.

In a more extensive analysis the generalization profiles of 16 × 16 pairs of odors were determined using the odor conditioning paradigm and compared with the results from optophysiological recordings. The perceptual distances correlate well with physiological distances. It was concluded that the functional groups of the primary and secondary aliphatic alcohols, aldehydes, and ketones, and carbon-chain lengths, are inner dimensions of the honeybee olfactory space and that neural activity in the AL reflects the perceptual quality of odors. In both of these studies the perceptual similarity measure was the generalization profile, the response probability to an odor that was not learned after the animal had been trained to a particular odor.

Another measure of stimulus similarity can be response time. In most examples studied so far, response time and accuracy are inversely related to each other and this appears to apply also for color discrimination of honeybees. Under given conditions of reward and motivation, the brain appears to accumulate the evidence against or in favor of a certain choice until a determined threshold is reached. Free-flying bees can be tested regarding how long they sniff an odor probe, and whether sniffing time differs for the discrimination of more similar or less similar odors. In this study, a behavioral assay was used in which bees had to discriminate odors consisting of mixtures of two components, thus odors that varied greatly between very similar and very different odors. Bees learned to discriminate all of the mixtures, including very similar ones, and even different concentrations of the same odor. Even though discriminating two very similar

Figure 1 Representation of aliphatic alcohols. (a) Schematic view of the honeybee antennal lobe (AL), with the three glomeruli T1-28, T1-17, and T1-33 as indicated. These three glomeruli are direct neighbors. (b) Responses of the T1-28, T1-17, and T1-33 glomeruli to a series of alcohols, varying in carbon-chain length from C5 (1-pentanol) to C10 (1-decanol). Note that T1-28 responds most strongly to short-chain alcohols, T1-17 to intermediate-chain lengths, and T1-33 to longer chain lengths. Each point represents the average of 14-21 individuals (error bars shown). Responses are shown relative to the response to hexanol in glomerulus T1-28 (asterisk). The shaded area indicates noise levels. (c) Spatial activity patterns elicited by the same six alcohols as those in (b). Red indicates strong activity and dark blue indicates low activity. Glomeruli that could not be measured are shown in gray. Note the continuous shift in activity between T1-28, T1-17, and T1-33 as the carbon-chain length increases. Also note that the response patterns are not limited to these neighboring glomeruli. Adapted from Sachse S, Rappert A, and Galizia CG (1999) The spatial representation of chemical structures in the AL of honeybees: Steps towards the olfactory code. *European Journal of Neuroscience* 11: 3970–3982.

odors appears to be a more difficult task than discriminating two very distinct substances, it was found that the time needed to make a choice (690 ms) for or against an odor was independent of odor similarity.

These data suggest that, irrespective of the nature of the olfactory code, the bee olfactory system evaluates odor quality after a constant interval. This may ensure that odors are only assessed after the olfactory network has optimized its representation, an aspect which will be addressed in the following sections.

Neural Processing in the AL

Glomeruli are connected by about 4000 local interneurons, many of which are immunoreactive to γ-aminobutyric acid (GABA). Comparing the activity patterns of glomeruli as measured predominantly from the input and the output sites of the glomeruli indicated a sharpening of the odor-induced patterns, decorrelating the activity patterns for different odors. Frequently inhibitory responses and 'off' responses were found in the output neurons of the glomeruli, the PNs. Interglomerular inhibition is most likely to occur between glomeruli with similar response profiles in order to sharpen their somewhat fuzzy response profiles.

Glomeruli with similar responses were often found to be direct neighbors, and such neighbors may mutually inhibit each other demonstrating lateral inhibitory mechanisms. However, interglomerular inhibition is not limited to direct neighbors, for the following reasons. First, all glomeruli are approximately equidistant from the center of the antennal lobe: the AL is spherical, with all glomeruli covering the outside of the sphere. Local interneurons innervate several glomeruli; however, their neurites do not travel from one glomerulus to a neighbor, but rather from one glomerulus to the central neuropil and from there to other glomeruli. Second, not all glomeruli with similar response profiles are direct neighbors. To investigate the underlying mechanisms, the GABA-receptor antagonist picrotoxin (PTX) was applied and two separate inhibitory networks were found: one that is GABAergic and modulates overall AL activity, another that is PTX-insensitive and glomerulus-specific.

The net result of the two inhibitory networks together is a globally modulated, contrast-enhanced, and predictable representation of odors in the olfactory output neurons.

Connecting the ALs with the Mushroom Bodies

The second-order neuropils of olfactory processing in the insect brain are the mushroom bodies and the lateral horns (LHs) (Figure 2 (a)). Four different morphological types of PNs leave the AL, two of which project to the lip region of the mushroom body (MB) and to the lateral protocerebrum, the LH. PNs in these two pathways have been analyzed more closely by intracellular recordings. PNs in the median antennocerebral tract (m-ACT) code odors by latency differences or specific inhibitory phases in combination with excitatory phases, have more specific activity profiles for different odors, and thus convey the information with odor-specific delay. The PNs of the lateral antennocerebral tract (l-ACT) code odors by spike rate differences, have broader activity profiles for different odors, and convey the information more quickly. Thus, less precise information about the olfactory stimulus appears to reach the MB and the LH via neurons of the l-ACT, and odor information subsequently becomes more specified by activities of neurons of the m-ACT.

Figure 2 The olfactory pathway in the bee brain and olfactory processing in the MB. (a) Scheme of the bee brain. Lateral antennocerebral tract (l-ACT) projection neurons (PN, green) were optically recorded at their dendrites in the antennal lobe (AL) and at their presynaptic boutons in the lip of the MB calyx. Dendrites and somata of clawed Kenyon cells (clawed KC, red) were recorded in the MB calyx. Yellow arrows indicate sites of dye injection: 1 for recording PN dendrites in the AL, 2 for recording PN boutons in the MB calyces, and 3 for recording KCs in the MB calyces. Squares represent the two imaged areas, AL (for measuring PN dendrites) and MB calyx (for measuring PN boutons and/or clawed KCs). (b) The wiring diagram illustrates the divergent and convergent connectivity between PNs and clawed KCs. About 400 cholinergic l-ACT PNs synapse onto roughly 20 000 clawed KCs. The dendrites of clawed KCs are small, arranged in columns, and feature few clawlike synaptic specializations (black circles). (c) Within the lip region, PNs synapse onto GABAergic neurons which, in turn, make inhibitory synapses with PNs and KCs. Moreover, GABAergic feedback neurons receive input in the MB lobes and send their axons to calyx lip region. Since they leave out the ventral vertical lobe, they presumably do not receive input from clawed KCs. Thus, GABAergic neurons may provide local, PN-driven inhibitory microcircuits within the MB calyx lip, and a more global inhibitory feedback loop between the MB output and input region. Adapted from Ganeshina O and Menzel R (2001) GABA-immunoreactive neurons in the mushroom bodies of the honeybee: An electron microscopic study. *Journal of Comparative Neurology* 437: 335–349.

It was concluded that the separation into two neural pathways from the primary to the secondary centers of olfactory processing is not related to the distinction between different odors, but rather relates to a dual coding of the same odor by two different neuronal strategies in the time domain. Part of the olfactory information may also lie in the timing of action potentials. For example, when olfactory processing is disturbed by applying the GABA-antagonist PTX (which also affects the temporal pattern of AL neuron firing, but may also affect the spatial representation of odors), similar odors are no longer distinguished by honeybees.

Many more experiments are needed to understand the relationship between temporal and spatial odor representation in both the insect and the vertebrate brain. One difficulty lies in the paucity of electrophysiologically recorded cells whose innervated glomeruli have been identified, and which can therefore be used to correlate the observed spatial and temporal activity patterns. The atlas of the AL in the bee brain is an excellent tool to establish, for each glomerulus, an olfactory response profile and temporal response patterns, both for the ORN input and the output via the PNs.

Learning-Related Plasticity in the AL

The plasticity of the neural network of the AL has been studied from two perspectives, that of neural correlates of sensory memory and that of associative memory after olfactory reward conditioning.

Sensory memory is a short-lived persistence of a sensory stimulus in the nervous system, such as iconic memory in the visual system. The effect of an odor stimulus on the postsynaptic responses in PNs was measured within the glomeruli. A single-odor presentation changed the timing of spontaneous activity across glomeruli, enhancing the probability

of coactivity of glomeruli that had been active during odor stimulation shortly before. Moreover, during the first few minutes after odor presentation, correlations between the spontaneous activity fluctuations suffice to reconstruct the stimulus. These results were interpreted to reflect modifiable fluctuations as substrates for Hebbian reverberations and sensory memory, a mechanism that might well be generalized to other neural systems.

Imaging glomerular activity during appetitive learning of an odor leads to an increased response in those glomeruli that are activated by the learned odor, but not in those that respond to a specifically untrained odor. The odor-specific activity pattern was not changed qualitatively, but only quantitatively. Since glomerular activity can also be enhanced by higher concentration of the odor, it is not yet clear how the learning-induced enhancement can be separated from the odor-concentration effect. Since these experiments were carried out under conditions in which the animal was trained to an odor, they not only documented a learning-specific plasticity in the AL, but also proved that the staining with the Ca-fluorescence dye and the imaging procedure did not interfere with the neural processing in the bee brain.

Recently similar associative conditioning experiments combined with Ca imaging were performed with specific staining of a subset of the postsynaptic elements in the glomeruli, the uniglomerular PNs of the lateral antennoglomerular tract. It was found that their responses to odors were remarkably resistant to plasticity following a variety of appetitive olfactory learning paradigms. There was no significant difference in the changes of odor-evoked activity between single- and multiple-trial forward or backward conditioning, differential conditioning, or unrewarded successive odor stimulation. PNs of the lateral antennoglomerular tract may thus be more involved in reliable odor coding rather than modified by learning. The role in olfactory learning and memory retrieval of PNs other than those of the imaged lateral antennoglomerular tract remains to be investigated.

Odor Processing in the MB

PNs convey the output of glomeruli to the MB and the LH (**Figure 2 (a)**). Whereas nothing is known so far about odor processing in the LH, the MBs have been studied recently with Ca-imaging techniques. The MBs are multisensory integration centers that play a dominant role in odor learning. They are densely packed with 170 000 Kenyon cells (KCs), which receive second-order sensory input in the MB calyces, with different modalities innervating spatially distinct areas. Olfactory input is confined to the lip region. KC axons target output neurons in the vertical and medial lobes of the MB. In these areas, GABAergic feedback neurons receive input and project back to the MB lip region, forming an inhibitory loop (**Figure 2 (b)**).

Electrophysiological recordings in locusts and imaging experiments in *Drosophila* indicated that odor representations do indeed differ remarkably in the AL and the MB. Unlike PNs, KCs respond to odors in a sparse way. However, it is unclear whether this transformation of odor representation is a result of the KCs' integration properties (as suggested for locust), or pre- and postsynaptic processing within the MB lip region. Since the bouton-like PN terminals in the MB lip are involved in reciprocal and feedback and forward microcircuits between GABAergic neurons and PNs, information flow from PNs onto KCs may not only be shaped by feed-forward processes, but also may include interactions between PNs and GABAergic neurons within the MB microcircuits.

It was, therefore, asked whether output activity of PN boutons is modified by presynaptic processing within the MB, by comparing odor-evoked responses in PN dendrites within the AL glomeruli and their boutons at the KC synapse. To reveal transformations taking place in the postsynaptic KCs, odor-evoked responses in KCs were recorded and compared to their presynaptic input from PNs (**Figure 3**). At all three processing stages (AL glomeruli, presynaptic boutons of PNs in the MB lip, and postsynaptic spine activity of KCs) odors reliably evoke combinatorial activity patterns. However, in contrast to PNs, KCs code odors in a sparse way, and generate only brief responses at stimulus onset. The KCs' high degree of odor specificity originates at two steps: first, in a presynaptic sharpening of PN synaptic output, and second, in a diminishing KC response. Interestingly, the temporal sharpening of KCs' responses is established only at the postsynaptic side. These results also show that PN activity generated within the first 200 ms determines whether a KC will respond. Thus, the complex temporal response patterns of PNs are transformed into brief phasic responses in KCs.

Thus, two types of transformations occur within the MB: diminishment of a combinatorial code, mediated by pre- and postsynaptic processing within the MB microcircuits, and temporal sharpening of postsynaptic KC responses, probably involving a broader loop of inhibitory recurrent neurons.

Sniffing and Odor Discrimination

As mentioned previously, bees need a constant sniffing time to discriminate similar and different odors. A task-independent choice time implies that quality is assessed after a predetermined time span, and not as soon as the neural codes for distinct odors differ to a sufficient degree in order to justify a decision. As

Figure 3 Response properties of l-ACT PNs. (a) Dendritic responses to odor stimulation in uniglomerular l-ACT PNs imaged in the frontal AL glomeruli. Traces represent the time courses of Ca^{2+} transients evoked by 1-hexanol in two glomeruli, (a, b). d, dorsal; m, medial; l, lateral; v, ventral. (b) Color-coded Ca^{2+} signals superimposed on the raw fluorescence image show that different odors activated overlapping combinatorial sets of PN dendrites. (c) Traces show representative excitatory and inhibitory dendritic odor responses in the AL ($n = 10$ bees). Ca^{2+} transients typically followed complex temporal dynamics. Odor stimulus is highlighted. (d) Odor responses in axon terminals (boutons) of PNs in the MB calyx. Boutons are visible in the raw fluorescence image. Stimulation with peppermint induced Ca^{2+} increase in many of the boutons (single measurement). (e) Different odors evoked excitatory and inhibitory responses in distinct boutons. The merged images of excitatory 1-hexanol (hx1, red) and linalool (lio, green) responses visualize distinct sets of activated boutons. In contrast, 1-hexanol (red) and 2-octanol (oc2, green) activated overlapping sets of boutons. All traces represent single measurements; images represent the averages of three stimulations. (f) Odor-evoked Ca^{2+} transients in PN boutons ($n = 8$ bees) show complex dynamics, as is the case in the dendrites. In the entire figure, traces $= \Delta F/F$; scale bars $= 50\,\mu m$. Adapted from Szyszka P, Ditzen M, Galkin A, et al. (2005) Sparsening and temporal sharpening of olfactory representations in the honeybee mushroom bodies. *Journal of Neurophysiology.* 94: 3303–3313.

pointed out by Ditzen *et al*. in 2003, this finding may be important in the context of olfactory coding, since it implies that information about the odor is only available at a predefined time point after stimulus onset. In the case of a 'combinatorial code,' one would have to postulate that the across-glomeruli activity patterns are only read out after a given delay. An internal 'clock' may provide such a signal in the form of odor-evoked oscillations. If these oscillations have a frequency of about 30 Hz in the bee brain – as in the locust brain – a time span of 690 ms gives a high-end estimate of 21 cycles, from which the time not involved in odor detection, such as further processing in the brain, and motor commands, will have to be subtracted.

Both the 'synchrony code' (as suggested for the locust) and a combinatorial code that develops its optimal spatial coding over time (as shown for the honeybee AL) rely on the sequence of activity patterns. The sequences of two very different odors may differ earlier than the sequences of two very similar odors. Under these conditions, one would expect that the brain would continuously monitor the evidence in favor of each alternative, and make a choice as soon as the evidence suffices for one, as has been shown in other experimental paradigms. However, the results reported in the foregoing text suggest that odor evaluation is not incremental, but rather occurs in single information units, consisting of the entire sequence of neural activity following an odor sample. It has been suggested by Ditzen et al. that an interim storage of the sequence would be needed in order to explain the time constancy. Obviously, in the odor coding models provided so far, there is a missing component: a mechanism that would allow for a constant readout time of olfactory quality. This constant time requirement for odor choice may guarantee that odor quality is assessed when its coding is optimal.

Introduction

Invertebrate models have been instrumental to the discovery of many of the fundamental principles of neuroscience. The use of these models in comparative studies provides information about basic principles of neural processing and highlights the constraints under which nervous systems have evolved. In addition to their inherent value to basic neuroscience, invertebrates merit study because of their economic and medical importance. In the past several decades, the hawkmoth *Manduca sexta* (hereinafter referred to as *Manduca*) has become established as an excellent model for the study of the neurobiology of olfaction. The relatively large and experimentally tractable nervous system of *Manduca*, combined with experimentation guided by the natural history of this insect, has placed *Manduca* at the forefront of olfactory research.

Natural History

Much of the research on the neural mechanisms of olfactory processing in *Manduca* has been guided by knowledge of the olfactory environment encountered by moths in nature. The nocturnally active adults must find flowers on which to feed, males must find mates, and females must find the proper plants on which to lay their eggs. For each task, *Manduca* must detect, identify, and discriminate volatile chemicals, both individually and in characteristic blends that signal host flowers (Figure 1(a)), conspecific mates (Figure 1(b)), and healthy leaves on which to lay eggs (Figure 1(c)). *Manduca* prefers the characteristic floral blends produced by certain plants but can learn to identify others as sources of nectar. The characteristic blend of sex pheromone components released by female moths may be present at very low concentrations and is encountered as discontinuous filaments blown downwind from their source. In addition, females avoid laying eggs on plants that are releasing elevated quantities of certain volatile compounds in response to damage by herbivory. A complete description of the neural mechanisms of olfaction in *Manduca* must explain how moths process information in the context of their specific olfactory environment.

Anatomy of the Olfactory System of *Manduca*

Olfactory Receptor Cells

The distalmost segment of the antenna – the flagellum – is the main olfactory organ of moths (Figure 2(a)). It carries thousands of hairlike, multiporous olfactory organules called sensilla, each containing one to a few sensory cells that function as odor detectors. Female antennas possess only short to medium-length sensilla, whereas the male antennas carry additional, male-specific, long sensilla. The antennal flagellum is divided into subsegments (flagellomeres or annuli) each bearing several types of sensilla. Different morphological types of sensilla are categorized based on their length, shape, surface features, pore density, and dendritic branching of their sensory cells. The best-studied types of sensilla in *Manduca* are the trichoid and basiconic sensilla. In addition to the antennal flagellum, there is also an olfactory organ, called the labial palp pit organ (LPO), in the third (distalmost) segment of each of the paired labial palps.

Trichoid and basiconic sensilla typically house two or three olfactory receptor cells (ORCs) that use acetylcholine as their neurotransmitter (Figure 2(b)). The dendrites of ORCs reside within the shaft of the sensillum, whereas the somata of ORCs and supporting sheath cells are located in the epithelium at the base of the sensillum. The axons of ORCs leave the sensillum via the antennal nerve (AN) and project to and terminate in the primary olfactory center in the brain, the antennal lobe (AL), which possesses an array of condensed neuropil structures called glomeruli. The ORCs in the sensilla of the LPO project axons via the labial palp nerve to the subesophageal ganglion and then through it to terminate in the AL. ORCs express specific olfactory receptor proteins (ORs), and axons of ORCs expressing the same OR(s) converge on a single glomerulus. Thus, activation of a particular type of OR can be observed in the activation of its corresponding glomerulus. ORCs expressing different ORs are intermingled throughout the antennas and the AN, but during pupal development the ORC axons, as they approach the AL through the AN, reorganize themselves into fascicles destined for specific glomeruli (Figure 2(c)). This occurs when the growth cones of the developing axons encounter a region rich in glial cells called the 'sorting zone' near the entrance to

Figure 2 Peripheral sensory structures of the olfactory system of *Manduca*. (a) Schematic frontal view of the moth's head. Each antennal lobe (AL) receives input from olfactory receptor cells in the antenna via axons projecting through the antennal nerve (AN). The AL also receives input from receptor cells located in the labial palp pit organs (LPOs) in the distalmost segment of each of the paired labial palps. The axons of these cells project from each LPO through its labial palp nerve (LPN) to the subesophageal ganglion (SEG) and through it to the AL. (b) Illustration of a multiporous sensillum which contains olfactory receptor cells (ORCs) and sheath cells. (c) Anterogradely stained ORC axons from one antenna of *Manduca*. As the axons of ORCs pass through the sorting zone (bracket), they reorganize into distinct bundles bound for specific glomeruli. the AL. At the developmental stage when the ORC axons grow through the sorting zone, the AL has a relatively undifferentiated, coarse neuropil surrounded by a rind of AL glia. The ORC axons project through that glial sheath to form a 'protoglomerular layer.' Soon after, the developing processes of AL intrinsic neurons innervate the protoglomerular layer, and AL glia surround and stabilize each protoglomerulus. Thus, the ORCs confer both a physiological and an anatomical identity on each glomerulus.

The Antennal Lobes

Glomeruli are uniquely identifiable, functional units of the AL and the first synaptic sites within the olfactory system. Glomeruli are composed of densely packed neurites of, and synapses among, ORCs, AL neurons, and centrifugal neurons and are surrounded by a sheath of glial cells. In *Manduca*, chemical synapses in the AL are confined to the glomeruli, which surround a region of coarse neuropil comprising neurites of AL neurons and centrifugal neurons projecting into the AL from elsewhere in the central nervous system. The ALs of both males (Figure 3(b)) and females (Figure 3(a)) have 63 ± 1 glomeruli, all of which have been characterized on the basis of their characteristic shapes, sizes, and relative positions. Some of these glomeruli also have been characterized physiologically. The AL of *Manduca* includes two olfactory subsystems, one of which is composed of approximately 60 sexually isomorphic glomeruli that process information about plant volatiles and possibly other odors. The second subsystem comprises three sexually dimorphic glomeruli situated near the entrance of the AN into the AL. In males, these specialized glomeruli (called cumulus, toroid 1, and toroid 2) belong to the macroglomerular complex (MGC) (Figure 3(b)) and are devoted to processing information about the sex pheromone released by conspecific female moths. The male-specific MGC glomeruli receive input from the long male-specific trichoid sensilla on the antenna. The female-specific glomeruli – a pair of 'large female glomeruli' (LFG) and a smaller glomerulus – process information about specific plant volatiles (Figure 3(a)). With the exception of the identified glomerulus that receives input from the ORCs of the LPO (the labial palp pit organ glomerulus (LPOG)) (Figures 2(d), 3(a), and 3(b)), AL glomeruli receive input from ORCs located in the antenna. Two classes of AL neurons have been identified: local interneurons (LNs; $n \approx 360$) (Figure 3(c)) and projection neurons (PNs; $n \approx 800$) (Figure 3(d)). The dendrites of uniglomerular PNs are restricted to a single glomerulus; multiglomerular PNs have arborizations in several glomeruli. The axons of PNs project from the AL to certain higher brain centers (Figures 3(e) and 3(f)). The LNs, which are all or mostly GABAergic inhibitory neurons, are restricted to the AL and vary greatly in morphology, arborizing in variable numbers of glomeruli. Thus, LNs interconnect glomeruli within the AL in a complex inhibitory network. In addition to the intrinsic AL neurons, there are also centrifugal neurons (including neurons that are believed to secrete serotonin and octopamine) that apparently provide feedback from other regions of the brain into the ALs.

Beyond the Antennal Lobe

The AL is connected to the protocerebrum (PC) by five well-defined tracts: the inner, middle, outer, dorsal, and dorsomedial antennocerebral tracts (IACT, MACT, OACT, DACT, and DMACT, respectively) (Figure 3(f)). The major targets of PN axons (via the IACT, MACT, or OACT) are the lateral horn of the PC, inferior lateral PC (ILPC), and calyces of the ipsilateral mushroom body (Figures 3(e) and 3(f)). The IACT is the most prominent connection between the AL and the PC and mainly carries the axons of uniglomerular PNs. In general, IACT fibers extend from the AL posteriorly, then turn laterally and send collateral branches into the calyces before terminating in the lateral PC. The axons of the MGC PNs in the IACT innervate the ILPC. The PNs that follow the MACT appear to be multiglomerular and terminate in the lateral horn, although the MGC PNs in the MACT project to the ILPC. The OACT carries axons primarily of multiglomerular PNs that project to the lateral horn or the ILPC, although some project to the contralateral lateral horn. Some PN axons in the IACT and OACT project first to the lateral PC and then to the calyces of the ipsilateral MB. Neurons in the two dorsal tracts terminate in the contralateral ILPC and lateral horn. The heterogeneity of the projection patterns from the AL to the PC suggests a complicated process of information segregation and integration at the level of the PC. In addition to PNs projecting from the AL to the PC, there are many neurons that project via the DACT or DMACT from the AL to the PC with somata in either the PC or the SEG, respectively.

Physiology and Behavior

The olfactory system of *Manduca* has evolved not only to identify odorants and discriminate them from one another but also to assess the concentration of odorants, identify natural odor mixtures in which components are presented at particular ratios, and follow the rapid changes that occur in natural odor plumes. Studies of olfaction in *Manduca* benefit from the facts that this sensory modality is decisive for the control of behaviors (e.g., finding mates, food, and oviposition sites), much is known about the chemical composition of natural olfactory stimuli (pheromonal and plant-derived volatiles), and glomeruli are identifiable and accessible for electrophysiological recording (Figure 4).

Odor Identification and Discrimination

Sexually receptive female *Manduca* release a sex pheromone comprising at least eight compounds

Figure 3 Neuroanatomy of the olfactory system of *Manduca*. (a) Three-dimensional reconstruction of a female antennal lobe (AL) highlighting the lateral and medial large female glomeruli (latLFG and medLFG, respectively), the labial palp pit organ glomerulus (LPOG), and the G35 glomerulus. (b) Three-dimensional reconstruction of a male AL highlighting the three glomeruli (cumulus, toroid 1, and toroid 2) of the macroglomerular complex as well as the LPOG and glomerulus G35. (c) Confocal microscopic scan of a local neuron showing the cell body (asterisk) in the lateral cell group of the AL and arborizations in all of the glomeruli in the AL. (d) Confocal microscopic scan of a uniglomerular projection neuron with cell body (asterisk) in the medial cell group of the AL, dense arborizations confined to one glomerulus (G), and an axon (Ax) that projects out of the AL and, shown in (e), to the protocerebrum where it terminates in the calyces (Ca) of ipsilateral mushroom body and the lateral horn (LH). (f) Projection neurons send axons to the protocerebrum through three major output tracts (left; representative neurons are shown on the right). The inner antennocerebral tract (red) projects to the Ca and LH and carries the axons of a majority of uniglomerular projection neurons. Neurons with axons in the outer antennocerebral tract (blue) and the middle antennocerebral tract (green) are largely multiglomerular and terminate in the inferior lateral protocerebrum (ILPC) and the LH. Note that the dorsal tracts (DACT and DMACT) are not shown in this image. (d–f) P, peduncle; α, α lobe; β, β lobe; γ, γ lobe; A, anterior; D, dorsal; L, lateral; M, medial; P, posterior. Scale bars = 100 μm (c–e).

Figure 4 Electrophysiological recordings from cells in the labial palp pit organ (LPO) and the antennal lobe responding to 50-ms pulses of air bearing an increased level of CO_2, delivered at a frequency of five per second. The top trace shows an intracellular recording from a projection neuron in the LPO glomerulus, and the middle trace shows a simultaneous extracellular recording from olfactory receptor cells in the LPO. Stimulus concentration was 600 ppm CO_2 increased from a baseline level of 280 ppm. Stimulus pulses are indicated in the third (bottom) trace. From Guerenstein PG, Christensen TA, and Hildebrand JG (2004) Sensory processing of ambient-CO_2 information in the brain of the moth *Manduca Sexta*. *Journal of Comparative Physiology A* 190: 707–725.

that have been shown to affect the behavior of recipient male moths, but a blend of just two major components ((*E*,*Z*)-10,12-hexadecadienal (bombykal) and (*E*,*E*,*Z*)-10,12,14-hexadecatrienal) is sufficient to attract conspecific males. The individual components alone are ineffective. There are at least four male-specific types of antennal ORCs and one type of sexually isomorphic ORC, all of which are highly sensitive and specific to single pheromone components, including bombykal and (*E*,*E*,*Z*)-10,12,14-hexadecatrienal. ORCs responding to bombykal project exclusively to toroid 1, whereas ORCs responding to (*E*,*E*,*Z*)-10,12,14-hexadecatrienal project to the cumulus. This chemotopic arrangement is preserved in the glomerular output: PNs with dendritic arborizations restricted to toroid 1 are excited selectively by bombykal, and PNs confined to the cumulus are excited selectively by (*E*,*E*,*Z*)-10,12,14-hexadecatrienal (Figures 5(a) and 5(b)). There are some multiglomerular PNs with dendrites in both the cumulus and toroid 1 that are excited by both components. Some neurons in the PC exhibit long-lasting excitation only in response to the proper mixture of the components of the blend, showing response selectivity for a blend at this higher level of processing.

Although the pheromone-specific subsystem in *Manduca* is a paradigm of high sensitivity and specificity, efforts have addressed the widespread notion that the ORCs and PNs associated with other, sexually isomorphic, glomeruli are broadly tuned. The degree of specificity of sexually isomorphic antennal ORCs to host plant volatiles is variable, from specialized ORCs that detect terpenoids to ORCs of intermediate specificity that detect aromatics and generalist ORCs that respond to compounds of different chemical classes at relatively high concentrations. Non-MGC PNs have also been shown to have a range of different specificities. For example, PNs arborizing in the lateral LFG (latLFG) in the ALs of females show preferential responses to the (+) enantiomer of the host plant monoterpenoid, linalool. PNs arborizing in an adjacent glomerulus respond preferentially to the (−) enantiomer, and PNs in other neighboring glomeruli respond equally well to both enantiomers. Thus, it is possible that the AL evaluates the naturally occurring ratios of the enantiomers. A high degree of specificity is also found in the ORCs of the LPO, which detect carbon dioxide (CO_2). CO_2 is emitted in high quantities by newly opened, nectar-producing flowers, and moths preferentially visit flowers releasing high levels of CO_2, suggesting that the moths use CO_2 levels to assess the quality of a nectar resource. Indeed, ORCs in the LPO of both sexes respond exclusively to CO_2, at levels comparable to those emitted by the flowers of host plants. CO_2-responsive ORCs project to the LPOG, which houses arborizations of PNs that respond exclusively to CO_2 (Figures 5(c) and 5(d)). PNs with arborizations limited to another sexually isomorphic glomerulus (G35) show preferential responses to the host plant volatile *Z*-3-hexenyl acetate and also respond to structurally similar odorants presented at higher concentrations (Figures 5(e) and 5(f)). These PNs were shown to be morphologically and physiologically equivalent in both sexes.

Although a PN arborizing in an individual glomerulus typically responds preferentially to a certain odorant (Figure 5), a single odor compound may activate a number of glomeruli (albeit with different intensities). Both multielectrode and optical imaging techniques have demonstrated that glomeruli in different regions of the AL respond preferentially to odorants of different chemical classes. Two structurally similar

Figure 5 Synergistic effect of stimulation with a blend of the two key pheromone components on pheromone-responsive macroglomerular complex neurons. (a) Intracellular traces showing the responses of a toroid 1 projection neuron (PN) evoked by a chemical mimic ('C15') of the natural (*E,E,Z*)-10,12,14-hexadecatrienal component of the sex pheromone, by bombykal (BAL), and by a blend (mixture of C15 and BAL in a 1:1 ratio). The C15 stimulus decreased the spiking rate, whereas BAL and the blend markedly increased the spiking rate. Note that the blend-evoked excitatory response had a shorter delay and higher spiking rate than the BAL-evoked responses. The stimulus marker is indicated below the traces. (b) The same PN was tested in five trials using the blend and BAL as antennal stimuli. The response latency and mean spiking rate were quantified from all five trials, and the two variables are plotted against each other. The differential responses to these two stimuli resulted in apparent clustering in the plot, indicating a consistent synergistic effect (shorter delay and higher spiking rate) induced by the blend stimuli across trials. (c) Rate histograms showing the time course of the PN's responses to five repeated stimuli. Again, the C15 stimuli suppressed the spiking activity (arrows) of this PN, and the blend stimuli evoked stronger excitatory responses than did the BAL stimuli.

odorants may elicit spatially similar excitatory responses from an ensemble of AL neurons, but the odor-activated correlations elicited by the two odorants among the neurons in the ensemble can differ significantly. Thus, the identity of an odor stimulus is encoded by an ensemble of neurons through both its spatial and its temporal activity patterns. Moreover, experiments using multielectrode recording and behavioral assays have shown that there is a direct correlation between neural (in the AL) and behavioral discrimination of two odorants. In addition, the pattern of odor activation in the AL can be altered with learning. As a moth learns to associate a particular odorant with a food reward, additional AL neurons become responsive to that odor stimulus, and the activity of other neurons changes.

Sensitivity/Concentration Coding

Natural odors are released by different sources at variable rates. Furthermore, the amount and relative composition of components in a blend change as the animal approaches the source. In order to mediate appropriate odor-oriented behavior, the olfactory system must encode information about both the identity and the quantity of an odor. Both ORCs and intrinsic AL neurons solve this problem by increasing their spiking activity as stimulus concentration increases. In contrast to generalist ORCs, specialist ORCs and PNs have low response thresholds and dose–response curves that span several orders of magnitude of odor intensity. Importantly, their highest specificity occurs at relatively low stimulus concentrations, such as those encountered in nature.

Pheromone-responsive ORCs typically exhibit higher sensitivities than ORCs that respond to plant volatiles. CO_2-responsive ORCs have a response range from less than one order of magnitude below the ambient level (~370 ppm) to at least two orders of magnitude above it. The population dynamic range is expanded, moreover, due to the fact that individual neurons have different but overlapping response ranges. As a consequence of the high degree of convergence of ORCs on a single glomerulus, the response threshold of PNs is generally lower than that of

ORCs. The response thresholds of sexually isomorphic PNs in the female are lower than those of the corresponding male PNs, which is likely due to the higher number of plant-responsive ORCs in female antennas. Furthermore, the sensitivity of the AL circuitry is subject to circadian modulation, at least in part, by serotonin, such that AL neurons are most sensitive in the evening when the moths are most active.

Temporal Resolution/Inhibition

Odors in a plume downwind from its source exist in packets or filaments of odor-bearing air interspersed with clean air. Flying moths orienting toward an odor source thus are not confronted with a concentration gradient but, rather, with discrete odor pulses of 10–50 ms duration at a frequency of 1–20 s^{-1}. The olfactory system of moths (and most other flying insects) has evolved to recognize this temporal variation as a characteristic feature of the stimulus. Within a pheromone plume, male moths fly in a zigzagging pattern that aids in the localization of the pheromone source. This characteristic pattern of behavior is elicited only when the olfactory system is stimulated intermittently. Neurons throughout the olfactory pathway encode the natural spatiotemporal dynamics of the odor stimulus. Pheromone-specific ORCs respond better to short pulses of pheromone components (up to a frequency of at least 3/s) rather than to prolonged exposure, due to adaptation and desensitization, and many pheromone-responsive PNs track odor pulses up to 10–20 s^{-1} (Figure 4). In addition, both CO_2-responsive ORCs and PNs can track pulses accurately up to at least 10 s^{-1} and are excited by increases in CO_2 level and inhibited by decreases. The capability of following high-frequency CO_2 fluctuations might help moths to find nearby CO_2 sources (e.g., flowers). PNs that respond to plant volatiles can also follow short odor pulses with brief bursts of action potentials. Thus, the olfactory system of *Manduca* encodes an important characteristic of the natural odor signal – its intermittency.

Extensive studies on the MGC have revealed neuronal mechanisms that underlie the ability of the AL to encode the temporal qualities of an olfactory stimulus. It was first observed that the responses of some pheromone-specific PNs are temporally complex. For instance, the PNs with arborizations confined to the cumulus receive excitatory input from ORCs responsive to the pheromone component (*E,E,Z*)-10,12,14-hexadecatrienal. These PNs also receive inhibitory input from LNs that have arborizations in numerous glomeruli, including the cumulus and toroid 1, and are activated by bombykal. The converse is true for PNs with arborizations limited to toroid 1. The presentation of a blend of these two key components of the sex pheromone at their natural blend ratio elicits a triphasic response that consists of a brief hyperpolarization followed by a depolarization with a burst of action potentials and, finally, a delayed, slow, and long-lasting hyperpolarization (Figure 5(b)). The ability of these PNs to follow the frequency and duration of pulses is improved when they are stimulated with the correct blend (i.e., with the correct balance of excitation and inhibition). However, unnaturally prolonged stimulation is not faithfully encoded by MGC PNs. It should be noted, however, that a triphasic response is also produced in PNs of sexually isomorphic glomeruli (Figures 5(d) and 5(f)). In addition to improving their pulse-tracking capability, the excitation/inhibition balance is also believed to contribute to the synergistic responses of some MGC PNs when stimulated with the blend. For instance, some MGC PNs produce a response with a faster onset (i.e., shorter latency) and higher rate of spiking upon stimulation of the antenna with the pheromone blend than with the excitatory component alone (Figure 6).

Although pheromone-responsive neurons in the PC often exhibit prolonged depolarization (long-lasting excitation) in response to the pheromone blend, a subset of these neurons exhibit a state-dependent response to stimulation that may preserve some of the temporal structure of the stimulus. When stimulated while in a state of low, background firing, these neurons respond to the pheromone blend with excitation that can last up to 30 s, regardless of the duration of the stimulus. When stimulated during this excited state, the neurons reduce their firing rate for several seconds after the onset of the stimulus before gradually increasing it to the initial, higher level. Combined with neurons that produce only brief excitation in response to an odor, it seems that the PC neurons can encode the pulsatile nature of the pheromone plume, which is necessary to produce the characteristic upwind flight response of males to female sex pheromone.

Inhibitory interactions (mediated by GABA) appear to have additional roles in olfactory coding. For example, in the MGC, slow, inhibitory, interglomerular interactions promote synchronization of firing across glomerular outputs, which may enhance the representation of a complex olfactory stimulus (e.g., the pheromone blend) in downstream, higher-order brain centers. Spiking activity in pairs of PNs innervating the same glomerulus is more coherent when the neurons are activated by antennal stimulation with the pheromonal blend rather than with the single excitatory component. In this way, when two functionally related glomeruli (e.g., toroid 1 and cumulus) receive their odor input simultaneously (the sex

Figure 6 Examples of projection neurons (PNs) arborizing in three reference glomeruli with similar levels of specificity and temporal response dynamics. (a) A PN limited to the cumulus (dotted outline) of the macroglomerular complex (note that toroid 1 is also outlined in this image). (b) Intracellular recording from the PN in a responding to stimulation with the sex pheromone blend. Note the triphasic response consisting of an initial short hyperpolarization (synaptic inhibition, I_1), followed by a burst of action potentials and then a longer lasting hyperpolarization (I_2). (c) A PN from the sexually isomorphic labial palp pit organ glomerulus (LPOG) (dotted border). (d) Intracellular recording from a CO_2-responsive PN in the LPOG, demonstrating the triphasic response to stimulation with increased CO_2. (e) A PN from the sexually isomorphic glomerulus G35, which lies ventromedial to the lateral large female glomeruli (latLFG; dotted border). (f) Intracellular recording demonstrating the triphasic response of the PN in (e) to stimulation with *Z*-3-hexenyl acetate. D, dorsal; L, lateral. Scale bars = 100 μm. (d) From Guerenstein PG, Christensen TA, and Hildebrand JG (2004) Sensory processing of ambient-CO_2 information in the brain of the moth *Manduca Sexta*. *Journal of Comparative Physiology A* 190: 707–725.

pheromone blend), the temporal tuning of output from each glomerulus is enhanced by reciprocal inhibitory interactions. Interglomerular inhibitory interactions also occur among other glomeruli in the AL. In females, stimulation with the compound that excites latLFG PNs hyperpolarizes PNs in the adjacent glomerulus G35, but apparently not vice versa. This suggests that glomeruli that encode the components of a behaviorally relevant blend are organized in functionally related, synaptically interconnected clusters. In addition, the LNs in an activated glomerulus suppress the spontaneous activity in other glomeruli, thus providing contrast enhancement of the spatial pattern of activation elicited by an olfactory stimulus. In summary, inhibition serves multiple tasks, including shaping the temporal response characteristics of PNs, contrast enhancement, and enhancing the representation of behaviorally relevant blends.

Conclusions

Naturalistic experimental approaches are particularly useful in sensory neurobiology. The preferred stimulus for a neuron or a neural circuit can be more easily

selected from myriad possible stimuli on the basis of understanding what the animal is likely to experience in its natural environment. Every olfactory system has evolved under selective pressures that have been imposed by the characteristics of their olfactory environment. The olfactory systems of animals that specialize in a small number of food sources have been under different selective constraints than have the olfactory systems of generalist feeders. Specialists may have to be more sensitive to certain odorants, whereas generalists may have to be able to detect and discriminate a larger range of odors. Likewise, animals in a more dynamic olfactory environment, such as that encountered during flight, have to be able to encode the spatiotemporal patterns of odors such as those in odor plumes. Adult *Manduca* must detect discrete, intermittent packets of sex pheromone in order to locate potential mates, and they must evaluate complex blends of low-concentration odorants that vary with increasing distance from their source in order to locate food and appropriate oviposition sites. Neurobiological and neuroethological experimentation within the framework of the natural history of the animal fosters understanding of how the different features of an odor are encoded by the olfactory system within the context of the evolutionary constraints exerted upon particular species under study. This approach highlights the basic principles and mechanisms by which olfactory systems encode information about the identity, intensity, and intermittency of natural odors and is essential for understanding the functional basis by which odors are sensed and perceived.

Laminar Organization of the Main Olfactory Bulb

The MOB of most mammals has a roughly concentric arrangement of seven layers, which are, from the surface (Figures 1–3), (1) the olfactory nerve layer (ONL), (2) glomerular layer (GL), (3) external plexiform layer (EPL), (4) mitral cell layer (MCL), (5) internal plexiform layer (IPL), (6) granule cell layer (GCL), and (7) subependymal–ependymal layer (SEL). In some species, the lateral ventricle extends into the olfactory bulb.

Fascicles of unmyelinated olfactory axons from the sensory epithelium penetrate the cribriform plate as fila olfactoria, reach the MOB from the ventromedial aspect, and comprise the outermost layer of the MOB, the ONL. In the ONL, bundles of olfactory nerves (ONs) are enclosed by ensheathing glia and penetrate into glomeruli in the GL. Glomeruli are one of the most distinctive structures in the brain, analogous to barrels or columns in the cerebral cortex. In the mammalian MOB, they are compactly packed almost two-dimensionally near the MOB surface, forming the GL. Each glomerulus is composed of neuropil-rich spheroidal structures surrounded by a distinctive shell of small to medium-sized neurons and glial cells (Figures 1–4). Within each glomerulus, ON axon terminals make contact with dendritic tufts of various types of neurons, which include both projection neurons (mitral and tufted cells) and intrinsic local circuit neurons (Figures 2 and 3).

Neurons in the periglomerular region (the region around and subjacent to glomeruli) are apparently heterogeneous but occasionally collectively referred to as 'juxtaglomerular neurons,' which are morphologically classified into three different types of neurons: periglomerular cells, superficial short-axon cells, and external (or superficial) tufted cells. Among these neurons, periglomerular cells and external tufted cells send dendrites into glomeruli, whereas superficial short-axon cells are believed to send dendrites into the periglomerular region but not into glomeruli. Somata of tufted cells and some types of so-called short-axon cells are located in the EPL. Secondary dendrites of mitral cells as well as tufted cells make dendrodendritic synapses in the EPL, including reciprocal synapses with granule cell dendrites and short-axon cell dendrites (Figures 5 and 6). The MCL is the thin layer where large somata of mitral cells and smaller somata of some other local circuit neurons are located (Figure 7). The IPL is a relatively cell-free thin layer. In the GCL, many clusters or rows of granule cell somata are compactly packed, among which a few larger somata of deep short-axon cells are scattered. The core region of the MOB is the SEL, which is a part of the pathway of the rostral migratory stream from the subventricular zone of the lateral ventricle.

Neuron Types and Synaptic Organization, Chemical Synapses, and Gap Junctions

As in other brain regions, there are two types of neuron groups in the MOB – the principal neurons and local circuit neurons. Both are heterogeneous in various aspects and summarized in Table 1 and Figures 2 and 3. It is important to note that recent studies, mainly immunocytochemical studies, have revealed various types of chemically defined neurons in MOBs of various mammals, many of which appear not to correspond well to any of the neuron types described previously in classical Golgi studies and do not yet have specific names but are collectively called short-axon cells (Figure 2(c)). Thus, future studies will classify these short-axon cells into several subtypes with characteristic structural and physiological features.

In considering the neuronal organization of the MOB, it is important to note one of the characteristic structural features of olfactory bulb neurons; that is, except for some short-axon cells, somata and dendrites of most neurons are not only postsynaptic but also presynaptic, making dendrodendritic synapses including reciprocal pairs or reciprocal synapses (Figures 5 and 6).

Principal Neurons

In the MOB, the principal neurons are mitral cells and tufted cells, most of which are considered to project to extrabulbar brain regions, although some tufted cells are considered to be intrabulbar association neurons rather than projection neurons. Mitral cells and tufted cells generally send their single primary dendrites into single glomeruli making characteristic tufts and several secondary dendrites in the EPL, although some external tufted cells lack secondary dendrites (Figures 2 and 3). Mitral and tufted cells show marked differences in the dendritic morphologies which tend to be correlated with the laminar

position of their somata. In addition, there are also differences in their interaction with different types of granule cells as well as in their axonal projections. Thus, as shown in Figure 3 and Table 1, mitral cells are classified into two subtypes, type 1 (M1) and type 2 (M2), based on the laminar distribution of their secondary dendrites in the EPL. M1 cells extend their secondary dendrites mainly in the inner sublamina of the EPL, whereas M2 cells extend their secondary dendrites mainly in the intermediate to outer sublamina. Tufted cells are classified into three subtypes – deep, middle, and external tufted cells – based on the location of their somata. In addition, mitral cells and tufted cells have also been shown to be chemically and physiologically different. Thus, the principal neurons of the MOB, mitral and tufted cells, are apparently heterogeneous in their structural, chemical, and physiological features. Furthermore, external tufted cells have been revealed to be heterogeneous in their axonal projections and are classified into three types: conventional projection-type external tufted cells, external tufted cells with the associational pathway between the opposing region of the medial and lateral sides of the MOB, and the local, interneuron-like (superficial) tufted cells. Thus, even the classical neuron type 'external tufted cell' is never regarded as a single type of neuron but consists of apparently diverse neurons. Among these external tufted cells, those with the intrabulbar associational system may be interesting because they send a topographically organized projection to the IPL of the opposite side of the same bulb, making a

point-to-point reciprocal connection between isofunctional glomeruli.

Local Circuit Neurons

In contrast with most principal neurons, local circuit neurons are considered to extend their axons within the olfactory bulb, or some are axonless. There are at least three types of local circuit neurons in the MOB – granule cells, periglomerular cells, and short-axon cells – although each type is apparently heterogeneous and further consists of some subtypes. In addition, there appear to be some uncharacterized or unidentified types of presumed local circuit neurons.

Periglomerular cells and granule cells are considered to be inhibitory neurons and make synapses with mitral/tufted cell dendritic tufts in glomeruli and secondary dendrites in the EPL, respectively (intraglomerular dendritic processes of mitral and tufted cells and those in the EPL are considered to be indistinguishable by electron microscope and thus are usually termed collectively as mitral/tufted cell dendrites). Some short-axon cells are also considered to be inhibitory neurons, but most of them remain to be analyzed.

Granule cells Granule cells are axonless and send peripheral dendrites into the EPL, where they bear

large spine-like protrusions, gemmules, and central processes with spines into the GCL. Gemmules contact mainly secondary dendrites of mitral/tufted cells and make reciprocal pairs of synapses (Figures 5 and 6). Based on the location of their somata and the distribution of their peripheral dendrites in the EPL, granule cells are proposed to be classified into three subtypes (Figure 3): type 1 (G1) cells extend their

dendrites throughout the EPL, type 2 (G2) in the deep half of the EPL, and type 3 (G3) in the superficial half of the EPL. Somata of type 2 and type 3 granule cells are mainly located in the deep and superficial parts of the GCL and are also termed deep and superficial granule cells, respectively. Most granule cells are believed to be GABAergic. In the rat MOB, some granule cells (approximately 10% of GABAergic granule cells) are enkephalin-like immunoreactive, located mainly in the deeper half of the GCL; consequently, the deeper half of the EPL is more intensely enkephalin-like immunoreactive than the superficial half of the EPL. Some other granule cells are calretinin immunoreactive, although calretinin is also contained in various neuronal elements in the MOB, such as ONs, subpopulations of mitral cells, periglomerular cells, and short-axon cells.

Periglomerular cells Periglomerular cells are located in the periglomerular region and send their dendrites into glomeruli and extend axons laterally. In glomeruli, their dendrites intermingle with mitral/tufted cell dendritic tufts (Figure 8(g)) and ONs. They have been considered to receive synapses from the ONs and make synapses, including reciprocal synapses, with mitral/tufted cell dendrites (Figure 8). However, some periglomerular cells have been reported to receive no or few synapses from the ONs. Thus, there appear to be at least two different types of periglomerular cells, which are closely related to the compartmental organization of the glomerulus (Figures 3, 4, and 8). Within the glomerulus, ONs do not spread diffusely but, rather, they cluster to make many irregular tortuous strands or islands with many small holes (Figure 4). At the electron microscopic (EM) level, clusters of electron-dense ONs are intermingled with electron-lucent dendrites. Some electron-lucent dendrites appear to penetrate into clusters of ONs, corresponding to

Figure 7 Electron micrograph of the mitral cell layer of the rat main olfactory bulb. AIS, axon initial segment; G, granule cell; M, mitral cell.

small holes in the ON strands (Figures 4 and 8). Thus, it is now considered that each glomerulus consists of two compartments or zones, the ON zone (or axonal or sensory subcompartment) and the non-ON zone (or dendritic or central subcompartment). The ON zone is mainly occupied by ON preterminals and terminals as well as fine dendritic processes of intrinsic neurons, indicating that the ON zone is the site where olfactory receptor cells make synapses on their targets. The non-ON zone is occupied mainly by dendritic processes of intrinsic neurons, where dendrodendritic interactions between intrinsic neurons occur. However, as described previously, many ON negative patches in the ON zone are continuous with the area of the non-ON zone (Figures 4 and 8). Thus, it is difficult to strictly define the border of the ON and non-ON zones.

Immunocytochemical studies at the light microscopic and EM levels have revealed that one group of periglomerular cells extend their dendrites in both the ON and non-ON zones and receive synapses from the ONs, whereas another group of cells restrict their dendrites in the non-ON zone as if to avoid the ONs and receive no or few synapses from the ON terminals (Figures 3 and 4). The former group of periglomerular cells correspond to the traditionally characterized periglomerular cells which are called type 1 periglomerular cells (PG1), whereas the latter group of periglomerular cells are newly recognized and called type 2 periglomerular cells (PG2). The differences in dendritic projection of the two groups of PG cells, especially their prominent differences in the synaptic inputs from the ON terminals, indicate their possible functional differences in the local circuits, which remain to be identified in future physiological studies. These two structurally different groups are also different in their chemical properties. In the rat MOB, PG1 cells include neurons immunoreactive for GABA, its synthesizing enzyme glutamic acid decarboxylase (GAD), and dopamine-synthesizing enzyme tyrosine hydroxylase (TH). PG2 cells include those immunoreactive for calbindin and calretinin. It is interesting to note that anatomically revealed direct contacts between ON terminals and PG1 cell dendrites correspond well with the results obtained by physiological studies, although the direction of the structurally identified synapses is reverse in relation to the function; dopamine and GABA presumably spilled over from PG1 cell dendrites contacting ON terminals, regulating the transmitter release from the ON terminals via D2 and GABA-B receptors on the ON terminals. However, we must be careful not to oversimplify the classification of neurons. For example, even in the rat MOB, we cannot regard all GABA-positive cells as PG1 cells *a priori*. We must consider the possibility that GABA-positive cells are heterogeneous and some are PG1 cells but others are PG2 cells. Furthermore, because there are many uncharacterized cells in the periglomerular region, there must be GABA-negative PG1 cells and calbindin negative/calretinin-negative PG2 cells. It is also noteworthy that in some other animals, such as laboratory musk shrews, almost all calbindin-positive cells are also GABA positive, but they are apparently PG2 cells. Thus, there are both type 1 and type 2 GABA-LIR and/or GAD-IR periglomerular cells in the MOBs of some mammals.

Short-axon cells In the MOB, mitral/tufted cells, granule cells, and periglomerular cells are major groups of neurons, but there are other types of neurons which are collectively named short-axon cells. Short-axon cells are distributed throughout the layers – that is, in the GL, EPL, ML, IPL, and GCL – and include diverse types of neurons, only some of which have been identified by classical Golgi studies and reported as distinct types of local circuit neurons (Figures 2(b) and 2(c); Table 1). Immunocytochemical studies have identified several chemical markers that characterize diverse types of short-axon cells, although most of these chemical markers are not

Table 1 Neuron types in the main olfactory bulb

	Neuron types	*Subtypes*	*Sub-subtypes*	*Neuroactive substances*	*Other chemical markers*
Principal neurons	Mitral cell (M)	Type 1 (M1)		Glutamate, CRF	Calretinin
		Type 2 (M2)			
	Tufted cell (T)	Deep tufted cell (DT)		Glutamate, CRF

Figure 8 (a–d) Electron micrographs of part of a glomerulus from serial sections. Color-labeled processes, two mitral/tufted cell dendrites (MT1 and 2), and two type 1 periglomerular cell dendrites (PD1 and 2) are reconstructed in (e). Synaptic connections among these four processes are shown in (f), in which synapses from ONs are not shown. (g) Volume-rendered three-dimensional confocal laser scanning microscope image showing the tracer (BDA)-labeled mitral cell dendrite (red) and CB-IR type 2 periglomerular cells (green), which are intermingled with each other.

necessarily specific to short-axon cells but, rather, are contained in other types of neurons; these chemical markers include calcium-binding proteins such as parvalbumin (Figure 2(d)), calretinin, calbindin, and neurocalcin and neuroactive substances such as vasoactive intestinal polypeptide (VIP), neuropeptide Y, somatostatin, and nitric oxide (nitric oxide synthase and NADPH diaphorase). Among these, some parvalbumin-positive short-axon cells in the EPL are characterized at the EM level and have been confirmed to make reciprocal synapses with mitral/tufted cell dendrites, suggesting that they are inhibitory local circuit neurons. On the other hand, some VIP-positive deep short-axon cells are also reported to be GABAergic and make symmetrical synapses on other local circuit neurons. Furthermore, a type of deep short-axon cell, Blanes cell, is also a GABAergic inhibitory neuron mediating persistent feed-forward inhibition onto granule cells. As described previously, short-axon cells are usually inhibitory local circuit neurons. However, 'superficial short-axon cells' have been reported to send interglomerular axons over long distances to form excitatory synapses with inhibitory periglomerular cells up to 20–30 glomeruli away, resulting in an interglomerular center–surround inhibitory network. These excitatory superficial short-axon cells are reported to have poorly branched dendrites but appear to

display intraglomerular dendrites or small tufts and thus may correspond to local, interneuron-like (superficial) tufted cells described previously. Whether these two groups of neurons correspond to each other remains to be determined. Most short-axon cells remain to be analyzed in detail. Furthermore, it remains to be determined whether so-called short-axon cells are really nonprojecting local circuit neurons or whether at least some of them project out of the OB. Compared to the neurons in the retina, in which diverse subtypes of each neuron type are characterized in detail, neuronal subtypes in the MOB remain to be identified, characterized in detail, and classified.

Chemical Synapses and Gap Junctions

Neuronal interactions are mediated in diverse ways. Chemical synapses and gap junctions are two major pathways through which neurons send signals to and receive signals from other neurons (Figures 9 and 10). A characteristic feature of chemical synapses in the MOB is the dominance of dendrodendritic reciprocal pairs of asymmetrical and symmetrical synapses between mitral/tufted cells and periglomerular/granule cells in the glomeruli and the EPL, respectively. Gap junctions are frequently observed in the MOB, especially in glomeruli, in which gap junctions occur between mitral/tufted cell dendrites and between mitral/tufted cell dendrites and dendrites of periglomerular cells and some uncharacterized local circuit neurons. In extraglomerular regions, the mitral/tufted cell somata, dendrites, and axon hillocks make gap junctions and mixed synapses with various types of interneuronal processes, including apparent granule cell dendritic gemmules and some types of sheetlike or calyx-like processes contacting the somata or large dendrites of mitral/tufted cells. The major chemical synaptic connections as well as gap junctions among neuronal elements in the rodent MOB are summarized in Figure 10.

Figure 9 Electron micrograph of the glomerulus of the mouse main olfactory bulb. A presumed mitral/tufted cell dendrite receives an asymmetrical synapse from an ON terminal and makes a gap junction (arrow; inset) with a presumed periglomerular cell dendrite containing vesicles.

Centrifugal Afferents

MOBs receive dense centrifugal inputs from diverse sources which are considered to be important for integration and modulation of the information. The centrifugal afferents are classified into two groups: afferents from olfactory-related structures and modulatory afferents from nonolfactory subcortical structures. Olfactory-related structures sending afferents to the MOB usually receive inputs from the MOB, making the reciprocal connections. On the other hand, there are three major sources of modulatory afferents from nonolfactory subcortical structures: the nucleus of the diagonal band, raphe nuclei, and locus coeruleus.

Afferents from the nucleus of the diagonal band contain both cholinergic and GABAergic nerves. Cholinergic nerves originate mainly from the Ch3 cell groups and distribute in the GCL, IPL, the deeper one-half to one-third of the EPL, and the GL of the MOB. Retrograde labeling studies have identified GABAergic neurons in the nucleus of the diagonal band projecting to the MOB, but their distribution in the MOB remains to be determined due to difficulty in discriminating the extrinsic GABAergic elements from the numerous intrinsic ones.

Raphe nuclei and locus coeruleus send serotonergic and noradrenergic fibers to the MOB, respectively. Serotonergic fibers distribute in the glomeruli, IPL, and GCL, whereas noradrenergic fibers distribute mainly in the IPL and GCL.

Structure of Nonrodent Mammalian Olfactory Bulbs, with Reference to the Organization of the Insectivore Olfactory Bulb

The major cell types and the clear lamination of the MOB are generally considered constant throughout mammals, and thus it is assumed that there is a considerable amount of similarity in the MOBs of mammals. However, the MOBs of laboratory musk shrews and moles, two insectivores, have a neuronal organization that is different from the well-known general organization of the rodent MOBs (Figure 11).

The compartmental organization of glomeruli and the existence of two types of periglomerular cells

Figure 10 Schemes of the neuronal organization in the rat main olfactory bulb. Summary of neuronal connections via chemical synapses and gap junctions in the glomerulus and in the extraglomerular region. In the glomerulus, synaptic connections among olfactory nerves (ONs) and dendrites of various types of neurons are shown. In the glomerulus, dendritic tufts of mitral/tufted (MT) cells and type 1 periglomerular cells (PG1) receive synapses from olfactory nerves (ONs), whereas type 2 periglomerular cells (PG2) do not receive synapses from ONs. GABA/GAD-positive cell dendrites occasionally make reciprocal pairs of synapses with MT cell dendrites. TH-positive cells also receive asymmetrical synapses from MT cells and make symmetrical synapses to MT cells. However, no TH-positive dendrites making reciprocal synapses have been encountered. CB-positive type 2 PG cells receive no or rare synapses from ONs but make many synapses, including reciprocal pairs, with MT cell dendrites. On the other hand, GABA/GAD-positive, TH-positive, and CB-positive PG cell dendrites receive symmetrical synapses from other PG cell dendrites (PG1 and-2), at least some of which are GABA/GAD positive. Gap junctions are seen between MT cell (including type B external tufted cell) dendrites, between MT cell dendrites and type 1 PG cell dendrites with as yet uncharacterized properties (U-PG), and between MT cell dendrites and dendrites of some interneurons (IN) different from PG cells. Type B external tufted cells are a type of external tufted cells which show cytological features slightly different from those of typical MT cells and show no reciprocal synapses with PG cells, even though they make asymmetrical synapses to PG cells and other interneurons and receive symmetrical synapses from PG cells as well as asymmetrical synapses from ON terminals. In the extraglomerular region MT cell somata and dendrites make chemical synapses including reciprocal pairs of synapses with granule cell gemmules and processes of other types of interneurons, such as Van Gehuchten cells. Gap junctions and mixed synapses are also seen between MT cell somata and dendrites and various processes of presumed interneuron origins. CB, calbindin or calretinin-positive type 2 periglomerular cell; DA-PG, tyrosine hydroxylase and GABA-positive type 1 periglomerular cell; ETB, type B external tufted cell, which shows cytological and synaptic features somewhat different from usually reported mitral/tufted cells; G-PG, GABA and/or glutamic acid decarboxylase-positive type 1 periglomerular cell; MT, mitral/tufted cell.

are confirmed even in the MOBs of these two insectivores. However, their MOBs contain a unique spheroidal synaptic region, the nidus, obviously different from the overlying glomerulus and never observed in the MOBs of rodents. In addition, there are at least two types of neuron specifically associated with the nidus, namely tasseled cells and perinidal cells. Tasseled cells are a type of projection neuron with small tuftlike dendritic branches, whereas perinidal cells are mostly a type of GABAergic interneuron which appears to be related to PG2 cells. In the laboratory musk shrew and mole MOBs, there are at least two separate projection neuron groups: the mitral/tufted cell group receives numerous direct inputs from ONs, and the tasseled cell group receives no or rare direct inputs from them (Figure 11). These two projection systems are believed to interact with each other via several types of GABAergic (and also presumably GABA-negative) local circuit eurons at multiple sites, including the nidus and the EPL. Thus, tasseled cells and mitral/tufted cells should be regarded as interacting at several different sites via different types of GABAergic interneurons (and presumably via other interneurons, such as GABA-negative,

Figure 11 Pseudo-colored confocal laser scanning microscope image of the shrew main olfactory bulb (MOB) (right) and scheme showing its organization (left). Double-immunostained for olfactory marker protein (red) and calbindin D28K (green) combined with the DAPI nuclear staining (blue). In the shrew MOB, there are at least two separate projection systems – the mitral/tufted (MT) cell system and the tasseled (TA) cell system. The MT cell system in the shrew MOB resembles that of the rat MOB, consisting of MT cells, type 1 and 2 periglomerular cells (PG), and granule cells (G). On the other hand, the TA cell system in the shrew MOB consists of TA cells and perinidal cells (PN). In contrast with MT cells receiving numerous direct inputs from the olfactory nerves (ONs), TA cells extend their dendritic tufts in the nidus instead of glomerulus and receive no or rare direct inputs from the ONs. Olfactory Bulb Mapping

K Mori, University of Tokyo, Tokyo Japan

Introduction

The olfactory bulb is the first relay station of the central olfactory system in the vertebrate brain and contains in its superficial layer a few thousand glomeruli, spherical neuropils with sharp borders (Figure 1). In mammals the diameter of glomeruli ranges from 30 to 200 μm. Individual olfactory sensory neurons in the epithelium of nose express only a single odorant receptor gene among a repertoire of numerous odorant receptor genes (e.g., nearly 1000 genes in mice). This is the one cell–one receptor rule in olfactory sensory neurons.

Each olfactory sensory neuron projects a single axon to a single glomerulus in the olfactory bulb. Within the glomerulus, olfactory axons form excitatory synaptic connections on the dendritic tufts of olfactory bulb neurons, mitral cells, and tufted cells. The olfactory axon projection to the glomeruli is precisely organized in such a way that olfactory sensory neurons expressing a given odorant receptor converge their axons to a few topographically fixed glomeruli (Figure 1). All the axons converging onto a single glomerulus originate from sensory neurons expressing the same odorant receptor (the glomerular convergence rule).

Because of the one cell–one receptor rule and the glomerular convergence rule, individual glomeruli represent a single odorant receptor. Therefore, the glomerular sheet of the olfactory bulb forms odorant receptor maps. This article summarizes an emerging view of the spatial organization of the odorant receptor maps in the olfactory bulb.

Each Olfactory Bulb Contains Two Symmetric Maps

In mice and rats, each olfactory bulb has two mirror-symmetric maps of odorant receptors, one map in the rostro-dorso-lateral part (lateral map) and the other in the caudo-ventro-medial part (medial map) of the olfactory bulb. A majority of odorant receptors are thus represented by two sites in the glomerular sheet of the olfactory bulb, one site in the lateral map and the other site in the medial map. In contrast, a small group of odorant receptors shows a single glomerulus representation and is represented by the glomeruli at the ventral midline of the olfactory bulb. The functional significance of the dual maps in each olfactory bulb is not well understood yet, although the two maps connect each other topographically via axon collaterals of tufted cells.

Zonal Organization

For a majority of odorant receptors, individual receptors are expressed by sensory neurons that are distributed widely in one of the four zones (zones 1, 2, 3, and 4 from the dorsomedial to the ventrolateral direction) in the olfactory epithelium (Figure 1). Glomeruli in both the lateral and medial maps of the olfactory bulb are arranged in a similar zonal fashion, and axons of olfactory sensory neurons expressing the zone-specific odorant receptors show a zone-to-zone projection pattern. Olfactory sensory neurons in zone 1 (and thus expressing zone 1 odorant receptors) project their axons selectively to zone 1 of the olfactory bulb. Sensory neurons in zones 2–4 project to zones 2–4 of the olfactory bulb.

Several studies related the molecular structure of odorants to the zonal organization of odorant receptor expression in the olfactory epithelium and to the zonal organization of odorant receptor representation in the olfactory bulb. For example, odorants that activate individual glomeruli in zone 1 have one or more polar functional groups in common, suggesting that the polar functional groups play a key role in activating zone 1 odorant receptors and thus zone 1 glomeruli. In contrast, odorants that activate individual glomeruli in zones 2–4 tend to have a similar hydrocarbon profile or relatively nonpolar molecular profiles, suggesting that the overall molecular shape is critical in activating zone 2–4 odorant receptors and zone 2–4 glomeruli.

Glomeruli as Molecular Feature-Detecting Units

When a large panel of odorants with systematic variation of their molecular structure is used to stimulate the olfactory epithelium in the mammalian nose, it is possible to estimate the range of odorants that activate an individual glomerulus. This is called the molecular receptive range (MRR) of the glomerulus. It is also possible to compare the molecular features of odorants that activate an individual glomerulus.

Recent optical imaging studies show that individual glomeruli typically respond to a range of odorants that share a specific combination of molecular features. Different glomeruli show different MRR properties, suggesting that each glomerulus in either the lateral map or the medial map may be unique in its

Figure 1 Axonal projection pattern of olfactory sensory neurons to the glomeruli of the rodent olfactory bulb. The olfactory epithelium in rats and mice is divided into four zones (zones 1–4). A given odorant receptor is expressed by sensory neurons located within one zone of the epithelium. Individual olfactory sensory neurons express a single odorant receptor. Olfactory sensory neurons expressing a given odorant receptor are distributed widely in the epithelial zone and converge their axons onto a few topographically fixed glomeruli that are located within a corresponding zone of the olfactory bulb. Thus, each glomerulus represents a single odorant receptor. The glomerular sheet of the olfactory bulb forms odorant receptor maps. Adapted from Mori K, Takahashi YK, Igarashi KM, and Yamaguchi M (2006) Maps of odorant molecular features in the mammalian olfactory bulb. *Physiology Review* 86: 409–433.

MRR property. The results support the idea that each glomerulus functions as a molecular feature-detecting unit.

Extracellular recording of spike activity from single neurons also shows that individual mitral and tufted cells in the mammalian olfactory bulb respond to a range of odorants that share a specific combination of molecular features. Because individual mitral and tufted cells in the mammalian olfactory bulb project a single primary dendrite to a single glomerulus and receive the olfactory axon inputs exclusively within the glomerulus, the MRR property of individual mitral and tufted cells may strongly reflect that of the affiliated glomerulus.

Thus, individual glomeruli are thought to be molecular feature-detecting modular units, just as individual odorant receptors are thought to be molecular feature-detecting molecular units. How are the molecular feature-detecting units spatially arranged in the glomerular sheet of the olfactory bulb?

Molecular Features of Odorants

Olfaction is mediated by a vast variety of odorants that are inhaled into the nose. To understand the molecular feature maps in the olfactory bulb, it is important to summarize the knowledge of molecular features of odorants. Odorants are small volatile compounds with molecular mass less than 300 Da. It has been estimated that more than 400 000 different compounds are odorous to the human nose. Organic and fragrance/flavor chemists and psychophysicists have documented a variety of relationships between the molecular structure of odorants and their subjectively perceived odor. This is called the structure–odor relationship.

The chemical and psychophysical studies have noted the importance of two categories of odorant molecular features in the structure–odor relationship. One category is a polar functional group that contains an oxygen, a nitrogen, or a sulfur atom. Polar functional groups that have a strong influence on the perceived odor include the carboxyl group (–COOH), aldehyde group (–CHO), hydroxyl group (–OH), ketone group (>CO), ester group (–COO–), amino group ($-NH_2$), and thiol group (–SH), among others. The other category is the molecular profile that is formed mainly by the overall molecular shape.

Combinatorial Coding

In order to spatially map the odorant-induced glomerular activity in the olfactory bulb, a variety of methods have been used. The mapping methods include 2-deoxyglucose uptake, optical imaging with voltage-sensitive dye, electrophysiological single-cell recordings from individual mitral/tufted cells, expression of immediate early genes such as c-fos, c-jun,

zif-268, and activity-regulated cytoskeleton-associated (ARC) genes, optical imaging of intrinsic signals, expression of phosphorylated extracellular signal-regulated kinase (ERK), imaging using pHluorin, and functional magnetic resonance imaging (fMRI).

The results obtained by these methods clearly show that a given odorant activates a specific combination of glomeruli that are located and distributed at stereotypical positions in the olfactory bulb. Different odorants are coded by different combinations of activated glomeruli. For each odorant, activated glomeruli are spatially arranged in a roughly symmetrical fashion across medial and lateral maps.

In summary, each odorant is coded by a specific combination of odorant receptors (molecular feature-detecting receptors), by a specific combination of olfactory sensory neurons (molecular feature-detecting cells), and by a specific combination of glomeruli (molecular feature-detecting modules). In other words, information carried by individual odorants is fractionated according to the odorant receptors that they bind and handled by a specific combination of molecular feature-detecting glomerular modules in the olfactory bulb. The principle of combinatorial coding at the odorant receptor level, olfactory sensory neuron level, and glomerular level is found in the olfactory system of a wide variety of vertebrates and invertebrates.

Molecular Feature Clusters of Glomeruli in the Olfactory Bulb

Comparison of the molecular features of odorants that activate individual glomeruli shows that glomeruli with a similar MRR property are located in proximity and form molecular feature clusters. The molecular feature clusters (also called molecular feature modules or domains) are located at stereotypical positions in the olfactory bulb. Figure 2 shows the spatial arrangement of nine molecular feature clusters (clusters A–I) in the lateral map of the rat olfactory bulb. These clusters were defined by the method of optical imaging of intrinsic signals.

Although different methods define the molecular feature clusters in different ways, the results of these studies are consistent with the idea that glomeruli that detect a similar combination of molecular features gather together in proximity and form molecular feature clusters. The molecular feature clusters are the basic spatial organization and appear to cover virtually all parts of the glomerular maps in the rodent olfactory bulb.

The finding of molecular feature clusters of glomeruli suggests that glomeruli in the same cluster represent odorant receptors having similar MRR properties and thus have similar odorant receptive site structures. This idea is consistent with the evidence that olfactory sensory neurons expressing homologous odorant receptor genes project their axons to neighboring glomeruli. These results suggest cluster-specific grouping and representation of subsets of odorant receptors.

Figure 2 Molecular feature clusters of glomeruli in the dorsal and postero-lateral surfaces of the olfactory bulb. Molecular feature clusters A–D are located in zone 1 of the glomerular map, while clusters F–I are in zones 2–4. Adapted from Mori K, Takahashi YK, Igarashi KM, and Yamaguchi M (2006) Maps of odorant molecular features in the mammalian olfactory bulb. *Physiology Review* 86: 409–433.

The clustering of glomeruli that detect similar molecular features is reported not only in the mammalian olfactory bulb but also in the fish olfactory bulb and even in the *Drosophila* antennal lobe. However, it remains to be determined whether the human olfactory bulb has similar molecular feature clusters of glomeruli.

Molecular Feature Maps

Because each glomerulus appears to be unique in its MRR property, an individual glomerulus can be characterized by determining the specific combination of molecular features that are shared by odorants effective in activating the glomerulus. This is called the characteristic molecular feature of a glomerulus. By superimposing the three-dimensional structure of odorants that are effective in activating a glomerulus, it is possible to deduce the characteristic molecular features of the glomerulus.

Although the detailed analysis is limited to only a small part in the glomerular maps, comparison of the characteristic molecular features of individual glomeruli along the axes of the glomerular maps

suggests that the glomerular sheet represents the characteristic molecular features in a systematic, gradual, and multidimensional fashion.

Representation of Basic Odor Quality

Odorants having a similar combination of molecular features tend to have a similar odor quality to the human nose. Because glomeruli with a similar MRR property form a molecular feature cluster in the mammalian olfactory bulb, molecular feature clusters might also be present in the human olfactory bulb and are part of the neural representation of basic odor quality.

Glomeruli in cluster C (Figure 2) in the rat olfactory bulb, for example, respond to phenol family odorants and phenyl ethers. These odorants share the molecular features composed of a benzene ring with a hydroxyl group or an alkoxyl group. To the human nose, these odorants contain phenolic and medicinal odor in common. This suggests that cluster C glomeruli, if present in the human olfactory bulb, may participate in the representation of phenolic and medicinal odor quality.

The idea that the molecular feature clusters in the olfactory bulb may participate in the neuronal representation of basic odor quality raises the issue of whether parosmia, smelling something other than the presented odor, might in part originate from the distorted maps in the human olfactory bulb or abnormal activity in it.

Functional Roles of Molecular Feature Maps

In addition to the possible participation in the perception of basic odor quality, the spatial arrangement of the molecular feature maps is critical in determining the manner of interactions among olfactory bulb neurons that are affiliated with different glomeruli. In the mammalian olfactory bulb, an individual glomerulus is innervated by several thousands of converging olfactory axons, ~10–20 mitral cells, and ~50–70 tufted cells.

Mitral/tufted cells affiliated with a particular glomerulus can interact with those affiliated with different glomeruli via local neuronal circuits in the olfactory bulb. One of the major local neuronal circuits involves dendrodendritic reciprocal synaptic connections between the long secondary dendrites of mitral/tufted cells and apical dendrites of granule cells. Another major local circuit involves juxtaglomerular interneurons.

First, mitral/tufted cells associated with a glomerulus in a particular molecular feature cluster can interact with those associated with neighboring glomeruli in the same cluster. In the cluster A of the rabbit olfactory bulb, for example, individual mitral cells are activated by a range of fatty acids with different carbon chain lengths. In addition, individual mitral cells are typically inhibited by fatty acids with carbon chain lengths slightly longer or slightly shorter than the effective odorants. The tuning of individual mitral cells to odorant molecular features is thus enhanced by the lateral inhibition from mitral cells associated with neighboring glomeruli.

Interaction among mitral cells associated with different molecular feature clusters is also observed in the rat olfactory bulb. Alkylamines that are generated by spoiled foods have an unpleasant fatty fishy odor and activate glomeruli in cluster A. Herb spices such as fennel and clove activate glomeruli in the neighboring molecular feature clusters and temporally inhibit the alkylamine-induced response of mitral cells in cluster A. Because fennel and clove are known to mask the fatty fishy smell as well as to add their own flavor, the masking of fatty fishy odor may be mediated at least in part by the lateral inhibition among mitral/tufted cells associated with different molecular feature clusters in the odor maps.

The local neuronal circuits are known to mediate synchronized oscillatory activity among mitral cells associated with different glomeruli. Because the synchronized oscillatory activity may be crucial in activating olfactory cortex neurons to which mitral cell axons project, the molecular feature maps provide the substrate for the local neuronal circuits to select specific subsets of mitral cells for the synchronization.

Olfactory Cortex Reads the Odor Maps in the Olfactory Bulb

Mitral cells project their axons via the lateral olfactory tract to various regions of the olfactory cortex. Recent studies show that mitral cells receiving input from a given odorant receptor (and thus associated with a few specific glomeruli) project their axons to specific clusters of olfactory cortex neurons that are arranged at stereotypical positions. Individual olfactory cortex neurons appear to receive inputs from multiple different odorant receptors and thus from multiple different glomeruli. However, it is not well understood how individual olfactory cortex neurons integrate signals derived from multiple different odorant receptors and thus from multiple different glomeruli. The knowledge of the molecular feature maps in the olfactory bulb may provide a basis for understanding how the olfactory cortex reads the odor maps in the olfactory bulb.

Introduction

The olfactory bulb is the first processing station in the central olfactory pathway. It receives olfactory nerve input from the sensory epithelium in the nose and sends mitral/tufted cell axonal output to the olfactory cortex. One critical determinant of olfactory bulb function is the nose-to-bulb projection. Olfactory sensory neurons expressing a given odor receptor gene project their axons into two or very few specific spherical structures called olfactory glomeruli. Such a unique sensory projection indicates that the glomerulus is a basic coding unit for olfactory signals. A single odorant activates one set of glomeruli that are distributed widely across the olfactory bulb surface. Different odorants activate distinct but overlapping sets of glomeruli. Thus, a central function of the olfactory bulb is to process odor coding patterns and relay processed odor codes to the higher olfactory brain centers.

Odor processing starts at the level of the olfactory glomerulus. Besides olfactory nerve terminals, the glomerulus is surrounded by hundreds of juxtaglomerular cells. It also receives dendritic projections from tens of mitral/tufted cells located more deeply. As mitral/tufted cells (and most juxtaglomerular cells) send their dendrites into only a single glomerulus for receiving olfactory nerve input, a glomerulus and its associated mitral/tufted and juxtaglomerular cells form a functional module. Thousands of glomerular modules serve as parallel channels for relaying odor signals throughout the olfactory bulb to the piriform cortex. Between these vertical or radial modules are two levels of horizontal circuits mediating lateral intermodular interactions. One is via short-axon cells in the glomerular layer, and the other is through mitral/tufted cell basal secondary dendrites in the external plexiform layer.

Radial Glomerular Modules

In a glomerular module, odor signals are transmitted from olfactory nerve terminals to distal dendritic tufts of mitral/tufted cells in the glomerulus and then from these glomerular tufts to the mitral/tufted cell soma–axon region via apical primary dendrites.

Olfactory Nerve Synapses

Olfactory nerve terminals make excitatory synapses with mitral/tufted cells and certain types of juxtaglomerular cells. These synapses are glutamatergic, and postsynaptic effects involve α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and *N*-methyl-D-aspartate (NMDA) receptors as well as metabotropic glutamate receptors. Transmitter release is highly reliable at these terminals, with a release probability of ≥ 0.8 and a linear dependence on extracellular calcium concentration. The synapses show strong paired pulse depression due to presynaptic activation of γ-aminobutyric acid (GABA) class-B ($GABA_B$) receptors and dopamine D_2 receptors by GABA and dopamine released from juxtaglomerular cells. Therefore, monosynaptic and disynaptic activation of GABAergic and dopaminergic juxtaglomerular cells can provide feedback inhibition onto olfactory nerve terminals (**Figure 1(a)**, upper-left inset).

The mitral cell response to olfactory nerve electric stimulation usually exhibits a long-lasting excitatory postsynaptic potential that is mediated by AMPA, NMDA, and type-1 metabotropic glutamate receptors. This process is initially triggered by release of glutamate from olfactory axon terminals and then prolonged by secondary and regenerative glutamate release from excited mitral/tufted-cell dendrodendritic synapses in the glomerulus. Such recurrent excitation further involves glutamate spillover within a glomerulus (**Figure 1(a)**, lower-left and upper-right insets). One likely function for these mechanisms is to amplify weak olfactory input. They are also involved in coordinating intraglomerular neuronal synchrony, as described further below in the section titled 'Intraglomerular microcircuits.'

Mitral Cell Apical Primary Dendrite

In the olfactory bulb, mitral/tufted cells are projection neurons sending axonal output to the olfactory cortex. Each mitral cell extends one apical primary dendrite superficially into a single glomerulus to form a tuft of branches containing both post- and presynaptic sites. Odor signal transmission from the glomerulus to the mitral cell soma–axon region is mediated by both passive spread of synaptic potentials and active propagation of action potentials along this dendrite. Dual-patch recordings made simultaneously from the mitral cell soma and distal primary dendrite have revealed that mitral cells possess some unique dendritic properties compared with other types of central neurons.

Figure 1 (a) Intraglomerular circuits. Upper-left circular inset, γ-aminobutyric acid (GABA) or dopamine released from periglomerular cells can act presynaptically via GABA$_B$ and dopamine D$_2$ receptors on olfactory nerve terminals to inhibit olfactory sensory input. Lower-left inset, a mitral cell glomerular dendritic branch releases glutamate to excite an inhibitory periglomerular cell dendrite, which in turn releases GABA back onto the mitral cell dendrite. Glutamate released from the mitral cell tuft branch can also act on autoreceptors, causing further regenerative release of glutamate. (Upper-right) Glutamate released from one mitral cell dendritic branch spills over to another mitral cell dendrite, causing lateral excitation. (Lower-right) Glutamate released from one mitral cell dendrite acts on autoreceptors, causing self-excitation which spreads into another mitral cell dendrite via electrical coupling to mediate lateral excitation. (b) Interglomerular circuits. Mitral cells, external tufted cells, and subpopulations of periglomerular cells receive monosynaptic inputs from olfactory nerve terminals. Excitation of GABAergic and dopaminergic periglomerular cells can inhibit olfactory nerve input by a presynaptic mechanism. Both mitral and external tufted cells can excite periglomerular cells, which can provide recurrent inhibition. The external tufted cell excites the short-axon cell, which in turn activates the GABAergic periglomerular cell in another glomerulus, causing interglomerular lateral inhibition. Adapted from Carlson GC, Shipley MT, and Keller A (2000) Long-lasting depolarizations in mitral cells of the rat olfactory bulb. *Journal of Neuroscience* 20: 2011–2021.

There are four different modes of action potential initiation and propagation along the mitral cell soma–primary dendrite axis (Figure 2).

With weak to moderate excitation of the mitral cell glomerular dendrites by olfactory nerve input, odor signals are first transmitted along the primary dendrite in the form of passive spread of postsynaptic potentials. Once this input drives the membrane potential reaching the firing threshold, an action potential is initiated in the axon initial segment and propagates forward down the axon to the olfactory cortex and backward into both the primary and secondary dendrites (Figure 2(a)). Increasing olfactory nerve synaptic excitation shifts the spike initiation site from the axon initial segment to the glomerular tuft branches, and in this case signal transmission takes form of forward spike propagation along the primary dendrite to the mitral cell soma and axon (Figure 2(b)). When strong olfactory nerve input is paired with strong synaptic inhibition near the cell body, an action potential is initiated in the distal primary dendrite but fails to propagate forward to the soma. This transforms the mitral cell from a projection neuron to a local interneuron producing dendrodendritic synaptic

Figure 2 Four different modes of action potential initiation and propagation along the mitral cell apical primary dendrite. (Top row) Dual-patch recordings from the mitral cell soma and distal primary dendrite in response to increasing olfactory nerve input from (a) to (b) (left) and to pairing a strong olfactory nerve input with granule cell inhibition evoked at different time intervals (right). output only within an olfactory glomerulus (Figure 2 (c)). With strong distal excitation paired with intermediate proximal inhibition, an action potential is initiated in the glomerular tuft. In the course of forward propagation, the spike jumps to the axon initial segment to generate a mitral cell axonal output and meanwhile to induce a spike back-propagation (Figure 2(d)).

These four different modes of spike initiation and propagation indicate that odor signal transmission within a vertical glomerular module is subject to modulation by lateral inhibitory synaptic circuits and that an odor map is not always faithfully transferred from the glomerular plane down to the mitral cell soma layer. Significant coding pattern transformation can occur within the olfactory bulb.

Intraglomerular Microcircuits

In each glomerular module, olfactory signals are relayed to about 20–30 mitral/tufted cells. The activity of these output neurons is coordinated by several intraglomerular mechanisms. First, surrounding a glomerulus are hundreds of juxtaglomerular neurons, which are heterogeneous and include external tufted, periglomerular, and short-axon cells. External tufted cells receive monosynaptic input from olfactory nerve terminals. They have unique intrinsic membrane properties that generate long-lasting depolarization plateau potentials and spike bursts. These neurons provide strong excitatory dendritic output to other neurons within the glomerulus and appear to play a key role in synchronizing the entire glomerular circuit. Second, mitral cells sharing a common glomerulus are connected by electrical coupling via gap junctions located in their glomerular dendritic branches (Figure 1(a), lower-right inset). This mechanism ensures that all principal neurons of a glomerular module can respond to sensory inputs synergistically as a single unit. Third, the glomerular dendritic tufts of mitral/tufted cells carry glutamate autoreceptors in their presynaptic membrane, which can mediate regenerative release of glutamate from these dendrites and eventually lead to glutamate spillover and intraglomerular neuronal synchrony (Figure 1(c)). As the glomerulus is a chemical compartment isolated by surrounding glial cells, glutamate spillover-mediated synchrony is specific to each glomerulus, which futher consolidates individual glomeruli as functional units.

In vivo olfactory bulb physiology reveals that mitral/tufted cells usually show two different timescales of synchronized activity. One is related to slow oscillations that are phase locked with animal respiratory cycles, and the other involves spike synchrony with a temporal precision less than 10 ms. Both forms of synchrony can happen among the cells either sharing a common glomerulus or belonging to different glomeruli. The mechanisms for interglomerular synchrony are described in the next section.

Lateral Interglomerular Circuits

As olfactory signals generated by a single odorant are usually distributed in multiple parallel glomerular modules, lateral interglomerular interactions are crucial for both synthesizing a unified odor percept and discriminating between different odorants. Such lateral interaction occurs in two distinct layers, the glomerular layer and external plexiform layer, each of which may represent a different processing stage.

Short-Axon Cells in the Glomerular Layer

Although neuronal circuits in the glomerular layer are mostly oriented to individual glomeruli, at least one type of neuron – the short-axon cell – presents an exception. In contrast to their name, these neurons give rise to a rich and extensive axonal plexus, which projects to multiple glomeruli located up to several hundred microns away (Figure 1(b), upper panel). The short-axon cells do not receive monosynaptic input from olfactory nerve terminals but are instead excited disynaptically via external tufted cells. The short-axon cells are considered to be glutamatergic in some studies and provide an excitatory synaptic input to periglomerular and external tufted cells in other glomeruli (Figure 1(b), lower panel).

The extensive innervation of individual short-axon cells gives rise to a long-range lateral circuit within the glomerular layer. The signal flow of this circuit is from olfactory nerve terminals to external tufted cells to short-axon cells in one glomerulus, and then through their axonal network to periglomerular cells and further to mitral cells in another distally located glomerulus. Many periglomerular cells are inhibitory, so strong activation of one glomerulus can lead to inhibition of mitral-cell tufts in other weakly activated glomeruli via this lateral circuit, yielding lateral inhibition in the glomerular layer.

Dendrodendritic Reciprocal Synapses

Just deep to the glomerular layer lies the external plexiform layer. Each mitral cell extends several lateral secondary dendrites in this layer over a long distance (>1000 μm). One unique feature of olfactory bulb circuits is reciprocal synapses between these secondary dendrites and dendritic spines of axonless granule cell interneurons. The mitral cell dendrite releases glutamate, activating both AMPA and NMDA receptors in the granule cell spine, which in turn release GABA back onto the mitral cell dendrite, causing $GABA_A$ receptor-mediated feedback or recurrent inhibition

Figure 3 Olfactory bulb dendrodendritic reciprocal synapses mediate mitral cell recurrent and lateral inhibition. (a) Pair recordings from two mitral cells. A depolarization pulse in Cell 1 induced a feedback inhibitory current in Cell 1 and also a lateral inhibitory current in Cell 2, both of which are reversibly blocked by an *N*-methyl-D-aspartate (NMDA) receptor antagonist (APV). (b) A diagram illustrating signal flow underlying recurrent and lateral inhibition. AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; GC, granule cell; Glu, glutamate, $GABA_A$, γ-aminobutyric acid class-A receptor; MC, mitral cell. Dashed-line arrow, Ca^{2+} diffusion; solid-line arrow, spread-out of postsynaptic depolarization potential. (Figure 3(a)). The feedback GABA release depends critically on the activation of NMDA rather than AMPA receptors, indicating that calcium influx through NMDA receptors can provide a direct route for triggering presynaptic transmitter release (Figure 3(b)). As different spines of a granule cell usually contact dendrites from different mitral cells, spread of excitatory postsynaptic potentials among these spines can lead to lateral inhibition between mitral cell pairs (Figure 3). Besides mediating feedback and lateral inhibition, the mitral–granule cell reciprocal synapses have been considered as the key loci for storage of odor memory. The dominant role of NMDA receptors at these synapses may confer on them an extraordinary capacity for plasticity.

Mitral Cell Basal Secondary Dendrites

The long extension of mitral cell secondary dendrites presents an anatomical basis for one glomerular module to interact laterally with hundreds of other modules in the olfactory bulb. This interaction is mediated by spike propagation along these dendrites. Unlike most other central neurons, mitral cells possess membrane mechanisms that can support active propagation of fast sodium spikes from the cell body all the way to the distal ends of secondary dendrites (Figure 4(a)). During such propagation, action potentials trigger dendritic release of glutamate to activate the mitral-to-granule cell dendrodendritic synapses. On the other hand, inhibitory granule-to-mitral cell synapses, activated either by other mitral cells or via centrifugal fibers, can block spike propagation dynamically at variable distances from the soma (Figures 4(b) and 4(c)). Such an interaction between spike propagation and dendrodendritic synaptic activation leads to the emergence of functional domains in the mitral cell secondary dendrites, which can expand and contract dynamically to provide a circuit mechanism for coupling and decoupling different sets of glomerular modules for the processing of different odorants.

Figure 4 (a) An action potential can propagate actively throughout the entire length of a mitral cell (Mi) secondary dendrite. (b, c) Granule cell (Gr) inhibitory synaptic inputs along the secondary dendrite can dynamically gate spike propagation and thus determine the spatial activation range of mitral-to-granule cell dendrodendritic synpases. Granule Cell Dendritic Signal Integration

As axonless interneurons in the olfactory bulb, granule cells extend their spiny dendrites perpendicularly with respect to mitral cell secondary dendrites, establishing the dendrodendritic reciprocal synapses at the site of contact. Although the horizontal span of dendritic branches is only about the dimension of one or two glomeruli, these cells receive excitatory synaptic inputs via mitral cell lateral dendrites from a wide range of glomerular modules and display a much broader odor tuning property than mitral cells do. For each granule cell, there are approximately a couple hundred spines, on which the reciprocal synapses rest. Both experimental and computational analyses have revealed that at least three different levels of processing can take place within a granule cell.

The first level of processing is confined to individual spines and mediates short-circuit recurrent inhibition of a connected mitral cell partner (Figure 3(b)). The second level is mediated by local spread of excitatory postsynaptic potentials out of originally activated spines into neighboring dendrites and spines. This

Figure 5 (Left) A granule cell morphology revealed by Golgi silver staining. (Right) A computational model based on morphometric data obtained from the cell shown on the left. A fast conductance simulating excitatory synaptic input is activated in each one of the seven dendritic spines, as denoted by 'SHxxx.' Each shaded area indicates a dendritic domain in which the steady state voltage differs by no more than 5% from the input spine, and all spines within such a domain are considered a functional cluster. Adapted from Woolf TB, Shepherd GM, and Greer CA (1990) Local information processing in dendritic trees: Subsets of spines in granule cells of the mammalian olfactory bulb. *Journal of Neuroscience* 11: 1837–1854.

spread of depolarizing potentials sums up enough depolarization to trigger GABA release synergistically from a cluster of spines (Figure 5) without raising the granule cell soma above its firing threshould. This local dendritic mechanism can mediate lateral inhibition between different mitral cells connected to the spine cluster. Due to the cable filtering effect, the NMDA receptor-mediated slow synaptic potential is more effective than the fast AMPA component in dendritic transmission and summation (Figure 3(b)). This renders the lateral inhibition also dependent critically on NMDA receptor activation. The third level of processing requires the summation of excitatory synaptic inputs from a wide range of spines for spike initiation. The action potential can subsequently propagate throughout the entire granule cell dendrites to generate a global inhibitory output to all connected mitral cells.

Such multilevel processing can be further extended by an inactivating A-type potassium current and a low-threshold calcium current. The A current in granule cell dendrites can specifically suppress AMPA receptor-mediated fast synaptic potential and thus operate as a temporal filter that delays spike initiation and enables NMDA receptors to set a slow pace for GABA release. The low-threshold calcium spike, on the other hand, can mediate in granule cells a new scale of inhibition that operates in a membrane potential range below the threshold for sodium spike generation. In addition, these different modes of processing in granule cells can be dynamically modulated by GABAergic inputs from Blanes cells distributed in the granule cell layer.

Functions of Lateral Inhibition

As in the visual and other sensory systems, lateral inhibition in the olfactory bulb can provide a mechanism to enhance the contrast of spatial coding patterns of similar odorants. In response to a homologous series of aliphatic aldehydes, the mitral cell odor-tuning curve is usually sharpened by lateral inhibition into a configuration of center excitation and surround inhibition (Figure 6).

Another possible function for olfactory lateral circuits is to mediate oscillatory firing synchrony among mitral cells connected either to a common glomerulus or to a group of coactivated glomeruli. One

Figure 6 (a) Single-unit recordings of a mitral cell in response to a homologous series of aliphatic aldehydes. The lowest trace records animal respiratory cycles, and the horizontal bar indicates the timing of odor delivery. This mitral cell fired spontaneously in each respiratory cycle. Aldehydes of five- to seven-carbon-chain length significantly increased its firing frequency, while four- or eight-carbon-chain aldehydes inhibited this cell from spiking. (b) A diagram illustrating possible circuit mechanisms that contribute to the sharpening of mitral cell odor-tuning specificity. On the right, different tuning curves of three glomeruli (A–C), reflecting different odor molecular receptive ranges of the receptor cell populations that project to them. The granule cell-mediated lateral inhibition sharpens the mitral cell tuning properties (D). GL, glomerulus; GR, granule cell; M/T, mitral/tufted cell; ORN, olfactory receptor neuron. prominent feature of the olfactory system is the use of a combinatorial coding strategy. A single odorant is represented by multiple widely distributed glomeruli, and different odorants activate distinct but overlapping sets of glomeruli. Neuronal synchrony, orchestrated by lateral inhibition, can function as an association signal to 'bind' such a distributed combinatorial code for synthesizing a unitary odor percept.

Centrifugal Modulation

In addition to odor processing via vertical and horizontal circuits, the olfactory bulb receives centrifugal inputs from various brain regions. These centrifugal projections are charterized by several different transmitter systems, including noradrenergic fibers from locus coeruleus, cholinergic and GABAergic inputs from the horizontal limb of the diagonal band of Broca, serotoninergic axons from raphe nuclei, and glutamatergic projections from the olfactory cortex. This indicates that odor processing in the bulb is subject to modulation by signals from higher-order olfactory centers as well as nonolfactory subcortical modulatory systems.

Centrifugal fibers from the olfactory cortex terminate mostly in the granule cell layer. They form excitatory synapses on granule cells, and may thus promote inhibition of mitral cell activity via dendrodendritic synapses as described above. The function of this long-loop feedback remains to be established. One of these projection systems may mediate bilateral interbulbar interactions. The tufted cells from one side of the olfactory bulb project to the ipsilateral anterior olfactory nucleus, which sends pyramidal cell axons topographically to the other bulb via the anterior commissure.

Nonolfactory subcortical systems project differentially to the olfactory bulb. Noradrenaline-containing fibers innervate mainly the granule cell and external plexiform layers, whereas the glomerular layer is nearly devoid of adrenergic input. The action of noradrenaline in the olfactory bulb is complicated. It can directly excite mitral cells via α_1 receptors. Meanwhile, it acts on α_2 receptors to suppress GABA release from granule cell spines and thus indirectly enhances mitral cell excitability. When the locus coeruleus is activated by novel or unanticipated events, noradrenaline leads to a transient increase in mitral cell sensitivity to weak odor stimuli. Both serotonin- and acetylcholine-containing fibers have a dense innervation within the glomerular layer. They also exhibit complicated modulatory actions on the olfactory bulb circuits. All these three modulators are critically involved in several forms of olfactory learning and memory, such as odor preference memory and maternal recognition of newborn pups.

Parallel Olfactory Pathways

The vertebrate olfactory bulb is not a homogeneous structure but is instead composed of several subsystems. The main olfactory bulb receives regular sensory input from the main olfactory epithelium, while the accessory olfactory bulb receives pheromone signals from the vomeronasal organ. In addition, the main olfactory bulb can be further divided at least into the regular glomerular system and necklace glomerular system on the basis of different olfactory signal transduction mechanisms employed in their respective sensory neurons. These different subsystems constitute parallel pathways for processing different types of odor signals.

In addition to these parallel pathways defined by separate sensory inputs, the mitral and tufted cell populations represent another set of parallel pathways based on their different intrabulbar circuits. Compared with the mitral cells, the tufted cell bodies are located more superficially, their lateral dendrites extending for a shorter distance, and their axonal projections more confined to the anterior part of the olfactory cortex. Within the main olfactory bulb, there appear to be at least three different populations of granule cells. Those with their soma located superficially in the granule cell layer tend to make reciprocal synapses with the tufted cells, while those deeply located establish synaptic contacts primarily with the mitral cells. The intermediate granule cells interact with both mitral and tufted cells. These two parallel pathways, even sharing inputs from a common glomerulus, may process different aspects of odor signals. The tufted cells, because of their relatively smaller size and higher input resistance, may be more sensitive to weak odor stimuli. On the other hand, their lateral circuits are less extensive than those of mitral cells. Accordingly, the tufted cell pathway may have high odor sensitivity but low discriminability for odorants with similar molecular structures.

A third set of parallel pathways comprises mirror glomeruli in the olfactory bulb. Sensory neurons expressing a given olfactory receptor usually project their axons to two glomeruli located on the medial and lateral sides, and thus each bulb possesses two identical sets of glomeruli. The functional significance of such duplication is not clear. It is interesting that these two sets of glomerular modules have point-to-point mutual inhibitory connections. The superficial tufted cells of one glomerulus project their axon collaterals to the other side, terminating in the internal plexiform layer right below the corresponding mirror glomerulus. These axon terminals make excitatory synapses with inhibitory granule cells and presumably mediate inhibition between the mirror glomeruli.

Circuit Rewiring via Adult Neurogenesis

Throughout the entire life span, sensory neurons in the nasal epithelium and interneurons in the olfactory bulb are continually replaced by newborn neurons every 3–6 months. One major function of adult neurogenesis in the olfactory bulb is to allow plasticity in already mature and relatively fixed circuits. For example, sensory deprivation can dramatically decrease the number, dendritic length, and spine density of newborn granule cells whereas preexisting granule cells show few morphological changes. Bulbar neurogenesis may also represent an adaptive mechanism to ever-changing olfactory peripheral input, which is due to the noxious environment exposed to sensory epithelium. Given such a continuous rewiring of olfactory neuronal circuits, it remains to be explored how odor perceptual constancy is maintained.

Introduction

Olfactory circuitry provides unique advantages for the analysis of information processing by neurons. The task of olfaction is challenging; it demands the ability to rapidly detect, identify, categorize, and prepare for memory storage of myriad odorants that vary in molecular structure and concentration. Yet, olfaction is achieved by relatively few layers of neurons, with anatomical structures and physiological mechanisms that appear repeatedly in widely divergent species. Thus, a study of olfaction offers the promise of insight into a successful and perhaps optimal biological algorithm for processing complex information. Theoretical and computational approaches have contributed substantially toward understanding the functions of olfactory circuitry.

Much current thinking about olfactory processing has been shaped by the compelling observation that the projections of olfactory receptor neurons delineate spatial maps within the olfactory bulb: histological and *in situ* hybridization studies demonstrate convincingly that receptor neurons expressing the same receptor gene converge on a small and specific subset of glomeruli. Based on these observations and on electrophysiological evidence, a model of olfactory information processing has emerged that proposes that individual structural features of odorants are recognized by different receptor neurons, each expressing a specific receptor gene, and that each receptor cell responds to many odorants sharing the same structural features. According to one version of this model, each odorant elicits responses from, and is thus represented by, a more or less static map – a unique spatial ensemble of activated glomeruli.

In addition to such results, a variety of experimental approaches have revealed that olfactory neurons (and those of other sensory systems as well) respond to a static stimulus with oscillatory and temporally structured responses. An example of temporal structure in responses of the olfactory system is the relatively slow, complex sequences of excitation and inhibition in olfactory neurons superimposed on stimulus-evoked oscillations. These patterns have been observed in neurons of the olfactory bulb of amphibians and mammals and within the antennal lobe of insects. In the locust olfactory system, these slow temporal firing patterns generally vary with the odor, and they are reproducible over repeated trials. Intracellular recordings made *in vivo* from locust antennal lobe projection neurons (PNs) have also revealed that individual PNs transiently phase-lock with population oscillations at times that vary with the stimulus. Thus, there is a fine temporal structure to the timing of PN action potentials within the population response that is stable over trials and is different for different PNs. This temporal structure appears to arise mainly from circuit interactions within the antennal lobe. Evidence for odor-evoked spatiotemporal patterns of neuronal activity is not unique to the insect; in salamander olfactory bulb complex spatiotemporal patterns of activity were revealed by voltage-sensitive dye imaging. Recordings from the turtle olfactory bulb have revealed that different assemblies of cells are activated during different cycles of field oscillations, supporting the hypothesis that odors are encoded by spatiotemporal patterns. Thus, the antennal lobe and olfactory lobe appear to process, or reformat, the olfactory information from a diverse population of receptors into a spatiotemporal code.

In vertebrates, output fibers from olfactory bulb neurons project onward to another level of processing in the olfactory (piriform) cortex. In insects, odor information processed in the antennal lobe is transferred to the mushroom body, a structure analogous to the olfactory cortex, and one important for memory formation. Normal cyclic AMP signaling specifically in mushroom body neurons is required for olfactory learning. In honeybees, mecamylamine injection into the mushroom body calyces strongly impaired olfactory learning, suggesting that the cholinergic network in the mushroom body is involved in memory formation. Genetic studies indicate that synaptic transmission from mushroom body neurons is required during memory retrieval but not during memory acquisition or storage. This indicates that acquisition and storage of olfactory memory may both occur upstream of synaptic transmission from the mushroom body, and it suggests that processes contributing to associative learning may reside within mushroom body neurons.

Whatever strategies the antennal lobe or olfactory bulb employs for encoding odors, its follower mushroom body, olfactory cortex, or other circuitry should be able to decode and categorize the information it receives. Therefore, it is of great interest to explore how odor decoding strategies at the downstream levels (mushroom body or olfactory cortex) match the encoding achieved at the first olfactory relay

(antennal lobe and olfactory bulb), providing efficient and optimal odor information processing. In this article, we discuss these coding strategies and specifically emphasize the use of computer models to test several interesting hypotheses of odor encoding and processing.

Encoding Olfactory Information at the First Olfactory Relay

The relative simplicity of the invertebrate olfactory system makes it an attractive system for theoretical and computational studies of olfactory coding. In the locust, each antenna contains approximately 50 000 cholinergic olfactory receptor neurons (numbers range from 2000 to 350 000 in different insect species) that send their axons to the ipsilateral antennal lobe. There, each axon terminates in a few glomeruli, where it forms synapses with the dendrites of GABAergic local neurons (LNs; ~300 in locust) and cholinergic projection neurons (PNs; ~830 in locust). PNs provide the only pathway for olfactory information from the antennal lobe. The number of glomeruli varies among insect species (e.g., from ~50 in *Drosophila melanogaster* to ~1000 in locust). Within the antennal lobe, PN projections can be mainly uniglomerular (e.g., *D. melanogaster*, bee, and cockroach) or multiglomerular (e.g., locust and wasp). Each PN makes connections with a large fraction of LNs, and each LN connects with many PNs as well as with other LNs.

PNs of the antennal lobe provide olfactory input to the mushroom body. In the locust, each mushroom body contains approximately 50 000 Kenyon cells (KCs). In addition to the direct excitatory input from PNs, the KCs of the locust mushroom body also receive competitive, inhibitory input, provided by lateral horn interneurons, which are themselves driven by PNs.

To a remarkable extent, the antennal lobe shares many features with the vertebrate olfactory bulb (OB). Similar to LN–PN circuitry of the antennal lobe, the OB includes interacting excitatory mitral cells and inhibitory granular cells. Lateral inhibition has been reported between granule/periglomerular cells of OB. Axons of the mitral cells project to the olfactory cortex, where they make connections with pyramidal cells and inhibitory interneurons that provide feed-forward inhibition to the pyramidal neurons. The anatomy and functions of OB circuitry are under intensive study.

In this article, we focus on computational approaches to olfactory coding in the insect olfactory system, emphasizing, when possible, similarities to the vertebrate system.

Oscillations and Fine Temporal Structure of Spiking in Olfactory Neurons

The presence of odor-elicited oscillations in the olfactory systems of many animals including insects suggests that oscillatory neural synchrony may play a fundamental role in odor encoding. A number of experimental results provide strong support for this idea. In the locust, pharmacologically blocking the inhibitory $GABA_A$ receptors in the antennal lobe by locally injecting picrotoxin eliminates the 20 Hz oscillations and leads to a breakdown in the specificity of odor responses in beta lobe interneurons, which are followers of KCs. Furthermore, behavioral experiments with honeybees demonstrate that oscillatory synchronization of the antennal lobe neurons is needed for fine odor discrimination; picrotoxin-induced antennal lobe desynchronization causes a loss of precise odor discrimination. Similarly, suppressing synchronous oscillations in the procerebral lobe of the terrestrial slug *Limax* by blocking nitric oxide with L-NAME impairs the animal's ability to discriminate between similar odorants.

In insects, physiological studies in which $GABA_A$ receptors were blocked with picrotoxin indicate that fast feedback inhibition within the antennal lobe is essential for the generation of network oscillations during odor stimulation. Also, similar roles for feedback inhibition mediated by local interneurons have been established for many well-investigated brain models, including those for cortical and hippocampal gamma oscillations. In these models of synchronized network oscillations, spikes in excitatory cells trigger spikes in postsynaptic inhibitory neurons, whose spikes in turn produce inhibitory postsynaptic potentials in excitatory cells. This inhibition systematically delays and synchronizes the generation of the next excitatory response, thereby creating widespread network oscillations. The frequency of the oscillations depends on the time constant of inhibition and synaptic conductance strength. **Figure 1** presents an example of periodic oscillations recorded *in vivo* from the locust antennal lobe (**Figure 1(a)**) and comparable oscillations simulated by a computational network model of the antennal lobe (**Figure 1(c)**) that includes populations of randomly connected PNs and LNs stimulated by an external input (**Figure 1(b)**). The oscillations in the model were triggered by a constant (except for low-amplitude additive noise) depolarizing input to an odor-specific subset of antennal lobe neurons (**Figure 1(b)**) and were mediated by excitatory–inhibitory connections between PNs and LNs.

Oscillation-generating networks in a variety of species have been studied with computational models. Typically, the emergence of synchronized oscillations has been shown to depend on fast feedback inhibition

Figure 1 Synchronization of PN responses in the antennal lobe. (a) Typical odor responses recorded *in vivo*. Odor stimulation evoked oscillations in the local field potential (top, recorded in the mushroom bodies) and action potentials in a PN (bottom). (b) Antennal lobe model. (c) Averaged PN activity (LFP) in the model shows periodic oscillations at approximately 20 Hz during stimulation. (d) For each PN, standard deviation of PN spike phases across trials plotted against the total number of LN spikes in all presynaptic LNs. Adapted from Bazhenov M, Stopfer M, Rabinovich M, et al. (2001) Model of transient synchronization in the locust antennal lobe. *Neuron* 30: 553–567, with permission from Elsevier.

within a circuit. Ermentrout and colleagues described stimulus-evoked synchronization of olfactory neurons in a model of the *Limax* olfactory lobe that requires input from inhibitory interneurons. A model of spike synchronization in the honeybee antennal lobe, also dependent on local inhibition, has been proposed by Linster and Cleland to explain the experimentally observed impairment of sensory discrimination when inhibition is blocked. Also, a role for inhibition in memory formation in the *Limax* olfactory lobe has been proposed by Ermentrout and colleagues. In this model, global inhibitory connections between oscillating cells were proposed to suppress activity in all but a small population of neurons, thus forming a single and unique 'memory band.' In this model, odor localization was transient and became possible only after the network activity was synchronized.

Interestingly, antennal lobe oscillations are generally not evoked by the first presentation of an odorant. As shown by Stopfer and Laurent, oscillations emerge gradually during the course of multiple encounters with a given odorant, provided the encounters occur close together in time. Electrophysiological and computational evidence suggests that the gradual increase in oscillatory synchronization results from activity-dependent neural plasticity within the antennal lobe. Models of this mechanism proposed by Bazhenov and colleagues indicate that this plasticity, when engaged by repeating odor stimuli (as often occurs in nature), achieves robust stability against noise. Such stability is essential in a neural system that works to amplify small differences in input patterns.

Odor-induced oscillatory activity in the gamma (30–60 Hz) frequency range has been described in many mammals, including primates. Despite intensive studies, the primary mechanism for generating these oscillations is unclear. Olfactory bulb circuitry includes feedback inhibition mediated by granule cells. Interactions between granule and mitral cells in the OB appear to resemble those between the PNs and LNs of the insect antennal lobe. A number of computational models support the idea that excitatory–inhibitory interactions between mitral cells and granule cells could underlie gamma oscillations in the OB. This hypothesis is also supported by recordings from OB neurons under conditions that mimic natural odor stimuli. Electrical coupling between mitral cells whose primary dendrites form

synapses within the same glomeruli appears to enhance the synchrony of mitral cell oscillations. However, important questions remain. The relatively slow decay time of inhibition from granule cells may not be consistent with the synchronization underlying fast oscillations observed in mitral cells. A different type of model suggests that aperiodic but correlated input from widely branching granule cells could provide for the synchronization of mitral cells. Galan and colleagues showed that the slow inhibition from granule cells can lead to the synchronization of mitral cells in the gamma frequency range when partially correlated aperiodic fluctuations are fast and mitral cells fire at a rate that is roughly constant.

Computational modeling work has led to several alternative proposals for mechanisms for the synchronization of olfactory neurons in the OB. One mechanism that does not rely on synaptic interactions among neurons within the bulb but, rather, on common oscillatory drive from receptor cells has been suggested by Hopfield and Brody. According to this model, mitral cells synchronize when they receive similar inputs during odor stimulation. If this input represents the sum of common drive from receptors, and a random bias current which is different for different mitral cells is applied, then only a fraction of the mitral cell population would become synchronized during a given odor stimulation. This and number of other models suggest, therefore, that similar to antennal lobe dynamics, the patterns of synchronization across mitral cells are critical for odor representation in the OB.

A model of the OB based on chaotic attractors has been proposed by Skarda and Freeman. In this model, the resting state of the OB before odor recognition is chaotic; this state keeps the bulb far from equilibrium and allows a more rapid conversion to limit cycles (corresponding to previously reinforced odorants) during odor recognition.

In the locust, $GABA_A$-dependent synchronization of a given pair of PNs is generally transient. Usually after only a few hundred milliseconds of firing spikes that are phase-locked to the oscillations, the synchrony between action potentials in a given PN and the field potential oscillations is lost; then, other subsets of PNs become synchronized. However, the times during repeated trials at which a given PN will phase lock are reliable and odor specific. A number of hypotheses have been proposed to explain mechanisms behind such odor-specific, transient synchronization of the olfactory network. Computer models of the locust antennal lobe have suggested that the transient nature of PN synchronization could be explained by variations in inhibitory drive from inhibitory LNs over the duration of the odor-elicited response. In a model by Bazhenov and colleagues, as *in vivo*, a portion of the PNs become phase locked to the oscillatory local field potential at different times when driven by an odor; the identities of the PNs and the times at which they phase-lock change when a different stimulus is presented. When the activity of sets of LNs that are presynaptic to each PN in the network, and for each cycle of oscillation, was analyzed, it became clear that the total number of Ca^{2+} spikes in presynaptic LNs and the degree of coordinated firing in their PNs were highly correlated (**Figure 1(d)**). As feedback inhibition increased in strength, the timing precision of PN spikes across trials also increased: Jitter in PN spike timing decreased (**Figure 1(d)**). Note that in this model, inhibition only controls the timing of PN spikes when PN firing is induced by excitatory input from receptors. In other studies, disinhibition complimented by intrinsic conductances could trigger firing in PNs. Factors such as lateral LN–LN inhibition, spike adaptation in LNs, and the identities of activated neurons contribute to the variations in LN activity in this model, consistent with other theoretical studies.

A number of computational models have also investigated a potential role for lateral inhibitory projections in contrast enhancement – a process hypothesized to amplify differences between sensory representations, improving the signal-to-noise ratio. In these models, stronger inputs typically suppress nearby, weaker inputs. Some models of the OB implement contrast enhancement either at the level of lateral mitral cells dendrites (by granule cells) or at the glomerular layer (by periglomerular cells). It was shown by Linster and Hasselmo that the latter mechanism could help keep the number of active mitral cells stable, independent of the intensity of the olfactory input. Earlier models explored a potential role for lateral inhibition in promoting competition among olfactory glomeruli, and a model of olfactory memory based on altering lateral inhibition in the honeybee's antennal lobe was proposed by Linster and Masson. Computational studies by Linster and colleagues suggest that the contrast enhancement between odorants in the honeybee antennal lobe is best achieved when inhibition between each pair of glomeruli is organized based on glomerular odor response profiles rather than on anatomical neighborhood relations. Further experimental and modeling work is needed to clarify the possible role of lateral inhibition in contrast enhancement in the olfactory system.

Slow Temporal Patterning of Olfactory Neuron Responses

Experiments performed *in vivo* have established that only the synchronization of PNs in the insects'

antennal lobe is eliminated by picrotoxin; the slower firing pattern structures (alternating periods of depolarization and hyperpolarization) remain intact. Such temporal structure has been described in the projection neurons of locusts and *Drosophila*, as well as in the mitral cells of vertebrates. To explain the origins of slow temporal patterns in the insect antennal lobe, two alternative hypotheses have been proposed and evaluated using computer models. According to a model by Bazhenov and colleagues, the slow inhibitory receptors between LNs and PNs, which are not sensitive to picrotoxin and which operate with a time constant of a few hundred milliseconds, could account for the stimulus-specific slow temporal patterning of PN responses. When slow inhibition was provided in this model, odor stimuli induced characteristic slow temporal patterns in the responses of individual cells. The pattern consisted of alternating depolarizing modes, during which Na^+ spikes were generated, and hyperpolarizing modes, during which only subthreshold oscillations were evident in PNs. Each mode usually lasted a few hundred milliseconds, in agreement with recordings made *in vivo*. The sequences in which these modes appeared differed among PNs and varied reliably with the stimulus. Blocking slow inhibitory receptors in the model, a test not currently possible in the locust, eliminated the slow temporal patterns; groups of PNs then showed similar responses that did not vary when a new stimulus was applied. Also, similar to findings obtained *in vivo*, the slow temporal patterns in individual PN responses remained essentially intact after the model's $GABA_A$ inhibition was blocked.

Work on *Drosophila* by Olsen et al. suggests that excitatory interactions within the antennal lobe, likely mediated by interneurons, also contribute to the spatiotemporal structure of olfactory responses.

In a model proposed by Sivan and Kopell, relatively slow calcium and calcium-dependent potassium channels of PNs, rather than slow inhibitory input from LNs, were used to provide for picrotoxin-resistant slow temporal patterning in projection neurons. This model, as well as the one by Bazhenov et al., displayed little change in the average firing rate of PNs after the blockade of fast inhibition, in agreement with experimental data from locust. Both approaches highlight the power of computational modeling because they lead to predictions that can be tested *in vivo*.

A possible role for inhibitory input from granule cells in controlling mitral cell firing rate has been explored in a simplified model of the OB by Linster and Gervais. This model demonstrated that modulation of granule cell inhibition can alter the firing frequencies of mitral cells and can also decrease overlap between output patterns. Reminiscent of models of the insect antennal lobe, this study suggests that alternations of granule cell activity over the duration of an odor response can mediate odor-specific slow temporal patterning in mitral cell activity.

In *Drosophila*, Wilson et al. have shown that the extent of activity and the complexity of temporal responses in groups of PNs exceed those of the sensory neurons that provide direct input. What is the functional significance of the temporal structure in olfactory neuron responses? As shown by Friedrich and Laurent, in zebra fish, the slow temporal patterning in mitral cells appears to play a major role in the decorrelation of odor representations. The responses of a population of mitral cells to chemically similar odorants were highly correlated immediately after the onset of the odor stimulation, but they became progressively less correlated over the duration of the odor response. This type of gradually evolving decorrelation was also tested by Bazhenov and colleagues with a computational model of the locust antennal lobe. When similar odors were presented, the response patterns of PNs at first greatly overlapped. Over the course of a few hundred milliseconds, overlaps between the distributed firing patterns representing similar odorants decreased, and the initial clusters of activated PNs disappeared; cross-correlations between PN activity patterns (calculated across all PNs) was reduced by 30–50%. These works suggest that the intrinsic dynamics of antennal lobe circuitry depend on interactions between PNs and LNs, and such dynamics can amplify small differences between similar odors, thus improving odor discriminability over time. Therefore, the evolving temporal structures appear to be important for the resolution of odor identity. However, behavioral evidence obtained from rodents suggests that some olfactory tasks can be achieved within the time of a single sniff, less than 150 ms. In another study, it has been proposed that spatial representation of odor in the OB evolves across a sniff; therefore, difficult discriminations of similar odors may require the olfactory system to 'wait' for later activated components.

Decoding Olfactory Information at Downstream Levels of Processing

In insects and vertebrates, output from relatively small populations of olfactory neurons in the antennal lobe or the OB fans out broadly to large interneuronal ensembles in the mushroom body or the olfactory cortex. Work on locust by Jortner et al., for example, demonstrates that half of all PNs synapse directly upon each KC, a connectivity scheme that maximizes the coding space available for odors.

Electrophysiological recordings from insects indicate that KCs of the mushroom body respond with high specificity to odors: A given odor induces a reliable response in only a very small subpopulation of KCs. Several mechanisms operating in parallel appear to contribute to this response specificity, including the intrinsic nonlinear membrane properties of the KCs. Intracellular recordings from KCs suggest that activation of certain intrinsic conductances can amplify and sharpen excitatory postsynaptic potential-in'duced depolarizations, thus generating narrow time windows during which KCs can integrate inputs from multiple PNs. Another mechanism, drawing on inhibitory input from lateral horn interneurons (LHIs), regulates the integration window as well: Feed-forward inhibition from LHIs, which are driven by PNs, faithfully follows, with a delay, the periodic excitation of KCs by PNs, thus creating independent and brief temporal windows over which KCs can summate their input from PNs. The existence of these relatively short integration windows suggests that KCs are extremely sensitive to synchronized inputs from the antennal lobe; KCs may respond only when sufficient numbers of input spikes arrive together.

A realistic computer model by Bazhenov and colleagues of an olfactory network endowed with coincidence detection properties was used to test the extent to which KCs can detect synchrony in the input spike trains from a population of PNs (**Figure 2(a)**). Each stimulus consisted of many spike trains, which were delivered to a single cell through a large set of distributed cholinergic synapses. Individual spike trains had temporal structures designed to match experimentally observed PN firing patterns and included transient synchrony among synaptic inputs. For each stimulus, only a very small fraction of KCs responded reliably with a Na^+ spike on each trial despite small variations in the inputs from one trial to the next (input spike number and timing were slightly varied) (**Figure 2(b)**). As *in vivo*, different KCs spiked at different times, and their spike timing depended on the timing of transient correlations between inputs. In most cases, however, KCs were silent or produced only a few random spikes when input spikes happened to coincide, exceeding the KC's threshold. Results from this computational model suggest that a network of KCs with a sufficiently small integration window can respond with a unique spatiotemporal pattern for different inputs, decoding the correlation structure of the input spike train.

Modeling work by Assisi et al. indicates that the integration window of KCs can vary with odor concentration. Higher concentrations of odors, which elicit greater oscillatory synchrony, also elicit stronger feedback inhibition from LHIs. The resulting shifting balance of coordinated excitation and inhibition maintains the sparseness of spiking in KCs over wide ranges of stimulus intensity.

Physiological and modeling results from Cassenaer and Laurent indicate that the precise timing established by antennal lobe circuitry is maintained not only within KCs but also by their neural followers in the beta lobe. Interestingly, odor-specific timing precision is maintained in the beta lobe neurons, in part, by spike timing-dependent plasticity.

Modeling studies of odor decoding in the mushroom body further suggest that a strategy of coincidence detection offers a number of advantages for encoding sensory information compared to a classical integrator model. The sensitivity of a coincidence detector to timing on a very fine scale provides an additional coding dimension that could allow the olfactory system to discriminate between similar odors, whose neural representations may differ only in the fine temporal structure of the antennal lobe input. In contrast, a decoding system integrating over longer timescales would have no such ability. Furthermore, because the coincidence detector model focuses on specific time windows within an oscillation cycle, in agreement with theoretical studies in other systems, it is thus less sensitive to uncorrelated noise in its input. When the KC model operating as a coincidence detector was explicitly compared to an integrator model possessing a large integrating window, the integrator model showed much greater sensitivity to the presence of random noise in the input (**Figure 2(c)**). In the locust, these coincidence detection mechanisms provide a powerful strategy with which to solve complex problems that every olfactory system encounters.

In the olfactory cortex, local inhibitory interneurons receive afferent input and provide feed-forward inhibition to the pyramidal cells, thus creating a circuit that can operate as a precise coincidence detector. This circuitry is similar to that found in insect mushroom body. It is unknown, however, whether the vertebrate olfactory system utilizes a similar coding strategy. Many types of studies in this rapidly developing field are under way. Studies in mice have shown that afferent inputs from mitral cells connected to specific OB glomeruli terminate in broad patches which overlap with the terminal patches of other glomeruli. As a result, individual odorants are represented by subsets of sparsely distributed cortical neurons. Individual pyramidal cell of the olfactory cortex can make a few thousand connections to other pyramidal cells, further facilitating the redistribution of afferent activity patterns. Furthermore, molecular analysis strategies applied to mouse olfactory cortex have revealed

Figure 2 Decoding olfactory information in the mushroom body (MB). (a) Olfactory model. (b) KC responses for odor stimuli. Each box represents one KC operating as a coincidence detector; 20 cells are shown. Each stimulus (1 s duration; bars) was presented 20 times (raster) and included small variations between trials. Two to four KCs fired reliably in response for each stimulus. Identities of these active KCs changed between odors. (c) Frequency distribution of KC response probabilities before and after noise (extra spikes) was added to the input. The coincidence detector model shows only a slight increase in response probability, whereas the integrator model exhibits a drastic reduction in response specificity. Adapted from Perez-Orive J, Bazhenov M, and Laurent G (2004) Intrinsic and circuit properties favor coincidence detection for decoding oscillatory input. *Journal of Neuroscience* 24(26): 6037–6047, with permission from the Society for Neuroscience.

that binary odorant mixtures activate many cortical neurons that do not respond to the individual components of the mixture. This finding supports a coincidence detection function for the olfactory neurons. However, electrophysiological work in slice preparations has revealed that relatively small numbers of mitral cells are sometimes able to activate individual pyramidal cells in rat olfactory cortex. Based on this finding, it has been proposed that complex odors are represented in olfactory cortex in a broadly distributed manner. It is unknown to what extent the temporal structure found in activity patterns of the OB neurons is reflected in olfactory cortex. Multichannel and single-unit electrophysiological recordings made in the rat olfactory cortex suggest that individual odorants evoke activity in a spatially scattered ensemble of olfactory cortex neurons, and the ensemble activity includes a rich temporal structure.

The literature regarding modeling of the information processing in the olfactory cortex is growing but is currently rather limited. Aforementioned work by Hopfield and Brody incorporates models of the cortical cell population with individual units operating as coincidence detectors on the input from the OB. Results from a study by Wilson and Bower, using a large-scale computer model of the olfactory cortex, suggest that during each 40 Hz cycle of EEG activity, there is a convergence of afferent information from the OB and from caudal cortex. This model reproduced patterns of activity recorded physiologically in response to electrical shocks to the afferent input. A series of models simulating cortical EEG dynamics were proposed by Walter Freeman.

Conclusion

Experimental and modeling studies of odor coding have developed, extended, and tested a wide range of ideas about information processing by networks of neurons. Computational models of the insect olfactory system have explored the proposal that antennal lobe circuitry reformats information about odors, distributing it into the identities of PNs responding to the odor and into the relative timing of spikes in those PNs. Although temporal patterning may not be required for relatively easy tasks, such as the discrimination of ensembles of PNs that do not significantly overlap with one another (activated, perhaps, by odorants with chemically distinct structures), temporal features appear to be critical when discrimination tasks are more challenging – when it is necessary to discriminate activated PN ensembles that substantially overlap. Thus, the antennal lobe actively sharpens information about the olfactory stimulus by employing time and transient synchrony as coding dimensions. The massive convergence of afferents from the olfactory epithelium to the antennal lobe contributes to the creation of reliable and reproducible odor-specific patterns of activity in the antennal lobe. The intrinsic dynamic properties of the antennal lobe optimize these spatiotemporal structures, helping to reduce overlap between representations of similar odors. Contained within the spatiotemporal patterns of antennal lobe activation is information not only about odor identity but also about odor concentration. KCs of the mushroom body, postsynaptic targets of the PN ensemble, decode the stimulus-specific spatiotemporal patterns of PN activity. Operating as coincidence detectors, and thus employing the useful coding dimension of precise timing, KCs transform spatiotemporal patterns of antennal lobe activity into new and very sparse distributed firing sequences. The very large number of KCs enables the insect olfactory system to minimize the overlap between response patterns elicited by even very similar odors. Thus, temporal coding implemented by the antennal lobe can magnify differences in odor representations while minimizing the influence of noise, dramatically reducing odor code overlap in the mushroom body compared to the initial coding by olfactory receptor cells. Understanding and testing hypotheses about these complex biological processes has been greatly facilitated by the use of computational models.

Introduction

The olfactory cortex is defined as that cortical region of the mammalian brain that receives direct afferent input from the olfactory bulb. The olfactory cortex can be divided into multiple subregions based on anatomical characteristics, the largest of which is the piriform cortex (PCx, also known as the pyriform or prepyriform cortex). The PCx has received the greatest attention of any olfactory cortical region, and thus PCx physiology is the focus of this description.

The PCx plays a critical role in odor discrimination and perception, synthetic processing of complex odorant mixtures, experience- and state-dependent sensory gating, short-term odor habituation, and odor memory. Afferent and intrinsic glutamatergic synapses demonstrate both a short- and long-term plasticity, contributing to these processes. The specific neural architecture of this paleocortical structure (not described here) also contributes significantly to its function.

Circuit Structure

An overview of PCx circuitry is necessary to provide a reference for physiological function. In brief, the primary afferent to the PCx is via mitral and tufted cell axons, which form the lateral olfactory tract. This input terminates on the distal half (layer Ia) of the apical dendrites of the principal cortical neurons, the pyramidal cells, the somata of which lie in layers II and III. The inner half of these dendrites (layer Ib) is dominated by intrinsic and commissural fibers. The lateral olfactory tract extends approximately to the midpoint of the rostral–caudal extent of the PCx, and its termination point is an anatomical marker for division of the PCx into anterior and posterior regions. The posterior PCx receives afferent input from distributed mitral/tufted cells axons, though the termination zone for afferent input is reduced to a thinner layer in posterior, compared to anterior, regions. In addition to afferent input from the olfactory bulb, the PCx also receives input from the entorhinal and orbitofrontal cortices, and input from several neuromodulatory systems, including the noradrenergic nucleus locus coeruleus and the cholinergic nucleus of the horizontal limb of the diagonal band of Broca. Finally, in addition to the principal pyramidal cells, the PCx contains several classes of inhibitory interneurons, including feedforward inhibitory interneurons in layer I, which receive direct input from the lateral olfactory tract, and feedback and lateral inhibitory interneurons in layer III, which receive input from PCx pyramidal cells. Pyramidal cells receive γ-aminobutyric acid (GABA)ergic inhibitory inputs on both their somata and apical dendrites (Figure 1).

Synaptic Physiology

Afferent input to the PCx evokes a sequence of synaptic actions on pyramidal neurons (Figure 2). The glutamatergic afferent input, though limited to distal apical synapses, is sufficiently strong to allow spike generation evoked by simultaneous input from just a few afferent fibers. This could provide an early mechanism for odorant feature synthesis. Spiking evoked by the afferent excitatory postsynaptic potential (EPSP), however, is controlled by an early-onset GABAergic, Cl^--mediated, somatic inhibitory postsynaptic potential (IPSP) that is depolarizing at resting potential in these cells and serves to shunt excitatory currents. In addition, the EPSP is followed by a longer (several hundred ms) K^+-mediated dendritic IPSP. The myelinated lateral olfactory tract provides nearly simultaneous activation of pyramidal neurons within anterior PCx. However, due to the fact that posterior PCx is innervated by long axon collaterals posterior to the termination of the lateral olfactory tract, the activation comes as a rostral-to-caudal wave.

If pyramidal cell spikes are evoked in response to afferent input, a second wave of excitation is generated via the pyramidal cell-mediated intrinsic fiber system. Individual pyramidal neurons are synaptically connected to several thousand other neurons throughout the PCx (and neighboring regions, including the olfactory bulb), thus providing a mechanism for rapid and widespread distribution of afferent input. The intrinsic fiber system provides a second substrate for convergence of information regarding multiple odorant features.

There is some evidence that the anatomical segregation of afferent and intrinsic fiber synapses on distal and proximal apical dendrites, respectively, provides a substrate for differential modulation of these two excitatory pathways. Thus, for example, both norepinephrine and acetylcholine appear to preferentially,

Figure 1 Basic piriform cortex circuitry. (a) Mitral/tufted cell axons conveying information from specific olfactory receptor types terminate in overlapping patches in anterior piriform cortex, and in broader, more overlapping regions in posterior piriform cortex. (b) Mitral/tufted cell axons form the lateral olfactory tract (LOT), which runs along the superficial layer of the anterior piriform cortex. Afferent axon branches (blue line) leave the lateral olfactory tract and terminate on the distal apical dendrites of piriform cortex pyramidal neurons (red) and also on a small population of feedforward inhibitory interneurons. Pyramidal cell axons form a dense, broadly projecting network of intrinsic association fibers (green line), which terminate on the proximal half of the pyramidal dendritic tree and on basal dendrites (not shown).

though not exclusively, modulate intrinsic fiber synapses compared to afferent synapses within PCx.

The combination of an afferent input-generated EPSP–IPSP sequence and the concomitant activation of intrinsic fiber-mediated spread of EPSPs can lead to circuit oscillations. Activity within the PCx expresses a theta band (2–10 Hz) frequency oscillation phasic with the respiratory cycle, as well as beta (10–40 Hz) and gamma (40–100 Hz) band oscillations. The higher frequency oscillations can occur as waves of activity riding the slower respiration-entrained oscillations (Figure 2). Beta frequency oscillations may originate within the PCx, and can then be transmitted to the olfactory bulb. Isolation of the bulb from the PCx eliminates olfactory bulb beta band oscillations. Gamma frequency oscillations have been further functionally divided into higher and lower subbands. These high-frequency beta and gamma oscillations are influenced by descending input from limbic and other cortical structures, as well as neuromodulatory inputs such as acetylcholine. High-frequency PCx oscillations may be indicative of, and correlate with, behavioral state, expectation, and stimulus familiarity/novelty. Their specific role in encoding stimulus identity is controversial.

The oscillatory nature of stimulus-evoked PCx activity may also contribute to neural plasticity in this system by enhancing synchrony between afferent and intrinsic fiber activity on sequential oscillatory cycles. Both afferent and intrinsic fiber synapses express use-dependent plasticity. Associative long-term synaptic potentiation (LTP) has been described at both afferent and intrinsic synapses, though LTP at intrinsic synapses appears most robust. LTP in the PCx is *N*-methyl-D-aspartate (NMDA) receptor dependent and can be modulated in a state-dependent manner through cholinergic regulation of GABAergic inhibition. Activation of cholinergic muscarinic receptors reduces GABAergic inhibition and enhances NMDA receptor-dependent LTP in PCx.

In addition to LTP, afferent synapses display an activity-dependent short-term depression, mediated by presynaptic group III metabotropic glutamate receptors. As described in the following section, this short-term depression contributes to cortical odor adaptation and short-term habituation.

Sensory Physiology

The PCx is generally considered the primary sensory cortex for olfaction, though it may also serve roles comparable to those of the higher order cortex of thalamocortical sensory systems. Cutting the lateral olfactory tract (LOT) input to PCx disrupts odor discrimination, and the PCx projects to limbic, hypothalamic, and neocortical regions that may underlie behavioral and autonomic responses to odor stimulation.

Odor stimulation single-unit and local field potential responses have been recorded in the PCx of awake and anesthetized animals. Odor-evoked activity can also be observed in the human PCx using functional magnetic resonance imaging (fMRI) techniques.

Figure 2 Lateral olfactory tract-evoked and odor-evoked responses in rat piriform cortex. (a) Electrical stimulation of the lateral olfactory tract (red asterisk) evokes a monosynaptic excitatory postsynaptic potential in layer II/III pyramidal neurons. This excitatory postsynaptic potential is followed by a K^+-mediated inhibitory postsynaptic potential. A short-latency Cl^--mediated inhibitory postsynaptic potential (IPSP) precedes the slower inhibitory postsynaptic potential (not visible in this record at resting membrane potential, −72 mV). (b) Odor-evoked responses recorded intracellularly in an anesthetized rat show strong depolarizations in phase with the respiratory cycle. As in extracellular field potential recordings, these intracellular depolarizations may show high-frequency oscillatory components.

While olfactory receptor input to the olfactory bulbs is exclusively ipsilateral, individual neurons within the PCx can respond to odor stimulation from either the ipsilateral or contralateral receptor sheet, with different neurons expressing different relative lateralized responsiveness. PCx neurons in rodents also respond to a variety of nonolfactory stimuli, such as during approach to the odor sampling port, during consummation of water reward, or in response to foot shock, though the specific sensory nature of these responses is not clear. For example, given the modulatory inputs to the PCx and to the olfactory bulb, unit activity in PCx may change due to changes in arousal or behavioral state, rather than as a direct consequence of a specific sensory input. Nonetheless, activity changes within the PCx (and olfactory bulb) do not solely reflect primary odor input.

Single units in the PCx can display either excitatory or suppressive responses to odorants (Figure 2). Responses may be phasic with the respiratory cycle or more prolonged, extending across multiple cycles. Excitatory responses are associated with large depolarizing postsynaptic potentials giving rise to evoked spiking. Instantaneous evoked firing rates can attain 300 Hz during single inhalations. Combined with the theta frequency of the respiratory cycle, this pattern of activation (high-frequency bursts at theta frequency) is ideal for inducing LTP. Individual cells respond to multiple odorants, and based on both single-unit recordings and c-fos mapping studies, neurons responsive to a particular odorant are widely distributed throughout PCx. Neighboring cells may respond to different odorants. The distributed nature of odorant-evoked responses is consistent with patchy mitral cell termination zones and the broadly dispersed intrinsic fiber system, and suggests that odorant identity is encoded by a broad ensemble of PCx neurons.

The overlapping patches of input from mitral cells conveying information from specific olfactory receptors, and the amplification of this overlap and convergence via intrinsic fibers, provide an anatomical basis for synthesis of multiple odorant feature input within the PCx. This is particularly relevant given that most naturally occurring odors are mixtures of many different molecular species. Using immunohistochemical techniques, evidence has been presented suggesting that some single neurons may respond only to combinations of specific odorants, and not to the individual components of those mixtures. However, these combination-specific neurons have not been observed with electrophysiological techniques to date. In anesthetized rats, there are significant differences in single-unit activity between the anterior and posterior PCx. Posterior PCx neurons have lower average spontaneous activity and less intense odor-evoked activity compared to anterior PCx neurons. The anterior PCx can be further subdivided into dorsal and ventral regions based on local circuit anatomy. Immunohistochemical techniques suggest enhanced odor responsiveness in the dorsal anterior PCx compared to ventral anterior PCx.

In addition to their role in odor quality coding, PCx single units may encode odorant intensity. This topic has received sparse attention, but there may be a rostral-to-caudal gradient in PCx unit sensitivity to odorants, with more rostral regions showing greatest sensitivity. Based on functional imaging techniques and single-unit recording, increases in odorant

intensity activate increasingly more caudal regions of the anterior PCx. This gradient of sensitivity could reflect the gradient of mitral and tufted cell projections to the PCx, wherein tufted cells tend to terminate in more rostral regions while mitral cells terminate throughout. Tufted cells, especially superficial tufted cells, have a lower threshold for olfactory nerve input, and thus could produce an enhanced sensitivity of rostral regions of the anterior PCx.

Single-unit and local field potential responses to odorants are strongly influenced by behavioral state and past experience. Behavioral state (e.g., hunger/satiety or sleep/wakefulness) may modulate PCx responses either directly and/or via upstream modulation of olfactory bulb activity. Regulation of cortical responses by behavioral state is at least partially mediated by cholinergic input from the horizontal limb of the diagonal band of Broca. For example, pharmacological blockade of muscarinic receptors can eliminate the hunger/satiety modulation of PCx responses to food odor.

A shift from fast-wave to slow-wave neocortical activity in anesthetized rats, nominally similar to a shift from wakefulness to deep sleep, reduces PCx responsiveness to odorants. This state-dependent sensory gating in PCx is similar to that seen in the thalamus in thalamocortical sensory systems. PCx neurons during slow-wave state are hyperpolarized, with large membrane potential fluctuations. In fast-wave state, membrane potential is relatively depolarized and stable, allowing afferent input to more reliably evoke activity. The state-dependent change in membrane potential and PCx odor responsiveness is presumably due to fluctuations in modulatory inputs such as ACh, though this has not yet been determined.

Odorant-evoked PCx activity also reflects recent odor experience. As noted earlier, afferent inputs express a use-dependent, metabotropic glutamate receptor-mediated presynaptic depression. Prolonged or rapidly repeated odorant stimulation induces profound adaptation of cortical responses, despite relatively maintained olfactory bulb activity. Blockade of these presynaptic receptors can prevent cortical odorant adaptation and habituation of odorant-evoked autonomic reflexes. This presynaptic depression is also regulated by noradrenergic β-receptors, which could contribute to state- or attention-mediated blockade of adaptation to biologically important stimuli. PCx odor adaptation is highly odorant specific, and has been demonstrated to serve as a mechanism for odorant figure–ground separation when an odor is presented against a relatively stable background. The homosynaptic afferent depression allows the PCx to selectively respond to those dynamic components of the inhaled stimulus, while filtering the more stable, potentially background components.

Finally, PCx physiology and odorant-evoked responses are affected by odorant familiarity and associative conditioning, and some aspects of this plasticity may vary between the anterior and posterior PCx. Associative conditioning modifies the strength of odor-evoked local field potentials and the coherence of oscillations between different subregions of the piriform cortex and olfactory bulb. Using electrical stimulation of the olfactory bulb or lateral olfactory tract as artificial odors in a conditioning task enhances the PCx response evoked by that electrical stimulation, but only if the animal successfully learns the discrimination. Together, these two findings suggest that, as animals learn about odors and their meanings, synaptic strengths of afferent and intrinsic connections are modified in the PCx, leaving a long-term trace of the learned odor. The success of olfactory learning can be impaired by NMDA antagonists, suggesting that NMDA-dependent LTP is involved in the learned synaptic plasticity. Furthermore, neuromodulators such as acetylcholine and norepinephrine are also required for cortical changes.

Learned changes in PCx function not only store information about the learned odor, but also affect the discriminability of the familiar odor. Perceptual learning is an increase in discriminability with sensory experience and occurs in both human and nonhuman olfactory systems. Familiar odorants are more easily discriminated from molecularly similar odorants than from novel odorants. Perceptual learning is associated with enhanced PCx single-unit odorant discrimination. In cross-adaptation tests of discrimination, familiar odorants are more easily discriminated by anterior PCx single units, and single-unit populations, than are novel odors. Importantly, experience with odorant mixtures produces enhanced discrimination of those mixtures from their components by anterior PCx neurons. This synthesis of mixtures into stimuli distinct from their components is consistent with the synthetic or configural perception of odor mixtures and the impaired behavioral ability to correctly identify components of complex mixtures. Thus, an experience-dependent merging of multiple odorants and/or odorant features into unique perceptual odor objects maybe a critical function of the PCx. Perceptual learning at both the behavioral and cortical level is impaired by the cholinergic antagonist scopolamine.

Thus, as odors are learned, not only does the PCx store a long-term trace of that odor for subsequent recognition, but also anterior PCx encoding of the odorant is modified to enhance stimulus discriminability. In addition to these two changes following

odor learning, a series of short-term changes occur in PCx that increase the ability to learn new odors. Olfactory learning displays a form of rule learning, or learning-to-learn phenomenon, wherein learning one or more odor discriminations enhances the speed at which subsequent discriminations are learned. Odor rule learning is associated with increased excitability of PCx pyramidal cells, increased pyramidal cell apical dendrite spine density, and enhanced presynaptic transmitter release from intrinsic fibers – a series of effects that facilitate induction of long-term synaptic plasticity. Importantly, these changes are transient, lasting for at most a few days after the odor learning experience. Thus, a relatively rapid series of learning experiences increases the ability of the PCx to learn new odors, an advantage that fades after several days. As with the other forms of learning described earlier, olfactory rule learning is acetylcholine dependent.

Functional Implications

Based on cortical architecture, theoretical and computational models suggest that the PCx functions

Figure 3 Autoassociative network. (a) Initial exposure to an olfactory stimulus activates specific olfactory bulb glomerular and mitral/tufted cell patterns (shaded circular glomeruli and trapezoidal mitral cells), which in turn, via patchy terminations in the piriform cortex, activate a pattern of pyramidal cells. The coincident excitation of specific afferent and intrinsic association fiber synapses (blue dots) induces long-term potentiation, effectively stored as a template of the experienced pattern. (b) On reexposure to the same or partially degraded stimulus, the potentiated intrinsic association fiber synapses allow pattern completion (c) and a cortical output that matches the original, signifying stimulus recognition.

as an autoassociative, content-addressable memory system. Patterns of afferent input are stored through changes in weight of intrinsic association fiber synapses. Information is encoded by an ensemble of distributed, interconnected neurons, and familiar input patterns are matched with existing, stored templates through the enhanced retrieval of patterns with strengthened synapses. Increasingly, physiological evidence supports this model.

Autoassociative, content-addressable memory systems are capable of generating stable output patterns, given complex and variable inputs. For example, noisy or reduced inputs can reliably be reconstructed into completed output patterns, due to the activation of strengthened synapses within the stored template (Figure 3). Assuming a major function of the PCx is to discriminate and recognize odors, the autoassociative system is especially useful for at least two reasons. First, most naturally occurring odors are complex mixtures of different molecules, and individual olfactory receptor neurons and olfactory bulb mitral cells respond to multiple odorant molecules. This leads to a complex input pattern to the PCx, where information concerning odor identity or quality is encoded in the combinatorial pattern, rather than in the activity of a specified individual neuron or neuron class. Thus, complex pattern recognition by PCx circuits becomes critical for odor recognition and discrimination – a feat performed well by the autoassociative network. Second, given the complexity of odorant mixtures and the frequent presence of background odorants, a particular odor may vary in its precise combination or relative strengths of individual components, yet needs to be consistently identified. Again, the autoassociative network functions well in this circumstance to reconstruct the complete odor from degraded input patterns.

If the autoassociative, content-addressable memory model is applicable to PCx function then several predictions about PCx physiology can be made. First, PCx circuits must be capable of expressing use-dependent associative plasticity necessary for storing previous input patterns. As described earlier, several forms of synaptic plasticity have been described at PCx afferent and intrinsic fiber synapses, and this plasticity has been linked to behavioral odor memory. Second, discriminability of odors should improve with familiarity as those input patterns become stored. In support of this, perceptual learning has been described both behaviorally and in the ability of single PCx neurons to discriminate similar odorants. Pharmacological manipulations (e.g., cholinergic blockade) that disrupt normal PCx synaptic plasticity impair both behavioral and cortical experience-dependent improvement in odor discrimination. Third, the stored and reconstructed patterns may include more than simple olfactory-based afferent input. Given that the PCx receives extensive descending input from entorhinal and orbitofrontal cortex, stored patterns may include multimodal, contextual, or state-dependent information. This could allow context and expectation to influence the PCx output (and consequent perception) resulting from a given pattern of olfactory receptor activation. Behavioral evidence supports this effect (e.g., differentially coloring liquids can influence the odors assigned to them), and more recent local field potential recordings suggest that expectation and experience strongly influence PCx activity.

Introduction

The vertebrate olfactory system faces an enormous challenge. When one or a mixture of a seemingly limitless set of odorous molecules is encountered, the olfactory system must identify it, discriminate it from similar odors, recall information that has already been learned about the odor's significance, and incorporate any new information that might accompany the current presentation. Understanding the transfer of chemical information and the circuitry involved at the initial stages of processing yields some clues about how the olfactory system performs such tasks, but it is at the level of the olfactory cortex – complex, often multimodal sensory and association areas characterized by a high degree of convergence and interconnectedness – that odor information is integrated with other sensory cues, learned associations, and internal motivational states to generate a meaningful response to an odor.

This comparative review of the vertebrate olfactory cortical areas first examines what is known about the olfactory cortical areas in rodents, which have been the most well studied and widely used vertebrate experimental subjects in olfactory research. The structure and organization of the two major olfactory cortical areas, the piriform cortex and the anterior olfactory nucleus, are examined in detail, and the afferent, reciprocal, and efferent connections that these two areas have with other cortical structures are considered. Next, the structure and organization of the rodent olfactory cortex are discussed in relation to other mammalian and nonmammalian vertebrate species, and the article concludes with remarks about the potential function of the cortical areas in the vertebrate olfactory system.

What Is Olfactory Cortex?

In the broadest sense, olfactory cortex is defined as any cortical region that receives information from the olfactory system. The first structure that could be designated in such a way is the main olfactory bulb, which is the target for incoming information from the olfactory sensory neurons in the olfactory epithelium. Although the olfactory bulb is not usually regarded as a cortical structure, it has the features considered by neuroanatomists to characterize cortex: it is divisible into more than two tangential layers, the most superficial layer is a plexiform layer of incoming afferent fibers; it is connected by a network of neuronal processes that give rise to columnar functional units, and these functional units can interact with each other both within and across laminae. Regardless of whether it can be termed olfactory 'cortex,' the olfactory bulb is the first stage of olfactory information processing in the vertebrate central nervous system, and a great deal of synthesis and refinement of the olfactory signal occurs at this stage.

The two classes of principal cells in the olfactory bulb, the mitral and the tufted cells, project to a number of cortical structures, and these third-order structures are traditionally designated olfactory cortex (Figure 1). The largest of these is the piriform cortex, which is often referred to as 'primary olfactory cortex,' although this designation has more to do with its size than its functional similarities to other primary sensory cortices. The piriform cortex is also designated the pyriform or prepiriform cortex. The second-largest cortical recipient of mitral and tufted cell fibers is the anterior olfactory nucleus (AON), a large structure (cortical in nature, despite its name) situated within the olfactory peduncle between the olfactory bulb and the piriform cortex. Although the AON has received relatively little experimental attention, it likely plays a central role in processing olfactory information. These two cortical structures will be the focus of this review.

There are other cortical areas that receive direct input from the olfactory bulb, including the olfactory tubercle, lateral entorhinal cortex, prefrontal cortex, and cortical areas associated with the amygdala, although the direct olfactory bulb input to these areas often is nominal. Many of these areas also have reciprocal projections with the piriform cortex and the AON and can thus be designated, along with perirhinal, perihippocampal, and orbitofrontal cortices, as members of higher-order olfactory or multimodal cortical circuits.

Rodent Piriform Cortex

Organization

The piriform cortex is the largest cortical recipient of direct olfactory bulb projections, and it is also a very prominent part of the rodent brain, accounting for up to 10% of cortical volume in some species. Although it is generally agreed that the area is involved in higher-order processing of olfactory information, its function appears to be complex, and is not altogether well understood. Unlike 'primary' cortical structures

Figure 1 Schematic diagram showing the relative location and connectivity of olfactory cortical areas in the rodent. (a) Ventrolateral view of the rat brain, with the dorsal surface of the brain rotated 45° medially, showing the locations of the olfactory bulb (OB), anterior olfactory nucleus (AON), and the anterior (APC) and posterior (PPC) piriform cortices. The lateral olfactory tract (LOT) overlies the AON and a portion of the APC and is indicated by cross-hatching. Also shown are the orbitofrontal cortex (OFC) and olfactory tubercle (OT). The dorsal portion of the APC forms the ventromedial wall of the rhinal sulcus (RS). Scale bar = 1 mm. (b) Circuitry of the piriform cortex. Axon collaterals from the mitral and tufted cells exit the LOT to synapse on the distalmost portion of pyramidal cell apical dendrites in layer Ia of the piriform cortex. Although a light input from tufted cells is shown in dorsal APC (APC_D), it has been suggested that ventral APC (APC_V) may be the only region of piriform cortex that receives input from tufted cells. Tufted cell axons do not project to PPC. Axons from the OFC and from the AON project proximal to the input from the OB in layer Ib of APC. The remainder of input to pyramidal cell dendrites in layer Ib is from associative projections from piriform cortex, often originating in the same subregion as the target cell (so-called 'autoassociative' input). The projection from PPC onto other piriform pyramidal cells is primarily to basal dendrites in layer III. Other inputs to layer III, for example from the amygdala and OFC, are not shown.

in other sensory systems that are devoted to processing a single type of sensory information, the piriform cortex has a highly autoassociative architecture, with an extensive network of interconnections within and among its various subregions. Moreover, direct afferent fibers from the olfactory bulb make up only a small fraction of the input that neurons in piriform cortex receive on their dendritic tree; all other input to piriform cortex is from other neurons within piriform cortex, from higher-order areas such as orbitofrontal cortex or from structures that are most often associated with other systems or sensory modalities, such as entorhinal cortex and the amygdala.

A second feature of the rodent piriform cortex is its discrete laminar organization perpendicular to the cortical surface (Figures 1 and 2). Piriform cortex is three-layered paleocortex. The most superficial layer (layer I) is a highly ordered plexiform layer consisting of two parts: layer Ia, a superficial sublayer that includes axons from the mitral and tufted cells in the olfactory bulb, and a deeper layer, Ib, which consists of associative axons from other neurons in piriform cortex, from other ipsilateral cortical structures such as the AON, and from commissural axons from contralateral olfactory cortical neurons (Figure 1). The next deepest layer (layer II) is a compact cell body layer that houses the majority of the principal cells within piriform cortex. layer IIa is a superficial sublamina that houses a specialized population of pyramidal-type cells that lack basal dendrites, termed semilunar cells. The deeper layer, IIb, contains the cell bodies of superficial pyramidal cells and of small multipolar cells (Figure 1). Deep to layer II is layer III, which contains cell bodies of deep pyramidal cells, two populations of multipolar cells, and a large number of associational fibers, both from within piriform cortex and from other brain structures.

Deep to layer III is the endopiriform nucleus, which has also been termed layer IV of piriform cortex. This structure is dominated by multipolar neurons, and although it is interconnected with overlying piriform cortex, it does not receive direct input from the

Figure 2 The appearance of olfactory cortex in mammalian and nonmammalian vertebrates. Nissl-stained coronal sections through one hemisphere of one nonmammalian species, the cottonmouth snake (*Agkistrodon piscivorus*) and of two mammalian species, the Norway rat (*Rattus norvegicus*), and the domestic cat (*Felis catus*). In *A. piscivorous*, the medial (MC), dorsal (DC), and lateral (LC) cortices are labeled. The anterior region of LC is the primary olfactory cortex, while more posterior regions of lateral cortex receive convergent olfactory and vomeronasal input. In the mammals, the piriform cortex is shown ventromedial to the rhinal sulcus (RS), with its characteristic three-layered appearance visible in these sections (I, II, and III). LOT, lateral olfactory tract. Scale bar = 500 μm.

olfactory bulb, and its role in olfactory information processing has not been investigated directly.

As in most other cortical structures, the principal neurons are glutamatergic pyramidal cells, and γ-aminobutyric acid (GABA)ergic interneurons are distributed throughout the cortex. Further, the piriform cortex is the target of a variety of neuromodulators, including acetylcholine from the horizontal limb of the diagonal band of Broca, norepinephrine from the locus coeruleus, and serotonin from the raphe nucleus. These neuromodulatory inputs heavily terminate in layers Ib, II, and III, targeting both dendritic and axonal elements.

Piriform cortex is often referred to as a single structure, but it can be divided into five or more subregions on the basis of chemo- and cytoarchitectural features. This review will focus on three main subdivisions: anterior piriform cortex (APC), ventral APC (APC_V), and posterior piriform cortex (PPC; see Figure 1). These areas appear similar to one another, but there is good evidence that they receive different inputs, have distinct intrinsic architecture, and provide unique patterns of output. For example, APC_V may be the only portion of piriform cortex that receives input from tufted cells, and it receives a smaller complement of associative fibers originating in piriform cortex than do other subregions. In the rat, this region of the cortex also lacks characteristic GABAergic 'cartridges,' inhibitory features found elsewhere in APC that dampen neuronal activity and control recurrent excitation levels, which may account for the observation that this subregion is among the most epileptogenic sites within the rodent brain. The output from APC_V is almost exclusively to the dorsal APC and to orbitofrontal cortex, which sends a projection back to APC_V.

The PPC receives a much lighter input from the olfactory bulb, and this input is exclusively from mitral cells; tufted cell axons do not reach into the region of the PPC. Layer Ia is distinctly smaller in PPC than in APC, and PPC has a much thicker layer Ib than APC does, reflecting a much heavier associative input from the more anterior subdivisions of piriform cortex.

There is good evidence in the literature that the divisions made according to anatomical features reflect functional differences among subregions of piriform cortex. For example, responses to odors recorded from awake, behaving animals seem to be more stimulus specific in APC whereas responses in PPC appear to incorporate more associative information, perhaps reflecting the relative differences in afferent and associative input seen in each area.

Output

Piriform cortex projects to a widespread and diverse set of forebrain structures. These structures include the olfactory bulb, AON, lateral amygdala nucleus, entorhinal cortex, orbitofrontal cortex, and mediodorsal nucleus of the thalamus. The projections to the olfactory bulb terminate on GABAergic granule cell interneurons and thus allow a cortical feedback control of olfactory bulb excitability. It is not known how these back projections are organized within the olfactory bulb relative to the patterns of olfactory receptor afferent input. The projection to the amygdala derives primarily from the PPC. Both the APC and the PPC receive input from the basolateral amygdala nuclei, though this projection is most pronounced to the PPC. Thus, the PPC has a unique reciprocal relationship with the amygdala, which may be important in the incorporation of hedonic or associative meaning with the representation of odors. The relationship between the piriform cortex and the orbitofrontal cortex is similarly complex, with both direct and indirect (via the dorsomedial thalamic nucleus) projections.

The Piriform Cortex in Other Mammalian Species

In general structure, the piriform cortex in mammalian species outside the class Rodentia is recognizable by its characteristic lamination (Figure 2). Experimental study has been made of the piriform cortex of the opossum, cat, dog, and primates. Its relative size within the brain diminishes greatly with the enlargement of the frontal lobes seen in these mammals. In rodents and other small nonprimates such as possums and cats, the piriform cortex is located along the ventral or ventrolateral edge of the forebrain, with the myelinated lateral olfactory tract (LOT) overlying the anterior regions. In primates, the piriform cortex has moved more medially as neocortex has expanded and resides along the dorsal medial edge of the temporal lobe. Both gross anatomy and, as far as is known, local circuitry are generally conserved across these species.

Rodent AON

The AON is a large structure that lies within the olfactory peduncle, caudal to the olfactory bulb and rostral to the piriform cortex, with which it merges at its caudal end. As noted above, the AON is a cortical structure that was named by early investigators who recognized the outside-in pattern of development of the AON as seen in other brain nuclei, as opposed to the inside-out pattern observed in cortex. Nevertheless, the concept of the AON as a cortical structure has been argued for at least 80 years. The argument is based on structural features – a rigid laminar structure, the presence of pyramidal-shaped principal cells, and its continuity with the piriform cortex caudally – and on its functional role in the olfactory system. Its continued designation as the AON persists as a matter of historical consistency, although it has been proposed that functional groupings within the AON, when identified, should be renamed in a manner consistent with its cortical nature.

Organization

The AON exhibits a laminar structure similar to that of piriform cortex; it receives a direct projection from the mitral and tufted cells within the superficial plexiform layer (layer I), and these synapse on the apical dendritic tree of glutamatergic pyramidal cells that make up the principal cell population of the AON. Pyramidal cell bodies lie in layer II, and deep to layer II is an amorphous, poorly differentiated layer of neuromodulatory and corticofugal inputs to the AON. GABAergic cells and terminals are found distributed throughout the AON, suggesting internal processing of olfactory information within the AON, but the proportion of GABAergic cells that are intrinsic to the AON relative to those which project elsewhere is currently unknown.

One question that has surrounded the internal organization of the AON is whether it can be subdivided into functionally or anatomically discrete units. Traditionally, the AON has been divided into five subregions, termed *pars* (Latin for 'part'), that have been designated according to their physical location: pars medialis, pars dorsalis, pars lateralis, pars ventralis (or ventroposterioralis), and pars externa. Unfortunately, with the exception of pars medialis and pars externa, these designations have been made without a cytoarchitectural basis, and there are no anatomically or functionally defined features to discriminate among the remaining subregions. Nevertheless, ongoing research suggests that the AON is not homogeneous and is likely a collection of functionally discrete subregions that perform separate roles in processing olfactory information.

Output

Three structures are the primary targets for pyramidal cells in the AON: the olfactory bulb, the contralateral AON, and the piriform cortex. The output to the olfactory bulb is widespread, with terminations found within each layer, suggesting that the AON plays an important role in the initial stages of odor processing. It is interesting that there are substantial regional differences in the patterns of projections to

the olfactory bulb; for example, projections from pars medialis terminate in the deep granule cell layer of the ipsilateral bulb, while projections from pars externa predominately innervate the inner plexiform layer in the contralateral bulb. The remaining subregions have heterogeneous, bilateral projections to broader regions of the bulb.

The projection to the contralateral AON is substantial and widespread, and the AON is the first structure in the olfactory pathways to exhibit such interhemispheric connections. Because the subregions of the AON that receive input from the contralateral hemisphere also project back to the ipsilateral olfactory bulb, the AON may be an important component in a network that allows interbulbar feedback regulation of activity. Further, because the AON is the first structure to receive input from both olfactory bulbs, it is in a position to compare the incoming signals, perhaps to facilitate localizing olfactory cues in the environment.

The output from the AON to the piriform cortex is heaviest to the central and ventromedial portions of APC, deep to the LOT and extending from the border with the olfactory tubercle laterally to just beyond the border of the LOT. This projection arises predominantly from pars lateralis, with lesser involvement from adjacent regions of pars dorsalis and pars ventroposterior. The projection from the AON to the piriform cortex is bilateral, but evidence from tract-tracing experiments suggests that pars dorsalis may project more heavily to the ipsilateral piriform cortex, while the pars ventroposterior projects more heavily to the contralateral hemisphere.

Perhaps the most striking feature of the projection from the AON to the piriform cortex is that these fibers terminate on pyramidal cells at the most proximal portion of the apical dendritic tree in deep layer Ib. This suggests that the AON is an important source of input for driving activity in piriform cortex, and it indicates that higher-order cortical processing of olfactory information involves complex reciprocal connections between these two cortical structures.

AON: Other Mammalian Species

The AON in mammalian species outside the class Rodentia is recognizable by its location and laminar appearance but has remained poorly studied. In most primates, the AON loses its circular structure as the forebrain expands, and it appears instead as extended groupings or islands of cells at the end of the olfactory stalk. In the macaque monkey, the AON may be only 12 pyramidal cells wide in some coronal sections. This diminished size, and the consequent difficulty in reaching the area with experimental techniques, may contribute the current lack of scientific study of the AON in other mammals.

Comparative Anatomy of Olfactory Cortex: Nonmammalian Vertebrates

Nonmammalian terrestrial vertebrates lack neocortex, but many have three-layered paleocortex that receives olfactory projections (see Figure 2). Output from the olfactory bulb in many of these species can be divided into at least two main projections, a medial olfactory tract and a LOT, often with the presence of a third, intermediate tract. Mammals have medial projections from the olfactory bulb, for example to the tenia tecta, but do not have a fully separate medial olfactory tract distinct from the LOT. In reptiles, the LOT projects bilaterally to the lateral cortex and to portions of the amygdala. The medial (and intermediate) olfactory tract projects to more medial structures, again bilaterally, including structures along the medial wall of the forebrain.

Similarly, the medial and lateral olfactory pathways in birds project to three (or more) distinct cortical areas; medially, olfactory bulb afferents innervate the regio retrobulbaris and the 'piriform' or 'prepiriform' area, while lateral projections innervate the regio periamygdalaris. Each of these areas receives heavy input from the olfactory bulb, and each exhibits a characteristic three-layered structure. While it has been postulated that the regio retrobulbaris in birds corresponds to the mammalian AON, and the piriform area corresponds to the mammalian piriform cortex, the degree to which any of these areas is similar to mammalian olfactory cortex is not known.

In amphibians and fish, with no true cortex, the olfactory bulb projects to the lateral pallium via the LOT and to the medial pallium via the medial olfactory tract.

Does the olfactory cortex in nonmammalian animals serve a functional role similar to that postulated for mammals? Some evidence suggests that it does. In birds, a portion of the lateral cortex (a region that is analogous to mammalian piriform cortex) is critical for the use of olfactory information. Lesioning this region in homing pigeons does not affect homing behavior when birds are released from familiar locations, but it drastically impairs performance on homing from unfamiliar locations, where olfactory cues are necessary. Further, recent physiological recordings in catfish suggest that the projection to the olfactory forebrain may be spatially organized such that food odors (e.g., amino acids) may be processed in regions distinct from social odors (e.g., bile salts), mirroring a similar functional segregation in the fish olfactory

bulb. These findings suggest that the olfactory forebrain in fish and the lateral (olfactory) cortex in birds may play a role in associating chemosensory cues with behavioral outcomes, a role that is analogous to that attributed to piriform cortex in the mammalian brain.

Summary

The last decade has seen an expansion of cellular and molecular biological techniques applied to sensory and systems neuroscience. Arguably, there is no area of study that has benefited more from this influence than has the study of olfaction, where this work has led directly to an understanding of the structure and function of olfactory receptor neurons and the organization of their projections to the olfactory bulb.

Nevertheless, critical questions regarding the processing of olfactory information remain unanswered, and the answers are likely to come from a study of the olfactory cortical regions. For instance, rodents have little difficulty making discriminations between complex odor mixtures that share components, even though these mixtures evoke activity in overlapping populations of olfactory receptors and mitral and tufted cells. How are such discriminations carried out? How is the pattern of cells activated in the olfactory bulb deciphered by the cortex? Do cortical areas play an active role in shaping the responses of cells in the bulb, as might be suggested by the heavy cortico–bulbar projections?

This review has outlined the structure of the two most prominent olfactory cortical areas in the vertebrate, the AON and the piriform cortex. By virtue of their connections and their position in the olfactory pathways, these structures are likely to play significant roles in olfactory information processing. Although some aspects of organization and circuitry are species specific, each of these cortical structures is characterized by heavy reciprocal relationships with the olfactory bulb, and with higher-order cortical areas, in all vertebrate species that have been studied. Consequently, a complete understanding of olfaction will be achieved only after the roles of these cortical structures have been identified.

Olfactory Ensheathing Cells: Regeneration Following Spinal Cord Injury

M Nieto-Sampedro, Consejo Superior de Investigaciones Científicas, Madrid, Spain; and National Hospital of Paraplegics, Toledo, Spain

© 2009 Elsevier Ltd. All rights reserved.

Central Nervous System Regeneration Failure

The difficulty of central nervous system (CNS) lesion repair has been known since the pioneering work of Tello and Ramón y Cajal at the beginning of twentieth century. The failure of injured adult mammalian CNS to regenerate is due to (1) the formation in the injury area of the glial scar, a cellular–molecular structure inhibitory of axonal regrowth; (2) neuronal death secondary to the primary injury and delayed with respect to it; and (3) the postnatal loss of intrinsic CNS axonal growth capacity (Figure 1). Oligodendrocytes, reactive astrocytes, and reactive microglia are responsible for the unfavorable growth environment found in the CNS. Because Schwann cells in the peripheral nervous system favor axon regeneration by producing growth-promoting extracellular and soluble molecules, dorsal rhizotomy has been used extensively to investigate CNS regeneration. The gliotic tissue formed at the dorsal horn/dorsal root entry zone (DREZ) or in other CNS loci after injury has inhibitory properties that prevent penetration in the CNS tissue of the abundant sprouts formed after damage of the sensory axon central branch.

Transplantation near the DREZ of olfactory bulb ensheathing cells (OBECs) modifies the spinal environment, causing astrocyte reactivity to diminish/disappear and promoting regeneration and spinal ingrowth of damaged sensory fibers. However, due to innervation overlap by adjacent sensory roots, the functional deficit caused by damage to a single dorsal root is not clear enough to permit assessment of the recovery achieved with the help of OBEC transplants. Accordingly, multiple rhizotomy was performed at the cervical, lumbar, and lumbosacral levels, and OBEC transplants were used to repair the damage. Transplant site and technique influenced the extent of sensory function recovery and its anatomical and electrophysiological correlates. More recently, Nieto-Sampedro's proposal of using OBEC transplantation as a general strategy for CNS injury repair has been tested by several groups and partial recovery after complete spinal cord transection has been achieved in rodents.

Multiple Rhizotomy: Repair and Partial Recovery of Function

Variations of the OBEC transplantation technique (Figure 2) have been used to repair multiple dorsal rhizotomy at the cervical, lumbar, and lumbosacral levels, with partial recovery of the functions mediated by the repaired afferents. These studies showed that OBEC transplantation promoted axonal regrowth and reinnervation of the dorsal horn, activation of postsynaptic dorsal horn neurons, and restitution of polysynaptic reflex activity. Reinnervation led to recovery of anatomical and electrophysiological parameters, correlating with cutaneous, proprioceptive, and autonomic sensory function, as well as restoring withdrawal reflexes and organized suprasspinal nocifensive responses to forepaw stimulation.

Unilateral C4-to-T2 dorsal rhizotomy in the rat led to severe forepaw sensory deficits. Transplantation of OBECs medial to the DREZ of cut dorsal roots C7/C8 promoted significant recovery of sensory response to noxious stimuli as judged by C-*fos* protein expression. The increased expression of c-*fos* protein in intrinsic dorsal horn neurons of the superficial dorsal horn laminae, induced by immersion of the ipsilateral forepaw in water at 52 °C, was observed in nonoperated animals or in sham-operated controls, abolished in rhizotomized animals, and partially restored after ipsilateral OBEC transplantation in the dorsal horn. Therefore, OBEC transplants helped re-establish functional contacts between injured sensory axons and intrinsic dorsal horn neurons.

Direct evidence of functional restitution of cutaneous reflex circuits was obtained by recording biceps reflex activity in response to stimulation of the median nerve, ipsilateral to C4–T2 rhizotomy and C7/C8 OBEC transplantation. Stimulus–response curves were obtained for nonoperated animals, rhizotomized rats transplanted with cell culture medium, and rats transplanted with ensheathing cells. Median nerve activation with short (0.1 ms) or long (0.5 ms) pulse duration stimuli indicated that only small-diameter afferents regenerated in transplanted animals. Biceps reflexes recovered after OBEC transplantation showed a higher 'gain' than either normal or

Figure 1 The spinal cord before and after a traumatic lesion.

nontransplanted rhizotomized rats. The synchronized electromyographic discharge evoked by median nerve stimulation in the biceps in normal adult rats was lost after rhizotomy or rhizotomy plus transplant of DMEM alone. However, similar stimulation of animals rhizotomized and transplanted OBECs 6 months after injury evoked an unsynchronized biceps discharge, reminiscent of immature activity.

The repair of sensory input observed electrophysiologically occurred in parallel with restoration of sensory reflexes in the awake animal. Withdrawal reflex and supraspinal nocifensive responses to both radiant heat stimuli and mechanical stimuli applied to the ipsilateral forepaw plantar pad were assessed behaviorally before and up to 2 months after cervical dorsal rhizotomy. Mechanical stimulation of the forepaw after brachial rhizotomy did not evoke reflex activity in the nontransplanted group or in the OBEC-transplanted group (data not shown). In contrast, reflex responses to thermal stimuli showed significant recovery after OBEC transplantation. During the first month following rhizotomy, ipsilateral withdrawal reflexes were abolished in control groups, and they were partially restored in the OBEC-transplanted group during the second month after injury (10–15 s; Figure 3(a)), significantly better than in nontransplanted controls (20–22 s; Figure 3(b)). The same behavioral test was also used to measure the recovery of organized and unlearned supraspinal responses in transplanted animals. A defined nonparametric scale was developed to grade orientation of the head and paw-licking behavior in response to thermal stimulation of the forepaw. This nocifensive score (SNS) declined from a maximal value of 3 in normal animals to 0 after rhizotomy. The score remained at 0 in nontransplanted animals (indicating lack of awareness of thermal stimulation; Figure 3(c)). In contrast, the group of OBEC-transplanted rats recovered an SNS score of 1 during the second month following rhizotomy, indicating orientation toward the stimulated forepaw (Figure 3(d)). The recovery of supraspinal nocifensive responses after OBEC implantation correlated significantly with the recovery of withdrawal flexor activity, indicating that both reflexive and supraspinal behavioral responses measured activity evoked by regenerating afferents.

Repair of Transected Rat Spinal Cord

Spinal cord transection leads to permanent loss of central control of motor, sensory, and autonomic functions below the injured segment. The seemingly irreversible deficits are caused by neuronal death, together with the failure of axons to regenerate across the injury site. Upregulation of proteoglycans and myelin-associated inhibitors, lack of adequate supply of neurotrophic factors, and formation of a glial scar are the major obstacles of axonal regeneration. However, given the appropriate cellular environment, central axons can sprout and regrow long distances. We proposed transplantation of olfactory bulb ensheathing cells as a general environmental modification strategy for CNS injury repair. Such intervention

Figure 2 To optimize functional recovery mediated by afferents regrowing into the spinal cord after dorsal rhizotomy, various surgical techniques were used depending on the cord segment. In cervicothoracic segments, the OBEC suspension was injected in the dorsal horn, near the DREZ, and tens of micrometers below the Lissauer band. At the lumbar level, the OBEC suspension was injected in the central stump of the cut root. In the case of lumbosacral deafferentation, the transplant was carefully injected in the cord, near the sacral parasympathetic nucleus. In all cases, OBEC migration, both toward the central canal and toward the DREZ, was observed. Adapted from Taylor JS, Muñetón-Gómez VC, Equía-Recuero R, and Nieto-Sampedro M (2001) Transplants of olfactory bulb ensheathing cells promote functional repair of multiple dorsol rhizotomy. *Progress in Brain Research* 132: 651–664, with permission from Elsevier.

Figure 3 Supraspinal nocifensive response. (a) Withdrawal reflex latency was measured before and up to 2 months after complete ipsilateral brachial plexus (C4–T2) dorsal rhizotomy in response to radiant heat applied to the forepaw of rats. Rhizotomized animals received dorsal horn injections of DMEM only (open bars) or a suspension of OBECs in DMEM (solid bars). (b) Supraspinal nocifensive response to radiant heat as in a, before and up to 2 month after rhizotomy (format as in (a)). (c, d) Schematic of the behavioral results observed during the second month after rhizotomy indicating the reflex latency and supraspinal nocifensive score in nontransplanted (c) and OBEC-transplanted rats (d). Adapted from Taylor JS, Muñetón-Gómez VC, Equía-Recuero R, and Nieto-Sampedro M (2001) Transplants of olfactory bulb ensheathing cells promote functional repair of multiple dorsol rhizotomy. *Progress in Brain Research* 132: 651–664, with permission from Elsevier.

appears limited by the migration preferences of OBEC in the adult CNS and by the survival of transplanted cells in the free radical-rich injured tissue. Previous work in our laboratory showed that OBEC transplanted into mechanically or photochemically hemisected spinal cord had neuroprotective and pro-regenerative effects, improving functional outcome. Although the mechanisms underlying the neuroprotective/regenerative properties of OBEC are not completely understood, the publication of the

rhizotomy repair results encouraged the use of OBEC transplants to repair corticospinal tract lesions, demyelination, and complete spinal transections. The conditions for corticospinal tract repair of Li et al. were optimal in that experimental lesions (selective electrolytic lesions) were very small (approximately 500 μm) and neither bleeding nor fibroblast entry in the cord was allowed. Modulation of astrocyte reactivity and proteoglycan expression, promotion of neoangiogenesis, and release of neurotrophic factors are considered the main beneficial actions of the transplanted cells. In addition, OBECs promote regenerative and collateral axon sprouting and remyelination. Experimental studies by Navarro's group in Barcelona, Spain, analyzed the effects of OBEC grafts on axonal regeneration and target reinnervation after complete thoracic spinal cord transection in the adult rats, acutely or 1 week postlesion. Electrophysiological, immunohistochemical, and behavioral techniques were used to investigate the modulation by the transplants of the expression of glial fibrillary acidic protein (GFAP) and NG2. The CNS repair potential of OBEC transplants was manifested by their use for repair of optic or facial nerves.

However, the neuroprotective and pro-regenerative effects of OBEC grafts after spinal cord injury or dorsal rhizotomy have been questioned by other groups. Differences in the results may be due to different cell sources (olfactory bulb, olfactory nerve layer, or olfactory mucosa) and differences in cell culture, purification, and preservation protocols applied to different trauma models. Despite controversy, several clinical trials are ongoing that use OBEC grafts to treat human spinal cord injury, without concluding results. The National Institute of Neurological and Communication Disorders and Stroke and International Campaign for Cures of Spinal Cord Injury Paralysis panel guidelines to assess functional repair after spinal cord injury require histological and electrophysiological evidence of nerve disconnection after injury, of axonal regeneration across the lesion site, of postsynaptic responses to stimulation of regenerated fibers, and, finally, of functional recovery mediated by the new connections. The dangers of extrapolating the results from cell culture and rodent experimental models to the clinic, as well as the importance and potential pitfalls of the various models, have been carefully discussed by Dobkin.

Available and Foreseeable Central Nervous System Injury Repair Tools

Although it appears likely that OBEC transplantation will be the way to repair spinal cord injuries in the immediate future, several important problems remain to be solved before reliable clinical trials can be initiated. One problem concerns the amount of cells required to repair large injuries and the possibility of growing sufficient cells in primary culture or using immortalized cell lines. Another problem concerns the immunological compatibility of transplant donor and receptor, and a third problem regards the migration preferences of OBECs in the CNS. Various laboratories throughout the world are addressing these problems.

To search for OBEC-like glia with other migration preferences, we screened the adult rat brain for glial cells that, like OBECs, would be GFAP-, vimentin-, and p75-positive and could grow in culture from adult tissue dissociates. OBEC-like macroglial cells fulfilling these criteria were found in several brain loci, including the hypothalamus and the hypophysis. The macroglial types in these loci, tanycytes and pituicytes, have functions that involve rapid and reversible axon ensheathment. Furthermore, tanycytes and pituicytes have regeneration-promoting properties similar to both OBECs and Schwann cells. Tanycytes, pituicytes, olfactory bulb ensheathing cells, and pineal glia, in common with nonmyelinating Schwann cells, survive well when cultured from adult rodent brain tissue; exhibit morphologies similar to OBECs; and express a common distinctive set of immunological markers, namely p75 neurotrophin receptor, O4 antigen, estrogen receptor-α type, and insulin-like growth factor-1 (IGF-1) (Table 1).

Tanycytes extended long, fine, p75 immunoreactive processes, parallel to each other, from the ventricular wall to the ventral brain surface. All p75-positive tanycytes in both median eminence and infundibulum co-expressed GFAP, vimentin, estrogen receptor-α, and antigen O4. Immunoreactivity for estrogen receptor of the α type had previously been found exclusively in neuronal nuclei and in neuronal cytoplasmic processes. However, the well-characterized polyclonal antibody used by us (National Hormone and Pituitary Program, Rockville, MD), prepared against a synthetic peptide from residues 270–284 of domain D of estrogen receptor-α, immunostained in the adult rat brain the nuclei of hypothalamic neurons as well as the plasma membranes of olfactory bulb ensheathing cells and tanycytes. Preincubation with the peptide used as immunogen abolished both neuronal and glial immunostaining. Confocal microscopy of arcuate nucleus, median eminence, and pituitary stalk sections, doubly labeled with antibodies to the estrogen receptor D domain and to p75, showed co-localization of both receptors in the nonneuronal cells characteristic of these loci. These cells, when co-cultured with neurons, associated with

the neurites in a manner suggestive of enveloping and expressed peripheral myelinating phenotype.

The Schwann-like properties shown by these cells define a CNS macroglial type that would not fit in any of the conventional central glia classes (Table 1). We have called this distinct group of growth-promoting CNS macroglia 'aldynoglia' (Greek αλδαινο meaning 'make grow'). The proliferative and growth-promoting properties of aldynoglia seem to be retained during the entire lifetime of an organism in those CNS loci in which normal function depends on continuous axon renewal. The concomitant expression of estrogen receptor and low-affinity neurotrophin receptor may confer Schwann-like plasticity to these glial cells. Other glial cells, such as Müller cells, Bergmann glia, and cortical and spinal cord radial glia, show growth properties and immunological markers reminiscent of aldynoglia. Aldynoglia appears as an intermediate in the ontogeny of both neurons and macroglia. Its plasticity seems totally or partially lost with age, where and when it is no longer essential, as in the case of adult astroglia.

The problem of growing a sufficient number of cells in culture, as required for injury repair, has been approached in our laboratory as well as other laboratories, attempting to differentiate aldynoglia from neural stem cells and to transdifferentiate hematopoietic stem cells into neural stem cells and then into aldynoglia. These two projects differ in both their potential importance and the present state of the consensus. Neurospheres may be generated in abundance from embryonic rat striatum and differentiated to aldynoglia-like cells when plated onto an adhesive substrate in olfactory bulb ensheathing cell conditioned medium, supplemented with epidermal growth factor and basic fibroblast growth factor. The immunophenotype, messenger RNA expression (microarray analysis), and functional properties of the cells differentiated from neurospheres were similar to those of aldynoglia, although remarkably, they did not express the MHC II complex, an important result that needs further confirmation. Aldynoglia-like cells expressed, with respect to neurosphere cells, unchanged *nestin* levels and high GFAP, suggesting a glial phenotype with a possible role as precursor of neuronal and glial cells. Selective differentiation of these precursor cells may control the proportion of the various cell types in neural tissue during development and following injury.

Transdifferentiation, on the other hand, is proposed to explain how tissue-specific stem cells could generate cells typical of other organs, supporting the idea of enhanced adult stem cell plasticity. Although spontaneous cell fusion, rather than transdifferentiation, may explain some cell fate changes *in vivo*, such a mechanism does not explain possible transdifferentiation events *in vitro*, including the generation of neural cell types from cultured bone marrow-derived stem cells. Croft and Przyborski showed that bone marrow-derived stem cells expressed neural proteins in culture and formed neural-like structures under defined growth conditions. These changes in cell structure and protein expression were not typical of neural development, and the ability of bone marrow-derived stem cells to adopt a neural phenotype *in vitro* possibly occurred as a result of cellular stress and in response to removing cells from their niche and making them grow in different environmental conditions. Whatever the explanation for the growth behavior of bone marrow-derived cells, the most important question from a clinical standpoint is whether these cells will or will not perform as neural stem cells do when autotransplanted in CNS injury sites.

Functional Organization of the Mammalian Nose

The olfactory system recognizes a vast range of molecules that represent vital information about an animal's environment, including the location of prey and predators; the sexual, hormonal, and reproductive state of mating partners; and the level of aggression in rivals. How does the nose organize this complex mixture of olfactory information? Evidence from rodents has shown that there are several spatially segregated subpopulations of sensory neurons within the mammalian nose (Figure 1), each projecting to different areas of the brain and each likely serving as a somewhat distinct channel for different types of chemosensory information. Some of these subpopulations of sensory neurons use different signaling cascades for the transduction of information from chemosensory molecules into electrical membrane signals. The use of genetically altered animals in which each of these chemosensory information routes (Figure 1) is rendered nonfunctional in a selective manner will eventually lead to a better understanding of the precise roles that each subsystem plays in odor-dependent behaviors.

This article focuses on the mechanisms of odor transduction in the sensory neurons of the mammalian olfactory system, excluding two types of neurons from the vomeronasal organ (Figure 1) which are discussed separately. The mouse has rapidly emerged as one of the best model systems for investigating the cellular and molecular basis of odor transduction as well as the relationship between mechanisms underlying transduction and the significance of these signaling steps for odor-dependent behaviors. Knowledge gleaned from this work should also provide a solid foundation for understanding the molecular basis of odor transduction in other vertebrates, including humans, despite the fact that there are specific adaptations in each species regarding the overall organizational and structural features underlying olfactory sensing. Olfactory transduction in invertebrates is discussed elsewhere in this encyclopedia.

Olfactory Sensory Neurons of the Main Olfactory Epithelium

Signal Transduction: Olfactory Receptors, cAMP-Gated Channels, and Ca^{2+}

Odor transduction is best understood in ciliated olfactory sensory neurons (OSNs) of the main olfactory epithelium (MOE), which function as general sensors of the external chemical environment. Approximately 6–10 million OSNs form a sensory neuroepithelium that lines the nasal cavity in mammals (Figures 2(a) and 2(b)). The OSNs are bipolar neurons with a single dendrite that projects to the apical surface of the epithelium ending in a knoblike swelling from which emanate 10–30 very fine cilia (200–300 nm in diameter; Figure 2(c)). The cilia, which are covered by a thin layer of mucus, house the olfactory signal transduction machinery and serve as the primary interface between chemostimuli in the external environment and nervous system signaling. On the basal pole of each OSN, a thin unmyelinated axon projects to the main olfactory bulb (MOB). OSN axons form synapses with second-order neurons (mitral cells) and interneurons in dense regions of neuropil in the MOB that are collectively known as olfactory glomeruli.

The main olfactory system, like the immune system, is built on the condition that it is not possible to predict what molecules it might encounter. Therefore, it is necessary to maintain an indeterminate yet nonetheless precise sensory array. The olfactory system manages this complicated detection and discrimination task by expressing a surprisingly large family of G-protein-coupled receptors (GPCRs). This family of olfactory receptors, first identified by Buck and Axel, consists of as many as 1400 genes in mammals, making it the largest family of GPCRs and the largest gene family in the entire genome. Efforts in sequencing the entire human and mouse genomes have provided large databases of candidate olfactory receptors that can be accessed via the World Wide Web (Genbank and the Olfactory Receptor Database (ORDB)). However, specific ligands have only been identified for some receptors. Thus, many members of the olfactory receptor family are still considered orphan receptors.

How does the organization of the MOE allow for encoding an almost unlimited number of structurally diverse odor molecules? Although this critical question is still under investigation, several general principles have emerged. The first principle is that each OSN expresses only a single olfactory receptor (with

some exceptions) and that axons from OSNs that express the same receptor converge onto small sets of olfactory glomeruli at reproducible locations in each olfactory bulb. This allows for the creation of precise maps of receptor activation in the MOB. A second principle is that these receptors are relatively broadly tuned to odors. In other words, each OSN is sensitive to a different but overlapping set of odor ligands, and these tuning curves become less specific as odor concentration is increased. Thus, OSNs with the lowest threshold for a given odor molecule are activated first, and the less sensitive ones are recruited at higher concentrations, giving rise to a combinatorial coding scheme (Figure 3). The combinatorial coding scheme dictates that each odor ligand activates a unique subset of OSNs (and hence olfactory receptors), and this activation pattern depends on both the molecular identity of the stimulus and its concentration, allowing for a vast number of combinations.

Figure 1 Anatomical organization of chemosensory systems in the nose. Midsagittal view of the rodent nasal cavity (NC) and forebrain. Olfactory sensory neurons of the main olfactory epithelium (MOE) project to glomeruli in the main olfactory bulb (MOB; yellow). GC-D (guanylyl cyclase D-expressing) neurons (blue) are also located in the MOE but project to a limited number of necklace glomeruli (NG) in the caudal MOB. The septal organ of Masera (SOM) is an isolated island of olfactory sensory neurons that project axons to glomeruli in the ventromedial olfactory bulb. The Grueneberg ganglion (GG) projects axons to specific glomeruli in the caudal region of the MOB. Sensory neurons in the vomeronasal organ (VNO) project to the anterior (red) or posterior (green) accessory olfactory bulb (AOB).

Once the olfactory receptors have bound an odor ligand, a cascade of events is initiated, resulting in the generation of an electrical membrane current – a process called primary odor transduction. The odor-induced sensory current underlies the graded membrane depolarization known as receptor potential (Figures 4(a) and 4(b)). The basic transduction apparatus in the OSN cilia is composed of a G-protein-coupled cyclic adenosine 3′,5′-monophosphate (cAMP)-mediated second messenger cascade located in the ciliary plasma membrane (Figure 4(c)). The ligand-bound receptors activate a stimulatory GTP-binding protein ($G\alpha_{olf}$), which in turn activates type III adenylyl cyclase (ACIII), leading to the rapid production of the second messenger cAMP. Mutant mice with targeted deletions in either $G\alpha_{olf}$ or ACIII are unable to smell most odor molecules (anosmia). The main target for odor-induced cAMP is a cyclic nucleotide-gated (CNG) channel, which is closed in the absence of an odor stimulus but directly opened (gated) through the binding of cAMP to a specific site on the intracellular face of the channel. This CNG channel is a heteromultimeric protein composed of three distinct

Figure 2 Cytoarchitecture of the main olfactory epithelium. (a) Three-dimensional scanning view of a human olfactory epithelium. An olfactory sensory neuron (O) with its dendrite, knob, and cilia can be seen among supporting cells (S). Magnification, ×1241. (b) The main olfactory neuroepithelium (MOE) is a relatively simple tissue consisting of three major cell types: (1) the olfactory sensory neurons (OSNs; the only neuronal cell type), (2) supporting or sustentacular cells (S; a kind of glial cell whose function is not well understood), and (3) a stem cell population, known as basal cells, from which new OSNs are generated. (c) Three-dimensional view of a dendritic knob of a human olfactory neuron giving rise to cilia that gently taper as they extend over the epithelial surface. The cilia house the olfactory signal transduction machinery and serve as the primary interface between chemostimuli in the external environment and nervous system signaling. Magnification, ×18 525. Figure 3 Combinatorial receptor code for odorant detection. In this model, the receptors shown in dark red are those that recognize the odor ligand shown on the left. The identities of different odor ligands are encoded by different combinations of odor receptors (ORs). However, each OR can serve as one component of the combinatorial receptor code for many odor ligands. Given the immense number of possible combinations of ORs, this scheme could allow for discrimination of an almost unlimited number and variety of different odor ligands. Reprinted from Malnic B, Hirono J, Sato T, and Buck LB (1999) Combinatorial receptor codes for odors. *Cell* 96: 713–723, with permission from Elsevier.

subunits: CNGA2, CNGA4, and CNGB1b. CNGA2 is the principal subunit; mutant mice lacking this subunit are largely anosmic. CNGA4 and CNGB1b are modulatory subunits that play specific roles in odor adaptation. The CNG channel is permeable to monovalent cations such as Na^+ and K^+, but it also has a substantial permeability to the divalent cation Ca^{2+}. At rest, OSNs maintain a membrane potential near −65 mV. Odor stimulation leads to an influx of Na^+ and Ca^{2+} through the CNG channels and thus causes the inside of the cell to become approximately 30 mV less negative, generating a membrane depolarization. This, in turn, elicits action potentials which then propagate along the OSN axon into the forebrain, where they initiate nerve impulses in second-order neurons (mitral cells) in the olfactory bulb.

The odor-induced rise in intracellular Ca^{2+} concentration (Figures 4(c)–4(h)) is of particular significance for the transduction process because it acts as a negative feedback in olfactory signaling and allows rapid adaptation in this sensory system. As intracellular Ca^{2+} increases during the odor response, it acts on the CNG channel to decrease its sensitivity to cAMP (Figure 4(c)), thus diminishing the probability of opening the channel. This effect of Ca^{2+} requires the ubiquitous Ca^{2+}-binding protein calmodulin. Also essential for this feedback to function correctly are the modulatory CNG channel subunits CNGA4 and CNGB1b, which accelerate the Ca^{2+}/calmodulin-dependent channel desensitization. Mutant mice with a deletion in the CNGA4 gene are defective in odor adaptation. Thus, the Ca^{2+}-mediated negative feedback regulation of the CNG channel is essential for animals (and probably for humans as well) in continually assessing changes in odor environment and intensity in the presence of adapting background stimuli. Furthermore, the increase in Ca^{2+} has also been shown to mediate the Ca^{2+}/calmodulin kinase II-dependent attenuation of adenylyl cyclase activity.

Besides triggering adaptation, another important role of Ca^{2+} entering the olfactory cilia through the CNG channels is to mediate a special amplification mechanism based on the activation of a Ca^{2+}-gated Cl^- channel (Figure 4(c)). Normally, activation of Cl^- channels leads to membrane hyperpolarization. OSNs, however, maintain an unusually high intracellular Cl^- concentration of approximately 80 mM (with a corresponding Cl^- equilibrium potential of approximately −15 mV). Consequently, an intracellular increase in Ca^{2+} triggers Cl^- efflux through the activation of Cl^- channels, thereby further depolarizing the cells. The coexistence of ion fluxes through CNG channels and Ca^{2+}-gated Cl^- channels in the odor-induced sensory current may serve to reduce variations of the odor response resulting from changes in external ionic concentrations in the mucus surrounding the olfactory cilia. Identification of genes encoding this Cl^- channel and the targeted disruption of these genes should provide a more complete picture of the biological role of this amplification mechanism.

Not much attention has been directed toward understanding the downstream events responsible for the extrusion of Ca^{2+}. The Na^+/Ca^{2+} exchanger (NCX) is thought to be the primary Ca^{2+} extrusion mechanism in OSNs following odor stimulation. The Na^+ influx resulting from NCX activity is suggested to be recycled by an Na^+/K^+-ATPase. An additional pathway for Ca^{2+} extrusion could be provided by a plasma membrane calcium pump which has been described in OSNs of some species.

The Chemical Nature of Odorants

The main olfactory system has generally been regarded as a nonselective molecular analyzer of volatile odorants. Various lines of evidence have challenged this classical view, and a far greater complexity of chemosensory detection of olfactory cues has been suggested.

Terrestrial vertebrates aim their noses at regions of interest and sniff in order to acquire olfactory cues.

Figure 4 The cAMP-mediated chemoelectrical signal transduction cascade of odor-induced responses in the olfactory sensory neurons (OSNs). (a) Odor response measured in an isolated OSN using the perforated patch clamp technique. In the same OSN, the sensory current is measured using the voltage clamp technique at −60 mV and the receptor potential using the current clamp technique. Note the generation of a train of action potentials due to the receptor potential depolarization. OR, olfactory receptor; G_{olf}, α subunit of heterotrimeric GTP-binding protein; ACIII, type III adenylyl cyclase; CNGA2/CNGA4/CNGB1b, subunits that form a heteromultimeric cyclic nucleotide-gated channel; PDE, phosphodiesterase; CAM, calmodulin; cAMP, adenosine 3′,5′-cyclic monophosphate. (c–h) Transient Ca^{2+} elevation in individual olfactory cilia following the application of a single pulse of an odor ligand using optical imaging techniques. (c) Phase contrast image of an OSN showing several cilia emanating from an olfactory knob. (d–g) Fluorescence images (pseudocolor scale) taken at rest in the absence of odor ligand (d), near peak fluorescence (e), and 4 s (f) and 16 s (g) after stimulation. At rest, the knob and part of the dendrite are visible, but resting Ca^{2+} fluorescence in the cilia is below the resolution limit. (h) Time course of an odor-induced ciliary Ca^{2+} transient (taken from the cilium labeled by white arrow). Labeling indicates the time points for which individual frames were printed. (c–h) Reprinted from Leinders-Zufall T, Greer CA, Shepherd GM, and Zufall F (1998) Imaging odor-induced calcium transients in single olfactory cilia: Specificity of activation and role in transduction. *Journal of Neuroscience* 18: 5630–5639, with permission from the Society for Neuroscience.

Schlieren imaging, an optical airflow visualization method, revealed that animals use specific exhale and inhale sniffing paradigms which enable them to sample olfactory cues of different sizes and volatility. Other fluid dynamic methods have indicated that fine charcoal particles (0.5–5 μm) can be found as far into the nasal cavity as a dog's olfactory ethmoturbinates. Bodily secretions such as urine contain a plethora of chemosignals, from small volatile organic molecules to short nonvolatile peptides and larger proteins. Some of the nonvolatile constituents present in urine and other bodily secretions have been shown not only to gain access to the MOE following direct physical contact with the source but also to be detected by its sensory neurons. It also was surprising that some of the chemosignals established earlier as sensory stimuli of vomeronasal organ (VNO) neurons (often incorrectly portrayed as pheromones because they activate these types of neurons) are recognized by OSNs. Thus, the olfactory system can be stimulated by ligands (common odors and pheromones) independent of their chemical volatility.

Guanylyl Cyclase D-Expressing Neurons of the Main Olfactory Epithelium

Not all of the chemosensory transduction in the mammalian nose is mediated by cAMP. Ciliated OSNs of the main olfactory epithelium comprise a heterogeneous population, with groups of cells displaying different immunochemical and histochemical markers or unique patterns of gene expression. One of the most intriguing subpopulations represents less than 1% of all OSNs and expresses a receptor guanylyl cyclase, GC-D (Figure 1). The chemosensory stimuli detected by these neurons have not been identified, but it is clear that these cells exhibit both unique anatomical and functional characteristics. Unlike most OSNs,

which project their axons to hundreds of glomeruli on all aspects of the MOB, GC-D neurons project to a small group of approximately nine glomeruli, the necklace glomeruli, which circumscribe the caudal MOB and have been implicated in neonatal behaviors such as suckling. In contrast to most OSNs, GC-D neurons continue to provide active input to their glomerular targets in CNGA2 null mutant mice. GC-D neurons express none of the transduction components characteristic of most OSNs, including ACIII, $G\alpha_{olf}$, CNGA2, the cAMP-specific phosphodiesterase PDE4A, or the Ca^{2+}/calmodulin-sensitive phosphodiesterase PDE1C2. However, GC-D neurons do express two proteins reminiscent of a cGMP-mediated transduction pathway: a CNG channel similar or identical to the cGMP-specific channel subunit expressed in cone photoreceptors (CNGA3) and a cGMP-stimulated PDE2. Thus, it seems highly likely that these chemosensory neurons use cGMP, but not cAMP, as a second messenger for signal transduction. The targeted disruption of genes, such as that encoding GC-D, should allow for specific testing of this hypothesis and help identify the chemosensory cues that are sensed by this unique subset of OSNs.

The Septal Organ of Masera

In addition to the main olfactory epithelium, the septal organ of Masera (SOM) is another epithelium containing chemosensory neurons. It is located bilaterally on the nasal septum near the entrance of the nasopharynx and is completely encircled by respiratory epithelium (Figure 1). This island of olfactory sensory neurons projects axons to the MOB and targets a subset of glomeruli located in the posterior ventromedial bulb. Neurotracing studies revealed that a few of these glomeruli receive inputs mainly (if not exclusively) from the SOM, whereas others receive mixed inputs from both the SOM and the MOE. The SOM has been described in various vertebrate species, including rat and mouse, but seems to be absent in some mammals, such as cat and ferret. It resembles the MOE in its cytoarchitecture containing chemosensory neurons, supporting and basal cells, as well as Bowman's glands. The morphology of the chemosensory septal organ neurons shows some unique features, including flattened somata, shorter dendrites, and larger dendritic knobs.

Identical mechanisms of olfactory transduction are observed in these neurons compared to the MOE. The majority of septal organ neurons express $G\alpha_{olf}$ and ACIII. Adenylyl cyclase inhibitors suppress its odor-induced responses, suggesting a critical role for the cAMP signaling pathway in these neurons. Again, similar to the MOE, there is a small subset of cells expressing a cGMP-stimulated phosphodiesterase (PDE2), a marker for GC-D neurons. These results support the notion that the SOM might have evolved by segregating from the ventral part of the MOE during prenatal development.

A relatively complete expression profile of the olfactory receptors in the SOM has been achieved by combining cDNA cloning, Affymetrix GeneChips covering all mouse olfactory receptor (OR) genes, and *in situ* hybridization. Although cDNA cloning using degenerate primers allows identification of more than 120 candidate receptors from a repertoire of more than 1000 ORs, the majority of the septal organ neurons express only a few receptors in varying patterns. All the major septal ORs are expressed in the most ventral, lateral area of the MOE. Their expression patterns, however, do not match those in the SOM, in which some receptors are present in unusually high densities. The most prevalent receptor (MOR256-3) is expressed in nearly 50% of the cells, and the eight most prevalent receptors are expressed in more than 90% of the cells. This finding made it possible to test whether a single SOM neuron expresses only one receptor. Double-labeling studies using a systematic combination of all the major OR genes expressed in the SOM confirmed this hypothesis. The function of the septal organ remains obscure. Physiological and behavioral studies are needed to elucidate the function of this enigmatic chemosensory organ. In terms of chemoreceptor composition, the SOM is the best described region in the mammalian nose.

The Grueneberg Ganglion

The Grueneberg ganglion (GG) is a compact cluster of neurons located bilaterally at the anterior end of the nasal septum (Figure 1). This ganglion was previously thought to be nonsensory and part of the terminal nerve system. However, studies have indicated that these neurons express olfactory marker protein, a marker for mature chemosensory neurons. The axons of these neurons fasciculate into several nerve bundles that terminate in a subset of atypical glomeruli, the same region as the glomerular target of the GC-D neurons. It is not clear if these two different chemosensory neurons share the same glomeruli or if these glomeruli have different functions depending on their innervation by GC-D or GG neurons. However, it appears that the GG is part of the olfactory system, although its function remains to be determined.

Conclusion

The vertebrate olfactory system is classically divided into two anatomically separate, and morphologically distinct, sensory systems: the accessory and the main olfactory system. The accessory olfactory system,

discussed elsewhere in this encyclopedia, consists of the vomeronasal organ (enclosed in the vomer bone) and targets the accessory olfactory bulb (**Figure 1**). The main olfactory system consists of the OSNs in the nasal cavity that project to the MOB. However, it has become evident that the nasal cavity does not contain only the main olfactory system with its OSNs utilizing the cAMP-mediated signal transduction cascade. As discussed previously, there are additional olfactory neuroepithelia present, including the SOM and the GG. These chemosensory subsystems contain more than one type of sensory neuron, which can be distinguished based on morphology, signal transduction cascade, or its target in the brain. Some of these cells are microvilli cells that have been detected in the MOE. A population of nonneuronal chemosensory cells is scattered within the rostral nasal cavity. These seem to be innervated by trigeminal afferent nerve fibers. The use of transgenic animals has resulted in the discovery of new subpopulations. One subtype of these newly recognized chemosensory neurons can be identified due to the presence of a specific ion channel, the transient receptor potential channel subunit TRPM5 (a key element in taste transduction). Thus, the mammalian olfactory system is composed of several distinct subsystems. Some of them, such as OSNs in the MOE and the sensory neurons in the VNO, have been shown to detect partially overlapping sets of social signals, giving rise to a model that involves parallel processing of the same molecules in these systems. This proposal implies that information about the same olfactory stimuli derived from each system is integrated in higher brain centers to regulate mammalian social behavior. Current interest is focused on the role that each of the olfactory subsystems plays in detecting molecular information and regulating chemosensory-dependent behaviors.

Olfactory Glomeruli: Structure and Circuitry

Glomeruli as Anatomical and Functional Units

The projection of receptor neurons to olfactory glomeruli is massively convergent, with thousands of olfactory receptor neurons (ORNs) converging onto each glomerulus of the mammalian olfactory bulb. Each of the several thousand ORNs expressing the same seven-transmembrane odorant receptor (OR) converges onto one, two, or a few glomeruli in the olfactory bulb (OB). The result of this organization is such that, at the level of sensory input to the OB, OR identity is mapped across the surface of the OB, with glomeruli serving as the anatomical unit of this map. Several lines of evidence indicate that the glomerulus also serves as a functional unit in representing odor information. First, ORNs expressing the same OR show similar odorant response specificities *in vitro*, implying that ORN input to a glomerulus is functionally homogeneous. Second, glomeruli can be discretely activated in an odorant-specific manner as seen using a variety of methods including 2-deoxyglucose mapping, functional magnetic resonance imaging, intrinsic optical imaging, imaging with fluorescent activity probes such as calcium-sensitive dyes and voltage-sensitive dyes, genetically encoded activity probes, and electrophysiology recordings. Third, odors activate multiple glomeruli with overlapping, but different, response specificities. Thus, information about odorant identity is carried in the combination and relative level of activation of different glomeruli. This feature is not surprising given that the ORs which are represented by glomeruli also show distinct but overlapping odorant specificities. Together, these data suggest that, at the level of ORN input, the glomerulus is the smallest detectable unit contributing to the functional representation of odor information.

Glomerular activity maps show a loosely organized chemotopy across the OB. In mammals, structurally similar odorants preferentially activate glomeruli in similar OB regions. These 'modules' or 'domains' encompass between 10 and 50 glomeruli. As with the glomeruli, each module is duplicated on the medial and lateral halves of the bulb and is roughly conserved across individuals. Glomerular modules have only been defined functionally (i.e., based on their odorant response properties); it is unclear whether they correspond to particular OR subclasses or even how sharply delineated are the boundaries between different modules.

Intrinsic and Synaptic Properties of Juxtaglomerular Neurons

The spatial and temporal characteristics of glomerular activity maps discussed to this point are the results of properties inherent in ORNs and the 'rules' governing their glomerular targeting. These characteristics neither involve nor require interactions among ORNs. Upon synapsing in the glomerulus, ORNs release glutamate and engage postsynaptic circuits that initiate the neural processing of olfactory input. From this point on, neural processing involves not only the intrinsic properties of neurons but also the synaptic relationships that organize them into neural circuits.

Glomeruli are composed of a 'shell' of juxtaglomerular (JG) neurons and astrocyte cell bodies surrounding a globular assembly of neuropil. The neuropil contains the synaptic contacts between ORN axons, the apical dendrites of mitral and tufted cells, the dendrites of JG neurons, and synaptic linkages among these neurons. Although classical neuroanatomists recognized at least three types of JG neurons, there has been a tendency to view the glomerulus as composed of 'periglomerular' cells, which function as local GABAergic interneurons that negatively modulate ORN to mitral/tufted cell synaptic throughput. Research indicates that this view is too simplistic and that each glomerulus contains complex micronetworks that perform multiple, distinct operations on ORN input.

Early Golgi and electron microscopy (EM) studies identified three broad types of JG neurons: external tufted (ET), periglomerular (PG), and short axon (SA) cells. These cells can be distinguished not only by their morphologies but also by equally distinctive physiological characteristics, including intrinsic and synaptic properties (Figure 1). The advent of modern chemoanatomical methods revealed an additional level of complexity by showing that different JG cell subpopulations express a variety of neurotransmitters, receptors, and calcium-binding proteins. Cellular physiology analyses of JG neurons led to the recognition that the synaptic circuits are also are far more complex and play more roles in olfactory processing than previously appreciated.

ET cells are distinguished by their elaborate dendritic arbor, which ramifies extensively throughout a single glomerulus. The ET cell dendrite is actually

Figure 1 Physiology and morphology of ET, PG, and SA cells. ET cells: (a) reconstruction of a biocytin-filled ET cell. Note the highly branched tufted dendrites that ramify throughout only a single glomerulus. (b) The same ET cell in cell-attached mode and whole cell configuration. (c) ET cells monosynaptically excite PG and SA cells. Dual recordings from an ET cell in cell-attached (bottom traces) and a PG cell in whole cell voltage clamp (top traces). Example of a burst of EPSCs in a PG cell (bottom trace) evoked by a burst of spikes (top trace) elicited by extracellular application of a positive current pulse in a paired ET cell. Note the short, invariant latency between evoked spikes in the ET cell and EPSCs in the PG cell. (d) ET cells are entrained by patterned ON input across a frequency spectrum similar to breathing/sniffing frequencies. Peristimulus time histograms showing the activity of an ET cell in response to a train of 10 ON stimuli (arrows) delivered at 5 Hz (top), 8 Hz (middle), and 10 Hz (bottom). PG cells: (e) (top traces) current-clamp recordings show effects of steady hyperpolarizing or depolarizing current injection in a typical PG cell. Depolarizing or hyperpolarizing current injections do not generate spike bursts. The cell receives spontaneous long-duration bursts of EPSCs and generates spikes infrequently, notably during bursts of EPSPs (asterisk). (Bottom traces) Voltage-clamp recording (HP = −60 mV) shows bursts of spontaneous EPSCs in the same PG cell; the region enclosed in the box is shown at a faster timescale at right. (Right) Reconstruction of the recorded cell shows typical morphology of PG cells, including relatively small soma and one to three relatively thick primary dendritic shafts that give rise to thinner branches ramifying within a subregion of a single glomerulus. SA cells: (f) the resting activity of SA cells and their responses to current injection are similar to those of PG cells. SA cells receive bursts of spontaneous EPSCs. Reconstruction of the recorded cell at left shows typical morphology of SA cells, including several poorly branched dendrites extended into or between two to four glomeruli. (a, b, d–f) Reproduced from Hayer A, Karnup S, Shipley MT, and Ennis M (2004) Olfactory bulb glomeruli: External tufted cells intrinsically burst at theta frequency and are entrained by patterned olfactory input. *Journal of Neuroscience* 24:1190–1199, with permission from Society for Neuroscience. (c) Reproduced from Hayer A, Karnup S, Ennis M, and Shipley MT (2004) External tufted cells: A major excitatory element that coordinates glomerular activity. *Journal of Neuroscience* 24: 6676–6685, with permission from Society for Neuroscience.

more extensive on average than that of the mitral cell. A second distinctive morphological feature is that ET cells rarely extend lateral dendrites and, when present, do not enter into the external plexiform layer (EPL). Thus, unlike mitral and classical (superficial, middle, and deep) tufted cells, ET cells are not regulated by inhibitory inputs from granule cells. ET cells have a single axon that exits the glomerular layer and traverses the EPL without branching. The target(s) of ET cell axons is unclear, but they do appear to project beyond the bulb at least as far as the anterior olfactory nucleus.

The most distinctive characteristic of ET cells, however, is physiological: ET cells spontaneously generate rhythmical bursts of action potentials. Their ability to generate rhythmic bursts is due to intrinsic membrane properties and not to rhythmic synaptic input. Indeed, when synaptic transmission is pharmacologically blocked, the bursting frequency of each ET cell becomes more regular. ET cell bursting depends on the interplay of several intrinsic conductances, including a persistent sodium current that appears to be necessary to initiate the burst, an L/T-type calcium current that sustains the burst and gates a Ca^{2+}- and voltage-dependent K^{+} current, which terminates the burst. A second fundamental property of ET cells is that they all receive monosynaptic input from the olfactory nerve. This is in sharp contrast to the majority of PG cells and all SA cells, which do not receive monosynaptic olfactory nerve (ON) input.

PG cells have a less elaborate dendritic arbor that occupies a much smaller glomerular region than that of ET cells. Their physiological characteristics are also very different from ET cells. PG cells do not generate rhythmic burst of action potentials and in general have infrequent spontaneous action potentials. The intrinsic membrane properties of PG cells are more heterogeneous than those of ET cells, perhaps corresponding to their more heterogeneous morphologies and heterogeneous expression of transmitters, receptors, and calcium-binding proteins. PG cells can be divided into two groups based on synaptic input. Approximately 70–80% of all PG cells receive distinctive rhythmic bursts of spontaneous synaptic input and do not receive direct ON input; the remaining 20–30% receive direct olfactory nerve input but do not exhibit bursts of spontaneous synaptic events. Thus, although classic EM studies suggested that all PG cells receive monosynaptic ON input, only approximately 20–30% actually do. As discussed later, the vast majority of PG cells receive olfactory input via ET cells.

SA cells are the third and historically most obscure of the classical JG cell types. Studies have disclosed that SA cells play a key role in a newly discovered interglomerular lateral inhibitory network (Figure 2). Consistent with classical descriptions, SA cell dendrites – unlike those of ET and PG cells – ramify among several neighboring glomeruli. However, in contrast to their name, 'short axon' cells actually give rise to a rich and extensive interglomerular axonal network, which projects to glomeruli as far as 1 mm distant. The contradiction between their classical name and their actual morphology probably reflects the failure of the Golgi method to adequately impregnate their fine axons. Physiologically, the spontaneous activity of SA cells is very similar to that of the majority of PG cells; they exhibit rhythmic bursts of spontaneous synaptic events and do not receive monosynaptic ON input. Perhaps due to their extensive axonal arbor, SA cells have larger cell bodies and lower input resistances but otherwise are difficult to distinguish from PG cells based on spontaneous and ON-evoked activity.

Glomerular Circuits

The intrinsic neurons that comprise the glomerular network – ET, PG, and SA cells – are more complex and physiologically diverse than previously suspected. Based on new information on the major synaptic relationships among ET, PG, and SA neurons, at least four principal glomerular circuits can be postulated: the ON→M/T circuit, the ON→PG circuit, the ON→ET→PG circuit, and the ON→ET→SA circuit (Figure 3).

The ON→M/T→PG Circuit

A fundamental canon of olfactory circuitry is that ON terminals synapse directly on the apical intraglomerular dendrites of M/T cells (i.e., an ON→M/T circuit). Based on ultrastructural features, classical EM studies distinguished two types of intraglomerular dendrites postsynaptic to ON terminals: M/T cells and PG cells. These studies also posited that M/T cell intraglomerular dendrites are presynaptic to PG cells, leading to the idea that ON-evoked excitation of M/T cells causes M/T excitation of PG cells, thus providing feedback inhibition of M/T cells. This view needs to be reconsidered in light of new information about ET and PG cells. ET dendrites ramify at least as extensively within the glomerulus as M/T dendrites, and all ET cells receive monosynaptic ON input. The morphological criteria used to identify M/T cells in EM studies would certainly have included ET cell dendrites. Therefore, it is likely that some (perhaps appreciable) fraction of the ON→M/T synapses identified by classical EM studies were actually ON→ET synapses.

Figure 2 Center surround inhibitory network among olfactory bulb glomeruli. (a) Reconstruction of a biocytin-filled SA cell showing extensive branched axonal projections across multiple glomeruli and a less complicated dendritic projection (dendrites, gray; axon, black). (b) Diagram showing center surround inhibition via excitatory SA cells. (c) PG and ET cells responded with EPSPs to distant glomerular layer stimulation. The inset shows a 2 ms response latency, consistent with a monosynaptic event. (d) Biocytin-filled mitral cell (white) and nuclear stain (gray). Cuts through the ONL and deep bulb layers isolating the interglomerular circuit are clearly visible. (e) (Top trace) Mitral cells respond to ON stimulation with an LLD (black trace) that is abruptly terminated by stimulation of a distant glomerulus (arrow, gray trace). (Middle trace) Stimulation of interglomerular connections evokes an IPSP in mitral cells. (Lower trace) In the presence of gabazine, olfactory nerve evoked LLDs are no longer suppressed by glomerular layer stimulation (black trace, ON stimulation alone; gray trace, ON plus interglomerular stimulation).

Figure 3 Principal glomerular circuits. The small panels show four principal glomerular circuits: ON→M/T→PG, ON→PG, ON→ET→PG, and ON→ET→SA→PG→M/T interglomerular circuit. The central panel shows all four glomerular circuits together with the mitral–granule–mitral (M→G→M) circuit.

What about the physiological evidence for monosynaptic ON inputs to M/T cells? Mitral cells respond to ON stimulation with a short latency, low-variance excitatory postsynaptic current (EPSC). Thus, there is physiological support for the conclusion that M/T cells receive monosynaptic ON input. However, this initial response is followed by a series of longer, more variable latency EPSCs that sum to produce large, long-lasting events termed 'long-lasting depolarizations' (LLDs). The events contributing to the LLD are too long latency and recur over too long a time frame to be due to monosynaptic ON input. LLDs have been attributed to recurrent input via 'glutamate spillover' from the apical dendrites neighboring mitral and/or tufted cells. The finding that ET cells generate prolonged, repetitive bursts of action potentials in response to monosynaptic ON input suggests the possibility that ON-evoked ET cell bursts also play a role in LLDs by amplifying and prolonging ON activation of M/T cells. Additional investigation is needed to determine if the ON→M/T excitatory circuit is supplemented by ON→ET→M/T excitation.

The ON→PG Cell Circuit

Classical EM studies also showed that PG cells receive ON synaptic contacts, leading to the inference that ON input directly excites PG cells, which in turn provide feed-forward inhibitory input to MT cells. Therefore, the second principal glomerular circuit is the ON→PG circuit. In contrast to the classical anatomical picture, electrophysiological studies show that the olfactory nerve provides monosynaptic excitatory input to only approximately 20–30% of all

PG cells. Thus, PG cells are divided into two broad groups on the basis of synaptic input – the approximately 20–30% of 'mono' PG cells which receive direct ON input and the 70–80% of 'poly' PG cells which receive indirect polysynaptic ON input. However, although less is known about its influence on the ON→PG cell circuit, it should not be dismissed as 'minor' simply because it comprises only 20–30% of the PG cell population. PG cells comprise approximately 70% of the entire JG cell population; therefore, the 'minor' monoPG cells are as numerous as ET or SA cells. The ON→PG cell circuit may correspond to the classical ON→PG→M/T cell circuit postulated by early EM studies. This circuit might operate in parallel with the ON→ET→PG→M/T circuit (discussed later), both providing delayed feed-forward inhibition of M/T cells.

Another established role for the ON→PG circuit is presynaptic inhibition of ON terminals via an ON→PG→ON circuit. Feedback from PG cells onto ORN axon terminals suppresses transmitter release (i.e., presynaptic inhibition). In mammalian glomeruli, both GABA and dopamine are involved in this presynaptic inhibition. ORNs express $GABA_B$ and dopamine D_2 receptors on their axon terminals, and both $GABA_B$ and D_2 agonists suppress postsynaptic activity evoked by ON shock. Direct depolarization of GABAergic periglomerular interneurons (PG cells) also suppresses ON input, indicating that the circuit mediating feedback presynaptic inhibition is intrinsic to the glomerular layer. Presynaptic inhibition of ORNs is predominately mediated by a suppression of calcium influx through N-type voltage-sensitive calcium channels.

The ON→ET→PG Circuit

ON provides monosynaptic input to all ET cells, which in turn monosynaptically excite PG cells. ON-evoked monosynaptic EPSCs in ET cells are followed by a longer latency, compound inhibitory postsynaptic current, which is due to GABAergic input from PG cells. Thus, one extension of the ON→ET→PG circuit is an ON→ET→PG→ET feedback circuit. The temporal sequence of excitation followed by feedback inhibition generated by this circuit may function to shape postsynaptic responses to sensory input possibly by creating a temporal 'window of opportunity' for sensory signals to achieve glomerular throughput and influence downstream olfactory circuits. Since only 20% of PG cells receive monosynaptic ON input, some of the intraglomerular inhibition of M/T cell dendrites, classically attributed to the ON→M/T→PG→M/T circuit, may actually be due to the operation of an ON→ET→PG→MT cell circuit.

The ON→ET→SA Interglomerular Circuit

SA cells lack monosynaptic ON input but do receive excitatory monosynaptic input from ET cells. Thus, the fourth principal glomerular circuit is the ON→ET→SA cell circuit. SA cells give rise to a rich axonal plexus that contacts multiple glomeruli up to a millimeter distant. The existence of this interglomerular network suggested that SA cells mediate interactions among glomeruli. Experiments using voltage-sensitive dyes showed these interglomerular connections to be excitatory. SA cells make glutamatergic synapses with neurons in distant glomeruli and stimulation of interglomerular axons produce EPSCs in PG and ET cells of target glomeruli. This raised the possibility that the interglomerular circuit could inhibit M/T cells via an SA→PG→M/T cell circuit. This was confirmed by showing that stimulation of interglomerular axons produced a compound inhibitory postsynaptic potential (IPSP) in mitral cells; the IPSP was blocked by the $GABA_A$ receptor antagonist gabazine. The inhibition produced by activating the interglomerular circuit was sufficient to terminate ON-evoked LLDs in mitral cells. Thus, there is a network composed, minimally, of an ON→ET→SA→(distal glomerulus)→PG→M circuit, which provides interglomerular lateral inhibition. Strong ON activation of a given glomerulus activates the ON→ET→SA→(distal glomerulus)→PG→M circuit, which inhibits mitral cells – and thus glomerular throughput – in weakly activated glomeruli. Such lateral inhibition could function to enhance contrast among differentially activated glomeruli.

The length of SA axons does not necessarily limit the spatial propagation of interglomerular activity. Since stimulation of the SA interglomerular axons excites ET cells of distant glomeruli, it is possible that ET cells excite additional local SA cells which further inhibit more distant glomeruli, via an ON→ET→SA→(distal glomerulus) ET→SA→(distal glomerulus) multisynaptic interglomerular circuit. Mathematical modeling of this propagating network suggests that the interglomerular circuit may provide input to all glomeruli that represents the average of glomerular activity over much of the bulb. A consequence of this is that an overall increase in glomerular activity, such as during high-concentration odor exposure, would result in a higher level of activity in the interglomerular network and a higher level of inhibition onto mitral cells. This putative averaging function could 'normalize' postsynaptic activity to changes in odor concentration.

The External Tufted Cell: A Glomerular Gatekeeper?

The ET cell is a key player in the glomerular circuitry. ET cells are the primary JG cell targets of monosynaptic ON input. Only 20–30% of PG cells and no SA cells are synaptically contacted by ON terminals. Thus, ET cells are ideally positioned to mediate sensory input to other PG and SA cells. Simultaneous dual whole cell recordings from ET and PG or SA cells show that spontaneous and ON-evoked bursts of action potentials in ET cells are highly correlated with subsequent bursts of EPSCs in simultaneously voltage-clamped PG/SA cells, suggesting that the ET cell population provides excitatory input to PG and SA cells. In many paired recordings, spike-triggered averaging revealed activity correlations indicative of monosynaptic ET to PG/SA cell input. In such cases, direct stimulation of the ET cell generated short, invariant latency EPSCs in the PG/SA cell. These events were blocked by an AMPA/kainate glutamate receptor antagonist, demonstrating that ET cells provide monosynaptic, glutamatergic input to PG and SA cells. Thus, the ET cell directly mediates olfactory nerve input to the majority of other intrinsic glomerular neurons. The additional fact that ET cells respond to suprathreshold ON input with a burst of action potentials suggests that ET cells amplify and/or increase the synaptic security of sensory input to other postsynaptic glomerular targets. Thus, the ET cell is a key excitatory element in the glomerular network.

Two properties of ET cells suggest that glomerular circuits are specialized to deal with the dynamics that sniffing confers upon odorant sampling. One property results from ET cell bursting and the second from the observation that ET cells of the same glomerulus have coupled (i.e., quasi-synchronous) activity which may function, in part, to coordinate and possibly synchronize intraglomerular activity.

Synchrony

ET cells of the same glomerulus have correlated spontaneous activity, which is expressed at the level of action potentials as well as oscillations of membrane potential. ET cells associated with different glomeruli do not have such correlated activity. Thus, the mechanisms that couple ET cells are of intraglomerular origin. Several intraglomerular synaptic and electrical coupling mechanisms have been identified, indicating that both synaptic transmission and gap junction coupling contribute to this correlated spontaneous bursting of ET cells. The coupled activity of ET cells of the same glomerulus, in addition to the fact that two of the four principal glomerular circuits – ON→ET→PG and ON→ET→SA – are primarily driven by the ET cell, suggests that glomerular circuits are specialized for highly coordinated activity. This coordinate activity may function to synchronize and temporally gate or window glomerular output.

Several lines of evidence indicate that glomerular output is synchronized by intraglomerular mechanisms. ON stimulation produces a short-latency EPSC in mitral cells. This short-latency monosynaptic EPSC is then augmented by recurrent EPSCs, leading to a long-lasting (400–800 ms) depolarization. Mitral cells whose dendrites ramify in the same glomerulus have synchronous LLDs, whereas LLDs in mitral cells associated with different glomeruli are not correlated. Thus, LLDs are initiated within the glomerulus and intraglomerular mechanisms synchronize at least some aspects of mitral cell activity. Stronger ON stimulation also triggers slow (2 Hz) oscillations in mitral cells. These events, like LLDs, and conventional EPSPs are also highly synchronous in mitral cells associated with the same glomerulus. Depolarization of mitral cell pairs generates action potentials that are correlated on a timescale of $\leq$10 ms for cells associated with the same glomerulus. This correlated spiking appears to depend on both intraglomerular electrical (gap junction) and chemical (AMPA receptors) coupling. Thus, at several temporal levels, the activity of mitral cells of the same glomerulus is synchronous and the mechanisms regulating this synchronous activity are of intraglomerular origin. ET cells may also play a role in this synchronization. A single shock to the olfactory nerve generates a brief monosynaptic excitatory response in ET cells. This brief input is converted into a prolonged output by the burst of action potentials. ET cell bursts could contribute to the synchrony of mitral/tufted activity cells via glutamate spillover and gap junctions in a manner similar to mitral cells whose dendrites are associated with the same glomerulus.

ET cells monosynaptically excite PG cells, which in turn provide intraglomerular feedback and inhibition of ET cells. This arrangement is similar to the mitral→granule→mitral cell (M→G→M) circuit in which mitral cells excite granule cells, which in turn provide feedback to the same and lateral inhibition to other mitral cells. The M→G→M circuit provides contrast enhancement of strongly versus weakly activated glomeruli (i.e., interglomerular spatial contrast enhancement). It is not obvious what functional role would be served by intraglomerular spatial contrast enhancement via the ET→PG→ET circuit. However, the M→G→M circuit also provides a temporal

windowing function via feedback inhibition of mitral cells. After strong excitation, M→G→M feedback inhibition temporarily reduces mitral cell excitability, thus reducing sensitivity to sensory input. The ET→PG→ET circuit is well suited to provide a similar intraglomerular temporal windowing function. Thus, the ET→PG→ET intraglomerular circuit may function first to amplify olfactory nerve input and second to generate a temporal window, within which sensory inputs are integrated to generate synchronous glomerular output.

ET Bursting and Sniffing

The ability of ET cells to generate rhythmical bursts of action potentials is due entirely to ET cell intrinsic membrane properties. When synaptic inputs are blocked with receptor antagonists, not only do ET cells continue to rhythmically burst but also the bursting frequency becomes significantly more regular. Under such conditions, each ET cell expresses a bursting frequency characteristic for that cell. This 'native' or 'steady-state' bursting frequency is different for each cell. The distribution of bursting frequencies across the entire population of ET cells comprises a relatively narrow spectrum ranging from approximately 0.2 to 10 Hz. This is nearly identical to the spectrum of normal breathing and sniffing frequencies exhibited by rats and mice. This correspondence suggested that the ability of ET cells to generate intrinsic bursting might be a physiological specialization that allows them to respond optimally to rhythmical (i.e., sniff-related odorant input). Indeed, ET cells follow repetitive ON stimulation at all frequencies in the range from approximately 0.2 to 10 Hz and a given ET cell follows (i.e., is entrained) by frequencies at or above the cell's native frequency.

This finding has important functional implications. As the frequency of sniffing increases, more ET cells will be entrained as each cell follows all input frequencies above its native bursting frequency. Since ET cells provide the excitatory input to the majority of PG and to all SA cells, as the number of entrained ET cells increases with higher sniffing frequency, the excitatory drive on and temporal synchrony of PG and SA cells will increase. The increased excitatory drive on PG cells will increase the inhibitory feedback onto ET cells via the ON→ET→PG→ET circuit and onto M/T cells via the ON→ET→PG→M/T circuit. The combination of ON→ET entrainment and PG→ET feedback inhibition should generate an increasingly narrow temporal window for the integration of sensory input as sniff frequency increases. This may impose critical timing constraints on glomerular throughput. Sniff frequency should also impact the dynamics of the ON→ET→SA→interglomerular circuit. As sniffing frequency increases, more ET cells are entrained and the excitatory drive on SA cells will increase and become more synchronous. This should increase SA excitatory drive on PG cells in distant glomeruli, which in turn will increase GABAergic inhibition of M/T cells in those glomeruli. Thus, at higher sniffing frequencies, interglomerular inhibition should increase, with the result that more strongly (and synchronously?) activated glomeruli should more effectively inhibit weakly activated glomeruli – that is, interglomerular contrast enhancement should increase in proportion to sniffing frequency.

Role of Glomerular Processing in Shaping Odor Representations

How might the presynaptic and postsynaptic glomerular network function together to shape spatial and temporal patterns of activity as olfactory input is transmitted from ORNs to MT cells? We speculate that this network is optimally organized to impose brief temporal windows over which MT cells can be excited by rhythmic ORN inputs while at the same time maintaining responsiveness across a wide range of input strengths. We further speculate that spatial patterns of MT activity are sharpened via interglomerular inhibition. The interglomerular circuit may also normalize relative levels of glomerular activity in the face of changing concentration. A key feature of the circuitry underlying these functions is that the strength and dynamics of both intra- and interglomerular inhibition are dependent on the frequency with which odorants are sampled via sniffing. At low sniff frequencies characteristic of anesthetized and resting awake animals (1–3 Hz), ORN input to glomeruli occurs as brief bursts which are repeated with each inspiration and which drive transient activity in postsynaptic neurons. Intraglomerular excitatory mechanisms synchronize MT firing with the transient ORN inputs, whereas intraglomerular inhibitory pathways (mediated by the ET→PG cell circuit) mediate fast $GABA_A$-mediated inhibition of MT cells and slow $GABA_B$-mediated presynaptic inhibition of ORN input. The dynamics of the slower presynaptic inhibition are ideally suited to suppress ORN input in a manner that is graded with sniff frequency without affecting the dynamics of input evoked by an individual sniff. Thus, we hypothesize that as sniff frequency increases and more ET cells are entrained to fire synchronously, ORN inputs become more strongly suppressed. At the same time, the strength of fast inhibitory input to MT cells

increases as more ET cells are recruited, preventing excessive autoexcitation and further sharpening the temporal window over which excitatory inputs are integrated.

How could this circuitry affect spatial patterns of MT cell activity? First, given that the latency and rise time of sniff-driven ORN input to a glomerulus varies across glomeruli and across odorants, the temporal window over which inputs are able to excite MT cells is critical in determining how spatial maps of input to glomeruli are transformed into MT cell response patterns. Because this temporal window narrows at higher sniff frequencies, one possibility is that only MT cells innervating glomeruli receiving the fastest onset input are activated. At the same time, increased ET cell activation at higher sniff frequencies would be expected to increase the strength of interglomerular inhibition via the ET→SA→PG cell network, additionally sharpening MT response patterns such that MT cells innervating glomeruli receiving weaker and longer latency input are not excited. These processes are conjectural, but one implication of this organization is that the degree to which spatial patterns of glomerular activity are sharpened by glomerular processing can change depending on the frequency of sniffing. This hypothesis, which is testable, implies that odor representations depend not only on the identity of the olfactory stimulus but also on the way in which it is sampled.

Introduction

As with other sensory modalities, olfactory information must be transmitted from peripheral olfactory structures (the olfactory epithelium) to more-central structures (the primary olfactory cortex), integrated to detect and discriminate specific stimuli, and then transferred to other parts of the brain in order to reach sensory consciousness and affect behavior. The central olfactory system, however, and particularly the olfactory cortex, is different from the other sensory systems in two key ways.

First, olfactory sensory activity is transferred directly from the olfactory bulb to the primary olfactory cortex, and from there to the orbital neocortex, without a thalamic relay. Although there is a projection from the olfactory cortex to the mediodorsal thalamic nucleus, which is reciprocally connected with the posterior orbital/agranular insular cortex, this transthalamic pathway involves fewer neurons than the monosynaptic projection from the primary olfactory cortex to the same orbital/insular areas. The transthalamic projection is therefore not required for relay of olfactory sensory information to the neocortex.

The second difference is that the analysis of olfactory stimuli may not involve a topographic organization beyond the olfactory bulb. Olfactory stimuli are not distributed along an obvious spatial or frequency map, and it has been difficult to determine how the stimuli are organized. An organization has been found in the projection from the olfactory epithelium to the olfactory bulb, but there is little solid indication of a topographic organization from the bulb to the olfactory cortex. Instead, axons of single mitral or tufted cells have multiple axon collaterals that make synapses throughout a large part of the olfactory cortical areas. A more complex organization may eventually be discovered, but on the present evidence, it is also likely that specific odors are discriminated by differences in the spatiotemporal pattern of activity across large regions of the olfactory cortex.

Axons from the olfactory bulb extend through the olfactory tract to a varied set of cortical regions on the surface of the ventral forebrain that can generally be referred to as the olfactory cortical areas or primary olfactory cortex (Figures 1 and 2). The olfactory tract is often called the lateral olfactory tract, but it is now recognized that there is no medial olfactory tract. Although the primary olfactory cortex should not be considered equivalent to the primary visual, somatic sensory, or auditory areas in the cerebral neocortex, it is a major site for integration of sensory stimuli and appears to be involved in olfactory detection, discrimination, and even memory.

Throughout the olfactory cortex, fibers from the olfactory bulb end in the superficial lamina of layer I (layer Ia). There is also a complex set of associational connections that originate in many of the olfactory cortical areas and terminate in the deeper lamina of layer I (layer Ib) and layer III. Projections from the several olfactory areas convey information to many other parts of the brain, including the hypothalamus, amygdala, hippocampal formation, frontal and insular cortex, mediodorsal thalamus, and ventral striatum. These not only support olfactory sensation but also allow olfactory stimuli to influence both conscious behavior and subconscious visceral function.

Projection of Olfactory Bulb and Accessory Olfactory Bulb

The relay cells in the olfactory bulb and accessory bulb (the mitral and tufted cells) send their axons into the lateral olfactory tract, which runs caudally through the lateral part of the olfactory peduncle and the rostral part of the olfactory cortex. Axon collaterals branch off the larger axons in the tract and extend medially, laterally, caudally, and deep to the olfactory tract itself, to synapse in all the olfactory cortical areas. The thickness of layer Ia and the density of termination are greatest in the regions nearest to the lateral olfactory tract (for example in the medial edge of the piriform cortex immediately deep to the tract), and become progressively less in areas of cortex more distant from the tract.

The smaller tufted cells have less extensive axonal ramifications and reach only the anterior half to two-thirds of the olfactory cortex, whereas the larger mitral cells send axons to all parts of the cortex. Each parent axon in the lateral olfactory tract appears to give off a number of collateral branches, each of which makes numerous synapses as it runs through layer Ia of the cortex. Therefore, each mitral or tufted cell forms synapses in a wide region of the olfactory cortex.

Primary Olfactory Cortical Areas: Structure

At least seven distinct areas can be recognized that receive a monosynaptic input from the olfactory bulb and can therefore be considered olfactory cortical areas. All these areas are on the surface of the brain and have a generally cortical structure, in that they are composed primarily of pyramidal-type cells arranged in layers, with dendrites arrayed in a more-or-less radial manner. The cortical lamination is considerably simpler than in the neocortex, such that most of the areas have only two or three layers. There is considerable variation among different areas, however, and some have a more elaborate 'cortical' structure than others.

Anterior Olfactory Nucleus

The anterior olfactory nucleus (AON) is the most rostral of the olfactory cortical areas. In rats and most other small mammals, it consists of a ring of cells situated around the olfactory peduncle, surrounding the anterior limb of the anterior commissure. It is usually subdivided into dorsal, lateral, ventral, medial, and external parts. In primates, including humans, the olfactory bulb is pulled rostrally, and the olfactory peduncle is a long, slender stalk. A 'bulbar' part of the AON is located in the deep part of the olfactory bulb, while medial and lateral portions of the AON are near the point where the olfactory tract fuses to the frontal lobe. As in other olfactory cortical areas, axons of the mitral and tufted cells synapse on the distal segments of dendrites that extend into the plexiform layer around the neuron clusters. More-caudal subdivisions of the AO are situated on either side of the lateral olfactory tract where it joins the orbital cortex, at the posterior end of the olfactory peduncle.

Piriform Cortex

Caudal to the AON, the lateral olfactory tract runs along the junction of the olfactory tubercle, medially, and the piriform cortex, dorsal and laterally (Figure 1). The piriform cortex is the largest and most distinctive olfactory cortical area (Figure 3). Functional and behavioral studies suggest that it plays a central role in the detection and discrimination of olfactory sensory stimuli. In rodents and other small mammals, the piriform cortex occupies a large part of the ventral surface of the cerebral hemisphere, ventromedial to the rhinal sulcus. It forms a much smaller part of the cortical surface in monkeys and humans, on the caudolateral part of the ventral frontal lobe and the rostral part of the medial temporal lobe. The piriform cortex is characterized by a densely packed layer II composed of moderately large pyramidal cell bodies, and a less dense layer III of slightly larger pyramidal cells and other neurons. Layer III is well developed only in the caudal part of the cortex. Deep to the cortex, a ventral continuation of the claustrum forms the endopiriform nucleus. There is little data on this nucleus in primates, but in rodents it appears to represent a deep component of the overlying piriform cortex.

Figure 3 Photomicrographs of sections of rat (above) and monkey (below) brains, taken through the piriform cortex (PC), olfactory tubercle (OT), and (in monkey) the periamygdaloid (PAC) and entorhinal cortex (EC). Ant Com, anterior commissure; NuAcc, nucleus accumbens; lot, lateral olfactory tract.

As discussed in the section titled 'Intracortical associational fiber system,' the piriform cortex gives rise to a substantial associational fiber system that extends throughout all parts of the primary olfactory cortex. The piriform cortex also provides substantial projections to the ventral striatum and the agranular insula/posterior orbital cortex. There are further outputs through the deep cells of the endopirifom nucleus to the mediodorsal thalamic nucleus and the lateral hypothalamus.

Olfactory Tubercle

The olfactory tubercle is a prominent structure in rodents and carnivores, with a well-developed laminar structure similar to that in other olfactory cortical areas (Figure 3). It is much less distinct in primates but still has a laminar arrangement of cell bodies and afferent fibers. In all mammals, collaterals of axons in the lateral olfactory tract leave the medial side of the tract and run through the superficial part of layer I of the olfactory tubercle to contact apical dendrites of cells with somata in layers II and III. Although this laminar structure is clearly cortical, other features of the olfactory tubercle resemble the underlying corpus striatum, and it has often been included with the nucleus accumbens in the ventral striatum. For example, cells of the tubercle resemble the medium spiny cells of the striatum, and it has a high concentration of acetylcholinesterase, as well as a prominent dopaminergic input from the ventral midbrain. Its major output is to the ventral pallidum, which is similar to and dorsally continuous with the globus pallidus.

Clusters of small neurons called the islands of Calleja are inserted into layers II and III of the olfactory tubercle. Ventral pallidal elements are distributed somewhat loosely within the deep part of the tubercle rostrally, with more distinct components of the ventral pallidum found farther caudally and dorsally. The nucleus accumbens extends to the ventral surface in both monkeys and humans and occupies much of the area referred to as the olfactory tubercle in gross anatomical terms.

Anterior Cortical Nucleus of the Amygdala and Periamygdaloid Cortex

In the caudal part of the olfactory cortex, the axons from the olfactory bulb extend into several small areas on the medial surface of the amygdala. The anterior cortical amygdaloid nucleus is characterized by a relatively loosely packed layer II and even more diffuse layer III. The periamygdaloid cortex is a larger area, which is heterogeneous in monkeys and humans. There is a relatively thin zone of termination of olfactory bulb axons (layer Ia) in the periamygdaloid cortex, and the most caudal part does not receive any olfactory bulb input in primates.

Entorhinal Cortex

The entorhinal cortex has a more elaborate laminar structure than other parts of the olfactory cortex have, with at least five layers. It is notable because it provides the major input to the hippocampus. In rodents and carnivores, it is common to divide the entorhinal cortex into a relatively large lateral part, which receives fibers from the olfactory bulb, and a medial part that does not. In contrast, in primates the olfactory bulb input is limited to a small rostral olfactory zone that makes up only 10% or less of the entorhinal cortex as a whole. Even in the rostral part of the monkey entorhinal cortex, the olfactory input is relatively slight.

Accessory Olfactory Cortical Areas

In addition to the olfactory bulb, the accessory olfactory bulb provides a chemosensory input to specific areas of the amygdala, the medial and posterior cortical amygdaloid nuclei. This projection is almost entirely complementary to the olfactory bulb projection. The medial nucleus is situated immediately adjacent to the anterior cortical amygdaloid nucleus, while the posterior cortical nucleus is farther caudal. Both of these have important projections to the anterior and medial hypothalamus. In rodents, these connections have been shown to be involved in mating behavior and a variety of related functions.

Intracortical Associational Fiber System

There is an extensive system of intracortical connections within the primary olfactory cortex, which seems to interact with the input from the olfactory bulb to create patterns of activity across the cortex. It is possible that the olfactory cortex functions as a correlative system, possibly comparable to higher-order association cortex in other sensory systems.

The piriform cortex provides the greatest number of association fibers, but the fibers originate in all the olfactory cortical areas except the olfactory tubercle. The fibers are distributed throughout the olfactory cortex, and individual neurons in the piriform cortex have axons that extend into all or most of these areas. The association fibers terminate primarily in the deep part of layer I (layer Ib) and in layer III, complementary to the pattern of termination of the fibers from the olfactory bulb in layer Ia. In the tangential dimension of the cortex, there is a broad and relatively complex organization within the association fibers, which has been best defined in rats. Cortical regions near the lateral olfactory tract project to other parts of the olfactory cortex near the tract, whereas regions distant to the tract tend to project to regions at the edges of the olfactory cortex.

The AON and the anterior part of the piriform cortex also project through the anterior commissure to the contralateral olfactory cortex. The laminar and areal pattern of termination in the contralateral cortex are approximately the same as on the ipsilateral side.

Presumably, the association system interacts with the sensory activity from the olfactory bulb to support olfactory discrimination. In contrast to the olfactory bulb, neither of these fiber systems has the sort of detailed topographic organization that would be expected if odors were represented in a spatial code. It is possible that cells related to different odors are dispersed in many parts of the cortex, and appropriate bulbar and association fibers synapse on them in a selective manner. It may be more likely, however, that olfactory discrimination depends on a system of spatiotemporal patterning across the cortex, in which adjustments in synaptic strength are built up from sensory experience.

Olfactory Projections beyond the Primary Olfactory Cortex

Olfactory information is transmitted from the primary olfactory cortex to several other parts of the forebrain, including the orbital cortex, amygdala, hippocampus, ventral striatum, hypothalamus, and mediodorsal thalamus (Figure 4). The connections have been best studied in rodents, but there is also some experimental data from monkeys, and functional imaging studies have recently provided data on humans.

Projections to the Amygdala and Hippocampus

Both the amygdala and hippocampus have often been considered to be closely associated with olfaction, especially in lower animals. These inputs arise primarily in the periamygdaloid cortex and the olfactory part of the entorhinal cortex, which project both to deep amygdaloid nuclei and to several parts of the hippocampus. In rats, there is an especially strong olfactory input to the hippocampus, because more than half of the entorhinal cortex receives olfactory inputs. In primates, amygdala and hippocampus have become dominated by other sensory inputs, especially vision, but they still have direct olfactory connections.

Projections to the Hypothalamus

In rats, both electrophysiological recordings and axonal tracer experiments indicate that there are olfactory inputs to several parts of the hypothalamus. The most direct projection arises from cells in the deepest layer of the piriform cortex and other olfactory cortical areas. Although the fibers run through the full rostrocaudal extent of the hypothalamus, in the medial forebrain bundle, they terminate predominantly in the caudal half of the lateral hypothalamic area. Axons from the anterior cortical nucleus and medial nucleus of the amygdala end in more rostral and medial parts of the hypothalamus.

The olfactory inputs to the hypothalamus have not been as well defined in monkeys. Experiments with retrograde tracer injections in the lateral hypothalamus, however, label neurons in most of the olfactory cortical areas, as well as in related orbital/insular cortical areas. Electrophysiological responses to olfactory stimuli have also been recorded in the lateral hypothalamic area in monkeys.

Olfactory Projections to the Striatum, Pallidum, and Thalamus

Along with the amygdala, the olfactory cortex projects to the ventral part of the striatum, including

Figure 4 Diagram of the connections of the central olfactory system.

the accumbens nucleus and the olfactory tubercle. The olfactory projections are largely restricted to the olfactory tubercle and the caudal, ventrolateral part of the nucleus accumbens. These areas project out to the ventral pallidum, a continuation of the globus pallidus ventral to the anterior commissure. The major output of the ventral pallidum, in turn, is to the mediodorsal thalamic nucleus. As with the dorsal striatopallidothalamic system, the inputs to the ventral striatum are glutamatergic, but the striatopallidal and pallidothalamic projections are γ-aminobutyricacidergic (GABAergic).

As in other mammals, both electrophysiological recording and axonal tracing in monkeys also indicate excitatory olfactory input to the mediodorsal thalamic nucleus (MD) from the olfactory cortex. The neurons that project to MD are primarily located in the deep layers of the piriform cortex and other olfactory cortical areas. There are relatively small numbers of these neurons, and it appears that they may relay convergent activity from a relatively large portion of the olfactory cortex. Within MD in monkeys, fibers from small areas of the olfactory cortex or the amygdala end in small 'patches,' suggesting that inputs from restricted regions converge onto a few thalamic neurons. Similarly, olfactory-responsive units are restricted to a relatively small region of the medial, magnocellular part of MD. Compared with the hypothalamus, the olfactory-related units in MD appear to be relatively broadly tuned and respond to many different odors.

In addition to MD, anatomical and electrophysiological studies in both rats and monkeys indicate that there is an olfactory projection to the anteroventral portion of the submedial thalamic nucleus. This small nucleus is separated from MD only by the internal medullary lamina, and it may represent a portion of the same nucleus functionally. In rats, the projection to the submedial nucleus arises in a relatively restricted zone at the junction of the piriform cortex and olfactory tubercle.

The portion of medial MD that receives olfactory input is reciprocally connected with several areas in the posterior orbital cortex and rostral agranular insular cortex. The cortical connections of SM are to a more restricted area near the junction of the olfactory peduncle and the frontal lobe (especially area 13a). It might be presumed, therefore, that MD would relay olfactory information to the orbital cortex. As discussed in the section titled 'Olfactory projections to neocortical areas,' however, these same cortical areas receive more-numerous, monosynaptic projections directly from the primary olfactory cortex. These corticocortical projections appear to be better suited to relay detailed sensory information. It is likely, therefore, that the transthalamic projection does not represent a sensory relay as such.

Olfactory Projections to Neocortical Areas

In the 1970s and 1980s, Takagi and his colleagues reported that odorant stimuli or electrical stimulation of the olfactory bulb could evoke neuronal responses in the orbital cortex. Two areas, in the lateral and central parts of the posterior orbital cortex, were identified. In the lateral area, the units were relatively specific, responding to only one or two odorants, whereas in the more central area, units responded to several odorants. These studies suggested that the sensory information reached the orbital cortex from the primary olfactory cortex through the hypothalamus and thalamus. There is now clear anatomical evidence in monkeys and other animals, however, that the principal pathway is directly from the primary olfactory cortex to the orbital cortex.

Injections of anterograde axonal tracers in the piriform cortex of monkeys label axons in several areas of the agranular insula/posterior orbital cortex (areas Iam, Iapm, Iai, Ial, 13a, 13m, and 14c; **Figure 5**). All these cortical areas are agranular or dysgranular, and the areas nearest to the primary olfactory cortex have sometimes been referred to as periallocortex. The projection is different from more usual sensory inputs to cortex that are relayed through the thalamus, because the label is heaviest in layer I. Retrograde axonal tracer injections into the same agranular insula/posterior orbital areas label neurons in many parts of the primary olfactory cortex, including the AON, piriform cortex, anterior cortical amygdaloid nucleus, periamygdaloid cortex, and olfactory part of the entorhinal cortex. The labeled cells are located in both layer II and layer III. Electrical stimulation of the olfactory bulb also evokes unit and field potential responses in most of the areas where there is anatomical evidence of olfactory input.

The projections from the primary olfactory cortex are largely reciprocated by fibers from agranular insula/posterior orbital areas. Anterograde axonal tracer injections into several of the agranular insular areas label axons in the rostral parts of the primary olfactory cortex. These include the olfactory tubercle, which is the only olfactory cortical area that does not project to the orbital cortex.

The agranular insula/orbital cortical areas that receive olfactory input interact with other areas on the orbital surface through corticocortical connections to integrate olfactory sensory information with

Figure 5 Diagrammatic summary of the projections from the primary olfactory cortical areas to the neocortical areas in the posterior orbital cortex in monkey. ai, agranular insula; AON, anterior olfactory nucleus.

other sensory modalities. Taste information reaches the orbital cortex through the thalamic gustatory relay and the primary gustatory cortex. The orbital cortex is the first place where olfactory information and taste information converge, so it presumably underlies the sensation of flavor, which depends on both of the primary modalities. In addition, there are corticocortical somatosensory and visual inputs to the orbital cortex from the parietal and inferior temporal cortex. The somatosensory inputs appear to be related to the hand and mouth. The corticocortical connections between orbital areas form an orbital network that appears to function in the integration and analysis of food-related sensory information.

Recordings in the orbital cortex in monkeys show neuronal responses to food and food-related stimuli, including visual stimuli that are associated with food. It is important to note that the responses reflect the affective or reward significance of the stimuli as well as their sensory properties. For example, the neuronal response to a particular visual stimulus (e.g., a triangle) will change markedly if the association of the stimulus with a food reward changes. In addition, if the animal is fed to satiety with a food stimulus, the neuronal response to that food will decrease.

Imaging of Olfactory Sensory Activity in Humans

Several studies have used functional imaging methods to identify the human cortical areas activated by olfactory stimuli. Although odorant-induced responses have been obtained in the region of primary cortex, other studies have failed to find substantial activation of primary olfactory areas. This discrepancy is probably due to technical issues that make it difficult to image activity in the primary olfactory cortex, including the rapidly adapting nature of olfactory sensation.

Olfactory-related activity has more consistently been detected in the central orbital cortex. Activation in the lateral orbital/anterior insular cortex has also been found following stimulation with aversive odors. The amygdala was also activated to the same odors.

The central orbital cortical region that responds to odorants also is activated by taste stimuli. This agrees well with the anatomical evidence in monkeys that corticocortical interconnections within the orbital cortex correlate olfactory and gustatory sensory information. Other sensory modalities, especially related to visual and somatic-sensory aspects of food stimuli, are also represented within the orbital cortex. The sensory responses in the orbital cortex also depend on hedonic properties of the stimuli. For example, functional magnetic resonance imaging responses to food-related olfactory stimuli are decreased after animals are fed to satiety with that food. Taken together, the evidence indicates that the orbital cortex is part of a system for analysis and assessment of food and food-related stimuli. Possibly because food is a primary reward, the system also may provide more-general analysis of reward. It should not be considered as simply secondary olfaction cortex or secondary taste cortex.

Introduction

The peripheral olfactory system of mammals has two unusual properties – the ability to detect external chemical signals (odors), of course, and also the capacity for adult neurogenesis. The odor signals animals detect are often linked to biological imperatives such as reproduction, other social interactions, and assessing the quality of the local environment (food, shelter, and predators). These are powerful selective forces driving the detection of external chemicals at high sensitivity, a problem solved by exposing a set of neurons to the external environment. The seemingly unavoidable consequence of damage to these exposed neurons appears to be why the olfactory epithelium retains substantial neurogenic capacity throughout adulthood, in contrast to better protected regions of the nervous system. Much effort investigating the olfactory system goes toward understanding these two properties, and a growing component of our advancing knowledge of them stems from work using expression profiling approaches.

The history of gene discovery approaches in the study of the olfactory system stretches back more than 25 years to the identification of olfactory marker protein (OMP), an enigmatic protein that has proved useful as a specific marker of mature olfactory sensory neurons. Since that time, molecular identification and analyses of individual genes have paid dividends for our understanding of the olfactory system. Prime examples are the discovery of the odorant receptors and consequent elucidation of their role in determining the odor quality map of the olfactory bulb glomeruli that must be the basis for odor discrimination by the CNS. Such studies of single genes and proteins are the foundation for recent functional genomics studies that continue to expand our knowledge of genes important to the olfactory system, and promise to build a system-level understanding of the molecular functions that give the olfactory system its capacity to detect odors and replace damaged neurons. The most compelling advances in olfactory genomics have arisen from studies that creatively combined expression profiling techniques with other approaches. After all, expression profiling techniques measure just one parameter, mRNA abundance – albeit with the advantage of simultaneously measuring (nearly) all mRNAs. Interpretation of expression profiling data has therefore depended critically on providing additional context to these data.

Functional Genomics of the Olfactory Epithelium

Olfactory Sensory Neurons

The task of detecting and encoding odor signals falls to the olfactory sensory neurons (OSNs) of the main olfactory epithelium and to the vomeronasal sensory neurons (VSNs) of the vomeronasal organ. These two neural epithelia are located in the nasal cavity and their neurons project axons ipsilaterally to the main and accessory olfactory bulbs of the CNS, respectively (Figure 1). While these epithelia contain several cell types (Figure 2), the vast majority of studies have understandably concentrated on the neurons, and therefore on the genes they express. As a group, OSNs and VSNs express an unusually large number of genes that have highly restricted expression patterns. This category of gene is dominated by the odorant receptors (ORs) and vomeronasal receptors (V1Rs and V2Rs), but several other genes also appear to be expressed solely or primarily in these sensory neurons. By definition, such genes encode proteins that are often directly involved in the detection and encoding of odor signals, but sometimes playing supporting roles in chemosensory neurons instead. Although the genes that encode the chemosensory receptors and their associated transduction mechanisms certainly differ between OSNs and VSNs, and while no quantitative measures have yet been made, OSNs and VSNs appear to overlap extensively in the remainder of their gene expression patterns.

The abundance of olfactory-enriched gene products has contributed to the successful use of single-cell polymerase chain reaction (PCR) as an expression profiling method to identify olfactory-enriched sequences. For example, the V1R family of vomeronasal receptors was discovered in this way. Similarly, single-cell PCR methods led to the discovery of a putative OR chaperone/trafficking complex, components (e.g., Rtp1 and Rtp2) of which are examples of olfactory-specific gene products that play supporting roles in the odor detection process. Furthermore, cells of the olfactory epithelium were the substrate for pioneering work that combined single-cell PCR amplification and microarray analysis. The advantage of knowing the cell expressing each mRNA meant that each mRNA could

Figure 1 The location of the main components of the first two levels of the olfactory system, depicted in sagittal section of a rodent head. The main olfactory epithelium (OE; light green) resides in the nasal cavity, where it covers the turbinates laterally and septum medially. The olfactory sensory neurons in the olfactory epithelium project axons directly through the cribriform plate to the main olfactory bulb (OB; dark green) of the forebrain. Vomeronasal sensory neurons, which reside in the vomeronasal organ (VNO; light blue) at the base of the septum, send their axons to the accessory olfactory bulb (AOB; dark blue).

be interpreted in the context of adding one more item to the list of molecular functions present in that cell type.

Genes expressed in OSNs have also been identified by detecting mRNAs that decrease when mature OSNs are forced to apoptose, accomplished by severing OSN axons during removal of the olfactory bulbs (bulbectomy). This approach tends to detect only mRNAs enriched in mature OSNs, because most mRNAs shared with neighboring cells, which survive damage to the OSNs, show relatively small changes in abundance. More inclusive data that identified what appears to be the majority of mRNAs present in OSNs required the purification of a large pool of OSNs and the development of microarrays that assess nearly the entire genome. By comparing ratios of mRNA abundance in OSNs versus the pool of neighboring cells with cell type identification from *in situ* hybridization data, these analyses gave a probability of expression in OSNs for each mRNA and predicted that OSNs express more than 10 000 genes. Applying bioinformatics analyses to this list of genes predicts not only individual molecular functions present in OSNs, but also the biological processes that require them (Figure 2).

One such process is ciliogenesis, which happens as immature OSNs complete differentiation and become mature. The previously known molecular link between OSNs and sperm, revealed by evidence that a few OR genes mediate sperm chemotaxis, pales in comparison to the extensive molecular similarity between OSN cilia and sperm flagella. These similarities include components of the axoneme, the structural foundation of cilia and flagella, and the proteins of cilia support structures, such as basal bodies, ciliary rootlets, and trafficking compartments.

Another intriguing process enriched in OSNs is chromatin remodeling/assembly. Components of all of the major chromatin remodeling complexes are expressed in OSNs or OSN progenitor cells, including SWI/SNF complexes, Polycomb complexes, and NuRD complexes. The modification of chromatin is a mechanism of transcriptional control that acts at the level of regions of DNA as well as at the single-gene level. As such, it is critical to development and differentiation, consistent with evidence that many chromatin remodeling mRNAs are most abundant in OSN progenitors and immature OSNs. However, several mRNAs associated with chromatin remodeling (*Cbx4*, *Cbx8*, *H2afy*, *Tlk1*, and *Setd7*) are most abundant in mature OSNs, suggesting that epigenetic mechanisms also have a role in the fully differentiated phenotype.

Other surprises relate to the cell signaling capacities of OSNs. For example, the wealth of nonchemosensory receptor mRNAs found in OSNs included 16 growth factor receptors and at least 30 G-protein-coupled receptors, most not previously detected in OSNs. These include receptors for glutamate, acetylcholine, somatostatin, serotonin, Wnts, latrophilins, prostaglandins, epidermal growth factor, insulin-like growth factors, interleukins, and members of the transforming growth factor-β family of signals (especially bone morphogenetic proteins). OSNs also express 14 growth factor mRNAs and at least 80 mRNAs encoding proteins involved in cell adhesion. OSNs appear to pay attention to, and to send, many more signals than previously suspected.

The number of transcription factors expressed by OSNs is impressive. The data predict that OSNs express at least 268 mRNAs that are known or implicated by sequence similarity to be proximal regulators of transcription. Some illustrative examples are listed in Figure 2. The functions in OSNs of very few of these transcription factors are known, but in other tissues some are known to be involved in processes consistent with known OSN functions: stress responses, differentiation, ciliogenesis, and responses to Ca^{2+} signals or neural activity, for example. A likely harbinger of a trend was expression profiling of olfactory epithelia of mice lacking the transcription factor, Klf7. Klf7-deficient mice have reduced amounts of several synaptic mRNAs and the OSN-specific mRNAs, including OMP and adenylyl cyclase type 3, implicating Klf7 in the terminal events of OSN differentiation.

Figure 2 Mature olfactory sensory neurons (mOSNs) have been a major focus of expression profiling studies in the olfactory system. Their cell bodies occupy the middle of the pseudostratified olfactory epithelium, as shown in this *in situ* hybridization for olfactory marker protein, the mRNA for which is specific to mOSNs. Biological processes overly abundant in expression profiling data from OSNs are listed (overrepresented processes). Also shown is a partial list of the more than 250 transcription factors identified among the >10 000 genes expressed by OSNs. Dashed line, location of the basal lamina; Sus, sustentacular cell (a glial-like supporting cell); iOSN, immature OSN layer. Progenitor cells with the capacity to proliferate new OSNs reside in the basal (globose and horizontal) cell layer. Scale bar = 10 μm.

Odorant Receptors

At more than 1000 members, odorant receptors are encoded by the largest family of genes in mammalian genomes. ORs are also very diverse, with sequence similarities ranging down to about 20%. To cope with such size and diversity, a GeneChip microarray devoted to mouse ORs and V1Rs was developed. As expected, use of this GeneChip determined that at least 800 of the ORs are expressed in the olfactory epithelium. While a few dozen OR mRNAs were detected in other tissues (cerebellum, heart, liver, muscle, and testis), very few were more abundant in these tissues than in the olfactory epithelium, and many were several-fold more abundant in the olfactory epithelium. OR gene classification, though based largely on protein length, a few small conserved motifs, and a predicted seven-transmembrane domain topology, rather than on sequence similarity, therefore appears to be largely correct.

The OR GeneChip has also provided a broader view of the zonality of OR gene expression. Data from just a few dozen ORs indicate that ORs are expressed in restricted regions along the dorsoventral axis of the olfactory epithelium. Expression profiling of dorsal versus ventral olfactory epithelium supports and extends this conclusion to more than 600 ORs. Class I ORs, which have homology to fish ORs, were detected only in dorsal region samples, while the more recently evolved class II ORs were found in both dorsal and ventral regions. Given that ORs differ in their odorant agonists, these findings are consistent with long-standing evidence that regions of the olfactory epithelium are differentially sensitive to odorants. They are also consistent with suppositions about the evolutionary origins and expansion of the OR family from fish, with a single OR expression domain, to amphibians, with separate air and water OR compartments, to mammals, in which the entire olfactory epithelium is exposed to air but the ancestral expression pattern of two OR expression domains is at least partially retained and even divided into smaller zones in the case of the ventral domain.

Other Cell Types in the Olfactory Epithelium

While other cell types in the olfactory epithelium and in central olfactory pathways have not yet been investigated in detail by expression profiling methods, one of the by-products of the existing expression

profiling data has been the discovery of new tools that help discriminate cell types. These tools include *Reg3g* for respiratory epithelium, *Cbr2* and *Epas1* for sustentacular cells, *Ptgds* and *Igf2* for olfactory bulb leptomeninges, and *Ntf3* for a subset of olfactory bulb mitral cells. Another by-product comes from the comparison of the expression profile of the pool of immature OSNs, sustentacular cells, basal cells, respiratory epithelium, and lamina propria cells against the profile of purified mature OSNs. While more difficult to interpret because the identities of the source cells are ambiguous, more than 13 000 mRNAs were detected in this sample. Expression profiling data on adult olfactory neurogenesis provide insight into the function of some of these gene products in the olfactory epithelium (see later).

Novel Genes

Not surprisingly, a majority of the more than 14 000 mRNAs detected in the olfactory epithelium encode proteins with no known function. The genes are difficult to investigate, but they also represent opportunities to make truly novel contributions. The available evidence does provide some guidance for many of these mRNAs. Some, like *Tmem16b*, are at most weakly expressed in other tissues, thereby predicting olfactory-specific functions. Others, like *Susd4* and *Tspyl4*, are abundant only in neural tissues, predicting a role important to neurons in general. Still others, like *1110012D08Rik*, appear to be ubiquitous and therefore part of a function required by all cells.

Functional Genomics of Adult Olfactory Neurogenesis

Olfactory Sensory Neuron Response to Axotomy

The ability of the olfactory epithelium to replace damaged OSNs even in adulthood and yet not lose the capacity to discriminate odors is a remarkable example of the plasticity of the nervous system. It is also an example of the potential of neural replacement therapies for the treatment of neurological disorders. The cellular events that support adult neurogenesis in the olfactory epithelium are well understood (Figure 3). Damaged OSNs apoptose, then infiltrating immune cells (predominantly macrophages) clear the resulting cellular debris and also secrete signals that help stimulate basal progenitor cell proliferation, leading to the production of new immature OSNs that differentiate into mature OSNs. As a model for adult neurogenesis, OSN replacement has the advantage that it can be massively and synchronously induced by selectively damaging the OSNs in any of several ways, but most easily by bulbectomy, the removal of the olfactory bulbs and consequent severing of the OSN axons.

While a few important molecular markers of this process were known, recent expression profiling results have identified hundreds of additional mRNAs which change in abundance during the replacement process. The most striking finding is the degree of agreement between molecular and cellular events. The vast majority of affected mRNAs changed abundance along temporal profiles that matched the profiles of the critical cellular events of OSN apoptosis, immune cell infiltration, basal cell proliferation, and OSN differentiation. The identities of the mRNAs in each of these temporal profiles corresponded to functions necessary for the matching cellular events.

Within the OSNs, the expression profiling data reveal a common apoptotic theme. OSNs shift into a proapoptotic state reflected by a decrease in antiapoptotic mRNAs and an increase in proapoptotic mRNAs. The major antiapoptotic genes affected are *Bcl2* and *Birc6*. The major proapoptotic genes affected are *Bcl2l11* (*Bim*), *Bax*, *Bid*, *Casp3*, *Casp6*, *Casp8*, *Gadd45a*, and *Gadd45b*. Exactly how these mRNA abundance changes are triggered by signals, such as activated caspases, traveling back from the severed axons of the OSNs is not yet clear.

Immune Cell Infiltration

Also anticipated among the events evident during OSN replacement was the infiltration of immune cells, especially macrophages, that follows the apoptosis of OSNs. Increases in chemokines such as chemokine (C-C motif) ligand 2 (CCL2) and interleukin-1β (IL-1β) are consistent with the documented recruitment of macrophages. Molecular evidence that dendritic cells may also be recruited has not yet been substantiated. Later increases in mRNAs associated with macrophage maturation, such as *Cd1d1*, *Cd83*, *Lsp1*, *Pparg*, and *Csf1r*, and antigen presentation mRNAs suggest that infiltrating macrophages reduce their rate of migration and mature while in the olfactory epithelium. These events are important not only because macrophages phagocytose debris from apoptotic cells, but also because they secrete signals that enhance the proliferation of basal cells. A clever approach to assessing this involved profiling mRNA abundance in the olfactory epithelium of mice lacking scavenger receptor A, important for macrophage responses to apoptosing cells. The data showed evidence of molecular changes after bulbectomy that are consistent with cellular defects in these knockout mice – fewer infiltrating macrophages, reduced basal cell proliferation, and accumulation of apoptotic debris.

Figure 3 Expression profiling has had a significant impact on our understanding of the control of adult neurogenesis in the olfactory epithelium. The olfactory sensory neuron (OSN) cell lineage begins with an as yet unidentified stem cell (hypothesized to be a subtype of basal cell) and progresses through at least two types of proliferative globose basal cells (GBCs) – a transit-amplifying GBC and an immediate neuronal precursor GBC – before differentiation generates immature OSNs and subsequently mature OSNs. With the exception of the stem cell, known differentially expressed genes (green italics) allow identification of the cell types. The other important cellular event is immune cell (primarily macrophages) infiltration; the infiltrating immune cells aid neurogenesis by phagocytosing debris and secreting proliferative signals. Expression profiling studies have identified processes that are active during adult neurogenesis (active processes; red text). These are depicted next to their presumed locations in the cell lineage. Similarly, expression profiling predicts transcription factors responsible for the molecular changes that control adult neurogenesis. A subset of these transcription factors is listed (purple text).

Proliferation and Differentiation

The synchronization of OSN replacement by bulbectomy leads to a robust increase in cell proliferation that peaks about 6 days later in mice. Expression profiling data from this time period reveal increases in many positive regulators of the cell cycle and other markers of cell proliferation. Of paramount interest are the proteins that control this proliferative process. Proteins known to stimulate proliferation or inhibit lineage commitment detected as increased mRNAs include transcription factors Gata2, Mycn (Nmyc1), Myc (c-Myc), Mybl1, Myb, Id1, and Id3 (Figure 3). These transcription factors are therefore candidates to control the proliferative events that underlie OSN replacement. Also important are transcription factors that promote exit from the cell cycle, determine cell fate, and contribute to the subsequent differentiation of OSNs. Expression profiling identified Nhlh1, Neurog1 (Ngn1), Lmo1, Sox11, Hes6, and Mxd4 as candidates to control these events. Associated with differentiation of neurons should be the extension of neurites, and increases in numerous mRNAs encoding proteins involved in axon outgrowth were observed: *Gap43*, *Basp1*, *Ablim1*, *Marcksl1*, *Stmn1*, *Chl1*, *Dbn1*, *Dpysl3*, *Syn1*, *p116Rip*, *Celsr1*, *Fyn*, *Dlx5*, *Myh10*, *Crym*, *Rasa3*, and *Ppp2cb*. These mRNAs are very likely to be enriched in immature OSNs and relatively less abundant in mature OSNs. *In situ* hybridization data have confirmed this prediction for several of these mRNAs.

Adult and Embryonic Neurogenesis Are Transcriptionally Similar

More broadly, expression profiling of induced OSN replacement speaks to the question of whether adult neurogenesis is substantially different from embryonic neurogenesis. When compared with expression profiling of mouse brain embryonic development, >300 mRNAs are shared – more than half of the mRNAs that increased during the period of basal cell proliferation and OSN differentiation. Comparison of embryonic and adult neurogenesis within the olfactory epithelium would probably show even more similarity. While some differences between adult and embryonic neurogenesis probably exist, the available evidence suggests that many molecular elements are shared.

Functional Genomics of the Olfactory Bulb and Behavior

Expression profiling methods have as yet had little impact on our understanding of central olfactory pathways. Several interesting opportunities exist, however. For example, the olfactory central nervous system (CNS) has functional and cellular plasticity that should be intriguing as a substrate for expression profiling. Associative learning involving odors is an example of robust functional plasticity. Cellular plasticity happens continuously in the olfactory bulb, where interneurons are replaced from progenitors that arise in the subventricular zone and migrate to the bulb in the rostral migratory stream. The one question that has been probed by microarray analysis is the regionalization of the olfactory bulb. The olfactory bulb has an overall regional organization that may help organize the odor quality map of OR-specific glomeruli, a map that is presumably critical for odor discrimination. At least nine mRNAs are differentially distributed across the olfactory bulb. Several of them (*Jag1*, *Cadm1* (*RA175C*), *Ntf3*, *Vtn*, *Col5a2*, and *Cdh11*) have functional links to synapse formation and axon connectivity, and therefore might contribute to the synaptic organization of the bulb or its cortical targets.

Expression profiling should also be of value in linking genes and behaviors mediated by olfaction. Heritable mutations that alter olfactory-guided behaviors are most likely of two types: changes in proteins that are central to the detection of odors, such as ORs, or changes in proteins that cause pleiotropic effects that are not so obviously related to olfaction. Pleiotropic effects resulting from single gene mutations are likely to involve changes in the abundance of gene products and are therefore suitable targets for expression profiling. One such situation has been investigated by profiling five co-isogenic smell-blind mutant *Drosophila* lines known to have epistatic relationships. Significant overlap was detected in mRNA abundance changes among these epistatic fly lines, with more than 150 altered mRNAs shared by at least two lines. The inverse of this, mRNAs specific to each line, is also informative. As should happen with genomic level analyses, the identities of the affected mRNAs suggest hypotheses about affected processes. For example, mutant line *smi21F* was associated with chemical recognition mRNAs, *smi28F* was associated with ligand carrier protein and biotransformation enzyme mRNAs, and *smi26D* was associated with synaptic function mRNAs. Ways in which altered levels of these gene products could alter odor-stimulated behaviors are easy to imagine.

Expectations for the Future

Expression profiling has much more to reveal about the olfactory system. Most of what has been learned to date is descriptive, predictive, and correlative, but the breadth and depth of these data make them valuable resources. We can expect the trend to characterize the capacities of individual cell types to expand to additional cell types in the olfactory epithelium and probably even to the neurons of the olfactory bulb and higher olfactory centers. We should expect to gain insight into physiological and developmental details by more expression profiling of gene knockout mice or mice with more sophisticated mutations that generate proteins with altered function. In addition, we can expect expression profiling to shed light on the importance of alternative splicing within the olfactory system, a topic as yet ignored. We can also expect to see more work on model systems in which gene expression patterns can be linked to olfactory behaviors.

Overview of Olfactory Epithelium and Vomeronasal Organ Structure and Cell Types

In terrestrial vertebrates, the primary relay neurons of the olfactory system are contained within two specialized sensory epithelia in the head – the main olfactory epithelium (OE), which lines the nasal cavity and is involved in detection of odors, and the vomeronasal sensory epithelium, which lines the vomeronasal organ (VNO; a bean-shaped structure located in the anterior–ventral region of the nasal septum) and mediates detection of nonvolatile pheromones (Figure 1(a)). Cell bodies of olfactory receptor neurons (ORNs) lie within the epithelia of the OE and VNO. ORNs are bipolar primary sensory neurons: they have apical dendrites, with cilia- or microvilli-covered surfaces that extend into the nasal or VNO cavities, and they extend axons that synapse upon neurons within the central nervous system. In the case of the OE, the axons of ORNs form the first cranial nerve and synapse upon cells of the main olfactory bulb (MOB) of the forebrain. The sensory neurons of the VNO extend axons to form the vomeronasal nerve, which synapses upon the accessory olfactory bulb (AOB), a prominent structure in rodents that lies immediately adjacent to the MOB.

Because rodents have a highly developed sense of smell and have been used for many years as model organisms in the study of olfaction, information provided in this article concentrates primarily on studies of OE and VNO in rodents, particularly rats and mice. Studies of primary olfactory pathway development in mouse mutants have shown that the process of neurogenesis in both the OE and the VNO is regulated to a large extent by the same genes, which are expressed by cells at distinct stages in the neuronal lineages of the two epithelia (Figure 1(b)). The OE and VNO are also similar in that, once their structures are established during the final third of gestation, the neural cell types within them are arranged in roughly comparable laminar organizations (Figure 1(c)). Thus, in both epithelia, neural stem cells and committed neuronal progenitors are located in the basal compartment (near the basement membrane, which forms the boundary between sensory epithelium and underlying connective tissue stroma – i.e., the lamina propria). Committed neuronal progenitors give rise to terminally differentiated sensory neurons (ORNs), which comprise the majority of cells within both epithelia. Another major cell type within the two sensory epithelia is the supporting, or sustentacular, cell, best characterized in the main OE. The cell bodies of supporting cells lie in a distinct layer in the apical compartment of the OE and their processes extend to the basal lamina; they appear to be analogous to glial cells of the brain, and studies of mouse mutants suggest that ORNs and supporting cells are both derived from a common neural stem cell in the OE.

Another cell type found associated with the OE is the olfactory ensheathing cell (OEC). OECs, which encircle bundles of ORN axons in the stroma underlying OE, possess characteristics of both Schwann cells and astrocytes. Interestingly, transplanted OECs appear to promote recovery in a variety of nerve lesion models, and it has been proposed that their presence is responsible for the ability of lesioned ORN axons to regenerate and reinnervate the central nervous system. Some experimental embryology studies suggest that OECs may originate from the olfactory placode, and tissue culture studies have also reported that cells resembling OECs arise in cultures made from OE proper. However, no definitive lineage-tracing study has been performed to demonstrate unequivocally that OECs arise from the olfactory placode or OE proper, and at present their origin remains uncertain. Thus, although the provocative possibility exists that OECs are, like ORNs, products of a multipotential OE stem cell, this hypothesis remains to be proved, and OECs are not discussed further in this article.

Neuronal Cell Types of the OE and VNO

Newly generated neurons in the OE and VNO are products of differentiation pathways known to contain at least three distinct proliferating cell types. These cell types have been most extensively characterized in the main OE (Figure 1(b)): (1) neural stem cells divide to give rise to a population of (2) committed neuronal progenitor cells that express the proneural gene *mammalian achaete scute homolog 1* (*Mash1*; also known as *Ascl1*), and *Mash1*-expressing progenitor cells are committed to a neuronal fate and undergo amplifying divisions to rise to (3) immediate neuronal precursors (INPs), which express a different proneural gene, *neurogenin1* (*Ngn1*; also known as *Nurog1*). Studies using retroviral lineage tracing and

Figure 1 Location of main olfactory epithelium (OE) and vomeronasal organ (VNO) in mouse head, and lineage and distribution of different cell types within the OE. (a) Sagittal section through an adult head reveals the position of the VNO relative to the OE. While the vomeronasal nerves (VNN) target the accessory olfactory bulb (AOB), axons of olfactory receptor neurons (first cranial nerve; 1st N) target the main olfactory bulb (MOB). (b) Scheme of the neuronal differentiation pathway in the OE. (c) Histological arrangement of cells in mature OE. Neuronal stem cells (black) located at the basal layer (Ba) adjacent to the stroma (Str) give rise to transit-amplifying progenitors expressing the *Mash1* gene (round gray-blue cells) followed by *Ngn1*-expressing precursors (turquoise cells). The immature ORNs (light blue elongated cells) arise from the *Ngn1*-positive cells and mature into *Ncam*-expressing neurons (dark blue elongated cells). Supporting cells (SUP) lie in a single layer on the apical surface of the OE, at the nasal cavity (NC), while olfactory ensheathing cells wrap around nerve bundles in the underlying stroma. The VNO (not shown) has a similar histological arrangement, with basal cells at the boundary between epithelium and mesenchyme and neurons populating the bulk of the epithelium. Adapted from Kawauchi S, Beites CL, Crocker CE, et al. (2004) Molecular signals regulating proliferation of stem and progenitor cells in mouse olfactory epithelium. *Developmental Neuroscience* 26: 166–180, with permission. Copyright 2004 by S. Karger AG, Basel, Switzerland.

molecular markers for different cell types indicate that, in the established OE (see later), INPs, *Mash1*-expressing neuronal progenitors, and neural stem cells are all found in the basal compartment of the epithelium. INPs are, like *Mash1*-expressing progenitors, transit-amplifying cells, but INPs are committed ultimately to generating daughter cells that undergo terminal differentiation into ORNs. ORNs express many genes generally characteristic of terminally differentiated neurons, as well as genes specific to their sensory function (odorant receptors, cell-type-specific channels, etc.). Two well-known markers for ORNs are the neuronal cell adhesion molecule (NCAM1) and the olfactory marker protein (OMP). Interestingly, in the main OE, the differentiation and maturation of ORNs from stem and progenitor cells observed during embryonic development appear to be maintained during regenerative neurogenesis, which occurs when ORNs in the main OE have been lost due to disease or environmental insult.

ORNs of the main OE and VNO express different classes of odorant receptors (the catalytic receptors that transduce odor stimuli into cytoplasmic signals), reflecting their different functions: detection of 'common' odors in the main OE, and pheromone detection in the VNO. Odorant receptors in both sensory epithelia are seven-transmembrane, G-protein-coupled receptors. In the main OE, each ORN appears to express only one odorant receptor gene (of over 1000 estimated receptor genes), and those ORNs expressing the same odorant receptor converge their axons homotypically onto selected glomeruli of the MOB. Thus, a specific set of ORNs, with receptors that have been activated by a specific odorant, will stimulate postsynaptic neurons (mitral and tufted cells) within a specific set of MOB glomeruli, which then transduce this information to higher-order olfactory structures in the brain. In the VNO, two families of receptors, the V1Rs and V2Rs, serve as pheromone receptors, and expression of different receptors from these two families appears to divide VNO sensory neurons into two distinct populations: neurons within the apical zone of the VNO neuroepithelium express V1Rs, and their axons project to the anterior portion of the AOB, while neurons in the basal zone of the VNO neuroepithelium express V2Rs and project to the posterior portion of the AOB.

Two Phases of Olfactory Neurogenesis

Both anatomical studies and, more recently, studies of mouse mutants indicate that olfactory neurogenesis can be divided into two phases. The first is an early, morphogenetic phase, in which the neuronal lineage is established and the basic structures of the primary olfactory pathway (OE and VNO) are set up (primary neurogenesis); the second phase is established neurogenesis, during which the characteristic morphology of the nasal cavity and mature pattern of distribution of different cell types within the epithelia emerge, and the signaling systems that control expansion and regenerative neurogenesis come to predominate in the regulation of neuronal cell number. These phases of neurogenesis are depicted in Figure 2.

During primary neurogenesis, the OE forms from the olfactory placodes, thickenings of embryonic ectoderm that first appear as two oval epithelial patches in the anterolateral region of the head around day 9 of gestation (e9) in the mouse. As development proceeds, the olfactory placodes invaginate to form the nasal pits, which by e10.5 are already lined by neuroepithelium that contains cells at every stage of the neurogenic pathway. By e11.5, the nasal pits continue to deepen and fold, and it is during this period that the VNO becomes recognizable as a thickening in the epithelium of the medial wall of the nasal pit. At e12.5, the end of primary neurogenesis, developing nasal turbinates – the elaborate foldings of which will permit a greatly expanded OE surface area – begin to be recognizable in the main olfactory cavity. It is during this period that VNO morphogenesis takes place, as the ventral medial fold of developing neuroepithelium invaginates and pinches off from the main nasal cavity, forming a tube that is closed posteriorly, and anteriorly communicates via its own duct with the developing oral cavity, nasal cavity, or sometimes both.

In the OE that lines the developing nasal pit as early as e10, the three mitotic neuronal cell types (neural stem cells, *Mash1*-expressing progenitors and *Ngn1*-expressing INPs), as well as *Ncam*-expressing ORNs, are all present. These cell types are initially localized in concentric patterns, with the least differentiated cells lying closest to the rim and the most differentiated cells (ORNs) at the center (Figure 3(a)). Expression of *Sox2*, which encodes a marker for OE neural stem cells during established neurogenesis, defines the entire neuroepithelial domain of the developing nasal pit during primary neurogenesis. However, a small group of *Sox2*-expressing cells, which lie closest to the rim of the pit, also express *fibroblast growth factor 8* (*Fgf8*). *Fgf8* encodes a signaling molecule known to be required for OE neurogenesis, nasal cavity formation, and development of the VNO (see later); the cells in the rim of the olfactory pit that co-express *Sox2* and *Fgf8* are thought to be primordial neural stem cells responsible for initiating primary olfactory neurogenesis (by analogy to the primordial germ cells that ultimately give rise to gametes) (Figure 3(b)).

Around e14.5 in the mouse, the overall number of mitotic figures in the OE starts to decrease in the

Figure 2 Schematic model and description of primary and established neurogenesis during mouse olfactory epithelium development. Coronal sections through heads at days 9.5–12.5 of gestation (e9.5–e12.5) are depicted for the phase of primary neurogenesis, while horizontal sections at e14.5 and e17.5 (immediately before birth) are portrayed for the phase of established neurogenesis. FB, forebrain; MNP, medial nasal process; VNO, vomeronasal organ; LNP, lateral nasal process; S, nasal septum; NC, nasal cavity. Adapted from Kawauchi S, Shou J, Santos R, et al. (2005) Fgf8 expression defines a morphogenetic center required for olfactory neurogenesis and nasal cavity development in the mouse. *Development* 132(23): 5211–5223.

Figure 3 Expression of *Fgf8* and neuronal cell markers in developing olfactory epithelium (OE). (a) Five successive images show *in situ* hybridization for *Fgf8* and OE neuronal lineage markers in invaginating nasal pit (NP) at day 10.5 of gestation (FB, forebrain). While *Sox2* is expressed throughout the neuroepithelium, *Fgf8* is localized to the borders of the invaginating pit. *Mash1* (arrowheads) expression is located next to the *Fgf8*-expressing cells at the inner rim of the nasal pit, while *Ncam*-expressing neurons (arrow) are located at the center of the pit. (b) Double-label *in situ* hybridization for *Fgf8* (orange) and *Sox2* (blue) demonstrates overlap of the two markers in a small rim of surface ectoderm and adjacent invaginating neuroepithelium (bracket). (c) Model of peripheral-to-central process of neuronal differentiation in developing OE and origin of *Sox2*-expressing neural stem cells from *Fgf8*-expressing ectoderm (LNP, lateral nasal process; MNP, medial nasal process). Scale bar = 200 μm (a), 50 μm (b). Adapted from Kawauchi S, Shou J, Santos R, et al. (2005) Fgf8 expression defines a morphogenetic center required for olfactory neurogenesis and nasal cavity development in the mouse. *Development* 132(23): 5211–5223.

epithelium, and different cell types of the OE begin to take on the laminar positions that they will ultimately maintain throughout life. This is the onset of the established phase of neurogenesis, when the mature structure of the nasal cavity also emerges: turbinates and definitive septum form, the sensory epithelium becomes localized to the posterior and dorsal nasal cavity, and the more anterior nasal cavity comes to be lined with respiratory epithelium. Within the OE proper, supporting (sustentacular) cells emerge as a distinct cell population at this time, and their cell bodies begin to form the apical cell layer of the neuroepithelium. *Ncam*-expressing ORNs now lie in the middle compartment of the epithelium, and *Mash1*- and *Ngn1*-expressing neuronal progenitors predominate in the basal compartment of both OE and VNO (Figure 4). With the emergence of this organized pattern begins a new phase of neurogenesis Scale bar = 200 μm (a), 50 μm (b) that is dedicated to maintaining and regulating ORN number. From this time on, the proportions of different cell types are maintained at a fairly constant level within the OE, and the locations of populations expressing different cell-type-specific genes within the epithelium remain essentially the same throughout life.

During the established phase of neurogenesis, an asymmetry develops in the VNO epithelial lining, such that its lateral wall is lined with nonsensory epithelium, whereas the medial wall is lined with a thicker sensory neuroepithelium. This is analogous to the asymmetry that develops in the main nasal cavity, wherein nonsensory, respiratory epithelium predominates in the lining of the anterior and ventral regions of the cavity, whereas the thicker sensory neuroepithelium containing ORNs tends to be localized to more posterior and dorsal regions, covering the turbinates and the posterior two-thirds of the nasal septum.

Intrinsic Factors: Transcription Factors Regulating Mitotic Cell Populations

Neurogenesis and nerve cell renewal take place throughout life in both the OE and the VNO. This

Figure 4 Cell-type-specific markers for committed neuronal progenitors and differentiated olfactory receptor neurons in the established phase of neurogenesis in main olfactory epithelium (OE) and vomeronasal organ (VNO). *In situ* hybridization is shown for mRNAs encoding *Mash1*, *Ngn1*, and *Ncam* in the OE and VNO of mice at day 14.5 of gestation, when the pattern of neurogenesis becomes established in the two sensory epithelia. Even at this stage in prenatal development, the characteristic laminar patterns of cells are apparent, and the relative proportions of cells at different stages of differentiation are similar to what is seen in the postnatal epithelia. (Top panel) *Mash1* and *Ngn1* messages are all expressed in basal areas of the OE, while some apical cells express *Mash1* but not *Ngn1*. *Ncam*, an olfactory receptor neuron marker, is expressed throughout the OE but is absent from the supporting cell layer that lines the nasal cavity. (Bottom panel) *Mash1* and *Ngn1* are similarly located in the VNO, at the boundary between basal epithelium and underlying connective tissue. *Ncam*-positive cells populate the majority of the sensory epithelium, from the concave side of the lumen to the basal layer. Adapted from Murray RC, Navi D, Fesenko J, et al. (2003) Widespread defects in the primary olfactory pathway caused by loss of Mash1 function. *Journal of Neuroscience* 23(5): 1769–1780, with permission. Copyright 2003 by the Society for Neuroscience.

capacity for ongoing neurogenesis is coupled with the ability to regenerate the sensory neuron compartment quickly, at least in the main OE. When ORN number is reduced dramatically by surgical or chemical ablation, progenitor cells in the basal compartment of the OE rapidly upregulate proliferation and produce new differentiated ORNs to replenish the damaged epithelium. These observations imply that stem and neuronal progenitor cells, as well as the microenvironment in which they reside, produce signals that stimulate proliferation and differentiation. Moreover, it must also be the case that OE neuronal stem and progenitor cells express intrinsic factors that endow them with the capacity to respond to these signals.

Work from a number of groups has demonstrated that as cells progress through the OE neuronal lineage, they successively express transcription factors that are characteristic of, and required for, differentiation of stem cells into committed neuronal progenitors and, ultimately, ORNs. Thus, expression of these cell-intrinsic factors both provides unique molecular 'signatures' for neuronal progenitor cells at specific developmental stages and determines the ultimate fates of these cells. This feature makes the OE an ideal system for studies of the regulatory roles that such transcription factors play in neurogenesis, and also provides the molecular markers needed to decode effects of extrinsic factors, such as signaling molecules, on the regulation of neurogenesis. Indeed, studies of mice with mutations in genes encoding regulatory transcription factors have proved to be extremely informative in understanding the roles that such factors play in regulating ORN and VNO development.

Although no definitive stem cell marker has been found for OE and VNO stem cells, a likely candidate is the transcription factor, Sox2. Sox2, a transcription factor of the SoxB1-type SRY transcription factor family, is thought to be a general neuronal stem cell marker: It is expressed throughout the neural primordium in rodents, is an important regulator of embryonic development, and has been shown to direct neural progenitor identity. Moreover, in a number of

neural tissues, *Sox2*-expressing cells have been shown to be capable of both self-renewal and differentiation, suggesting that *Sox2* gene expression is a trait shared by stem cells in many neural systems. During primary neurogenesis in the OE, expression of *Sox2* mRNA defines the neuroepithelial domain of the invaginating olfactory pit, and co-expression of *Sox2* and *Fgf8* has recently been reported to define a population of primordial neural stem cells that will give rise to all subsequent neural stem and progenitor cell types of the OE (**Figure 3**). Indeed, in mice in which the *Fgf8* gene is inactivated in anterior neural structures, this *Sox2–Fgf8* co-expressing cell population undergoes apoptosis, leading to a failure in subsequent OE neurogenesis, nasal cavity formation, and morphogenesis of the VNO (see later). Thus, although no stem cell marker has been identified for the VNO, the observation that the VNO fails to develop at all in *Fgf8* conditional mutant mice strongly suggests that the *Sox2–Fgf8* co-expressing primordial neural stem cells, observed to play a critical role in the early stages of primary neurogenesis in the OE, give rise to the neurogenic population of the VNO as well.

During primary neurogenesis at e10–e11, cells expressing the proneural gene, *Mash1*, are found in close apposition to *Sox2–Fgf8* co-expressing primordial neural stem cells near the rim of the invaginating olfactory pit (**Figure 3**). A day or so later in development (e12.5), *Mash1* mRNA can be detected in cells found in the apical, middle, and basal compartments of the OE, coincident with the location of mitotic figures at this age. As the OE matures and enters the phase of established neurogenesis, *Mash1*-expressing cells come to be located primarily in the basal compartment of the OE, suggesting that the action of *Mash1* is required early in the ORN lineage. *Mash1* has been shown in genetic studies to be required for ORN development, and in studies *in vitro*, in OE cultures, and *in vivo*, in surgical models of induced neurogenesis, *Mash1* has been shown to be expressed by early-stage transit-amplifying progenitors of the ORN lineage (**Figure 1(b)**). Indeed, in mice with targeted inactivation of the *Mash1* gene, *Ngn1*-expressing INPs, as well as ORNs, fail to develop, indicating that *Mash1* acts upstream of *Ngn1* to direct neuronal differentiation in the OE.

Recent studies indicate that, in the absence of *Mash1* function, the OE reverts to a state in which it maintains high levels of both proliferation and apoptosis. Proliferating cells express *Sox2*, the *Mash1* 3′-untranslated region (3′-UTR; which is still present in the targeted mutant), and *Steel*, a marker of supporting cells. This has led to the hypothesis that these proliferating cells in the OE of *Mash1*$^{-/-}$ mice are 'frozen' at an early stage of differentiation, and the fact that these cells co-express markers of both supporting cells (*Steel*) and early neuronal progenitors (*Mash1* 3′-UTR) suggests that they would be capable, if they did not undergo apoptosis (the precipitating cause of neurogenic failure in the *Mash1* mutant), of giving rise to both ORNs and supporting cells. These observations provide indirect evidence that the neural stem cell of the OE is a bipotential stem cell, capable of giving rise to both glial and neuronal cell types. Interestingly, neurogenesis also fails in the VNO of *Mash1*$^{-/-}$ mice, and in the same manner as in main OE: *Ngn1* expression fails to occur and neurons fail to form, while the *Mash1* 3′-UTR is expressed in abundant proliferating cells that undergo high levels of apoptosis. Thus, the developmental hierarchy of gene expression in both the main OE and the VNO appear to be fundamentally similar.

As they progress through the ORN lineage, *Mash1*-expressing progenitors lose expression of *Mash1* and upregulate expression of a different proneural gene, *Ngn1*. *Ngn1* expression defines the immediate neuronal precursor, which has been shown by tissue culture and genetic studies to be committed to ORN differentiation after one to two rounds of division. Evidence for the function of *Ngn1* as a neural determination gene first came from studies in *Xenopus*. In *Xenopus*, misexpression of an *Ngn1* homolog can convert nonneurogenic ectodermal cells to neurons. In *Ngn1* mutant OE, most ORNs fail to develop and differentiate (at least by the end of primary neurogenesis at e12.5), suggesting that mammalian *Ngn1* plays a role similar to that of its *Xenopus* counterpart. Moreover, although *Ngn1* expression is severely reduced in the OE of *Mash1* mutant mice, *Mash1* expression is not significantly affected in the OE of *Ngn1*-null mice, indicating that *Mash1* and *Ngn1* expression are essential at different stages of differentiation and that *Mash1* acts upstream of *Ngn1* in the ORN lineage.

A number of other transcription factor genes play roles in regulating neuronal differentiation in the OE, including *RunX1* and *NeuroD*. *Runx1* encodes a member of the Runt/Runx family of transcription factors, whereas *NeuroD*, like *Mash1* and *Ngn1*, encodes a basic helix–loop–helix transcription factor. In the OE, expression of *Runx1* and *NeuroD* is restricted primarily to cells in the basal half of the epithelium. Evidence from developmental genetic studies suggests that *NeuroD* is expressed at the stage when late, *Ngn1*-expressing neuronal progenitors are just differentiating into ORNs. Gene expression studies indicate that only a few cells co-express *Runx1* and *Mash1*, whereas virtually all cells expressing *NeuroD* also express *Runx1*. Thus, expression data suggest that both *Runx1* and *NeuroD* act at the time when

late-stage neuronal progenitors (INPs) are undergoing terminal differentiation into ORNs. OE development in mice with targeted inactivation of the *Runx1* gene has only been examined up to the end of the primary phase of neurogenesis, since homozygous nulls die at e12.5. Interestingly, in the OE of e12.5 *Runx1*$^{-/-}$ embryos, the total number of cells, and the number of *Mash1*-expressing cells, appear to be unchanged; however, there is a decrease in the number of *NeuroD*-expressing cells and an increase in cells expressing the early neuronal marker β-III tubulin. Since Runx1 is also known to repress expression of cyclin-dependent kinase inhibitors (which act as 'brakes' on mitotic cells in the G1/S transition; see later), these observations have been interpreted as showing a role for Runx1 in regulating *NeuroD* expression and terminal differentiation of OE neuronal progenitors into postmitotic ORNs. Since *NeuroD* is expressed in the VNO in a pattern analogous to its expression in OE, by extension it seems possible that Runx1 may function in this tissue as well to regulate sensory neuron differentiation, although this has not yet been investigated.

Control of Neurogenesis by Extrinsic Factors

Developmental transitions in expression of transcriptional regulators, cell proliferation, cell differentiation, and intraepithelial cell location in the OE are directed by the actions of extrinsic signaling molecules. Different signaling molecules appear to predominate during the primary and established phases of neurogenesis, and these factors are produced both within the OE itself and by its underlying mesenchymal stroma (also known as the lamina propria of the mature epithelium). The actions of these secreted signaling molecules in regulating programs of neuronal cell proliferation and differentiation in the OE are classified into two categories: (1) proneurogenic effects, which are positive effects on OE neurogenesis and include stimulation of progenitor cell proliferation and cell survival, and (2) antineurogenic effects, which include suppression of cell proliferation and, directly or indirectly, increases in cell death (apoptosis). Both categories of action are important for OE and VNO morphogenesis and acquisition and maintenance of proper sensory neuron number, and therefore for OE function during development and postnatal life. Over the past several years, studies have revealed that OE neurogenesis is critically dependent on signaling molecules from two different polypeptide growth factor superfamilies, fibroblast growth factors (FGFs) and transforming growth factor-βs (TGF-βs). Each of these superfamilies of signaling molecules includes many members, all of which have specific patterns of expression and differing functions during development and tissue homeostasis. During OE neurogenesis it has been found that different factors from these two superfamilies interact in at least two ways: first, opposing signals converge on neuronal stem and progenitor cells at specific developmental stages in the ORN lineage, regulating proliferation and the stepwise progression of neuronal differentiation. Second, TGF-βs and their secreted antagonists play key roles in feedback loops that regulate the size of progenitor cell pools and the number of ORNs that differentiate from these cell pools. Since these developmental pathways have been worked out almost exclusively in the main OE of rodents, particularly the mouse, the following discussion deals primarily with mouse main OE.

Fibroblast Growth Factors

During OE development, several different FGFs are known to be expressed, and since expression of these FGFs is developmentally regulated, it is thought that the functions of different FGFs predominate at different developmental stages. It has recently been established that FGF8 plays a crucial role in OE development during the early stages of primary neurogenesis. Tissue-specific inactivation of the *Fgf8* gene has shown that *Fgf8* expression, which is highest in the ectoderm and neuroepithelium that outlines the rim of the invaginating pit at e10–e11 in the mouse, defines a morphogenetic center of function that is crucial for OE neurogenesis, nasal cavity morphogenesis, and development of the VNO. As mentioned previously, a subpopulation of *Sox2*-expressing neural stem cells, located in the outermost rim of the invaginating OE neuroepithelium, also express *Fgf8* (**Figure 3**); these cells have been termed 'primordial' neural stem cells of the OE. In mice with tissue-specific inactivation of *Fgf8*, these *Sox2–Fgf8* co-expressing cells undergo apoptosis (**Figure 5(a)**). As a result, OE neurogenesis fails, as does nasal cavity formation; indeed, by e14.5, only a small vestige of remaining OE, with just a few neural cells, can be observed – and this is seen only in the least severely affected mutants (**Figures 5(b) and 5(c)**). These animals also lack any VNO, indicating that FGF8 is a crucial signal for morphogenesis and neurogenesis in the VNO as well as in the main OE. The effects of the neurogenic deficits resulting from absence of FGF8 are long lasting: although animals survive until birth, no OE or VNO ever forms, and only a few, scattered neural cells are observed in the malformed oral–nasal cavity that does develop. These observations indicate

Figure 5 *Fgf8* is required for cell survival in the neurogenic domain. (a) Terminal dUTP nick end labeling (TUNEL) of olfactory epithelium of mutant (cKO; conditional knockout) and control littermates at day 10.5 of gestation shows a high number of apoptotic cells in mutants in ectoderm and olfactory epithelium (white arrowhead; magnified in inset) of invaginating nasal pit (NP). Hoescht panel (blue, right) shows extent of invaginating NP. Broken white line indicates the boundary of the neuroepithelium lining the NP and lateral nasal process (LNP). (b) *In situ* hybridization on horizontal sections of mutant and control littermates (day 14.5 of gestation) shows the near absence of OE in the mutants and the lack of neuronal markers in the remaining OE (arrow) (FB, forebrain; S, nasal septum; NR, neural retina). (c) Role of *Fgf8* in olfactory neurogenesis. Schematic of primary neurogenesis at day 10.5 of gestation in wild-type OE and *Fgf8* mutant OE, illustrating the relative positions (MNP, medial nasal process) of the *Fgf8* expression domain and different neuronal cell types: *Fgf8* expression domain, orange; *Sox2*-expressing neuroepithelium, yellow; *Sox2*- and *Fgf8*-expressing primordial stem cells, green; *Mash1*-expressing progenitors, blue; immediate neuronal precursors (INPs),turquoise; *Ncam*-expressing olfactory receptor neurons, pink. In the mutant invaginating pit, cells undergoing apoptosis due to *Fgf8* inactivation are shown in red and apoptotic primordial neural stem cells are green with red jagged borders. Diminished populations of other neuronal cell types are shown in their corresponding colors, but with jagged edges. Adapted from Kawauchi S, Shou J, Santos R, et al. (2005) Fgf8 expression defines a morphogenetic center required for olfactory neurogenesis and nasal cavity development in the mouse. *Development* 132(23): 5211–5223.

that FGF8 is required not only for the survival and expansion of the neural stem cell pool during primary neurogenesis (Figure 5(c)), but also that it is required for maintenance of primary neurogenesis and, as a result, the initiation of the established phase of neurogenesis. Interestingly, *Fgf8* expression declines by the end of primary neurogenesis (e12.5), when another closely related FGF, encoded by *Fgf18*, begins to be expressed within the neuroepithelium of the OE. It has been hypothesized that FGF18 assumes FGF8's role in maintenance of the stem cell population during the embryonic stages of the established phase of neurogenesis, although this idea has not been tested directly in *Fgf18* mutant mice.

Unlike *Fgf8*, *Fgf2* does not appear to be expressed at significant levels in prenatal mouse OE, but in adult mice, it is expressed throughout the neuronal cell layers of the main OE. By 3 weeks of age, FGF2 expression can also be detected in axon bundles that converge below the basal lamina, en route to the olfactory bulb. Like FGF8, FGF2 can also function as a proneurogenic factor: In cultures of OE, addition of FGF2 increases the number of proliferating INPs, by promoting multiple rounds of INP divisions before INP daughter cells undergo terminal differentiation into ORNs; FGF2 has also been shown to be capable of promoting survival and proliferation of putative stem cells in OE cultures. Taken together with the pattern of *Fgf2* expression, these observations suggest that FGF2 is likely to be involved in maintaining neuronal stem and progenitor cells, as well as in serving as a mitogen for these cells, in order to regulate ORN number in postnatal OE.

TGF-β Superfamily

Bone morphogenetic proteins Many studies indicate that the bone morphogenetic proteins (BMPs), a subfamily of TGF-βs structurally related to the *Drosophila* signaling molecules Dpp and 60A, have important roles in regulating neuronal fate determination and neurogenesis during vertebrate development. For example, endogenous BMP4 promotes acquisition of an epidermal fate, at the expense of neural tissue, in developing ectoderm, and BMP2 and BMP4 have been shown to inhibit proliferation and/or induce apoptosis of neural progenitor cells in several systems. Studies of the OE have shown that BMPs can exert both pro- and antineurogenic effects, depending on the concentration and identity of the BMP in question and the identity of the target cell that is acted upon.

Bmp2, *Bmp4*, and *Bmp7* are all expressed in and/or near OE proper during embryonic development in the mouse, and all three of the secreted proteins (BMP4, BMP2, and BMP7) can inhibit OE neurogenesis *in vitro* by acting on *Mash1*-expressing neuronal progenitors. Exposure to any of the three BMPs causes these progenitors to target preexisting *Mash1*-encoded protein for proteasome-mediated degradation, resulting in apoptosis and termination of the ORN developmental pathway at the *Mash1*-expressing stage. Interestingly, however, low concentrations of BMP4, but not BMP7, stimulate OE neurogenesis: In this case, the action of BMP4 is to promote survival of newly generated ORNs. Since BMP4 and BMP7 selectively activate different subsets of serine–threonine kinase type I BMP receptors, which are known to be differentially expressed within the OE, it is likely that differential responsiveness of specific OE neuronal stem/progenitor cells to different concentrations of specific BMPs is dictated by the identity of the cell surface receptors that are activated in the various target cell types. The OE is thus proving to be a useful model system for dissecting out the cellular basis of concentration-dependent responses to BMPs, an area of broad interest to both developmental biologists and cancer biologists.

Growth and differentiation factor 11 and feedback inhibition of neurogenesis Studies *in vitro* and *in vivo* have shown that generation of new ORNs by their progenitors is inhibited by a signal produced by OE neuronal cells themselves; this process has been termed feedback inhibition of neurogenesis. Recently, growth and differentiation factor 11 (GDF11), a member of a small subgroup of activin-like TGF-β s that includes the muscle regulatory factor GDF8 (also called myostatin), has been shown to mediate feedback inhibition of INP proliferation during the established phase of OE neurogenesis. *Gdf11* is expressed by both committed neuronal progenitors and newly differentiated ORNs in the OE, as are its serine–threonine kinase transmembrane receptors (ALK5 and ActRIIb). Both *Gdf11* and the gene that encodes its secreted antagonist, follistatin (FST), are first expressed at significant levels at the onset of the established phase of neurogenesis, and their expression continues through adult life (*Gdf11* is expressed only within OE neuroepithelium proper; *Fst* is expressed in OE stroma and, at lower levels, in OE proper). Recombinant GDF11 inhibits OE neurogenesis *in vitro*, by reversibly arresting INP divisions; this action is accompanied by induction of the cyclin-dependent kinase inhibitor $p27^{Kip1}$ in these neuronal progenitors. The antiproliferative effect of GDF11 on INPs is abrogated by addition of FST to OE cultures, but, interestingly, GDF11 actions

predominate over the proliferative effect of FGFs on INPs. *Gdf11*-null mice show increased cell proliferation in the OE, and the number of *Ngn1*-expressing INPs is increased, as is overall OE thickness, relative to that of wild-type control littermates. These supernumerary INPs go on to give rise to ORNs, as demonstrated by an increase in *Ncam*-expressing cells in *Gdf11*-null OE (Figure 6(a)). FST, a secreted protein that prevents effective binding and signaling by GDF11, is able to completely antagonize the antineurogenic effect of GDF11 on INPs in OE cultures. Importantly, the number of INPs and ORNs is dramatically decreased in $Fst^{-/-}$ OE, consistent with what would be expected with removal of a crucial brake on the antineurogenic actions of endogenous GDF11 in the OE neuroepithelium (Figure 6(b)). These observations have led to the proposal of a model in which GDF11 and FST interact to maintain neuron number in the OE by tightly regulating INP divisions and ORN production. Since GDF11 arrests INP proliferation but does not kill INPs, its role in feedback inhibition of OE neurogenesis is likely to be one of maintaining INPs in stasis, such that they are capable of responding rapidly to a decrease in ambient GDF11 levels (as when OE neuronal cells are lost through injury or disease) by rapidly reentering the cell cycle and giving rise to ORNs (Figure 6(c)).

Summary and Conclusions

In addition to revealing major steps in morphogenesis and neurogenesis of the OE and VNO, studies of the development of these two sensory neuroepithelia have revealed important aspects of the molecular regulation of neurogenesis. Studies of main OE development in particular have led to the concept that neurogenesis in olfactory sensory epithelia proceeds in a linear manner, with expression of specific transcription factors marking the progressive restriction in fate observed as neuronal stem and committed progenitor cells differentiate through the ORN developmental pathway. Both these intrinsic signals, which operate in a cell-autonomous manner, and extrinsic (secreted) signals present in the local microenvironment of developing cells (the stem/progenitor cell niche) play important roles in regulating this process. The factors that predominate during primary olfactory neurogenesis play an expansionary, morphogenetic role. For example, FGF8, which is crucial for increasing the size of the stem cell pool, is of vital importance at this stage in order to establish the ORN lineage in the main OE and to permit formation of the VNO (Figure 7). Once the OE neurogenesis enters its established phase, both FGFs and TGF-βs participate in regulating neuronal cell number. Studies of the

Figure 6 Disruption of neurogenesis in mice with loss or gain of function of *Gdf11*. (a) *In situ* hybridization on horizontal sections (AP, apical layer; BL, basal layer) of olfactory epithelium of $Gdf11^{tm2/tm2}$ mice reveals an increase in *Ngn1*-expressing cells and a corresponding increase in *Ncam*-expressing cells: the *Ncam*-expressing cell layer is thicker by 20% (9 μm), about the diameter of one olfactory receptor neuron (ORN), in $Gdf11^{tm2/tm2}$ olfactory epithelium, compared to in wild type. (b) Mice lacking a functional *follistatin* (*Fst*) gene show decreased olfactory epithelium neurogenesis. *In situ* hybridization for *Ngn1* and *Ncam* shows large decreases in expression of both markers as well as aberrantly thin olfactory epithelium in the *Fst* mutant. (c) Schematic model of growth and differentiation factor 11 (GDF11) action in ORN neurogenesis. GDF11 is produced by both *Ngn1*+ progenitors and *Ncam*+ ORNs (gray broken-line arrows). GDF11 reversibly arrests *Ngn1*+ progenitors through induction of the cycle-dependent kinase inhibitor $p27^{Kip1}$, thus preventing ORN generation. Reproduced from Wu HH, Ivkovic S, Murray RC, et al. (2003) Autoregulation of neurogenesis by GDF11. *Neuron* 37: 197–207, with permission from Elsevier.

Figure 7 Summary of molecular signals involved in both primary and established olfactory epithelium (OE) neurogenesis. During primary neurogenesis (yellow box), fibroblast growth factor 8 (FGF8) and other factors are involved in producing the stem cell pool and initially establishing the different progenitors in the olfactory receptor neuron lineage. FGF8 is also necessary for initial vomeronasal organ (VNO) formation. After day 12.5 of gestation, once the lineage is established (blue box), FGFs and transforming growth factor-βs (BMP, bone morphogenetic protein; FST, follistatin; GDF, growth and differentiation factor) converge on different cell types in the OE lineage to achieve and maintain proper neuron number. Green arrows indicate stimulatory interactions; red bars indicate inhibitory interactions. Adapted from Kawauchi S, Beites CL, Crocker CE, et al. (2004) Molecular signals regulating proliferation of stem and progenitor cells in mouse olfactory epithelium. *Developmental Neuroscience* 26: 166–180, with permission. Copyright 2004 by S. Karger AG, Basel, Switzerland.

actions of TGF-βs and their secreted antagonists in regulating OE neurogenesis have led to the concept of feedback inhibition of neurogenesis, in which feedback circuits consisting of endogenous secreted antineurogenic factors regulate the size of the stem/progenitor cell pool and total neuron number. Ultimately, determining whether similarities in these processes exist between the OE and other regions of the nervous system should provide important knowledge for understanding how neuronal stem/progenitor cell pools are controlled in all neural tissues, and for overcoming roadblocks to recovery in regions of the

adult nervous system where – unlike the OE – neuronal regeneration is limited or absent.

Olfactory Receptor Genes: Human Loss During Evolution

Y Gilad, University of Chicago, Chicago, IL, USA

Introduction

Buck and Axel identified the odorant receptor gene family more than a decade ago, based primarily on the observation that the candidate genes were exclusively expressed in olfactory epithelium in rats, but not detected in a number of other nonolfactory tissues. They originally hypothesized that there were at least 100–200 olfactory receptor (OR) genes in the rat genome. Nearly all mammalian OR genes are encoded by only one coding exon of roughly 1 kb. They are members of the G-protein-coupled receptor (GPCR) gene superfamily and based on their protein sequence are assumed to have the hallmark seven transmembrane domain structure. These features were used to recognize additional coding regions of OR genes in mammalian genomic sequence. Specifically, the search relied on their similarity to the first set of confirmed OR genes and by the presence of certain protein motifs.

Mammalian OR genes are currently divided into two classes, 17 families and ~250 subfamilies, based on protein sequence similarity. Class I OR genes are closely related to OR genes that are found in fish and hence are referred to as 'fishlike,' while class II OR genes are specific to tetrapods. OR genes from the same family and subfamily are defined as sharing 40% and 60% or more of their amino acid sequence, respectively. It is thought that OR genes from the same subfamily bind the same type of odorants, while differing in their affinity to close structural variants.

Recently, the complete genomic sequence of a number of mammalian species became available, permitting interspecies comparisons of complete OR gene repertoires. Such interspecies comparisons increase our understanding of the evolution of the OR gene repertoires and, in particular, of the molecular basis for inter- and intraspecies differences in the sense of smell. The analyses of published mammalian genomes suggested that the original estimate of the size of the mammalian OR gene repertoire was a severe underestimate. Indeed, it is now thought that mammalian genomes carry 800–1400 OR genes, which are typically organized in gene clusters and are found on many chromosomes. With roughly 3% of all genes coding for odorant receptors, OR genes are by far the largest gene family in mammalian genomes.

In humans, OR genes have a tendency to cluster in subtelomeric regions, and they are found on all chromosomes except for chromosomes 20 and Y. Class I OR genes are all found in a single cluster on chromosome 11. These genes were originally thought to be an evolutionary relic, the original function of which was to bind water-soluble odorants (in fish). However, many class I OR genes remained intact, putatively functional, in human as well as in other mammalian species. This observation raises the possibility that class I OR genes now have a function in terrestrial mammals.

The largest cluster of class II human OR genes is found on chromosome 11, and is thought to be the original tetrapod-specific OR gene cluster from which all other class II OR genes have originated. The OR gene family is thought to have evolved in mammals through a process of gene birth and death, with an evolutionary pressure for functional diversification of the repertoire (through mutations and/or gene conversion events).

Human Loss of OR Genes

The completion of the human genome project enabled the identification of the entire repertoire of human OR genes. Humans have roughly 900 OR genes, but more than 50% of them carry one or more coding region disruptions and therefore are annotated as pseudogenes. However, not all OR pseudogenes represent gene loss. For example, roughly 80 of the human OR pseudogenes belong to subfamily 7E, a recent expansion of a cluster of three OR pseudogenes that is thought to have occurred only in apes.

Early anecdotal observations of a human-specific OR coding region disruption raised the hypothesis that the rapid accumulation of OR pseudogenes occurred in parallel to a reduction in the sense of smell in primates and, specifically, in humans. This hypothesis found some measure of support when the mouse genome, and consequently its complete repertoire of OR genes, became available. The mouse OR gene repertoire is ~30% larger than that of man, but contains only 20% pseudogenes. Thus, the mouse putative functional OR gene repertoire is estimated to be more than three times larger than that of humans. Similarly low proportions of OR pseudogenes were later found in dogs and rats.

Among apes, the relative rates of accumulating OR coding region disruptions were first estimated by direct sequencing of 50 randomly chosen human OR genes and orthologs from chimpanzee, gorilla,

orangutan, and one Old World monkey (rhesus macaque). Using this data set, OR coding region disruptions could be mapped to specific lineages (Figure 1) and their lineage-specific fixation rates could be estimated. This analysis suggested that while apes have been accumulating OR pseudogenes faster than rodents, humans have been accumulating OR pseudogenes much faster than any of the other apes.

Recently, the availability of the chimpanzee genomic sequence enabled a direct comparison of the entire OR gene repertoires of humans with that of our closest evolutionary relative. In agreement with previous estimates based on small samples of OR genes, it was found that humans have a significantly smaller number of intact OR genes than chimpanzees (Figure 2). Moreover, the hypothesis, that humans and chimpanzees accumulated OR pseudogenes at a constant rate since the divergence of human and chimpanzee could be rejected, again suggested that the rate of OR gene disruption was higher in the human lineage.

Figure 1 Gilad et al. resequenced 50 orthologous OR genes from five primate species. Of these 50 OR genes, the number of OR genes that were lost in each branch is indicated. The branch lengths represent the species divergence time. As can be seen from this sample, humans have lost OR genes much more rapidly than any of the other species.

Thus, the picture that emerges was that of a decrease in the size of the putatively functional OR gene repertoire in apes relative to other mammals, with a further deterioration specifically in the human evolutionary lineage. This relaxation of evolutionary constraint on human OR genes is thought to be the result of differences between humans and other apes in several aspects of the lifestyle that have been shown to be influenced by the olfactory system, including differences in social behavior, shifts in nutrition, and the factors that determine mating choice.

Although the causes are unclear, it seemed reasonable to speculate that the high fraction of OR pseudogenes in apes compared to rodents reflects a decreased reliance on the sense of smell in species for whom auditory and visual cues may be more important. To examine this, a random set of 100 OR genes were sequenced from 19 primate species, including apes, Old World monkeys, and New World monkeys. These OR loci were not sets of orthologous genes, so that the lineage-specific rates of accumulating OR coding region disruptions could not be estimated. However, under the assumption that the OR gene repertoire is of similar size in all the studied species (a reasonable assumption given that the size of the OR gene repertoire in human, chimpanzee, mouse, rat, and dog was found to be similar), the number of putatively functional OR genes in each species can be estimated using the proportion of pseudogenes in the random samples that were sequenced. Using this approach, the intact OR gene repertoire of most New World monkeys was estimated to be similar to that of mouse, dog, and rat. In contrast, significantly higher proportion of OR pseudogenes were found in two distinct evolutionary lineages: in the ancestors of Old World monkeys and apes; and in only one New World monkey, the howler monkey. Interestingly, the howler monkey is also the only New World monkey to possess full trichromatic color vision, along with all Old World monkeys and apes. Hence, these

Figure 2 An estimate of the number of intact, putatively functional OR genes in mammalian species with available genomic sequence.

findings suggest that the deterioration of the functional OR gene repertoire in primates may have been associated with the acquisition of full trichromatic color vision.

Segregating Pseudogenes in Humans

The observation that OR pseudogenes have accumulated in the human lineage at a rapid rate suggested that this process is ongoing. In particular, approximately 70 of the hundreds of human OR pseudogenes have only one disruption in their coding region. These loci are likely to be the youngest human OR pseudogenes, as additional coding region disruptions have not had the time to accumulate. This suggests that the disruptive mutations in these loci may not yet have reached fixation in the entire human population; in other words, that both the intact and the pseudogene alleles are still expected to segregate in human populations.

To test this hypothesis, the single disruptive mutation in 50 human OR pseudogenes was genotyped in a sample of 192 individuals, half of whom were Europeans and half African Americans. Of the 50 loci, 26 were found to segregate both the intact and pseudogene alleles. Because these segregating mutations disrupt the OR coding regions, they represent promising candidates for functional polymorphisms that affect the sense of smell and may underlie, at least in part, the observed interindividual variation in olfactory sensitivity. For example, individuals that carry two OR pseudogene alleles at a given locus (i.e., homozygotes for the null allele) probably experience a loss of olfactory function, possibly specific anosmia. If this is the case, then when all 26 segregating pseudogenes are considered, each of the 192 individuals that were genotyped is inferred to have a different functional OR gene repertoire (Figure 3).

In that respect, it is interesting to note that human populations may vary in the mean size of the functional olfactory receptor gene repertoire. As an illustration, in the 26 segregating pseudogenes, the intact OR gene alleles tended to be at significantly higher frequency in African Americans compared to Europeans. Thus, on average, European individuals in the sample carry two null alleles more often than do the African American individuals. While intriguing, there currently exist no data with which to test the functional implications of this observation.

Positive Selection on Human OR Genes

The difference in the proportion of OR pseudogenes between different mammals suggests that the selective pressures on the OR gene repertoire vary among species. One extreme example are dolphins, which no longer require the ability to detect volatile odorants, and consequently lost all of their class II OR genes. The high proportion of OR pseudogenes in humans raises two related questions: (1) Does the rapid accumulation of OR pseudogenes in the human lineage suggests that humans do not need a keen sense of smell? (2) Are we in the process of losing all of our OR genes?

Figure 3 Menashe et al. genotyped the coding region disruption in 26 segregating pseudogenes from 192 human individuals. This is a representation of the genotype of the 192 individuals across the 26 OR loci. No two individuals have the same genotype. If loss of function is assumed for individuals who are homozygotes for a pseudogene allele, even by considering only these 26 OR loci, no two individuals have the same functional OR gene repertoire.

By examining patterns of within- and between-species variation at the DNA level, it is possible to infer the selective forces that shaped different genomic regions. The most popular approach is to estimate the ratio Dn/Ds, the ratio of the rate of nucleotide substitutions that changed amino acids (Dn) to the rate of silent nucleotide substitutions that did not change the amino acid (Ds). When both classes of substitutions are neutral, that is, are not affected by selection, then a Dn/Ds ratio of 1 is expected. In contrast, if mutations that replace the amino acid are selected against and only rarely are allowed to become fixed, while synonymous mutations are effectively neutral, then a lower Dn/Ds ratio is expected. Finally, a Dn/Ds larger than 1 reflects selection in favor of mutations that alter the amino acid, leading these to become preferentially fixed.

Using this approach, OR pseudogenes were inferred to have evolved under no selective constraint in both human and chimpanzee. This result is expected, as pseudogenes are assumed not to have a function and hence mutations in them are not expected to affect phenotype and be subject to natural

selection. In contrast, in chimpanzees, but not in humans, intact OR genes showed patterns of variability that were consistent with purifying selection. This finding is consistent with the observation that chimpanzee maintained a larger number of intact OR genes compared to humans. Indeed, based on the observation of a rapid accumulation of human OR pseudogenes, we expect human OR genes to evolve under less evolutionary constraint than OR genes in other apes.

Interestingly, several studies also reported that in humans, patterns of genetic variation at a subset of intact OR genes were consistent with the action of positive selection. This may seem surprising, given the relaxation of selection that seems to have occurred on the human lineage. However, these apparently contradictory observations can be reconciled if humans do not require most of their OR genes, but there exists a class of OR genes that have adapted in response to hominid-specific needs. Again, this could be caused by the pronounced differences in life style between humans and nonhuman apes. In addition to a greater reliance on vision and hearing which rendered the human sense of smell overall less important, such differences may have led to certain novel human olfactory needs, not shared with other primates. For example, humans are the only primates who consume cooked food, with potentially widespread effects on nutrition, ecology, and social relationships. This shift may have had a strong impact on the OR gene repertoire, since the sense of taste is largely a function of olfaction.

What Exactly Did We Lose?

The human decrease in the number of intact OR genes is assumed to result in reduced sense of smell compared to other mammals. However, when only the intact (putatively functional) OR gene repertoires of human and mouse are compared, it emerges that more than 160 (~65%) of the different OR gene subfamilies are shared by both species. If, as is commonly assumed, OR genes from the same subfamily bind the same type of odorants, this observation might suggest that, in spite of the much smaller functional repertoire of human relative to mouse, the repertoires of odors that can be sensed by the two species are similar.

Very little functional psychophysical data exist with which to test this hypothesis. In one of the only olfactory functional studies that involved primates, Laska et al. compared threshold sensitivities between several species for nine odorants, from four chemical groups. They showed that humans perform as well or better than the squirrel monkey (a New World monkey) and that, with respect to the odorants tested, humans also perform as well or better than dog and/or rat. Based on these observations, it was suggested that the human sense of smell may be as keen as that of macrosmatic mammals such as mice, dogs, and rats, typically thought to be highly dependent on their sense of smell. If true, there would appear to be a contradiction between the interspecies psychophysical data on one hand and the relative size of the OR gene repertoires on the other. One possibility is that interspecies differences in nonreceptor aspects of the olfactory mechanism (such as the size of the olfactory bulb, the size of the brain, and the nasal cavity) are responsible for differences in the sense of smell.

To account for the discrepancy between the relative sizes of OR gene repertoires and the psychophysical data as well as the observation of multiple modes of selection acting on human OR genes, we need a better understanding of the relationship between olfactory receptors and the binding of odorants. Unfortunately, almost all of the OR genes are orphan receptors, as very few ligand (odorant)–receptor interactions have been demonstrated for OR genes. Similarly, there exist few interspecies odorant detection comparisons. Future high-throughput approaches to study the binding capacity of OR genes may help addressing this issue.

Conclusions

It is unclear whether the size of the functional OR gene repertoire is the main determinant of how good a species' sense of smell is. Nevertheless, the reduction in the number of functional OR genes was found to be more rapid in mammalian species that rely less on their sense of smell. Humans have fewer intact OR genes than any studied mammalian species, and the process of OR gene loss in humans is still ongoing. Given this observation, it is reasonable to assume that humans reduced reliance on the sense of smell rendered many human OR genes unnecessary and therefore they are free to become pseudogenes. However, humans did not forfeit the sense of smell entirely, as there is evidence that a subset of OR genes evolved under positive selection in humans, presumably to respond to human-specific olfactory requirements.

Background

Based on evidence for the involvement of G-protein-mediated channel activation in olfactory signal transduction, Buck and Axel hypothesized that receptor proteins for odorants must be expressed in the olfactory epithelium and must belong to a family of seven-transmembrane G-protein-coupled receptors (GPCR). In the early 1990s state-of-the-art molecular biological techniques allowed them to identify a multigene family that appears to encode candidate receptors for odorants. The genes were named olfactory receptor or odorant receptor (OR) genes: olfactory receptor because the proteins are expressed in olfactory neurons and play a crucial role in olfaction, and odorant receptor because the proteins bind odorant molecules.

Structure

OR proteins are classified as part of the GPCR superfamily because of the presence of structural features common to GPCRs and because of their function in coupling and activating heterotrimeric G-proteins. ORs possess seven hydrophobic transmembrane domains, a disulfide bond between the conserved cysteines in the extracellular loops, a conserved glycosylation site in the N-terminal region, and several amino acid sequence patterns that are conserved in the OR family (Figure 1). These conserved motifs probably contribute to proper folding of ORs in the plasma membrane so that the ORs can function in binding odorants and in coupling to the appropriate G-proteins. In contrast, the transmembrane regions play a role in forming odorant-binding pockets; for this reason, the sequences are relatively variable, so that ORs can cover a wide variety of odorant molecules in the ligand recognition spectrum.

The size of the OR family was estimated to be at least several hundred when it was originally found in rat. In the past several years, whole-genome sequencing projects have allowed for comprehensive analysis of the OR gene family, revealing the genomic structure and distribution of OR genes in various organisms. The most recent data for vertebrate ORs are shown in Table 1. In mammals, the OR repertoire comprises 800∼1500 members, while fish have a relatively small OR family of ∼100. Thus, OR gene expansion occurred when animals shifted their living space from an aqueous to a terrestrial environment.

A significant portion of the OR gene family has been pseudogenized in vertebrates; hominoids have a high pseudogene content (∼50%), while the proportion of pseudogenes is ∼20% in mouse and dog and 25–35% in primates. The OR family was found to comprise the most changeable set of genes in the lineage of each animal species, undergoing rapid molecular evolution. The fraction of pseudogenes increased during evolution in the order rodents, monkeys, and humans, suggesting that reduced function of olfaction correlates with a loss of functional OR genes. Indeed, in whale and dolphin, in which the auditory system is dominant, 70–80% of OR genes appear to be pseudogenes.

The OR genes constitute an exon that contains an intronless coding region of ∼1 kb, and upstream exons whose number varies from one to four. The OR genes form genomic clusters and are distributed widely in chromosomes. The distribution, however, is not even; for example, almost half of mouse OR genes are located on chromosomes 2 and 7, which have orthologous relationships with chromosome 11 in humans. Further, OR genes are highly polymorphic, as suggested for human leukocyte antigen-linked OR genes and dog OR genes, possibly accounting for individual differences in odor perception ability and sometimes causing specific anosmia.

Expression Pattern

In rodents, OR genes start to be expressed at embryonic stages. The onset of expression in mouse was determined to be during mouse embryonic days E12–E14 using *in situ* probes for several ORs. Microarray analysis of the developmental course of OR gene expression revealed that the number of transcribed OR genes remains at a relatively low level until birth (100∼200 ORs), and a large number of OR genes appear to be detected only after birth; within 2–3 weeks postnatally, the number of detected OR genes reaches a peak (∼500 ORs). Recently, specific antibodies against ORs have become available. The OR proteins can be visualized in dendritic knobs of olfactory sensory neurons by specific antibodies as early as E12, before the initiation of ciliogenesis. As the olfactory cilia are formed at E13, the OR proteins appear to migrate into the developing cilia, and strong labeling by the antibody is observed in expanded tips of cilia. Up to E18, the number of cilia per neuron continues to increase, and OR immunostaining is clearly visible during this time.

Figure 1 Structure and topology of an olfactory receptor protein, and a model for the odorant-binding mode. (Top) Schematic depicting components in the olfactory receptor family: red, variable amino acids; blue, conserved amino acids; TM, transmembrane domain. Table 1 Number of functional olfactory receptor genes and proportion of pseudogenes in various vertebrate species

Organism	*Total number of genes*	*Number of intact genes*	*Pseudogene %*
Human	802	388	52
Mouse	1391	1037	25
Rat	1493	1202	20
Dog	1094	872	20
Frog	888	410	54
Zebra fish	133	98	26
Puffer fish	94	40	57

In situ hybridization experiments using different OR probes have suggested that each OR gene is expressed only in a certain region of the olfactory epithelium (Figure 2). Thus, the epithelium can be divided into at least four spatial zones in which different sets of OR genes are expressed. The distinct spatial expression pattern appears to be conserved among the vertebrate species, although expression of fish OR genes is not as clearly segregated as is that of mammalian OR genes. Initially, the spatial zones observed in rodents were thought to be sharply segregated, but careful *in situ* hybridization studies have revealed that each OR gene is expressed in a distinct zone in a continuous and overlapping manner. Therefore, multiple overlapping bands are formed along the dorsomedial/ventrolateral axis, although the boundary of the most dorsal region, corresponding to that of the olfactory cell adhesion molecule (OCAM)-positive neuronal layer, is maintained.

There are some exceptions to the zonal expression rule. First, some OR genes are expressed in the septal

Figure 2 Anatomical structure of the mouse nasal cavity. The olfactory receptor genes are expressed in a unique and distinct zone in a continuous and overlapping manner, and olfactory sensory neurons expressing a given olfactory receptor project their axons to defined glomeruli in the olfactory bulb (shown by red and green neurons expressing distinct olfactory receptors).

organ, an isolated island of olfactory sensory neurons located on the nasal septum near the entrance of the nasopharynx. Second, the OR37 subfamily shows patch-like distribution in clustered populations of neurons in the central turbinates. Although there are some promoter motifs that may control the expression domain in the nasal cavity, the regulatory factors that determine positional information remain to be identified. Together, ORs appear to play a critical role in the development of olfactory sensory neurons for proper spatial and temporal neuronal network formation.

Single Receptor Choice

Each olfactory sensory neuron expresses just one OR from thousands in the OR repertoire. The one-neuron/one-receptor rule has been confirmed by a variety of techniques: *in situ* hybridization, single-cell reverse transcriptase polymerase chain reaction (RT-PCR) analysis, and transgenic experiments. Further, the selected OR appears to be transcribed from only one of two alleles, either the maternal or paternal allele. The mutually exclusive expression pattern is preserved even between transgenes and endogenous copies, supporting the stochastic model. Indeed, a single OR choice is observed from a minigene comprising a few kilobases upstream of the transcription start site, implicating *cis*-regulatory elements. In contrast, the expression of one cluster of OR genes, including MOR28 in transgenic mice, requires a long upstream region of ~100 kb containing an enhancer element, called the H-region. The expression levels differ up to 300-fold among ORs due to inequalities in the numbers of expressing cells and in cell transcript levels. In addition to positive regulation of OR gene expression by *cis*-regulatory elements, negative-feedback regulation must also be present to suppress the expression of additional receptors. It appears that functional OR proteins, although not mRNA, play an inhibitory role by preventing further activation of other OR genes, although the molecular mechanism remains to be elucidated.

Odorant Response Assays

To assess OR function, olfactory neurons were first targeted as an OR expression system, because they should possess the appropriate cellular machinery for OR expression and transmission of odorant signals. Adenovirus-mediated gene transfer was used for overexpression of ectopic ORs in the olfactory epithelium and the ligand responses were measured either by electro-olfactography (EOG) or by Ca^{2+} imaging of infected neurons. In addition, a gene-targeting approach was used to tag defined OR-expressing olfactory neurons using green fluorescent protein, and to record the responses of the fluorescent cells to cognate odorants. However, both virus-mediated gene transfer and the gene-targeting approach are tedious and involve much time and labor; therefore, the establishment of heterologous expression systems is still awaited.

It is not easy to express functional ORs in heterologous cells because ORs appear not to be efficiently translocated to the plasma membrane. In some cases, addition of an N-terminal leader sequence from another GPCR has resulted in limited expression of functional ORs in the plasma membrane, and in successful odorant-response recording in heterologous systems such as HEK293 cells. Thus, in HEK293 cells co-expressing tagged ORs and promiscuous G-protein, ($G\alpha15$), Ca^{2+} responses are observed when the cells are stimulated with their ligands. Without co-expression of $G\alpha15$, ORs activate endogenous $G\alpha s$ upon ligand stimulation, resulting in an increase in cAMP level in various mammalian cell lines (e.g., HEK293, COS-7, and CHO-K1 cells). A luciferase-reporter assay system using the zif268 promoter allows luminescent detection of cAMP increases upon stimulation with an odorant. *Xenopus laevis* oocyte is another good heterologous expression system for ORs.

None of these expression systems, however, is applicable to all ORs. To overcome this problem, a chaperone molecule which helps with membrane translocation of ORs has been investigated. A one-transmembrane receptor transporter protein, RTP1, was found to enhance cell surface expression of ORs, and some ORs have been deorphanized by co-expressing RTP1. In addition, Ric-8B, a putative guanine nucleotide exchange factor for $G\alpha_{olf}$, promotes efficient signal transduction of ORs. Thus, it

is thought that the problem can be solved if we can introduce all of the factors required for OR expression, which are present in olfactory neurons but lacking in the heterologous expression system. In addition, a methodology to allow stable retention of ORs in the cell surface should be developed, because ORs have been shown to undergo continuous internalization and recycling in heterologous cells. Thus, the level of surface expression still appears to be critical for efficient OR assay.

Pharmacology

The best-characterized OR is a mouse OR, mOR-EG (MOR174-9), which was originally isolated from a single eugenol (EG)-responsive neuron by Ca^{2+}-imaging and single-cell RT-PCR techniques. The mOR-EG recognizes 22 odorants that share certain molecular determinants, with EC_{50} values ranging from a few micromolars to several hundred micromolars (Figure 3(a)). Structure–activity relationship studies for mOR-EG suggest that ORs have a broad but selective molecular receptive range, and that selectivity is determined by the shape, size, and length of a ligand. This pharmacological concept is common to many ORs, as has been shown by studies on rat I7 and other deorphanized ORs. However, there seem to be some ORs whose ligand spectra are relatively narrowly tuned. Ligand specificity appears to be determined by the environment of the binding site in each OR. Considering that there are a thousand ORs, each of which has a unique ligand spectrum, and that each odorant is recognized by multiple ORs, it is reasonable to conclude that odorant information is coded by a combination of ORs activated by the odorant.

As is the case for other GPCRs, odorants function as agonists for ORs, but also as antagonists for other ORs, suggesting that the interaction between ORs and odorants in the mixture is sometimes more complex than expected. For example, the eugenol response of mOR-EG is potently blocked by certain structurally related odorants, such as methyl isoeugenol and isosafrol (Figure 3(b)). The antagonism is observed in mOR-EG-expressing olfactory neurons using intact olfactory epithelium slice preparation. Further, rat I7 has been shown to be antagonized by citral, and undecanal has been identified as an inhibitor for hOR17-4. Thus, OR antagonism between odorants may contribute significantly to formation of the receptor code for an odorant mixture in the olfactory system. However, the possibility of mixture interaction in real life may be low, because the chance of being an antagonist is not sufficiently high. Indeed, optical recording of the olfactory bulb shows that the receptor code for natural odors such as coffee and cumin is more or less the sum of the responses to its individual components. Quantitative recording using a Ca^{2+} imaging technique, however, demonstrates that partial inhibition of the response by antagonists is observed in the OR-defined glomerulus, which may contribute to a change in odor perception.

(b) Dose-dependent inhibition curves of Ca^{2+} responses of a mouse olfactory receptor, mOR-EG, to eugenol by odorant antagonists.

Odorant-Binding Site

Multiple alignment analysis of the OR superfamily has allowed the determination of highly conserved and variable regions that are likely to be involved in structural organization and ligand recognition, respectively. Some of the earlier attempts, such as correlated mutation analysis and Fourier analysis of multiple OR sequences, supported the hypothesis that variable residues are responsible for odorant binding. An alternative method for identification of odorant-sensing residues is prediction of the binding site using a combined approach of computer modeling and docking simulation when cognate ligands for ORs are identified. Based on the coordinates of bacteriorhodopsin, a non-GPCR seven-transmembrane (TM) helix protein, and, more recently, on the X-ray structure and computationally determined three-dimensional structure of rhodopsin, using only the primary structure, computer modeling and calculation of lowest ligand-binding energy for several ORs has led to hypothesis that 10–20 residues in TM3, TM4, TM5, and TM6 are involved in ligand recognition and are responsible for odorant specificity.

A systematic experimental approach to decipher the odorant-binding site was taken for mOR-EG. Thus, functional analysis was carried out on a series of site-directed mutants, and ligand docking simulation studies were performed in parallel to define the odorant-binding environment. It was found that most of the critical residues involved in odorant recognition, and therefore sensitive to mutation, were hydrophobic, and that the binding pocket was in the space formed by TM3, TM5, and TM6 (Figure 1). The spatial location of the binding pocket is similar to that for other biogenic GPCRs; however, other GPCRs tend to form multiple electrostatic interactions with ligands, while hydrophobic amino acids appear to play critical roles in OR odorant recognition. Further, the accuracy of the binding model has been validated by the fact that single amino acid changes result in predictable changes in agonist and antagonist specificity. Thus, it can be concluded that the stereospecific receptor theory is proved by functional identification of odorant-binding site, and ligand information appears to be transduced by the three-dimensional configuration of the binding pocket and its specific odorant ligand.

Other Functions

Olfactory sensory neurons expressing a given OR project their axons to defined glomeruli in the olfactory bulb (Figure 2). Genetic manipulation that results either in deletion or in receptor swap suggests that the OR protein is instructive in axon guidance of olfactory neurons. Indeed, the OR proteins are present in olfactory axonal terminals as well as in cells of the cribriform mesenchyme involved in fasciculation and sorting of outgrowing axons. A point mutation in the OR protein results in formation of novel glomeruli, indicating that the OR amino acid sequence encodes information on axonal identity. The OR, however, is not a sole player in the axonal convergence; membrane receptors such as ephrin receptor, and cell adhesion molecules, are coordinatively involved in determination of the sensory map in the olfactory bulb. In addition, the instructive role in axon guidance is not restricted to ORs; a β_2-adrenergic receptor can substitute for an OR in glomerular formation, suggesting that GPCRs may have a common function. It should be noted, however, that both ORs and β_2-adrenergic receptors couple to the stimulatory G-proteins, Gαs. It is consistently found that OR-mediated Gα signaling is a positional determinant. Thus, the OR proteins expressed on the olfactory neuronal cilia and dendrites recognize odorants from the external environment, whereas the same OR proteins localized on axon termini appear to function as a critical factor in transmitting information for proper axon guidance.

Analogous to axon guidance, wherein olfactory neurons are attracted and navigated to a defined glomerulus by the ORs, testicular ORs are probably involved in proper navigation of sperm toward egg in mammals. Human OR17-4, expressed in sperm, recognizes bourgeonal, a floral aldehyde odorant, resulting in induction of chemotaxis and chemokinesis. MOR23, expressed in mouse sperm, recognizes lyral, again a floral aldehyde odorant, resulting in regulation of sperm motility. Since both bourgeonal and lyral are synthetic fragrances, identification of endogenous ligands for these ORs is necessary in order to elucidate the biological function of sperm ORs. Multiple testicular ORs have been shown to be expressed by various types of spermatids and spermatocytes in different developmental stages in mice, suggesting that some ORs are involved in spermatogenesis rather than in sperm physiology. In any event, ORs may function as a chemosensor in nonolfactory tissues.

Signal Transduction

The odorant signal received by ORs is converted to an electrical signal in olfactory sensory neurons (Figure 4). The first step in signal transduction is the activation of olfactory G-proteins, $G\alpha_{olf}$, by odorant-bound activated ORs. Some amino acids in

Figure 4 Signal transduction in olfactory sensory neurons. An olfactory receptor (OR), which is properly translocated to the plasma membrane by virtue of a chaperone receptor transporter protein (RTP), binds an odorant and couples to stimulatory G-protein ($G\alpha_{olf}$), which in turn activates type III adenylyl cyclase (ACIII), resulting in a cyclic adenosine monophosphate (cAMP) increase followed by an opening of cyclic nucleotide-gated (CNG) channel and Cl^- channel. Ric-8B, a guanine nucleotide exchange factor, enhances the G-protein-coupling efficiency.

the C-terminal domain and the third intracellular loop of ORs appear to be involved in coupling and activation of $G\alpha_{olf}$. Unlike in the case of rhodopsin, signal amplification does not occur in the OR–G-protein activation cycle. Instead, Ric-8B, a guanine nucleotide exchange factor, enhances accumulation of $G\alpha_{olf}$ at the cell membrane, thus improving the efficiency of OR coupling to $G\alpha_{olf}$. The activated $G\alpha_{olf}$ in turn stimulates adenylyl cyclase III, resulting in cAMP increase. The elevated cAMP interacts with and opens up the cyclic nucleotide-gated (CNG) channel, leading to cation influx and depolarization of the receptor neuron. Further, Ca^{2+} activates a Cl^- channel, leading to an efflux of Cl^-, which contributes to amplification of sensory depolarization. Bestrophin-2 is a candidate for a molecular component of the olfactory Ca^{2+}-activated Cl^- channel.

Gene knockout mice lacking either of the three molecular components (i.e., $G\alpha_{olf}$, adenylyl cyclase III, or CNG channel) failed to respond to odorants, suggesting that the cAMP cascade was dominant in transmitting the odorant signal in olfactory neurons. However, it was later demonstrated that CNGA2 knockout mice could detect a subset of odorants including 2-heptanone and 2,5-dimethylpyrazine, which are constituents of urine. Two additional olfactory pathways have been proposed: one involves membrane-bound guanylyl cyclase and phosphodiesterase type 2, and another involves phospholipase C and a transient receptor potential (TRP) channel. The multiple pathways in olfactory neurons may allow mice to respond readily to complex biological signals for social and sexual communication.

The activated olfactory neurons must return to the steady state, which is called desensitization. As is the case for other GPCRs, G-protein-coupled ORs could be phosphorylated upon odorant binding by protein kinases such as protein kinase A (PKA) and G-protein-coupled receptor kinase (GRK), resulting in desensitization. Indeed, knockout mice lacking GRK show slower recovery from cAMP increases, implying involvement of GRK in OR desensitization. In addition, it has been shown that PKA-mediated phosphorylation and subsequent internalization of ORs along with β-arrestin lead to reduction in the amount of ORs in the membrane. Although direct evidence for OR phosphorylation has not been obtained, desensitization mechanisms are likely to exist at the OR level. In addition, the influx of Ca^{2+} ions via the CNG channel downregulates itself, leading to closing of the CNG channel. Ca^{2+} also negatively regulates adenylyl cyclase activity. These Ca^{2+}-mediated negative feedback mechanisms allow activated olfactory neurons to revert to the steady state and prepare for the next stimulus.

Introduction to Olfactory Receptors

Organisms use their olfactory systems to detect and discriminate among thousands of low-mass molecules that reveal food sources, signal the presence of predators, and influence the organisms' social and sexual behaviors. Two olfactory systems have been developed in most animals. The main olfactory system senses environmental signals, which is the primary sense used by animals to find food, detect predators and prey, and recognize environmental cues. To enhance the ability of species and individuals to defeat their competitors, the olfactory system has evolved to have great discriminatory power and breadth, accomplished by a large family of olfactory receptors (ORs) residing in the nasal sensory epithelium. A second, or accessory, system developed to specialize in some species for finding a receptive mate. The sensory organ of this system is known as the vomeronasal organ (VNO). It is the sensor for species-specific olfactory signals, produced by one gender and perceived by the other, which play important roles in sexual behaviors and other social behaviors, such as territoriality, aggression, and suckling. These behaviors are initially executed by two types of receptors, known as vomeronasal receptors 1 and 2 (V1Rs and V2Rs), residing in the accessory olfactory system and binding with pheromones and related molecules. This review focuses on the ORs.

ORs were first discovered in 1991 by Linda Buck and Richard Axel, who were awarded the Nobel Prize in 2004 for their landmark work. As expected, OR genes turn out to be G-protein-coupled receptors (GPCRs), just like the receptors used in neurotransmission, photoreception, and many other cellular processes. Unexpectedly, the OR gene family size was found to be as large as 1000 in mammals, making it the largest gene family of GPCRs. The number of OR genes discovered was relatively small at the beginning because labor-intensive reverse transcription-polymerase chain reaction (RT-PCR) and rapid amplification of complementary DNA ends (RACE) studies were used to identify new OR genes. When the genome was sequenced, however, it became possible to computationally identify OR genes based on genomic sequences. From comprehensive data mining research in different genomes, it was found that rodents, such as mouse and rat, have in the range of 1000–1500 functional ORs, and that primates, such as human and chimp, have only around 350 functional ORs but a high percentage (~60%) of pseudogenes. Fish and amphibians are less well endowed, with about 100 ORs, and fly and other insects have about 60 ORs (Table 1).

Expression of ORs was first verified through traditional molecular methods such as RT-PCR. Subsequently, *in situ* experiments were carried out to examine the expression pattern and choice of ORs in olfactory sensory neurons. It was confirmed with single-cell RT-PCR that only one receptor gene is expressed in each sensory neuron, hence the so-called one neuron, one receptor rule. An advance was made through molecular-genetic studies, which showed that the H region in the 5′ upstream region of an OR cluster on chromosome 14 is involved with OR choice. OR expression also reveals spatial patterning; each receptor gene is expressed only in a subset of neurons that are randomly distributed in one of the several zones of olfactory epithelium (OE). In addition, it was reported that ORs are expressed in non-olfactory tissues, notably in testis. It is particularly interesting that at least one OR-like gene was found to function as a chemotaxis sensor in germ cells, directing their movement to the ovum.

Necessity of Microarray

Critical to the development of olfactory studies are genome-wide approaches. A family of more than 1000 genes could not be handled easily with standard molecular techniques. However, they are ideally suited to computational and high-throughput analysis. The protein coding regions of ORs, in common with many other GPCRs, are encoded by a single exon, which indicates that OR diversity could not be realized through gene rearrangement or alternative splicing, as occurs in the immune system. The fact that no exon–intron prediction is needed facilitates the data mining of receptor genes on the basis of similarity models. As the genome sequences become available, the OR repertoire has been examined computationally. However, it is not possible for molecular biologists to perform more than 1000 *in situ* experiments to verify the expression of each OR with regard to time and efficiency. Microarray technology is a good technique for studying OR expression as arrays allow the detection of many transcripts at the same time. Because of extensive similarity among paralogs,

Table 1 Total number of olfactory receptors in different organisms

Organism	*Number of putative functional genes*
Worm	1100[a]
Fruit fly	62
Fugu fish	47
Zebra fish	99
Chicken	347
Mouse	1191
Rat	1284
Canine	757
Chimp	411
Human	356

[a]This is actually the total number of sensory receptor genes for both smell and taste.

selecting unique probes for *in situ* study of ORs is an issue. One advantage of microarray design is that the probes on the chip do not need to be continuous in the original gene sequence; therefore, the regions with most cross-hybridization potential can be avoided in array design.

Standard commercial chips usually contain genes with known messenger RNA (mRNA) sequences and annotations from biological experiments, but few OR genes have mRNA sequences available. As a result, most OR genes are not represented on commercial chips. Furthermore, traditional gene expression design relies on 3′ ends of the mRNA sequences, which are largely unknown for OR genes. The limit of biological experiments and lack of OR genes on the commercial chips prompted the design of a custom chip specialized for ORs.

Design of OR Custom Array

As already discussed, an OR custom array is an excellent way to explore the expression of the whole OR repertoire. The Affymetrix Expression Array is based on reverse transcription (RT) of mRNAs with oligo (dT) primers. The RT reaction is 3′ biased, so only probes close to the 3′ end of the mRNA will detect signals in the array. Designing an array for genes with unknown mRNA sequences is challenging because the locations of the 3′ ends of the mRNAs are not known. The 3′ untranslated region (3′ UTR) downstream of the coding region for each OR was predicted by looking for polyadenylic acid (polyA) signals. Sequence analysis with the coding regions and the corresponding 3′ flanking sequences revealed that the latter are much more variable, which is an additional advantage to facilitate this unique probe selection. For each OR gene, polyA sites were predicted up to 5 kbp downstream of the coding region, and probe sets were designed closely upstream of the predicted polyA sites. To compensate for any inaccuracy of the prediction program, multiple probe sets were used per gene. Each probe set consisted of 11 probe pairs; each pair contained one perfect match probe and one mismatch probe. The mismatch probe, designed as the interior negative control, had almost the same nucleotide composition as the perfect match probe except for one mutation in the middle position of the 25-mer oligo. Besides 3′ UTRs, the coding regions of OR genes were also represented in the array. For OR genes with long 3′ UTRs, only the UTR probe sets would pick up signal, while the coding probe would have no signal. However, random-priming RT of mRNAs is an alternative to oligo(dT) primer-based RT. Samples from random-priming RT will have full-length coverage of the mRNA, and the coding probe sets will become useful.

Validation and Data Analysis of OR Custom Array

Custom high-density oligonucleotide arrays containing probes for all the putative ORs and VRs (V1R and V2R) were designed and manufactured in consultation with Affymetrix. Two generations of OR arrays were designed as the OR repertoire was updated, and more 3′ UTR sequences are available with the improved genome assembly. The improvement in the 3′ UTR sequences is important for detecting the expression of OR genes because the oligo(dT) priming process in the mRNA labeling requires the probes designed to be near the 3′ end of the transcripts. False negative results would be obtained for those ORs with long 3′ UTRs if probes for them were selected from the coding region. The custom arrays were produced with the same technology used extensively by Affymetrix in biological and medical applications, and subject to the same quality control.

Extensive tests were carried out to validate the custom arrays and optimize the experimental conditions and data analysis. Because each neuron expresses only one of more than 1000 ORs, each gene is present on average in about 0.1% of neurons, resulting in a very low expression level for each individual OR. To optimize the overall detection capability, the arrays were tested with different amounts of labeled cRNAs to find the appropriate point at which the number of detected genes reaches the maximum but noise level remains low. For data analysis of the GeneChip data, there are also multiple options. The dChip was chosen because of its flexibility in normalization matches with the property of the custom array. Other software may be better in probe-level

analysis, but distribution-based normalization may result in high false discovery rates. The perfect match–mismatch (PM-MM) difference model was used to calculate the expression level for each probe set, which was subject to differential analysis using Significance Analysis of Microarrays (SAM) software. SAM is based on adjusted *t*-statistics for small sample size data, producing an estimated false discovery rate through multiple permutations.

Expression of ORs in OE

Because the majority of sequences of ORs were obtained from computational prediction, it remains possible that some of them do not function as ORs or even not as a functional gene at all. Their specific expression in the sensory organ will confirm whether these genes are chemosensory receptors or not. The expression of genes was first compared between OE and the VNO, which are thought to mediate different types of environmental stimuli. It was found that most OR genes are highly enriched in the OE, compared with the VNO and other tissues, such as lung, liver, etc. From the first-generation mouse OR array, a total of 817 ORs were classified as enriched in OE, while about 1000 ORs were classified to be enriched in the OE with the second-generation mouse OR array. More ORs were detected in the second-generation array because multiple probes were designed for each gene when the correct polyA sites were unknown. Similarly, V1R and V2R genes are mostly specifically expressed in VNO, consistent with their roles as pheromone receptors.

The expression level varies dramatically among ORs. Since hybridization intensity could be affected by the nucleotide composition, the expression level used was calculated by GCRMA, in which the effect of GC content is compromised to some extent, for comparison among different ORs. ORs with extremely high identity in their protein sequences were found to have manifold differences in their mRNA expression level; similarly, ORs located next to each other in the genome can also have quite different expression levels. These data indicate that gene expression levels of ORs are regulated individually. The different levels of expression observed for very similar ORs suggest that the array approach was able to distinguish these genes, presumably by selecting unique probes in the 3′ UTRs. It should be noted that the data from microarrays are proportional to the multiplicative product of cell numbers for a certain OR and the mRNA transcripts per cell. The expression variance among ORs could result from the diverse number of sensory neurons for each receptor or different transcript copies or both.

OR Expression in Nonolfactory Tissues

OR gene expression has been reported in various tissues, particularly in testis, and also in brain, heart, and other tissues. These reports are generally isolated examples without systematic discovery. OR custom array is ideally suited to examine the level of OR expression in these tissues. Besides OE, OR mRNAs were also detected in the olfactory bulb, testis, kidney, heart, lung, and other tissues. The detected message in olfactory bulb could be from the transported mRNAs along axons. In total, about 270 ORs were found to be expressed in non-OE tissues, and about 100 of them are not enriched in OE. These genes may not be real ORs in terms of their functions, but just OR-like genes because of sequence similarity. So far their functions are rarely known, except that by analogy they may be receptors recognizing low molecular weight molecules in other tissues. Combing all the tissues studied, the expression of about 1100 ORs, which constituted 92% of the explored putatively functional ORs, was detected.

Temporal Pattern of OR Expression

Before the application of OR custom arrays, the developmental courses of most ORs have not been documented. Mouse OE tissues were collected at various ages, and the expression level of ORs was compared. There was observation of OR expression as early as embryonic day 12 (E12); however, there are only a few OR-positive cells, making the detection by microarray marginal. It was thought that ORs begin to be expressed in relatively large numbers of cells between E15 and E16, which was also the stage when significant OR expression was first observed with the array. From the custom array, it was found that the number of detected ORs and their expression level jumped after birth. In the 10-day-old mouse, the majority of ORs are already detected, while their expression levels continue to increase as the mouse matures. At 3–4 months, the average expression level reaches a maximum, then descends as the mice age. At 18 months, about 15% of ORs are no longer detected. At 24 months, about 40% of ORs are lost. The birth and loss of ORs are most likely attributable to the turnover of sensory neurons, though it is not known whether the transcript copies per cell also fluctuate temporally (**Figure 1**).

Zonal Expression of ORs

One of the earliest findings about ORs was their expression in one of the four parallel zones that run rostral to caudal across the turbinates within the OE.

To obtain zonal expression data of ORs, the OE in the dorsal recess above the turbinates, a region that only includes zone 1, was dissected; the ventral proportions of the turbinates were then dissected such that only zone 4 and parts of zones 2 and 3 were included (shown in Figure 2). The dissection left out the dorsal portion of the turbinates to ensure a clean separation between zone 1 and other zones. From the microarray data, ~350 ORs were significantly enriched in zone 1 and ~400 ORs were enriched in other zones. For the nonclassified ORs, it is likely because part of the epithelium was excluded during the microdissection. Among the zone 1 expressed ORs, 110 of them are class I ORs, and the rest of them are class II ORs. However, among the ORs expressed in zones 2–4, none of them belong to class I. Since class I ORs are segregated from class II ORs on the chromosomes, this finding indicates that ORs segregated in the genome are also segregated spatially in the OE.

Figure 1 The number of expressed olfactory receptors (ORs) at different developmental stages. Four samples per time point were used for differential analysis compared to the vomeronasal organ. From postnatal day (P) 10 to postnatal month 4 (P4m) (shaded pink), the total number of expressed ORs is quite flat, whereas OR birth and loss happen at an early postnatal age and at old age, respectively.

3′ UTR

In this strategy, probe sets showing a specific expression signal should demonstrate the correct position of polyA sites, by which the 3′ UTR sequences of ORs were inferred. Multiple probe sets for different poly-A site predictions were put in the design, and the experimental data showed which of the predictions were correct. From the analysis, it was found that the length of 3′ UTRs varies among ORs. In fact, 40% of them have 3′ UTR shorter than 500 bp, while a few are longer than 2 kbp. The sequences of 3′ UTRs are much more diverse than the corresponding coding regions; therefore, they are perfect resources for unique probes selected for *in situ*.

The 3′ UTRs have been shown to be important regions for gene regulation; they are involved in mRNA stability, silencing, or activation mediated by microRNA or RNA-binding proteins, and so forth.

Figure 2 Olfactory receptor (OR) genes are differentially expressed in different zones of olfactory epithelium (OE). (a) Diagram showing the microdissection of the OE. Zone 1 (dorsal) is shaded in orange and zones 2–4 (ventral) in light blue. AOB, accessory olfactory bulb; OB, olfactory bulb; VNO, vomeronasal organ. (b) Differential expression of OR genes in zone 1 and zones 2–4. Each line represents the expression level of one OR. Orange lines represent ORs enriched in zone 1, and blue lines represent ORs enriched in zones 2–4.

So far very little is known about the function of 3′ UTRs of OR genes. The array data characterize the 3′ UTRs of a large number of OR genes, and this is a useful resource for future research on posttranscriptional regulation.

Future Perspectives for OR Microarrays

Microarrays have been used to study mRNA expression of ORs in different tissues, developmental time courses, and zones of OE, and to infer the 3′ UTR sequences for the ORs. However, the exploration of 5′ noncoding exons of OR genes has not been done yet. The transcription start site of OR genes may shed light on the regulation mechanisms. Current molecular techniques, such as RNA ligase-mediated-RACE, will be too time consuming to explore the 5′ exons for all OR genes. Tiling arrays would be a good choice to investigate this question. In this array design, probes would be tiled densely across the complete OR gene loci. Random primer-based reverse transcription would be used as the first step to amplify OR mRNAs to get complete coverage of the transcripts. Such experiments would generate the complete gene structure for OR genes. One could also use tiling arrays to explore the transcription factor binding sites by doing chromatin immunoprecipitation coupled with microarray and therefore generate data to decipher how OR genes are transcriptionally regulated. In addition, from computational analysis, many single-nucleotide polymorphisms (SNPs) were found in ORs and vomeronasal receptors between different strains. SNP arrays or allele-specific arrays could be used to associate genetic variance with variable odor perception.

Summary

Although the complete family of OR genes has been identified by genomic analysis, subsequent functional study of all these genes remains a challenge. OR microarrays have enabled high-throughput gene expression study for this large gene family, both temporally and spatially. The expression profiling results have provided important insights about the development and organization of the olfactory system. As cutting-edge technology, microarray-based tools will certainly play more important roles in the future study of neuroscience.

Introduction

The most difficult challenges in understanding sensory systems arise in the context of natural scenes. The problems inherent in the sampling, representation, and processing of sensory information within natural environments are substantial; some would even be considered crippling were it not already clear that functioning sensory systems do exist. Hence, understanding these processes as complex systems not only will yield insight into neural processing *per se*, but also offers the hope of fundamental new insights into stimulus processing for engineering and machine sensation, particularly in areas such as source separation, object construction and identification, and the utility of prior expectations. Given recent insights into the molecular and biochemical events underlying fundamental sensory transduction mechanisms, the complex neural algorithms underlying postacquisition stimulus processing are increasingly the limiting factors in understanding sensory system function. Studying sensory processing mechanisms as complex systems is a critical component of modern neuroscience.

The olfactory modality is particularly amenable to study at the systems level. While many of the difficulties imposed by olfactory natural scenes are analogous to those encountered in other sensory modalities, some of the resulting computational problems are considerably more tractable. For example, there is no clear olfactory analog to the problem in vision that a given visual object does not reliably generate a replicable primary representation – that is, the pattern of activation of retinal photoreceptors in response to a given visual stimulus object differs arbitrarily based upon both eye position and the spatial orientation of the object. In contrast, while the breadths of olfactory primary representations are affected by changes in stimulus intensity and other environmental factors, odor-evoked activation patterns among primary olfactory sensory neurons (OSNs) are fundamentally specific to odor quality and hence are reliable as channel-based primary representations, potentially rendering the olfactory binding problem a considerably more tractable goal than is its visual counterpart. In contrast, other elements of olfactory stimulus processing are more complex than are their analogs in other modalities. The regulation of receptive field breadth, for example, is classically mediated by lateral inhibitory interactions in modalities such as visual retinotopy or auditory frequency tuning, in which stimulus similarities can be mapped onto physical neighborhood relationships in the brain. In olfaction, however, the similarities among stimuli are mapped high dimensionally, rendering lateral interactions in functionally two-dimensional cortical networks incapable of mediating this basic sensory filtering process. Novel neural mechanisms are required to perform similarity-dependent transformations on high-dimensional sensory information.

While a comprehensive, systems-level analysis of olfactory processing that engages the problems posed by natural scenes becomes considerably more complex than are analyses limited to interpreting the results of highly constrained experimental studies, it also provides vital constraints on functional hypotheses that otherwise would go unrecognized. A robust neural system engages in numerous homeostatic tasks unrelated to stimulus coding *per se* – for example, pH regulation, energy conservation, prevention of excitotoxicity, maintenance of the appropriate dynamic ranges of individual neurons and networks, and compensatory responses to durable changes in synaptic weights or the incorporation of newly generated neurons that may be necessary for network stability. Such processes may correlate with sensory inputs and hence can easily be interpreted as contributing to 'stimulus coding' without casting much light on the dynamics of sensory system operation. Comprehensive, systems-level study of neural circuit operations in complex environments is required in order to come to understand the broader biological networks that underlie robust, functioning sensory systems *in vivo*.

Systems Analysis of the Olfactory Modality

In natural environments, airborne chemical stimuli are distributed unpredictably in time and space, and odorants from innumerable sources intermix freely. Furthermore, the mixtures of volatile molecules that define meaningful odors in an animal's environment are inherently variable both in quality and in intensity, depending on numerous external factors, including time of day, season, temperature, weather conditions, and the proximity of the animal to various odorant sources. An effective olfactory system must be able to detect potential signals of interest within these chemically noisy environments, correctly extract these signals from a complex and changing odor background

Figure 1 Schematic illustration of olfactory circuitry. (a) Olfactory sensory neurons and olfactory bulb circuitry. Olfactory sensory neurons (osn) expressing the same olfactory receptor project to a given glomerulus (glom) in the olfactory bulb, within which they make synaptic contacts with mitral cells (mi), periglomerular cells (pg), and external tufted cells (et). Periglomerular and mitral cells make reciprocal dendrodendritic synaptic contacts with each other within the glomerular neuropil: periglomerular cells inhibit mitral cells while mitral cells excite periglomerular cells. External tufted cells, together with short axon cells (sa), form a densely connected lateral excitatory network that spans the glomerular layer and they thus deliver excitatory inputs onto periglomerular cells. Deeper within the bulb, within the external plexiform layer, mitral cell secondary dendrites extend broadly and laterally, forming reciprocal dendrodendritic synapses with inhibitory granule cells (gr). Spike trains from mitral cells, the principal neurons of the olfactory bulb, are delivered to multiple secondary olfactory structures via the lateral olfactory tract (lot). (b) Circuitry of the piriform (olfactory) cortex. Within cortical layer Ia, mitral cell axons of the lateral olfactory tract (lot) excite both the primary apical dendrites of pyramidal cells (pyr) and the dendrites of feed-forward inhibitory interneurons (ff), which in turn locally inhibit the pyramidal cell dendrites. In layer Ib, the pyramidal cell dendrites also receive excitatory inputs from other pyramidal cells. These dense excitatory feedback connections are called association fibers and are known to undergo long-term potentiation. Pyramidal cells also excite a second class of inhibitory local interneurons called feedback interneurons (fb), which in turn inhibit a small number of nearby pyramidal cells. The cell bodies of pyramidal cells and feedback interneurons comprise layer II of piriform cortex.

to form stimulus representations, identify these constructed representations with respect to previously experienced odors, differentiate relevant from irrelevant stimuli, and cue an appropriate response. Current theoretical and experimental approaches have tended to break this process down into sets of roughly sequential problems, such as the following sequence: (1) detect and transduce airborne chemical signals, (2) improve the signal-to-noise ratio, (3) modulate selectivity (contrast), (4) translate the representation from a form optimized for stimulus sampling to one compatible with common cortical processing mechanisms (generally considered to be sparse and spike timing sensitive), filter out multiple confusing sources of variance, including (5) differences in intensity (normalization) and (6) unrelated background odorants, and (7) identify relevant stimuli with reference to previous experience. The neural tissues involved in odor detection and recognition processes contain specialized circuitry to perform these essential tasks. Primary OSNs transduce chemical stimuli into electrical signals with high sensitivities and broad dynamic ranges that initially appear to defy mass action law. The axons of all OSNs expressing the same olfactory receptor converge upon one or two common neuropilar regions in the olfactory bulb input layer, termed glomeruli; the resulting high convergence ratios enable substantial improvement in the signal-to-noise ratios of olfactory sensory responses. Local inhibitory circuits within the olfactory bulb filter this primary representation, regulating stimulus selectivity and segregating odor quality information from response differences owing to different stimulus intensities. Other olfactory circuits are thought to utilize short-term synaptic plasticity for odor–background segmentation, whereas long-term plasticity and associative memory networks within the piriform cortex may contribute to the memorization and identification of stimuli sampled from noisy backgrounds. Extensive feedback interactions between the olfactory bulb and deeper olfactory cortices synchronize the activity of related circuits, providing a timebase for the representation and processing of olfactory information on short timescales (loosely termed 'temporal coding'). Here, we outline a functional description of olfactory signal processing emphasizing the functional roles of different neural circuits within olfactory structures (see Figure 1).

Stimulus Transduction and Signal-to-Noise Enhancement

Primary OSNs number in the millions in rodents. Specialized cellular properties within individual OSNs have been hypothesized to improve their sensitivities to

Figure 2 Combinatorial stimulus representation and signal-to-noise improvement. (a) Every odorant chemical binds to several types of olfactory receptors with different characteristic affinities, hence activating several different classes of olfactory sensory neurons (OSNs) to differing degrees (depicted by color saturation). Furthermore, the same OSN may be activated by many different odorants. Consequently, each chemical activates a unique combination of receptors with a characteristic pattern of activation levels. With only 10 OSNs, assuming only four discrete activation levels for each OSN (as depicted), 4^{10}, or 1 048 576, odors can be uniquely represented by the ensemble. Furthermore, combinatorial representations degrade gracefully; substantial information about odorant quality is preserved even if subpopulations of OSNs are destroyed or inactive. (b) OSN convergence improves the olfactory signal-to-noise ratio (SNR). In the present context, the signal-to-noise ratio can be defined as the number (or density) of spikes evoked by the signal of interest (odor presentation) divided by the total number (density) of spikes produced during the time of observation. Spikes specifically evoked in OSNs by odorant presentation are depicted by thicker vertical lines; thinner lines denote background spiking activity. Hundreds or thousands of OSNs with similar selectivity for odorants converge upon each mitral cell in the olfactory bulb. Even if the signal-to-noise ratio is extremely low in individual OSNs (i.e., if the stimulus-evoked increase in activity is nearly undetectable with respect to the OSN's baseline activity, as depicted), the convergence of many such neurons will evoke a substantial increase in the density of incoming spikes impacting a single mitral cell (Mi), reliably affecting its level of activation. This corresponds to a higher SNR in mitral cells when compared with any of its cognate OSNs.

odor ligands well beyond their ligand–receptor dissociation constants, while their large, redundant populations and correspondingly high convergence ratios onto the glomeruli of the olfactory bulb have been proposed to yield advantages such as improved signal-to-noise ratios and broader dynamic ranges. The molecular receptive ranges, or chemical receptive fields, of different odorant receptors overlap substantially, such that the identity of odorants is not associated with the activation of a specific receptor, but rather is represented by a distributed, combinatorial representation. From a theoretical point of view, this type of representation has several advantages: first, the number of unique odor representations is not limited to the number of different receptor types, but can be estimated as m^n, where n denotes the number of receptor types and m denotes the number of recognizable states that each sensor can assume, ultimately limited by the signal-to-noise ratio of the system. Second, the fact that structurally and perceptually similar odorant molecules activate correspondingly overlapping sets of olfactory receptors establishes a basis for the recognition of stimulus similarity in the olfactory system. A reliable metric for stimulus similarity facilitates a tolerance for variance among repeated stimulus samples and also is prerequisite for basic postsensory cognitive processes such as generalization. Combinatorial representations not only exhibit greater coding capacities than do labeled-line systems, but also are more robust to degradation, noise, and natural variation in stimulus parameters. Figure 2 illustrates the characteristics and advantages of combinatorial stimulus representation in the olfactory system.

Contrast Modulation and Normalization

Distributed patterns of activity in response to chemical stimuli are transmitted to the olfactory bulb via OSN axons that terminate in the glomeruli of its input layer. The olfactory bulb is believed to filter and transform these incoming sensory data, performing normalization, contrast enhancement, and similar operations before conveying the processed olfactory information to several different secondary olfactory structures via mitral cell axon collaterals. Because of the patchy and nontopographically organized representation of olfactory stimulus similarity across the olfactory bulb, contrast enhancement operations in this system cannot rely on physical proximity-based mechanisms such as center-surround lateral inhibition. (Indeed, olfactory stimulus similarity is not a static property; maps of olfactory similarity space depend on the statistics of the odor environment as well as on the structures of olfactory receptors expressed in the nose.) Instead,

the bulb appears to mediate an analogous operation relying solely on local feed-forward inhibition coupled with global, nonselective feedback inhibition. In addition to enabling contrast enhancement in a high-dimensional modality such as olfaction, this nontopographical mechanism does not require a built-in foreknowledge of the similarities in molecular receptive ranges expressed by different olfactory bulb glomeruli in order to distribute inhibition correctly, and is entirely independent of the physical location of glomeruli within the olfactory bulb. Briefly, OSN axonal arbors in each glomerulus deliver glutamatergic excitation upon mitral cell dendrites as well as the dendritic spines of local inhibitory neurons known as periglomerular cells. These periglomerular cell spines directly deliver γ-aminobutyric acid $(GABA)_A$ergic shunt inhibition onto mitral cell dendrites in parallel to the excitatory inputs that the latter receive from OSNs (Figure 3(a)). Theoretical models indicate that this configuration enables nontopographical contrast enhancement in a similarity space naturally inherited from the current chemosensory environment; mitral cells associated with a given odorant receptor are activated only by the highest affinity odor ligands, responding to lesser degrees of cognate OSN activation with a net inhibitory response (Figure 3(b)). Odor-evoked activity patterns across mitral cell ensembles (secondary representations) are consequently sparser and less overlapping than are the corresponding primary representations observed among OSNs, as visualized in imaging studies of glomerular activation patterns (Figure 3(c)). Furthermore, the stringency of

Figure 3 Local computation of contrast enhancement. (a) Odor presentation evokes a distributed pattern of activation among olfactory sensory neurons (OSNs), communicated to the olfactory bulb via convergent axonal projections. OSN activation excites both mitral (Mi) and periglomerular (PG) cells in the olfactory bulb input layer, while periglomerular cell dendritic spines concurrently inhibit mitral cell primary dendrites, resulting in a final activation pattern among mitral cells that is narrower and more precise than that originally evoked among OSNs. Corresponding to the schematic at the top are the five columns depicting neuronal activity (from left to right): spike trains in sensitive OSNs, synaptic activation of periglomerular cells by OSNs, synaptic activation of mitral cells by OSNs, net synaptic activation of mitral cells after factoring in periglomerular shunt inhibition, and evoked spiking activity in mitral cells. (b) Computational modeling of glomerular circuitry, demonstrating nontopographical contrast enhancement. Odorants with low affinity for the depicted mitral cell's cognate odorant receptor evoke no response in the mitral cell depicted, while odorants with moderate affinity activate OSNs but evoke a net inhibitory response in the corresponding mitral cell. Only the highest affinity odorants evoke action potentials in mitral cells. (c) These local computations result in distributed, odor-specific activity patterns at the level of mitral cells that are considerably sparser than those conveyed by the OSNs, thereby establishing greater contrast (less overlap) between the representations of structurally similar odorants. (b) Adapted from Cleland TA and Sethupathy P (2006) Non-topographical contrast enhancement in the olfactory bulb. *BMC Neuroscience* 7: 7, with permission.

this transformation appears to be regulated by centrifugal neuromodulatory inputs, specifically including inputs mediated by nicotinic cholinergic receptors in the glomerular layer.

In general, higher stimulus intensities both increase the activity of sensitive primary sensory neurons and broaden the neural response by recruiting additional, more weakly tuned primary sensory neurons into the activated ensemble. In the olfactory system, this corresponds to increased probabilities of ligand–receptor binding as ligand concentration rises, eventually binding significantly even to receptors for which the ligand in question has very low affinities. Hence, as odor concentrations rise, an increasingly broad range of OSNs become activated, substantially broadening the primary representation. In contrast, mitral cell activity in response to increasing odorant concentrations is variable; individual mitral cells may increase or reduce their response levels (to greater or lesser degrees), may exhibit shorter spike latencies, or may transition from a net excitation to inhibition, or vice versa. They do not, however, exhibit reliably monotonic increases in activation levels comparable to those observed in individual OSNs or populations of convergent OSNs (the latter observed via glomerular activity imaging). That is, some form of normalization process is clearly active between the primary representation across the OSN population and the secondary representation composed of mitral cell spiking activity patterns.

Normalization processes in sensory systems are essential for segregating quality from concentration effects and for constructing intensity-independent representations of stimulus quality. Indeed, identifying methods of forming intensity-independent representations is a major research concern in many sensory modalities. In principle, intensity normalization processes require global feedback inhibition, in which uniform inhibition is delivered to all units in proportion to the mean activity level of all sensory inputs. In the olfactory system, this normalization has been proposed to rely upon a lateral excitatory network formed by external tufted and short axon cells in the glomerular layer of the olfactory bulb. Briefly, this widespread, densely connected lateral network is excited by direct OSN excitation of external tufted cells within glomeruli. The lateral excitatory network integrates these heterogeneous activation levels across the bulbar input layer and delivers a uniform level of excitation onto a subclass of periglomerular cells, which in turn inhibit mitral cells. The result of this computation, manifested in the pattern of afferent input to mitral cells, is a preservation of relative activity levels among glomeruli independent of absolute stimulus intensity (Figure 4).

Figure 4 Normalization of odorant concentrations by glomerular-layer processing. (a) At the lowest odor concentrations, for sake of argument, the spatial pattern of activity among mitral cells (Mi) may largely reflect the pattern of activated glomeruli in turn reflecting presynaptic olfactory sensory neuron (OSN) activity (activation profiles of bulbar interneurons not shown). (b) When higher concentrations of the same odor are presented, increased ligand–receptor binding evokes both stronger activation of sensitive OSNs and the recruitment of additional OSNs expressing lower affinity receptors into the activated ensemble, broadening the primary representation (column 1, OSN). This intensified and broadened OSN activity evokes correspondingly broader and more intense excitatory synaptic input to mitral cell dendritic tufts (column 2) as well as to periglomerular cells (not depicted here; see Figure 3) and external tufted cells (ET). External tufted cells, along with short-axon cells (SA), are interconnected in a dense lateral excitatory feedback cellular network that is capable of integrating the input activity across all bulbar glomeruli and computing an average level of bulbar activation (column 3, ET/SA). This summed activity is transmitted to periglomerular (PG) cells (column 4), which oppose the direct excitation of mitral cells with shunt inhibition. The outcome of this computation is to subtract the mean bulbar activity from the activation at each glomerulus, resulting in a mitral cell representation that is normalized with respect to the mean (column 5, Mi). This normalization generates relatively concentration-independent representations of odor quality at the level of mitral cell output, presumably facilitating the recognition of odors irrespective of intensity (column 6; compare with a).

Synchronization and Binding

After the excitatory and inhibitory inputs converging on mitral cell primary dendrites have been integrated, olfactory stimuli are represented in broadly distributed levels of mitral cell activation across the olfactory bulb that largely determine whether any given mitral cell will evoke action potentials in response to a given odorant presentation. The timing of mitral cell spikes, however, is influenced by the intrinsic dynamics of the olfactory bulb as well as by the dynamics of feedback from other brain areas. Both intrinsic mitral cell membrane properties and network dynamics between mitral and granule cells are believed to influence mitral cell spike timing; indeed, synchronization of the spikes produced by those mitral cells most responsive to a given stimulus can further refine the representation of this stimulus and alter its capacity to drive activity in postsynaptic neurons (Figure 5(a)). Furthermore, due to activity-dependent synaptic plasticity between inhibitory granule cells and mitral cell lateral dendrites, the degree of synchronization as well as the identities of the neurons most tightly synchronized with one other can be regulated dynamically (Figure 5(b)). Indeed, mitral cell synchronization properties depend strongly on descending cortical and neuromodulatory inputs, suggesting additional mechanisms by which odor representations can be modified by centrifugal factors.

Odor–Background Segmentation and Mixture Interactions

Olfactory segmentation problems arise when two or more odors from different sources are present at the same time. The basis of the problem is that there is no *a priori* reason why the multitude of odorous molecules that together comprise one natural odor, such as the scent of oranges, should be processed as a single complex stimulus, while other odorous molecules, present at the same time, do not contribute to the perceived scent of the stimulus. The outcome is that an orange can be identified by scent largely irrespective of whether it is being smelled while standing on a beach,

Figure 5 Synchronization of mitral cell firing. (a) The timing of mitral cell (Mi) action potentials is shaped by glomerular computations. Intrinsic subthreshold oscillations within mitral cells as well as recurrent synaptic interactions among mitral and granule cells (Gr) can regulate spike timing so as to regulate the synchronization of spiking activity among mitral cells. Mitral cells receive odor-specific patterns of afferent input excitation from olfactory sensory neurons (OSNs; column 1); activated mitral cells in turn activate granule cells. Due to the excitatory–inhibitory feedback interactions among mitral and granule cells, as well as between the olfactory bulb and higher olfactory cortices, rapid field potential oscillations in the olfactory bulb (column 2) are evoked by olfactory input as well as by the process of active sampling. The regular, synchronized delivery of inhibitory synaptic inputs onto mitral cell lateral dendrites interacts with the differing levels of input activity among mitral cells to shape the timing of evoked action potentials in mitral cells (column 3). Groups of activated mitral cells thereby form synchronized assemblies representing the odor stimulus presented. (b) Due to activity-dependent synaptic plasticity between mitral and granule cells, bulbar oscillatory dynamics in response to learned or behaviorally relevant odorants can be enhanced with respect to those evoked by novel odorants. Here, computational modeling output showing mitral cell response profiles to two different odorants (activating different subsets of mitral cells) is depicted. Owing to the pattern of altered synaptic weights between mitral and granule cells induced by prior learning, the odorant previously learned by the model olfactory system exhibits coherent oscillations in mitral cell membrane potentials and in the local field potential (LFP), as well as in more sharply synchronized mitral cell spikes. The novel odorant evokes comparable levels of mitral cell spiking, but this activity is less able to induce coherent oscillations and synchronize spike timing among mitral cells.

in a perfumer's shop, or on a factory floor. The core mechanistic problem is how the broad profile of activated receptors can be correctly deconstructed into groups or patterns associated with given stimulus sources, even when the arrays of odorant receptors sensitive to each stimulus source overlap substantially.

Odor segmentation problems can be classified into two categories: odor–background segmentation, in which a novel odor is detected and identified in the presence of a preexisting odorous background, and mixture segmentation, in which multiple odor stimuli are detected at roughly the same time. Recent electrophysiological studies have shown that odor–background segmentation can be achieved at the level of second-order sensory synapses. Synaptic interactions between olfactory bulb mitral cells and pyramidal cells in the piriform cortex undergo a form of short-term plasticity which results in the suppression of information transmission between these two structures after approximately 50 s when an odorant is continuously present. Consequently, piriform pyramidal cells rapidly suppress their responses to background odorants, but remain excitable in response to novel odorants (Figure 6(a)). Interestingly, this adaptation of pyramidal cell responses is specific to configural odors, rather than to odor elements, such that responses to the individual elements of a fully adapted odor mixture, if presented separately, are not suppressed to the same degree as is the response to the mixture (Figure 6(b)). This clearly suggests a regulation of synaptic suppression that is more complex than simple feed-forward desensitization, and that is deployed with reference to a preestablished configural odor representation, or odor template. This, of course, begs the question of how such configural odor representations are constructed and retained at this level.

Simultaneous-onset mixture interactions pose a substantially more complex computational problem. While mixture processing has been studied at the perceptual level using intramodal blocking, overshadowing, and comparable behavioral paradigms, to date there is no satisfactory model of how simultaneously presented odor mixtures can be segmented and identified. Computational efforts toward addressing this problem have relied upon built-in cues specifying the odor source to which a given response element belongs, avoiding the heart of the problem. Indeed, current theories suggest that this problem may not be solvable by feed-forward properties alone, but rather may rely critically on learned, preexisting odor templates. If correct, this suggests an essential role for associative memory and network

Figure 6 Odor–background segmentation in the piriform cortex. (a) Mitral cell (Mi) axons project from the olfactory bulb via the lateral olfactory tract (lot) to synapse with pyramidal cells (Pyr) in the piriform cortex. Piriform pyramidal cells and olfactory bulb mitral cells have receptive fields for odorants that are comparably broad. The excitatory synapse between mitral cells and piriform pyramidal cells undergoes short-term synaptic plasticity when an odorant is continuously presented for roughly 50 s, suppressing the pyramidal cell activity previously evoked by that odorant. Due to internal computations within the piriform cortex, this adaptation to prolonged odor stimulation is relatively specific to the broad, complex activity patterns evoked by configural odors rather than to each elemental chemical feature (odotope). Hence, even pyramidal cells that are fully adapted in response to a background odor still remain responsive to novel odors. No topological specificity is retained between mitral cells and piriform pyramidal cells; the alignments of pyramidal cell spike trains in shaded regions do not correspond to the rows illustrating connectivity between olfactory sensory neurons (OSNs) and their cognate mitral cells. (b) Prolonged presentation of a binary odorant mixture (A+B) leads to adaptation of evoked activity in piriform cortex due to suppression of mitral cell synaptic inputs. Subsequent presentations of that mixture elicit minimal responses. However, presentation of a single component (A) of this binary mixture again evokes increased activity, demonstrating that pyramidal cell adaptation is specific to complex, configural odors.

attractor dynamics, not only in olfactory learning as traditionally construed, but also in the very process of odor identification.

Odor Binding and Associative Memory

Binding among the multiple features of any given odor stimulus has been proposed to occur in the piriform cortex. Briefly, the ensemble of activated mitral cells that fire quasi-synchronously in response to a given odor stimulus activates a corresponding population of pyramidal cells. Whereas, at the level of the olfactory bulb, individual mitral cell responses predominantly reflect the elemental chemical features (odotopes) of odorant molecules, the combined representations of these features are integrated at the level of piriform cortex and are durably associated with one another via long-term synaptic plasticity across the pyramidal cell network. The feedback excitatory 'associative fibers' that mediate these patterns of association are prominent features of piriform cortex, along with feed-forward and feedback inhibitory pathways. Indeed, the piriform cortex has long been modeled as an autoassociative memory network capable of learning odorrepresentations and later reconstructing these learned representations from partial or degraded inputs, while also excluding unexpected or spurious additional inputs, a property known as pattern completion

Figure 7 Associative memory and reward associations. (a) The highly interconnected association fiber network of the piriform cortex is thought to underlie learned associations between the elements of odor stimuli, generating and imprinting the patterned representations of complex odors. During the presentation of a rewarded odor stimulus, excitatory associative synapses from mitral cells (Mi), arriving via the lateral olfactory tract (lot), are strengthened among those piriform pyramidal cells (Pyr) responsive to that stimulus. No topological specificity is retained between mitral cells and piriform pyramidal cells; the alignments of pyramidal cell spike trains in shaded regions do not correspond to the rows illustrating connectivity between olfactory sensory neurons (OSNs) and their cognate mitral cells. (b) Upon subsequent presentation of the same odor, even if a subset of the normally activated pyramidal cells is not activated by the afferent inputs, associative circuitry within piriform cortex can perform pattern completion (pc), recreating the complete odor-specific activity pattern in pyramidal cells. (c) Other piriform circuitry incorporating feedback (fb) and feed-forward (ff) inhibitory interneurons can perform the complementary operation, reducing noise in the representation by suppressing pyramidal cell activity extraneous to the learned activity pattern. Both pattern completion and noise reduction are important for the robust comparison of noisy and variable stimulus representations with the memorized patterns of previously encountered stimuli. (d) Pyramidal neurons in orbitofrontal cortex (ocPyr) can be responsive to olfactory stimuli, but their responses are primarily dependent on learned associations and context. Most orbitofrontal pyramidal neurons change their responses to an odor stimulus depending on its predictive properties (e.g., for a reward, or even for the absence of a reward in a context where reward is associated with other odor cues). Weak responses are depicted in response to two novel odors (left-hand pair of columns). After both odorants are used in rewarded odor discrimination training, with one predicting reward (+) and the other predicting no reward (−), the responses of orbitofrontal pyramidal cells to either odorant are durably altered (middle pair of columns). After reversal training, in which each odorant is associated with the opposite contingency, orbitofrontal responses to these odors are again modified (right-hand pair of columns).

(Figures 7(a)–7(c)). While considerable work remains to be done in this area, it is likely that the circuitry of piriform cortex is essential to the construction of potentially meaningful, configural odor representations.

Forming discrete, identified sensory objects is traditionally considered necessary before such objects can be associated with a contingency such as reward or punishment. In the orbitofrontal cortex (a multimodal sensory cortex which receives direct input from the piriform cortex as well as from structures associated with other sensory modalities), neurons can be activated by odor presentation, but their response properties depend substantially less on physical stimulus attributes and more on the learned, expected contingency of the odor (Figure 7(d)). Hence, orbitofrontal odor responses may be better described as representing expectation, or the acquired meaning of an odor stimulus, rather than as coding for odor identity in the physicochemical sense. Reciprocal orbitofrontal projections to anterior piriform cortex further suggest that these learned, configural representations may be used dynamically to shape cortical responses to odors.

Learning, Experience, and Neuromodulation

The neural activity elicited by odorant stimulation depends increasingly on experience, behavioral relevance, and the motivational state of the animal as the representation progresses centrally from the primary sensory epithelium, factors that are thought to be mediated by centrifugal projections into these olfactory structures. Indeed, most olfactory areas interact with one another and with deeper, multimodal cortices via feed-forward and feedback connections, and also receive neuromodulatory inputs from the horizontal limb of the diagonal band of Broca (cholinergic), the locus coeruleus (noradrenergic), and the raphe nucleus (serotonergic). These cortical and neuromodulatory inputs dramatically influence neural activity patterns and the dynamics of olfactory processing within the olfactory cascade, and presumably mediate these experience- and state-dependent contributions to sensory representations.

Conclusion

The promise of the olfactory system as a model for understanding sensory processing as a complex system – from physical stimulus properties to cognitive object – is becoming increasingly clear. The peripheral processing of odorant stimuli in the olfactory epithelium and olfactory bulb is predominantly oriented toward adequately sampling the volatile chemical environment. Olfactory neuronal properties and bulbar circuit architecture are adapted to the physical and statistical properties of chemical stimuli and serve to mitigate the ambiguities and limitations inherent in the sensory transduction of stimuli in this modality. Impressively, orbitofrontal cortical representations of the acquired meaning of odors are only three synapses removed from the primary sensory representation, suggesting a singularly compact and tractable cascade of neural representations that may provide unique opportunities to understand how afferent sensory inputs are integrated with the neural representations of memories and behavioral state in order to create meaningful percepts. While the problem must not be oversimplified – for example, mitral cells also project to the cortical amygdala, the subcortical olfactory tubercle, and a series of medial cortices, and piriform and entorhinal cortical circuitry is considerably more intricate than discussed herein – the olfactory system remains a particularly attractive target for research in neural systems.

Introduction

Sensory information needs to be converted from its 'raw' format (e.g., photons, molecules, and pressure) into a format that neurons in the brain can use for efficient internal computations. This format – which usually builds on the basic unit of neural communication, the action potential, or spike – is an important determinant of how the brain solves such problems as identifying and discriminating between stimuli, tracking time-varying stimuli in noisy environments, and remembering past encounters with a particular stimulus. However, such communication protocols or encoding strategies are difficult to study because they usually involve many neurons that together generate and use a so-called 'population code' or 'ensemble code.' These codes may depend, in ways not known *a priori*, on particular correlative aspects of activity in those neurons. In addition, the problem is usually underconstrained; that is, many different encoding and decoding strategies can be consistent with the limited sample of neural data collected by an experimenter. One approach to such issues is to record from as many neurons as possible and to decipher the encoding and decoding strategies used by the system itself. This is often difficult and far easier to achieve in smaller, simpler systems, such as the insect brain. Principles of circuit function extracted from simpler systems can then be tested on or applied to larger and more-complex brains as well.

Anatomy of the Locust Olfactory System

Insects are the most successful animal (metazoan) inhabitants of our planet and account for the majority of recorded species. A large part of their adaptive success must be correlated with remarkable sensory systems; indeed, insects occupy most ecological niches. Of all sensory systems, olfaction is considered the oldest – even bacteria have basic chemosensory capabilities. There are notable similarities between olfactory circuits across phyla, and insect olfactory circuits share structural and functional analogies with mammalian ones. This makes studying olfaction in insects all the more relevant to understanding the rules of olfactory coding in general.

Anatomy: Olfactory Receptor Neurons

As with other olfactory systems, information about an odor is first encoded across combinations of olfactory receptors (ORs). Different odorants interact with different subsets of ORs, and the activity of individual OR neurons (ORNs) is determined by the OR they express. Thus, a combinatorial activation of subsets of ORNs is the first odor-related electrical input to the brain. In both mammals and insects, the axons of ORNs expressing the same ORs converge to the same glomeruli in the olfactory bulb or antennal lobe (AL). There are ~90 000 ORNs in each locust antenna. Each ORN terminates in four to eight glomeruli organized in a semicircle. In the AL, ORNs contact two populations of neurons, the excitatory projection neurons (PNs) and the local neurons (LNs).

Anatomy: AL

Locust PNs, which, as in other insects, are the sole output of the AL, each extend dendrites to multiple glomeruli (each PN projects to about ten of about 1000 glomeruli in the AL). PN axons leave the AL in a common medial tract and project ipsilaterally to the mushroom body (MB) and to the lateral protocerebrum, or lateral horn (LH; see Figure 1(a)), where they make excitatory outputs mediated by acetylcholine. In the MB, the PN axon collaterals branch out profusely in a region known as the calyx, for its cuplike shape. The LNs are axonless, and each arborizes throughout the AL, influencing the spread of information across PN channels. In locust, LNs do not fire sodium-based action potentials; instead, they respond to odors with graded potentials and calcium spikelets. Transmitter release can occur both phasically, during a spikelet, and tonically, during maintained depolarization. LNs are γ-aminobutyric-acidergic (GABAergic) and inhibitory, although a significant fraction of them (up to 25%) may be cholinergic (as demonstrated in *Drosophila*).

Although all somata in the AL probably belong to PNs and LNs, the AL also contains the projections of a few extrinsic neurons. Most of these appear to be aminergic (i.e., they release biogenic amines, such as serotonin or octopamine) and are thought to be modulatory. One of these neurons is known as VUMmx1 in honeybees; it is octopaminergic and has a counterpart in locust and probably most other insect species. The AL also appears to be rich in the enzyme nitric oxide synthase (expressed by LNs). The gas neurotransmitter NO is therefore also a possible mediator of information processing in the AL.

Figure 1 Architecture of the early olfactory system of the locust. (a) Odor information is carried into the antennal lobe (AL) by olfactory receptor neurons (ORNs). After processing by projection neurons (PNs) and local neurons (LNs) in the AL, information travels to the lateral horn (LH) and mushroom body (MB). MB Kenyon cells (KCs) then send information on to the MB output lobes (alpha and beta). (b) Information converges from a large number of ORNs onto a much smaller set of PNs. By contrast, PN output diverges to the KC layer, and KC output converges again onto a small number of MB extrinsic neurons. (c) PN–KC connectivity is dense, with each KC receiving input from close to 50% of the PNs in an AL. LHI, lateral horn interneuron.

Anatomy: MB

Several decades of behavioral and genetic experiments in fruit flies and honeybees have established that the MB is required for associative learning and recall. The intrinsic MB neurons are known as Kenyon cells (KCs). Their small cell bodies are packed tightly above the calyx (as grapes in a wine glass); the dendrites of each KC occupy a small fraction of the volume of the calyx. Whereas the MB has been primarily associated with olfactory learning, KCs may receive inputs from other sensory modalities as well. There is good anatomical evidence for this in the honeybee.

There are many more KCs than PNs: ~50 000 versus ~830 in locusts. Thus, the early olfactory circuit features numerical convergence (ORNs onto PNs) followed by divergence (PNs to KCs), as depicted in Figure 1(b). ORN-to-PN convergence is highly ordered; in *Drosophila*, the ORNs that converge onto one PN generally originate from ORNs of the same molecular type. This indicates that ORN space and PN space are of similar dimensionalities and suggests that ORN convergence could be useful for noise reduction by signal averaging. The connectivity between PN and KC populations is only beginning to be studied. It is extensive in locust: approximately 50% of the PNs in an AL appear to connect to any given KC (Figure 1(c)). Whether this convergence is ordered or predetermined (genetically or developmentally) is not known.

The next stages of the KC pathway are in the MB output lobes. KC axons leave the calyx in a dense tract called a peduncle. There is morphological evidence for reciprocal chemical synaptic connections between adjacent KCs in this axon bundle. After they process down this tract, KC axons bifurcate and enter output regions called the α and β lobes, where they synapse onto MB-extrinsic neurons; KC output is excitatory. The MB-extrinsic neurons are odor-responsive, and their morphology has been studied to some extent as well. Their precise connectivity to KCs and their role in olfactory circuits is only beginning to be understood. Among the most interesting recent findings about KC input to MB-extrinsic neurons is the existence, in locust, of Hebbian spike timing-dependent plasticity, with consequences for the regulation of spike time precision and output synchronization and obvious potential roles for learning and memory.

Anatomy: LH

Not much is known about this region of the insect brain. It is generally thought that the LH plays a role in the processing of innate rather than learned responses to odor (a role assigned to the MB). In locust, among the LH neurons is a subpopulation of ~60 GABAergic neurons, called LH interneurons (LHIs), with convergent input from the PN population. Although these neurons respond to odors, their responses are not odor-specific. LHIs in turn send axonal projections to the MB, thus acting as a feedforward inhibitory circuit onto KCs.

Circuit Dynamics and Ensemble Coding in the Locust Olfactory System

Oscillations are a prominent feature of brain dynamics across phyla and brain structures. They are typically detected in field potentials, generated by the summed activity (electrical and synaptic) of populations of neurons. Oscillatory field potentials were first reported in human electroencephalogram recordings by Hans Berger in 1929 and in local field potential (LFP) recordings in the olfactory system of hedgehogs by Edgar Adrian in 1942. Oscillations have been hypothesized to be involved in numerous phenomena, such as attention, perceptual binding, memory, information transfer between brain regions, signal amplification, and gating of sensory input during sleep. They have also been proposed, by others, to be meaningless artifacts and epiphenomena. Oscillations are common in olfactory systems (from mollusks to mammals), and their possible function in olfactory processing/perception has received considerable attention.

Some studies have successfully correlated the presence or absence of oscillations with behavior (discrimination between sensory inputs), but it is increasingly clear that demonstrating causal links between such disparate levels of description is very difficult. The approach in this article is to present the potential role of oscillations by exploiting the relative simplicity of the locust olfactory system.

Fast and Slow Dynamics in the AL

One of the most conspicuous circuit-level features of the AL is the recurrent connectivity between excitatory (cholinergic) PNs and inhibitory (GABAergic) LNs. Indeed, PNs make local outputs within the AL (probably from glomerular neurites and, so far as is known, only onto LNs) in addition to axonal output to the MB and LH. The interplay between the PNs and LNs, together with fast and slow kinetics of $GABA_A$ and $GABA_B$ receptors, gives rise to AL dynamics on two timescales. First, PNs respond to odors with slow temporal spike patterns that last more than a second and outlast the odor stimulus. The patterns include both excitatory and inhibitory epochs (Figure 2(a)). Second, active PNs transiently synchronize with each other during an odor presentation, due to fast $GABA_A$-mediated negative feedback via LNs. This transient pairwise, distributed synchronization gives rise to odor-evoked, collective ~20 Hz oscillations, detected in LFPs recorded in the MB – a consequence of summed PN synaptic output (Figure 2(b)). These odor-evoked oscillations are also visible in the subthreshold odor-evoked activity of PNs, LNs, and the recipients of PN output in the MB, the KCs. Mechanistically, $GABA_A$ conductances in PNs and LNs underlie the synchronous periodicity of PN output and thus the oscillations. Synchronization can be abolished relatively selectively by the application of picrotoxin, a Cl^- channel blocker, in the AL. This pharmacological manipulation has been used to test the potential functions of synchronization, using both behavior and electrophysiology as functional assays. Oscillation frequency is independent of the stimulus and appears to be determined in great part by inhibitory postsynaptic potential kinetics.

Ensemble Coding and Population Dynamics in the AL

The combination of slow temporal patterning and synchronization by phasic inhibitory feedback during odor responses (Figure 2(c)) has important consequences for the format of PN output sent to the next layer of olfactory processing. PN population output can be thought of as sequences of high-dimensional state vectors the width of an oscillation cycle (Figure 2(d)). Each dimension (that is, each row of the PN ensemble vectors shown in Figure 2(d)) captures the state of one PN and tracks the number of spikes fired by this PN in each oscillation cycle. These ~830-dimensional vectors (assuming one dimension for each PN in the AL, although the number of independent dimensions could be smaller if, for example, there are multiple PNs of identical type) are updated at each oscillation cycle. The dimensions define the coordinates of PN phase space within which the PN ensemble vectors exist. An individual odor response produces a progression of ensemble states and therefore a trajectory in PN phase space (Figure 2(e) shows the trajectory for PNs 1 and 2 from the red box in Figure 2(d)). The evolution of a particular odor trajectory depends on the sequence of specific combinations of transiently synchronous PNs; the rate of evolution of the

Figure 2 Dynamics of projection neuron (PN) ensemble odor responses. (a) Odor responses of two simultaneously recorded PNs. Each row of dots for PN1 represents a spike train recorded at the same time as the corresponding row for PN2. Shown are 21 successive trials with the same odor. Response patterns are highly reliable across trials. (b) Local field potential (LFP) recorded in the mushroom body (MB) shows ~20 Hz oscillations during the period of odor presentation. (c) PNs transiently synchronize their firing (thanks to fast local inhibitory feedback through γ-aminobutyricacidergic (GABAergic) local neurons (LNs) in the antennal lobe (AL)) in response to odors, producing ~20 Hz LFP oscillation that can be recorded in the MB. (d) Oscillations define a clock for this olfactory network. PN spike trains can be thought of as being formatted into bins the width of an oscillation cycle for the next layer in the network. The state of the PN ensemble is represented during each cycle by the 830-dimensional vector of spikes across PNs during that cycle. (e) The state of the PN ensemble (in this illustration, including only PNs in the red box in (d), PNs 1 and 2) can be represented on a phase plot in which each point represents the number of spikes produced by each neuron during one cycle. The entire response is then represented by the trajectory connecting the sequence of such points. (f) If more than two PNs are included in the ensemble, dimensionality reduction techniques (such as principal components analysis) are needed to visualize an approximation of the high-dimensional trajectories. Shown here is a schematic of PN ensemble trajectories to two different odors. The dynamics of the response are restricted to periods near odor onset and offset, with longer pulses producing periods of stationarity in the PN ensemble response (as represented by the fixed point, FP). AP, action potential.

trajectory is thus affected by both the slow and fast dynamics of individual PN responses. If the animal is exposed to a sustained odor, the slow temporal patterning usually ceases after ~2 s, at which time the PN ensemble reaches a fixed point: individual PNs are either stably active or silent until the odor is switched off. At that time, there is further patterning before a return to near-baseline levels of activity (Figure 2(f)).

The off-transient so defined is always different from the on-transient but is also odor-specific. The correlation width (the time on either side of a given cycle during which PN ensemble vectors are still significantly correlated) is on the order of 100 ms early in the response and can be many hundreds of milliseconds in the later stages of the response. It is interesting that the greatest pairwise distances between the trajectories defined by different odors and the lowest noise levels (correspondingly, the highest success in odor classification by observers) are reached early (within about 200 ms) in the on- and off-transient phases of the response rather than at the fixed points. The fixed points are thus not optimal for odor identification. Said differently, the optimal epochs for stimulus identification from PN activity vectors are when the PN population is in motion.

During a typical odor response (for a 1 s-long stimulus), more than half the PNs are active at some point at least during the response period. In a given oscillation cycle, however, only about 100–150 action potentials are produced. Of these, 55% are produced by a reliable PN (representing about 10% of the entire PN population). The remaining spikes originate from a pool of less reliable PNs (representing about 30% of the PN population). The remaining 60% of the PNs are reliably silent. Thus, the ensemble vector that represents the state of the PN population includes casts of reliably and unreliably firing PNs, whose identities change from oscillation cycle to oscillation cycle. This becomes relevant for how the PN vectors are decoded, which is discussed in the next section.

Decoding PN Ensemble Activity: Sparse Coding in the KCs

MB KC firing patterns are very different from those of their input PNs (cf. Figures 3(a) and 3(b)). KCs are almost silent at baseline and respond to ~1–10% of odors with only approximately two spikes per response. The timing of those spikes is cell- and odor-specific. Thus, in contrast to the broad PN tuning (and resulting dense odor representations in the AL), odor representations by KCs are very sparse.

Sparse coding refers to an encoding and representational scheme that uses only a small number of narrowly tuned cells for any one item to be encoded. This coding strategy is found in other systems (e.g., song production circuits in zebra finches, rodent auditory cortex, and the medial temporal lobes of humans). Neurons whose responses are extremely rare and contain only few action potentials (two on average with KCs) can be very hard to detect with extracellular recordings; such neurons and encoding strategies may thus be vastly underrepresented in the literature. There are important reasons to expect that neurons that are involved in associative memory, as KCs are thought to be, might be sparse encoders. Sparseness helps reduce the probability of overlap and potential interference between memories; that is, forming a new association is less likely to affect existing ones. Similarly, the number of synapses that need to be modified to form an association is small. Sparse strategies are thus efficient, particularly when implemented by almost binary spiking neurons. Finally, sparse codes lead to synthetic representations (ones that lack detail of the constituent parts). This is in fact how odors appear to be perceived: multicomponent mixtures, such as ground coffee or flower fragrances that excite a wide array of receptors, are generally perceived as singular. Sparse coding is limiting in terms of capacity, but this disadvantage can be offset by a large number of neurons; KCs are indeed the most numerous central neurons in the insect olfactory system (with about a third of a million KCs in cockroaches and up to 10 million KCs in the MB of a related arthropod, the horseshoe crab *Limulus*).

Mechanisms of Sparsening

How do sparse responses arise, or, stated differently, how is high response specificity generated? In locust KCs, experimental results indicate a combination of contributory mechanisms:

1. Each KC appears to be connected, with a narrow range of synaptic weights, to ~50% of its input population (PNs in the AL). This high number and the enormous space of PN combinations that it allows ($^{830}C_{400} \cong 10^{240}$) imply that KCs could, in principle, encode a very large number of input patterns or stimuli. It also implies that if only a minute fraction of this large number of possible combinations is realized (there are only 50 000 KCs per MB and thus only a maximum of 50 000 possible realizations), the corresponding input patterns are likely to be very different from one another. This could begin to explain why KC responses are so specific. Such high convergence (many PNs to one KC) and divergence (one PN to many KCs) should excite many KCs, however, unless KC firing thresholds are set appropriately high. This appears to be the case, with a requirement for >60 coincident PN spikes per oscillation cycle.

2. Intrinsic properties of KCs contribute to their action as coincidence detectors, allowing them to fire even with high voltage thresholds. Voltage-dependent conductances serve to sharpen excitatory postsynaptic potentials (EPSPs) when the KCs are depolarized. Thus, a PN spike that arrives synchronously with others can contribute disproportionately toward bringing a KC to spike threshold.

Figure 3 Transformation of odor representations from projection neurons (PNs) to Kenyon cells (KCs). (a) Responses of three simultaneously recorded PNs to 16 different odors. Most PNs respond to a large percentage of odors with a variety of spike patterns. These dense representations of odors are transformed to sparse representations in the mushroom body (MB). (b) Each KC responds to only a small number of odors, and KCs typically respond with very few spikes. (c) Lateral horn interneurons (LHIs) respond to all odors with similar response patterns. (d) Fan-out from PN to KC populations is ~50%; each KC thus samples about half of all PNs. KCs also receive delayed feed-forward inhibitory input from LHIs. (e) Oscillations constrain the time available to each KC to integrate the odor-specific excitatory input it receives from the PNs connected to it. PNs (excitation) tend to fire during the rising phase of the oscillation cycle; LHIs fire about half a cycle later, that is, between the middle and the end of the falling phase of the local field potential. This phase-lagged, nonspecific inhibitory input from LHIs curtails KC integration time to a half oscillation cycle, after which the KC membrane potential is effectively reset by an LHI inhibitory postsynaptic potential. Cit, citral; ger, geraniol.

3. KCs receive odor-evoked feed-forward inhibition from the LH neurons. These GABAergic neurons, which respond nonspecifically to odors (Figure 3(c)), have extensive axonal arborizations in the MB.

4. Excitatory (from PNs) and inhibitory (from LHIs) inputs to KCs arrive at specific times, clocked by the odor-evoked oscillations. PNs tend to fire preferentially during the rising phase of each cycle. LHIs, which receive their input also from the PNs, tend to fire with a delay, during the falling phase of each cycle. Thus, in each cycle during an odor response, each KC receives excitatory input from a subset of PNs (those among its presynaptic set that are coactive). Immediately after this, each KC receives nonspecific inhibitory input from the LHIs; this inhibitory input resets KC membrane potential, limiting or suppressing integration of EPSPs across oscillation cycles (Figures 3(d) and 3(e)). This inhibitory reset means that each KC has the opportunity to fire only during a small fraction of each oscillation cycle, and then only if it gets the appropriately synchronous input from a large enough fraction of the PNs it is connected to. KC firing phases reflect the strong effect of this oscillatory input. KCs are strongly phase-locked with the LFP and tend to fire in the period between the arrival of PN and LHI input (gray bar in Figure 3(e)). The importance of this phase-lagged inhibitory input has been tested pharmacologically. Blocking inhibition in the MB leads to a very significant increase in the width of KC tuning (and therefore, to a decrease in the sparseness of their responses) and to the loss of KC phase locking to the LFP.

In summary, dynamic PN population output, oscillatory PN output, delayed feed-forward inhibition of KCs, PN–KC connectivity, and nonlinear intrinsic properties of KCs all contribute to making the KCs sparse encoders. During an odor stimulus, each KC can be thought of as matching its PN connectivity matrix (the PNs it is connected to) with the entire ensemble PN state vector at every oscillation cycle. If there is significant overlap (i.e., a large-enough number of its presynaptic PNs fire synchronously near the top of a given cycle), the KC reaches threshold and fires. If this does not happen, the KC's membrane potential is reset by delayed inhibition from LHIs. The KC must wait until the next cycle to have a new opportunity to fire. However, because only ~55% of spikes (during a given odor-evoked oscillation cycle) are reliable, the threshold must be reached with the help of spikes from unreliable PNs. That is, although these spikes are not individually reliable, they contribute reliably as a collective during each cycle. Whether this design facilitates robustness to noise or confers other advantages is an open question. It has been observed, however, that intertrial noise in PN responses is smallest during the transient phases of the PN population output.

Processing of Complex Stimuli

The olfactory system has presumably evolved to process not only simple pulses of odors but also (and probably more likely) complex and dynamic stimuli such as caused by turbulent plumes. Realistic stimuli must therefore often be intermittent, unpredictable, and variable in duration, concentration, and chemical composition.

Intensity Invariance

The concentration of an odor can vary across many orders of magnitude depending on the strength of the source, distance from the source, and wind conditions. Animals can typically recognize odors across many concentrations. However, responses of ORNs typically increase with increasing concentration, and individual PNs are strongly affected by the concentration of the odor. Indeed, PN responses to different concentrations of an odor are often qualitatively similar to responses of a PN to different odors. How then does intensity coding differ from identity coding? The olfactory system resolves this seeming confusion by using gain control and ensemble coding. Total firing rate across the PN population does not increase significantly with concentration. Yet at the ensemble level, PN responses are more similar across concentrations of the same odor than they are across different odors. In PN phase space, this can be seen in the fact that PN trajectories for different concentrations of an odor lie within odor-specific surfaces (Figure 4(a)). Thus, KCs that receive inputs from PN ensembles that respond more similarly across concentrations could have similar responses to a wide range of odor intensities, presumably allowing the animal to recognize odors in an intensity-invariant manner. Concentration-invariant KCs do exist (see KC1 and KC2 in Figure 4(b); KC3 is an example of an odor- and concentration-specific KC), but whether invariance results from such connectivity is as yet unknown.

Effect of History and Initial Conditions

A sensory system's ability to process a particular stimulus correctly is often affected by the lasting effects of prior exposure to other stimuli. Such history dependence can limit or help the performance of a system under dynamic conditions, such as when multiple stimuli arrive in rapid succession. When presented with sequences of odors, for example, the AL and MB can respond differently to a given odor, depending on the

Figure 4 Projection neuron (PN) ensemble encoding and Kenyon cell (KC) decoding: intensity invariance and the effect of stimulus history. (a) Responses of 110 PNs to four different concentrations of three different odors, represented as trajectories after dimensionality reduction using locally linear embedding (LLE). PN ensemble responses to different concentrations of the same odor are more similar to each other than to responses to different odors. PN response trajectories for different concentrations of an odor lie on the same

timing and identity of the preceding stimulus. This effect is illustrated in Figures 4(c) and 4(d).

In general, PN ensembles are able to successfully track an individual odor even when it is preceded by another odor. This is seen in the successful switching of the black trajectory (representing the PN ensemble response during an overlapping odor sequence) from that corresponding to one odor to another in Figure 4(c)(iii). However, the trajectory that the ensemble of PNs follows under such conditions is different from the one it would follow if the odor was presented in isolation (shown in blue and green in the same figures). In some cases, the system is unable to make the switch (Figure 4(c)(ii)), and the second odor is effectively 'masked.' This has consequences for the downstream KCs as well. Each KC is, by virtue of its connectivity to a specific PN, tuned to a specific volume of PN phase space; the size and shape of this volume likely depend on factors such as the synaptic weights associated with its input PN vector, the range of input PN instantaneous firing rates, and the KC's own spike threshold and active properties. If the ensemble PN response trajectory passes through the KC's region of interest, that KC will respond, but not otherwise. In the case illustrated in Figure 4(c), the KC tuned to a particular early phase of the geraniol PN trajectory responds fully (Figure 4(c)(i)), less well (Figure 4(c)(ii)), or not at all (Figure 4(c)(iii)), depending on the path taken by the PN ensemble trajectory (and the overlap between the two odor pulses). In Figure 4(d), the converse is illustrated: the recorded KC responds neither to the two odors presented alone nor to their binary mixture. It responds only for particular conditions of odor overlap that cause the PN ensemble response trajectory to transition through a specific and distinct region of PN phase space. Thus, KCs can be highly tuned to the coactivation of specific PN combinations.

Conclusions and Future Directions

Summary

Understanding olfaction requires understanding how chemical signals, once transduced by ORN arrays, are processed by the brain for a variety of purposes, such as discrimination, tracking, orientation, association, learning/memorization, and recall. Studies in the locust olfactory system provide a window into the sorts of transformations that must occur as information makes its way from the periphery of a sensory system to higher brain centers. In this system, information about the odor environment is represented in dynamically evolving ensembles of PN firing patterns. Each odor condition causes the PN ensemble to travel through a specific sequence of states. These PN ensemble states are relevant for their targets in the MB, the KCs. KCs encode odors as sparse activity vectors, in a format suitable for associations with other sensory modalities and valence. Their responses are consistent with an oscillation-cycle-by-cycle detection of synchronous firing across a large fraction of their PN ensemble input. The design of the system seems suitable both for encoding a large number of odor conditions and for responding rapidly to changes in odor conditions.

Downstream Targets of KCs

The MB's involvement in associative memory in flies and honeybees suggests that downstream MB neurons may be critical for odor learning. It is known that beta lobe neurons respond to odors with phase-locked spikes in stimulus-specific patterns, and recent results show that their inputs from KCs are modulated by Hebbian spike timing-dependent plasticity rules, with a time window of plasticity that corresponds precisely to the oscillation period.

odor-specific surface. (b) KC responses can show varying degrees of intensity invariance, consistent with their receiving input from a large percentage of PNs. Consistent with their decoding of PN ensemble response patterns, KC responses are often odor- and time-specific but not intensity-specific. (c) PN ensemble and KC responses to overlapping presentations of two odors. The responses of individual KCs occur during particular epochs, specific to each odor–KC pair, and thus correspond to particular segments of the PN ensemble response trajectories. Both responses are sensitive to stimulus history. KC4 tends to fire specifically during the first 200 ms after the presentation of geraniol (ger). Its response is masked if citral (cit) is presented within 100 ms of the presentation of ger. If cit precedes ger, KC4 does not fire at all. (i) The period during which KC4 responds to ger (purple bar) is highlighted on the matching epoch of the PN ensemble response (purple segment on blue trajectory). Any PN response trajectory that passes through this part of PN phase space has a high probability of evoking a response in this KC. If the response trajectory (black, corresponding to ger- and cit-pulse onsets delayed between one another by 100 ms) passes through only a small part of this volume (ii), KC4 fires fewer spikes. In (iii), the PN ensemble response to cit preceding ger by 100 ms does not intersect the PN ensemble response to pure ger until much later than the period of KC4's response. Correspondingly, KC4 does not spike. (d) KC5 fires specifically during a transition from ger to cit for particular overlapping odor sequences. Consistent with the PN–KC decoding model, the regions of PN phase space that these transitory periods occupy (shown with purple bar under KC responses and on PN phase plots) are not traversed by any PN ensemble responses to pure odor conditions.

Large Odor Sets, Other Stimulus Paradigms, and Underlying Dynamics

How is the universe of odors represented in the locust brain? Although we are beginning to understand how the AL and MB process odors, the topology of PN and KC phase spaces remains unknown. Discovering structure in these spaces, if it exists, will require very large data sets, with many tens of stimuli. Finally, investigators need to understand the behavior of these networks as dynamical systems: clearly, the underlying motions are not described by classical attractor dynamics (fixed points or limit cycles). Alternative models, such as the recently described 'winnerless competition' must be explored and tested. Successful theoretical frameworks should ultimately explain the stability and advantages of transients for sensory encoding.

Comparison to Other Systems

Several computational features of the locust olfactory system find analogs in other systems. Sparse coding is found across sensory and motor systems and across phyla, with examples ranging from the song production circuits of zebra finches to rodent auditory cortex and the medial temporal lobe of humans. The circuit motif of feed-forward excitation and delayed feed-forward inhibition is seen across brain circuits, and its function in promoting the narrowing of integration time windows for target neurons has also been noted in thalamocortical networks in the rodent barrel cortex. Encoding with dynamic neural assemblies is also a feature of many nervous systems, from leech motor decision-making circuits to mammalian cortical and hippocampal networks. Oscillations are a prominent feature of numerous brain circuits although their precise functional role in other systems is not as clear. Thus, insights gained from a careful analysis of the locust olfactory system may have applications across animals, brains, and functional networks.

Oligodendrocyte and Schwann Cell Identification Methods

J Trotter and K Karram, Johannes Gutenberg University of Mainz, Mainz, Germany

© 2009 Elsevier Ltd. All rights reserved.

Definition of an Oligodendrocyte and a Schwann Cell by Morphology Using Light and Electron Microscopy

Oligodendrocytes (OLs) and Schwann cells (SCs) are the myelinating cells of the central nervous system (CNS) and peripheral nervous system (PNS), respectively, ensheathing large-diameter axons with multilamellar wrappings of myelin, a specialized subdomain of their plasma membrane. Myelination facilitates saltatory conduction; in addition, signaling between myelinating glia and axons is essential for maintenance of axonal health and integrity during development and in the adult. An oligodendrocyte is able to myelinate multiple axonal internodes; in contrast, an SC myelinates only one internode in the PNS. OLs and SCs were initially identified morphologically using light and electron microscopy (EM). The term oligodendrocyte was first used in 1921 by Rio Hortega and described cells with few processes visible by light microscopy after metallic impregnation techniques on brain sections. Subclasses of oligodendrocytes were defined by differences in the density of their cytoplasm visible by EM. In general, oligodendrocytes have a dense cytoplasm and nucleus, lack fibrils and glycogen in the cytoplasm, and have large numbers of microtubules in their processes. Later EM studies from the group of Richard Bunge showed definitively the connection of the oligodendrocyte to the myelinated axon and proved that one oligodendrocyte can myelinate several axonal internodes. Experiments in which myelinating oligodendrocytes in CNS sections are filled with a fluorescent dye such as Lucifer yellow allow the visualization of oligodendrocytes and their processes. OLs in white (myelinated) matter often appear as interfascicular rows of cells lying between the axon bundles. These can be most clearly seen in well-ordered areas such as the corpus callosum. Both OLs and SCs include nonmyelinating cells; in the adult PNS these nonmyelinating SCs lie interspersed between axon and also enwrap but do not myelinate groups of small-diameter axons. It is thought that these cells can be induced to differentiate into myelinating SCs after damage and demyelination of the PNS. In the CNS, the situation is more complicated: Nonmyelinating OL progenitors are present in gray matter (so-called satellite oligodendrocytes) and the identification and developmental potential of this cell population is a matter of debate.

Identification of Oligodendrocytes and Schwann Cells Using Immunostaining for the Expression of Myelin Proteins

A restricted number of proteins are expressed in CNS and PNS myelin, synthesized by the myelinating glia. Their expression can be determined by staining with specific antibodies *in vitro* and *in vivo*, permitting their use as markers to identify these cell types (Figure 1). In the PNS, SCs upregulate myelin proteins upon axonal contact. The expression of the proteins P0, PMP22, P2, and myelin-associated glycoprotein (MAG) characterize myelinating SCs. In the CNS, OLs can express all the main myelin proteins *in vitro* in the absence of axons, although the amount made and their subcellular location appear to be regulated by neuronal presence. The myelin proteins proteolipid protein, myelin basic protein, MAG, 2′,3′-cyclic nucleotide 3′-phosphohydrolase (CNP; Figure 2), and myelin oligodendrocyte glycoprotein are expressed by OLs. OLs also express minor proteins, such as the GPI-linked adhesion molecules NCAM 120 and F3. In contrast to OLs, SCs express the cell adhesion molecule L1, which is also expressed by neurons. Expression of L1 is downregulated on myelinating SCs. During myelination, the complex structure of the myelin sheath has to be elaborated and several minor myelin proteins are expressed by OLs and SCs which then are directed to specialized locations such as the paranodal areas of uncompacted myelin. These include members of the connexin family (e.g., connexin 29, which is in OLs and SCs), members of the claudin family (e.g., claudin 11 in OLs), and specific cytoskeletal-associated proteins such as ermin in OLs and periaxin in SCs. The myelin lipids sulfatide and galactocerebroside are present in both PNS and CNS myelin and thus antibodies against these lipids characterize OLs and SCs *in vivo* and *in vitro*. Immunostaining can also yield information about the site of expression of a gene product within the cell as well as heterogeneity within a population: Thus, myelin basic protein is expressed strongly in the myelin compartment of actively myelinating OLs, whereas the cell body is less strongly stained.

Delineation of OL and SC lineage and the protein and lipid antigens expressed by OLs and SCs during

Figure 1 Schematic summary of oligodendrocyte development. Antigenic profile of oligodendrocyte development in the central nervous system.

Figure 2 Microscope image of the cortex of a 75-day-old mouse stained with an antibody that recognizes CNP (arrows point to oligodendrocytes).

development has been aided by studies in cell culture. In the PNS, co-culture of SCs and, for example, dorsal root ganglion neurons has allowed the characterization of the expression and role of SC-expressed proteins in myelination. In the CNS, co-cultures of OL and DRG neurons will myelinate within 2 weeks and the use of explants of CNS tissue is common (Figure 3). These *in vitro* systems aid in the characterization of different populations of OLs and their precursor cells and allow a good comparison with

Figure 3 Immature murine Schwann cells in co-culture with DRG neurons express the L1 glycoprotein and the NG2 proteoglycan. (d) shows the overlay of (b) and (c), and (a) shows the corresponding phase-contrast picture. Scale bar = 25 μm. Reproduced from Schneider S, Bosse F, D'Urso D, et al. (2001) The AN2 protein is a novel marker for the Schwann cell lineage expressed by immature and nonmyelinating Schwann cells. *Journal of Neuroscience* 21(3): 920–933, with permission. Copyright 2001 by the Society for Neuroscience.

in vivo models. Since cell cultures can be manipulated, functional studies of new gene products can be carried out in dissociated and explant culture, and complement studies performed using genetically manipulated mice in which the gene product has been mutated or eliminated.

In Situ Hybridization to Detect the Presence of Myelin Proteins

Multiple studies have analyzed the *in situ* expression of myelin proteins by localizing the expression of mRNA for the protein. This has additionally facilitated the identification and *in situ* localization of OLs and SCs in sections of CNS and PNS.

Expression of Transcription Factors Specific for Oligodendrocytes and Schwann Cells

Expression of a range of transcription factors characterizes myelinating glia. Thus, Olig1, Olig2, and Sox10 are expressed in developing and mature OLs, and Sox10 is expressed by SCs. However, the expression of some of these transcription factors is not exclusive to OLs; for example, Olig2 is important for OL development and expressed by mature OLs but is also essential for the generation of groups of motor neurons. Sox9 is a transcription factor for glial determination and appears early in the OL precursor, but it is downregulated in late OL precursors, when they start expressing Sox10 and are destined to be myelinating OLs. In the PNS, Sox10 is a key regulator of differentiation of SCs, and Sox10 knockout mice lack SCs.

Electrophysiological Characterization of Oligodendrocytes and Schwann Cells

Myelinating glial cells exhibit characteristic electrophysiological properties due to the expression of a range of ion channels and neurotransmitters which were initially thought to be exclusively expressed by neuronal cells. These were first demonstrated in cell culture and subsequently in sections. In both cases, whole cell patch clamp is extensively used in combination with a range of antagonists and agonists of the specific receptors and channels. For example, OL lineage cells express receptors for glutamate: These include the AMPA/kainate and NMDA classes of

receptors, although the latter appear to be expressed mainly on the cell processes, making detection by patch clamp techniques difficult. The AMPA receptors are expressed predominantly by precursor cells, as are receptors for GABA (the A subtype). SCs also express neurotransmitter receptors and channels which differ from those expressed by OLs.

Use of Genetically Manipulated Mice to Identify and Study Oligodendrocytes and Schwann Cells *In Situ* and Follow Oligodendrocyte and Schwann Cell Development

Transgenic approaches have been utilized to aid in the identification of OLs and SCs *in situ*. These approaches use the promoter for a myelin protein gene to drive the expression of a fluorescent reporter such as enhanced green fluorescent protein (EGFP). In many instances, the constructs are inserted as transgenes randomly in the mouse genome after injections into oocytes. A more elegant approach consists of placing the fluorescent indicator under the expression of the endogenous promoter of the gene (so-called knockin technology), usually by homologous recombination in exon 1 of the gene in embryonic stem cells followed by blastocyst injection. This latter approach has the advantage that the expression of the reporter mimics the endogenous gene expression, and there is less risk of interfering with the expression of other genes due to random insertion of the transgene in the mouse genome. However, there is a risk that the endogenous promoter activity may not be sufficient to generate enough reporter protein to visualize the cells. Marking the cells with fluorescent reporters allows the visualization of cells in living brain slices and facilitates their analysis by electrophysiological and imaging techniques such as two-photon microscopy. In addition, technical advances in which cells can be visualized in living, anesthetized mice through the skull clearly increase the amount of biological information that can be obtained from such animals using relatively noninvasive methods. Furthermore, use of such reporters allows direct isolation of the labeled cells via fluorescence-activated cell sorting, without prior antibody binding. This is particularly advantageous when the antigen of interest is readily degradable by the proteases required to dissociate postnatal neural tissue. A further advantage of the knockin approach over the transgenic insertion of genes is the generation of a knockout mouse for the gene of interest when the knockin mice are bred to homozygosity. In this instance, the cells in which both alleles of the gene have been deleted are labeled, thus facilitating detailed comparison with the heterozygous mice which still carry one copy of the normal allele.

Figure 4 Confocal section of the brain of an adult mouse expressing the PLP-DsRed transgene. The transgene is expressed in oligodendrocytes and myelin. Courtesy of Dr. Frank Kirchhoff.

The bacterial Cre recombinase can be inserted after the endogenous OL or SC promoter; such mice can then be crossed to mice in which a reporter gene (e.g., EGFP) has been preceded by floxed stop sites. In cells in which the specific promoter is active, Cre recombinase is synthesized and deletes the stop sites, yielding labeled cells at the first incidence of promoter activity. In this way, all progeny resulting from an initial promoter activity are labeled. In contrast, in mice in which the reporter gene is inserted directly after the promoter of interest, the cells are labeled only during the period of promoter activity. More differentiated progeny in which the promoter is no longer active lose the label. In addition, animals expressing Cre under the influence of an OL-specific promoter can be used to delete genes (and thus proteins) specifically in OLs by crossing the Cre mice with mice in which the genes to be deleted are floxed.

PLP-EGFP transgenic mice, PLP-DsRed transgenic mice (Figure 4), and CNP-EGFP transgenic mice have been reported. The CNP-Cre knockin mouse has proven extremely useful to specifically target genes in the OL lineage.

Problems of Precursor Cells

Definition of the direct precursors to myelinating SCs and OLs is important. The SC lineage is relatively

Figure 5 Confocal image scan of the cortex of a 5-day-old mouse stained with the monoclonal AN2 antibody recognizing mouse NG2. NG2-expressing progenitor cells and NG2-expressing pericytes around a capillary are visible. Scale bar = 20 μm.

well-defined, but there is considerable confusion about oligodendrocyte progenitors. This has implications for human diseases, most notably multiple sclerosis, in which resynthesis of myelin does not occur in chronic lesions despite the presence of a population of cells bearing markers of OL precursors. OL precursors express the polysialylated form of N-CAM, receptors for platelet-derived growth factor AA, as well as antigens recognized by the O4 antibody. Expression of the NG2 proteoglycan was originally thought to define oligodendrocyte precursor cells, but there is now considerable speculation regarding whether all NG2+ cells which are found in white and gray matter in developing and adult brain are capable of developing into OLs *in vivo* (Figure 5). Furthermore, the question as to whether some of these cells can also generate neurons is a hotly debated area of research.

Additional Animal Models to Study Myelination

Zebra fish have been explored as a tool for the study of myelination. It was shown that the genes for the main myelin proteins are largely conserved in zebra fish. The advantages of zebra fish are the rapid embryonic development and the transparent embryos, permitting the visualization of fluorescently labeled cells during development in the living animal. It is hoped that the ability to rapidly mutagenize genes in the fish by adding substances to the aquarium water and the relative ease of screening many fish embryos expressing fluorescent constructs will permit the rapid isolation of mutants affecting OL and SC development and permit the delineation of subpopulations of these cells and their functions.

Oligodendrocyte Morphology

A M Butt, University of Portsmouth, Portsmouth, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Oligodendrocytes are defined as the cells that produce the myelin sheaths which insulate central nervous system (CNS) axons. Oligodendrocytes are one of the two major kinds of macroglial cell, the other being astrocytes. Embryologically, oligodendrocytes and astrocytes are of neural origin and are distinct from the third class of glial cell – microglia – which are nonneural in origin. Myelinating oligodendrocytes are most numerous within CNS white matter, and it is their fatty myelin sheaths that give white matter its translucent appearance when the CNS is labeled with histochemical dyes. The cellular morphology of myelinating oligodendrocytes was first described in 1928 by Del Rio Hortega, who used classical metal-impregnation staining techniques. He subdivided myelinating oligodendrocytes into four subtypes, types I–IV, characterized by the number of their processes and the size of the axons they myelinated. The cellular connection between oligodendrocytes and myelin sheaths was not confirmed until the 1960s by electron microscopy (EM). In recent decades, the use of intracellular dye injection has enabled us to visualize in their entirety individual myelinating oligodendrocyte units, defined as the cell body, processes, and myelin sheaths (Figure 1). Immunocytochemical and *in situ* hybridization techniques have provided further insight into, for example, the functions of myelin proteins, receptors, and transcription factors in myelination.

In addition to myelinating oligodendrocytes, there are also nonmyelinating or satellite oligodendrocytes found within the CNS gray matter, either closely apposed to neuronal cell bodies (perineuronal) or to blood vessels (perivascular). These cells were recognized by Del Rio Hortega, but they are only minor populations and their functions remain unresolved. The mature CNS also contains a significant population of adult oligodendrocyte precursors (OPCs), which were identified in the 1980s in cell cultures and *in vivo* by imunolabeling with antibodies for the NG2 chondroitin sulfate proteoglycan. These NG2-expressing glia are numerous in the gray and white matter, and it is not clear that all these cells are OPCs. Within the last few years, it has been proposed that NG2-expressing glia represent a fourth kind of morphologically distinct mature glial cell, termed synantocytes; their function is unresolved, although some may be capable of regenerating myelinating oligodendrocytes, which is of particular importance following demyelination.

Morphological Subtypes of Myelinating Oligodendrocytes

The rodent optic nerve and anterior medullary velum have been particularly useful model systems in which to examine oligodendrocyte morphological heterogeneity, using both intracellular dye injection and immunolabeling with the Rip antibody. Dye injected into the soma diffuses throughout the cytoplasm of the cell, delineating the cytoplasmic continuity between the soma, processes, terminal paranodal loops, and inner and outer tongue processes of myelinating oligodendrocytes (Figure 1). Similarly, Rip is almost unique in that it labels oligodendroglial cell somata, processes, and myelin sheaths (Figure 2); the majority of oligodendroglia-specific antibodies tend to label either the myelin sheaths (e.g., myelin basic protein) or cell bodies (e.g., carbonic anhydrase).

Characteristics of Oligodendrocyte Types I–IV

Type I and II oligodendrocytes have small somata from which extend four or more very fine primary processes, which then branch to contact and myelinate 10–30 small-diameter axons, generally less than 2 μm in diameter, with relatively short internodal lengths of 50–150 μm (Figures 1(a) and 2(a)). Type III oligodendrocytes have much larger cell bodies than type I and II oligodendrocytes, and they have thick primary processes which rarely branch and myelinate a small number (usually fewer than five) of large-diameter axons, greater than 4 μm, with long internodal lengths of 200–500 μm (Figures 1(b) and 2(b)). Type IV oligodendrocytes are directly applied to a single large-diameter axon (similar to the one-to-one relationship between a myelinating Schwann cell and an axon) and have internodal lengths as great as 1000 μm. The myelin sheaths of type III and IV oligodendrocytes have a network of cytoplasmic reticulations, called the Schmidt–Lantermann incisures, which are cytoplasmic intrusions into the compacted myelin sheaths.

Distributions of Oligodendrocyte Types I–IV

A range of transitional morphologies exist between types I and II and between types III and IV, but the range is less between types I–II, on the one hand, and types III–IV, on the other. It appears, therefore, that type I–II and type III–IV oligodendrocytes are two

Figure 1 Dye-filled oligodendrocytes: (a) type II oligodendrocyte from the rodent optic nerve, which myelinates multiple small-diameter axons; (b) type III oligodendrocyte from the rodent anterior medullary velum, myelianting two large-diameter axons. The injection of dye into the cell body distributes throughout the cell to fill the cell body, processes, and the cytoplasmic parts of the internodal myelin sheaths, which appear as parallel arrays of dye-filled processes. Dye injection reveals the morphological heterogeneity of oligodendrocytes. In (b), the dye-filled cytoplasmic ridges are seen spiraling around the axon (arrows). Scale bar = 25 μm. (a) Reproduced from Butt AM, Colquhoun C, and Berry M (1994) Confocal imaging of glial cells in the intact rat optic nerve. *Glia* 10: 315–322, with permission from John Wiley & Sons. Figure 2 Immunolabeling with the Rip antibody of oligodendrocytes in the postnatal rat anterior medullary velum: (a) distribution of type I–II oligodendrocytes, myelinating small-diameter axons; (b) distribution of type III–IV oligodendrocytes, myelinating large-diameter axons. Arrows indicate immature oligodendrocytes. Scale bar = 50 μm. (a) Reproduced from Butt AM, Ibrahim M, Ruge FM, and Berry M (1995) Biochemical subtypes of oligodendrocyte in the anterior medullary velum of the rat as revealed by the monoclonal antibody Rip. *Glia* 14: 185–197, with permission from John Wiley & Sons. (b) Reproduced from Butt AM, Ibrahim M, and Berry M (1997) The relationship between developing oligodendrocyte units and maturing axons during myelinogenesis in the anterior medullary velum of neonatal rats. *Journal of Neurocytology* 26: 327–338, with permission from Springer-Verlag Berlin.

discrete populations which myelinate small- and large-diameter axons, respectively. Hence, type I–II oligodendrocytes are found in areas with the smallest-diameter axons – type I in the forebrain, cerebellum, and spinal cord and type II in the white matter, such as the corpus callosum; optic nerve; and cerebellum. Type III oligodendrocytes are found in areas with large-diameter axons, mainly the cerebral and cerebellar peduncles, the medulla oblongata, and the spinal cord. Type IV oligodendrocytes are restricted to tracts containing the largest-diameter fibers and occur near the entrance of nerve roots into the CNS. Thus, although oligodendrocytes are morphologically heterogeneous overall, they are generally quite homogeneous within a given tract determined by the diameter of axons below and above a critical diameter of 2–4 μm.

The Myelin Sheath

Consecutive myelin sheaths along axons are separated by nodes of Ranvier, and the myelin sheath between nodes is the internode. Each myelin sheath comprises a large sheet which is wrapped around the axon to form concentric layers or lamellae. If unwrapped, the myelin sheath would appear as an extraordinarily large trapezoid extension of the oligodendroglial cell membrane, with most of the cytoplasm extruded to leave a cytoplasmic ridge which surrounds the compacted myelin. The cytoplasmic

Figure 3 Dimensions of the myelin sheath. If they could be unwrapped, myelin sheaths would appear as large sheets of compacted cell membrane with ridges of cytoplasm, which correspond to the external tongue process (etp), paranodal loops (pl), and internal tongue process (itp) observed in electron microscopic transverse and longitudinal sections. Dye injected into the cell body (ocp) passes down the connecting processes (cp) to fill the cytoplasmic ridges, tracing the pathway by which myelin components are transported from the cell body to the myelin sheets. Reproduced from Butt AM and Ransom BR (1989) Visualization of oligodendrocytes and astrocytes in the intact rat optic nerve by intracellular injection of Lucifer yellow and horseradish peroxidase. *Glia* 2: 470–475, with permission from John Wiley & Sons.

ridge is continuous with the cytoplasm of the oligodendroglial processes and cell body (Figure 3). Thus, each myelin sheath is formed by the fusion of apposed cytoplasmic faces of the plasma membrane (to form the major dense line), which is wrapped around the axon by fusion of the outer faces of the plasma membrane (to form the intraperiod line). When wrapped around the axon, the inner and outer cytoplasmic ridges form the mesaxons and the lateral cytoplasmic ridges build up at the termini of the internodal sheath to form the paranodal loops which are apposed to the axolemma by complex axoglial junctions (Figure 3). The cytoplasmic ridges are the intracellular pathway along which all of the myelin products are transported from the cell body and targeted to the myelin sheath, over hundreds and potentially thousands of micra. This is achieved by intracellular transport involving microtubules and other components of the cytoskeleton. One of the most interesting aspects of protein targeting in oligodendrocytes is the myelin basic proteins. These proteins are not translated in the cell body because they are strongly charged and this would impede their transport to the myelin sheath; instead, the mRNA for myelin basic protein is translocated to the cytoplasmic ridges, where the protein is translated and inserted into the myelin sheath.

Dimensions of the Myelin Sheath

There are strict relationships between the dimensions of the myelin sheath and axon diameter, and these determine the conduction properties of the axon. The thickness of the myelin sheath (i.e., the number of lamellae, N) and the internodal length (L) are directly and positively correlated with axon diameter (D); that is, the larger the axon, the thicker and longer its myelin sheath is. The number of lamellae determines the insulating properties of the myelin sheath, and the internodal length determines the speed of conduction, both of which are greater for large-diameter axons. Thus, axons in type III–IV axon–oligodendrocyte units conduct faster than those in type I–II axon–oligodendrocyte units. The dimensions of each myelin sheath can be calculated as πDNL, and to determine the total amount of myelin supported by a single oligodendrocyte, this must then be multiplied by the number of sheaths within the unit. The ratio of axons to oligodendrocytes is less than 5:1 in type III–IV units and greater than 15:1 in type I–II units and is negatively correlated to the diameter of axons in the unit. There is a sharp demarcation between type I–II oligodendrocytes, which support myelin volumes of approximately 500 μm^3, and type III–IV oligodendrocytes, which support myelin volumes of approximately 30 000 μm^3, and those that myelinate the largest-diameter spinal cord axons as much as 150 000 μm^3. Hence, a single oligodendrocyte would be visible to the naked eye if the entire expanse of its myelin were laid out. The production of these large membranes places a considerable metabolic load on the cell, and it is perhaps not surprising that oligodendrocytes direct their entire energy to the exclusive function of myelin production. The large cell bodies and thick radial processes of type III–IV units and their prominent Schmidt–Lantermann incisures facilitate the distribution of myelin gene products.

Composition of the Myelin Sheath

Compacted myelin comprises multiple fused phospholipid bilayers, and it is these lipids that provide the insulating properties of the sheath. Galactocerebroside (GalC) is a specific oligodendroglial lipid and is a useful immunohistochemical tool for studying oligodendrocytes. The other main constituent of myelin are proteins (30% of its dry weight), the major ones being myelin basic protein (MBP) and

proteolipid protein (PLP), which are specific to myelin and are used immunohistochemically to identify and study myelinating oligodendrocytes. The main functions of MBP and PLP are in the fusion of the cytoplasmic and extracellular interfaces of the myelin lamellae, respectively. In addition, there are a number of proteins that in the CNS are specific to oligodendrocytes and which are important in myelin formation, including 2′,3′-cyclic nucleotide-3′-phosphodiesterase (CNP), myelin/oligodendrocyte specific protein (MOSP), myelin-associated/oligodendrocyte basic protein (MOBP), transferrin, carbonic anhydrase, and members of the tetraspan-protein family. Still other myelin-specific proteins are important in cell–cell interactions, for example, myelin-associated glycoprotein (MAG), myelin oligodendrocyte glycoprotein (MOG), and oligodendrocyte-myelin glycoprotein (OMgp). Myelin is one of the most complex structures in the body and this is underscored by the large number of specialized proteins required for its formation and maintenance.

Oligodendrocyte Development

During development, myelinating oligodendrocytes develop from OPCs that originate in ventricular zones in the brain and spinal cord, and migrate to their final sites in the brain and spinal cord, where they undergo local proliferation and differentiation, or apoptosis, in response to multiple cellular and extracellular signals. Oligodendrocytes pass through a series of distinct developmental phases that can be identified by the expression of stage-specific antigens (Figure 4): OPCs express platelet-derived growth factor α receptors (PDGFαR) and NG2; as they differentiate into immature oligodendrocytes they first gain expression of the sulfatides recognized by the O4 antibody and then GalC, as they lose PDGFαR and NG2 but not O4; finally, oligodendrocytes then begin to express myelin-related gene products, such as MBP and Rip.

Morphological Changes during Myelination

A progression of morphological alterations during myelination has been identified using intracellular dye-filling and immunohistochemistry (Figure 4). Immature oligodendrocytes express myelin-related proteins prior to axon ensheathment and extend a large number of fine processes in all directions for 3–20 μm. Processes that engage axons bifurcate and extend initiator processes that begin to spiral longitudinally along axons. These initial ensheathments are uncompacted myelin sheaths, and their growth along the axons is remarkably uniform and symmetrical

Figure 4 Oligodendrocyte development of the postnatal anterior medullary velum: (a) double *in situ* hybridization labeling; (b–d) immunofluorescence labeling. Oligodendrocyte progenitor cells are identified by the expression of PDGFαR (in panel (a) blue) and NG2 (in panel (b), green). As oligodendrocyte progenitors differentiate into oligodendrocytes, they begin to express myelin proteins, such as MBP (in panel (a), red) and Rip (in panel (c), green). Progenitors extend numerous radial processes which form multiple contacts with unmyelinated axons (in panel (a), red). Premyelinating oligodendrocytes have a more complex morphology and extend innumerable fine branching processes that contact axons via fine filipodia and extend short initiator processes along axons (in panel (b), red). In (d), oligodendrocytes go through a remodeling phase during which they lose non-ensheathing processes and the number of sheaths per unit is established. Scale bar = 100 μm (a), 75 μm (b,c), and 20 μm (d). (a) Reprinted from Butt AM, Hornby MF, Ibrahim M, Kirvell S, Graham A, and Berry M (1997) PDGF-α receptor and myelin basic protein mRNAs are not coexpressed by oligodendrocytes *in vivo*: A double *in situ* hybridization study in the anterior medullary velum of the neonatal rat. *Molecular and Cellular Neuroscience* 8: 311–322, with permission from Elsevier. (d) Reproduced from Butt AM, Ibrahim M and Berry M (1997) The relationship between developing oligodendrocyte units and maturing axons during myelinogenesis in the anterior medullary velum of neonatal rats. *Journal of Neurocytology* 26: 327–338, with permission from Springer-Verlag Berlin.

Figure 5 NG2-expressing synantocyte. Confocal micrograph of triple immunolabeled anterior medullary velum. A synantocyte (labeled with antibodies to NG2, green) extends process along myelin sheaths (labeled with antibodies to myelin basic protein, blue) to form contacts multiple nodes of Ranvier (labeled with antibodies to ankyrin-3G, red). Reproduced from Butt AM, Hamilton N, Hubbard P, Pugh M, and Ibrahim M (2005) Synantocytes: The fifth element. *Journal of Anatomy* 207: 695–706, with permission from Blackwell Publishing.

within a single unit. Oligodendrocytes then go through a remodeling phase in which nonensheathing processes are lost and the number of axons per oligodendrocyte unit is established. The final ratio is greater for type I–II oligodendrocytes than for type III–IV oligodendrocytes, but the factors regulating the phenotypic divergence are unknown. Definitive internodal lengths are established by longitudinal growth during the transition to compact myelin, accompanied by the development of paranodal axoglial junctions and the establishment of nodes of Ranvier. The growth of the myelin sheath (both radially, by increasing the number of lamellae, and longitudinally, by growth of the internode) and the radial growth of axons are interrelated, but the factors controlling these relationships are unresolved.

Nonmyelinating Oligodendrocytes

OPCs that do not form myelin persist in the adult as NG2-expressing synantocytes, which are equally numerous in CNS white and gray matter. In addition, there are satellite oligodendrocytes in the gray matter, although their developmental relations to myelinating oligodendrocytes are not clear. Synantocytes and satellite oligodendrocytes are distinguished from astrocytes by their lack of cytoplasmic intermediate filaments and from myelinating oligodendrocytes by the lack of expression of myelin proteins.

Synantocytes (Adult Oligodendrocyte Progenitor Cells)

During development, OPCs give rise to both myelinating oligodendrocytes and synantocytes, which retain the antigenic phenotype of OPCs. Synantocytes, or at least a subpopulation of them, can regenerate myelinating oligodendrocytes following demyelination. The distribution and process outgrowth of synantocytes is directly related to neurons, and they form exquisite contacts with neurons at synapses and nodes of Ranvier (Figure 5). Synantocytes respond to neurotransmitters released during neuronal activity, and they may be specialized to monitor and respond rapidly to changes in neuronal activity. The physiological functions of synantocytes are unknown, but it is known that synantocytes respond rapidly to any insult to the CNS by a stereotypic reactive gliosis, and this may be a primary function of these cells in the adult CNS.

Oligodendrocyte Specification

W D Richardson, University College London, London, UK

© 2009 Published by Elsevier Ltd.

Specification of Oligodendrocyte Precursor Cells in the Embryonic Neural Tube

All the neurons and glial cells of the central nervous system (CNS) are derived from the neuroepithelial progenitor cells that form the walls of the embryonic neural tube. The neuroepithelial cell layer (ventricular zone (VZ)) of the spinal cord and brain stem can be subdivided along the dorsal–ventral axis into 11 distinct microdomains, defined by expression of different combinations of transcription factors (Figure 1). These progenitor domains generate different types of neurons followed by glial cells (oligodendrocytes or astrocytes). Fully differentiated glia are not formed directly from the neuroepithelium but via intermediate glial precursors. During or after neuronogenesis, the neuroepithelial progenitors give rise to so-called radial glial cells, which express characteristic gene products such as the glutamate transporter GLAST and the radial cell antigen RC2. Radial glia subsequently generate dedicated astrocyte or oligodendrocyte precursors. In a given domain of the VZ, radial glia produce either mainly astrocytes or mainly oligodendrocytes. For example, the pMN domain of the ventral spinal cord (Figure 1) generates motor neurons followed by oligodendrocyte precursors (OPCs) but few astrocytes. Overall, approximately 80% of spinal cord oligodendrocytes are derived from ventrally derived OPCs, mainly pMN, and the remaining 20% from OPCs that originate in dorsal domains dP3–5 (Figure 1).

Visualizing Oligodendrocytes and Their Precursors *In Situ*

From the earliest stages of their development, migratory OPCs can be visualized by immunohistochemistry or *in situ* hybridization against a characteristic set of markers, including the platelet-derived growth factor receptor (α subunit) (PDGFRA), the proteoglycan NG2, the transcription factor SOX10, and, in chicken only, surface antigens recognized by monoclonal antibody O4. In rodents, O4 antigen does not appear until a later, premyelinating stage (called pro-oligodendrocytes) when the precursors have stopped migrating and are beginning to differentiate into oligodendrocytes. In both birds and rodents, actively myelinating oligodendrocytes can be easily recognized by the expression of proteins (or corresponding mRNAs) that are abundant structural components of myelin, such as myelin basic protein and myelin proteolipid protein.

Using these and other molecular markers, it has been shown that OPCs are first generated in the pMN progenitor domain of the ventral spinal cord at 12.5 days postfertilization (E12.5) in mice, E14 in rats, and E6 or E7 in chick. In human spinal cord, OPCs appear on or before 45 days postfertilization. The following discussion, unless otherwise stated, refers to mouse. After the OPCs first appear at the ventricular surface, they proliferate and migrate throughout the cord, becoming evenly distributed through the gray matter and developing white matter before birth. Starting at approximately E18 (birth is approximately E19 in mice), oligodendrocyte differentiation starts in the ventral white matter and continues for approximately 6 weeks, peaking at approximately postnatal days 10–14. In human spinal cord, myelination of corticospinal tracts continues into the teenage years.

Spatial Control of OPC Generation by Signals from the Ventral and Dorsal Midline

In the ventral spinal cord, specification of both motor neurons and OPCs depends on signaling molecules that are secreted from the notochord and floor plate at the ventral midline, notably the secreted protein Sonic hedgehog (SHH). If chicken embryos are treated *in ovo* with cyclopamine, an inhibitor of SHH signaling, then the appearance of OPCs in the ventral spinal cord is blocked. Conversely, supplying an ectopic source of SHH (e.g., by implanting SHH-expressing cells or fragments of notochord adjacent to the spinal cord) induces extra OPCs in misplaced positions. Members of the bone morphogenetic protein (BMP) family of signaling molecules are also involved in limiting the spatial extent of OPC generation in the ventral cord. BMPs (notably BMP2 and BMP4) are expressed in the dorsal spinal cord and exert long-range influences along the dorsal–ventral axis. This has been demonstrated by surgically removing the BMP-expressing domain *in ovo* or by transplanting cells that express the competitive BMP inhibitor Noggin next to the chick spinal cord. Both these manipulations caused the OPC-producing pMN domain to expand dorsally. The extra OPCs were generated at the expense of astrocytes, which are normally produced in the p2 progenitor domain, immediately dorsal to pMN. Therefore, it seems that the

Figure 1 Diagram of progenitor domains in the VZ of the embryonic (~E11) mouse spinal cord. Domains are known as p3, pMN, etc. in the ventral half of the cord and dP6, dP5, etc. in the dorsal half. To the left of the diagram are shown the expression limits of transcription factors, some of which are mentioned in the text. Dotted lines with small arrows indicate that the expression domain expands or shrinks after it is first established. On the right are shown the cell fates of progenitors in the indicated domains (the origins of astrocytes are still tentative). FP, floor plate; INs, interneurons; MNs, motor neurons; OPCs, oligodendrocyte precursor cells; RP, roof plate.

spatial extent of OPC and astrocyte production in the ventral cord is limited by mutually antagonistic actions of SHH and BMPs.

The majority (approximately 80%) of OPCs in the spinal cord are generated in the ventral VZ. The remainder are generated in other progenitor domains, including dorsal domains dP3–5. The dorsally derived OPCs appear later in development than the pMN-derived OPCs (approximately E15 vs. E12.5) and they migrate less widely than their ventrally derived counterparts. It seems unlikely that these dorsal progenitor domains are under the influence of SHH from the floor plate, suggesting that there might be a SHH-independent route to OPC specification. Indeed, OPCs can arise in cultures derived from SHH null spinal cord or in the presence of cyclopamine, if fibroblast growth factor-2 (FGF-2) is also present in the culture medium. OPC generation in the dorsal spinal cord might therefore depend on FGF signaling, possibly combined with a decline in BMP expression in the dorsal cord during late embryogenesis. There might even be a biochemical overlap between SHH and FGF signaling because it has been shown that both pathways depend on MAP kinase activity.

It is not known whether or not ventrally and dorsally derived OPCs in the spinal cord are functionally specialized. However, there is evidence that ventrally and dorsally derived OPCs in the forebrain can substitute for one another, implying that they are functionally equivalent.

OPC Generation in the Forebrain

The adult forebrain, including the cerebral cortex, develops from an embryonic structure called the telencephalon. Like the spinal cord, this starts as a simple neuroepithelial tube, although it becomes progressively more convoluted during development. There is no notochord underlying the telencephalon and no floor plate; however, the ventral neuroepithelial cells express SHH and its receptors, Patched (PTC) and Smoothened (SMO). At approximately E13.5, some cells in the ventral neuroepithelium (medial ganglionic eminence (MGE)) start to express OPC markers such as PDGFRA and SOX10 and migrate away from their origin through the ventral telencephalon. Generation of these early OPCs depends on SHH because they do not appear in embryos that lack SHH expression in the ventral telencephalon (*Nkx2.1* null mice). Later, other parts of the VZ generate OPCs in a temporal wave of production from ventral to dorsal. OPCs from the MGE and lateral ganglionic eminence (LGE) initially populate the developing forebrain including the cerebral cortex before birth, to be joined after birth by OPCs that originate within the cortex. The latter OPCs remain in the cortex and do not migrate ventrally.

The question of whether all these OPCs and the oligodendrocytes that they give rise to are functionally specialized, or equivalent, was addressed by killing specific subpopulations of OPCs at source. This was achieved by targeting diphtheria toxin A-chain expression to subpopulations of OPCs that originate in different domains of the telencephalic neuroepithelium (MGE, LGE, and cortex) by combinatorial use of an oligodendrocyte lineage-specific gene promoter (*Sox10*) and one of several promoters that are active in different parts of the VZ (*Nkx2.1*, *Gsh2*, or *Emx1*). These experiments showed that when OPCs originating within the cortical VZ (normally approximately 50% of all OPCs in the cortex) were ablated, the remaining ventrally derived populations expanded to make up the loss and the animals survived and lived a normal life span. Even when all telencephalic OPCs from MGE, LGE, and cortex were ablated simultaneously, they were replaced by OPCs that migrated forward from the diencephalon. A normal OPC cell density was restored – with a significant but ultimately harmless delay – indicating that OPCs from different parts of the embryonic neuroepithelium are not intrinsically different from one another despite the very different signaling environments in which they arise.

Of course, there might be subtle differences that would not be detected without detailed behavioral analysis of the ablated mice, but this remains to be investigated.

Role of Transcription Factors in OPC Development: The OLIG Genes

A major step forward in understanding the molecular control of oligodendrocyte lineage development resulted from the discovery of transcription factors that orchestrate OPC specification and differentiation. Prime among these are the oligodendrocyte lineage (OLIG) transcription factors, OLIG1 and OLIG2. These are members of the large family of basic helix–loop–helix factors that also includes the pro-neural proteins NGN1/2 and MASH1 and the cell lineage regulators MYOD and NEUROD. In the developing spinal cord, SHH induces expression of OLIG2 in pMN, prior to and during motor neuron (MN) production. OLIG2 is downregulated rapidly in postmitotic MNs but remains on in OPCs as they proliferate and migrate away through the parenchyma. OLIG2 is required for both MN and OPC specification because both cell types are lost in *Olig2* null spinal cords. Pockets of OPCs persist in the brains of *Olig2* null mice, but no OPCs are found anywhere in the CNS of *Olig1/2* compound nulls. Therefore, OLIG1 might partly compensate for loss of OLIG2 in the brain. There is no effect on OPC generation in either the brain or the spinal cord of *Olig1* null mice, although there can be severe myelination defects later. OLIG1 therefore seems to be mainly involved in the later stages of oligodendrocyte differentiation and myelination.

Note that different laboratories have reported different experiences with *Olig1* knockout mice, depending on whether or not the *PGK-Neo* cassette used to inactivate the locus was removed prior to establishing mouse lines. When the *PGK-Neo* cassette was left in place, there was no obvious dysmyelinating phenotype during development, possibly because of *cis*-acting effects of the *PGK-Neo* transcription unit on the nearby *Olig2* gene. However, even in the latter mice there was a striking effect on remyelination of adult mice that were subjected to gliotoxin-induced experimental demyelination; such demyelinated lesions are rapidly repaired in wild-type mice but remyelination was blocked in the *Olig1* knockouts.

The underlying mechanism by which OLIG2 governs the sequential production of MNs and OPCs ('neuron–glial switch') is not known. Presumably, OLIG2 switches binding partners (transcriptional cofactors) during the transition from MN to OPC production. During the period of MN production, OLIG2 and the homeodomain transcription factor NKX2.2 are mutually repressive so that the OLIG2 and NKX2.2 expression domains (pMN and p3, respectively) are sharply demarcated (Figure 2). Later, after MN production has ceased, the cross-repression seems to relax because NKX2.2 expression creeps dorsally into pMN and an overlap region develops. Initially, it was thought that OPCs might be generated specifically within this overlap region under the cooperative activities of OLIG2 and NKX2.2. In chick, it does appear that PDGFRA^{+} OPCs are formed exclusively within the overlap region, but in mice OPCs arise in all parts of the OLIG2-expressing pMN domain, not just the region of overlap with NKX2.2 (Figure 2). Moreover, OPC specification is not affected in *Nkx2.2* null mice,

Figure 2 (a) Immunolabeling of ventral progenitor domains p3 and pMN in the mouse spinal cord with antibodies against transcription factors NKX2.2 and OLIG2, respectively. Motor neurons are still being generated at E11. (b) Three-color immunolabeling of NKX2.2 (p3, green), OLIG2 (pMN, blue), and PDGFRA (newly forming OPCs, red) in the mouse ventral spinal cord at E13. The first OPCs are formed mainly within the OLIG2-expressing pMN domain in mouse, outside the NKX2.2-expressing p3 domain. After they are formed at the ventricular surface, the OPCs migrate away rapidly in all directions to populate the spinal cord.

although the later stages of oligodendrocyte differentiation and myelination are delayed. A similar delay in myelination is observed in mice that lack the high mobility group transcription factor SOX10, which is known to interact with OLIG1 and OLIG2. OLIG2 has also been shown to interact physically with NKX2.2. Therefore, a picture is emerging in which OLIG1/2, NKX2.2, and SOX10 cooperate in controlling myelin gene expression and axon ensheathment. OLIG2 and other members of the SOX family (including SOX8 and SOX9) are required earlier for OPC and/or MN specification, but so far there is no compelling explanation for the neuron–glial switch.

Notch–Delta signaling is clearly involved in the MN/OPC fate choice as in many other binary decisions during development. It has been shown that, in zebra fish, abrogation of Notch signaling results in excess production of MNs at the expense of OPCs. Conversely, constitutive activation of Notch signaling results in excess OPCs at the expense of MNs. A well-established general function of Notch–Delta signaling is to maintain precursor cells in an immature state and to inhibit premature cell cycle exit and differentiation, thus preserving part of the precursor pool for generation of later-born cell types. Since MNs are formed before OPCs, the gain- and loss-of-function experiments in zebra fish spinal cord can be interpreted in those terms – implying that Notch signaling might play a permissive rather than an instructive role in the MN/OPC fate choice.

Control of OPC Proliferation

After they are specified in the embryonic VZ, OPCs proliferate and migrate away from their sites of origin, distributing widely and uniformly throughout the CNS before associating with axons and differentiating into myelin-forming oligodendrocytes (Figure 3). Several mitogenic polypeptides have been shown to influence OPC proliferation in culture and/or *in vivo*, including PDGF, FGF, and cytokines. These probably act in concert with one another, possibly in different combinations in different regions of the CNS and/or at different stages of OPC development.

OPCs express receptors for PDGF (PDGFRA subtype), and many neurons and astrocytes synthesize PDGF-A. *PDGF-A* null mice have reduced OPC numbers (approximately 10% normal numbers in the spinal cord and approximately 50% in the cerebral cortex) and correspondingly reduced amounts of myelin. Therefore, homodimeric PDGF-AA is an essential mitogen for OPCs *in vivo*. PDGF-AA is also strongly mitogenic for OPCs in mixed neural cell cultures, such as mixed glial cell cultures derived from perinatal rat optic nerve. However, PDGF-AA is not very mitogenic for pure, immunoselected populations of OPCs cultured on their own in the absence of other cell types. There are other essential mitogens or mitogenic cofactors released into the extracellular medium of mixed cell cultures that are required to cooperate with PDGF-AA. One of these is the CXC cytokine GRO-alpha. Astrocytes are a major source of GRO-alpha in optic nerve cultures and probably also *in vivo*. Cell adhesion molecules, notably integrin family members, also synergize with PDGF and possibly other polypeptide mitogens to drive OPC proliferation at limiting mitogen concentrations.

FGF-2 also enhances the mitogenic effect of PDGF-AA for OPC glial cell cultures. OPCs cultured with both PDGF-AA and FGF-2 can proliferate seemingly indefinitely without differentiating, whereas PDGF-AA in the absence of FGF allows limited OPC proliferation followed by oligodendrocyte differentation. FGF-2 on its own in the absence of PDGF is mitogenic for a late stage of OPC development, when OPCs stop migrating and express the O4 antigen prior to

Figure 3 OPCs, visualized by *in situ* hybridization for *Pdgfra* mRNA, in the developing mouse spinal cord. The first OPCs appear in pMN at approximately E12.5, and then they proliferate in response to PDGF-AA and other mitogenic cofactors and migrate throughout the cord, becoming widely distributed by approximately E15. They first start to differentiate into oligodendrocytes in the ventral and dorsal axon tracts soon before birth (E19 in mice).

terminal oligodendrocyte differentiation – so-called 'pro-oligodendrocytes.' Studies on the role of FGF *in vivo* are complicated by the large number of potential ligands (>20 FGF family members) and the fact that OPCs express different FGF receptor subtypes (FGFR1–3) at different stages of their development. Nevertheless, retrovirus-mediated inhibition of FGF-2 activity *in vivo* has shown that FGF-2, acting through FGFR1, negatively regulates OPC terminal differentiation into oligodendrocytes during normal development and after experimental demyelination in adult mice.

Other signaling systems that have been implicated in the control of OPC proliferation include neurotrophin-3, neuregulin-1/glial growth factor (NRG1/GGF), and insulin-like growth factor-1. There is also a growing awareness of the importance of ion channels and neurotransmitters in OPC proliferation and differentiation control.

Control of OPC Differentiation

After OPCs have disseminated throughout the CNS and into the future gray and white matter, something triggers them to differentiate into oligodendrocytes. One key signal seems to be the thyroid hormone triiodothyronine (T3), a constituent of the defined culture medium commonly used for primary nerve cells. When T3 is omitted from the culture medium, OPCs divide for an extended period in response to PDGF-AA, well beyond their normal limit in the presence of T3. It appears that T3 is required for withdrawal from the cell cycle prior to terminal differentiation. This effect of T3 can be mimicked by glucocorticoids or retinoic acid.

There is an established literature on the role of thyroid hormone (TH) in brain development and myelination. The start of myelination is delayed in hypothyroid rats and accelerated in hyperthyroid rats or rats that receive postnatal injections of T3. Moreover, TH normally only becomes available in the rat when the thyroid gland becomes active after birth, which is approximately the time when myelin first starts to appear. Oligodendrocytes and OPCs possess receptors for T3, so it is likely that T3 acts directly on OPCs to control their differentiation *in vivo*.

Notch signaling is also implicated in the control of oligodendrocyte differentiation. OPCs express Notch-1, and adding the Notch ligand Jagged to optic nerve cell cultures inhibits OPC differentiation into oligodendrocytes *in vitro*. Jagged is expressed on optic nerve axons *in vivo*, suggesting that differentiation of OPCs in the optic nerve might be triggered in part by downregulation of Jagged in the retinal ganglion cells that project their axons through the nerve. In support of this general idea, conditional deletion of Notch-1 in OPCs in transgenic mice leads to premature expression of oligodendrocyte differentiation markers such as the myelin-associated glycoprotein.

Control of Myelination by Neuregulin-1/Glial Growth Factor

Not all axons are myelinated: Axons must reach a certain minimum size (diameter) threshold before myelination is triggered. Below this threshold the axon remains naked. This is true in both the CNS and the peripheral nervous system (PNS). In addition, there is a direct relationship between the diameter of a myelinated axon and the thickness of the myelin sheath that develops around that axon (i.e., larger diameter axons have more myelin wraps). The myelin-modulating signal resides on the axonal surface and is interpreted by the myelinating glia (oligodendrocytes or Schwann cells) which adjust their synthesis of myelin membrane accordingly.

Neuregulins are a family of signaling proteins encoded in three loci, *Nrg1–3*, each of which generates alternatively spliced products that can be either secreted or membrane bound. They bind to receptors of the ErbB family (ErbB1–4), which includes the epidermal growth factor receptor ErbB1. NRG1 type III, also known as GGF, is now known to be the main axon-bound regulator of myelination in the PNS, acting through ErbB receptors on Schwann cells. The expectation that one or more NRG isoforms might also regulate myelinogenesis in the CNS is supported by the finding that expressing a dominant negative ErbB transgene in oligodendrocytes results in thinner myelin sheaths and associated physiological deficits, including reduced conduction velocity and, unexpectedly, increased dopaminergic activity of neurons. The precise NRG isoform responsible is not known. These initial results are exciting because of the implied links between myelin deficiency, neuronal activity, and, potentially, psychiatric illness.

OPCs in the Adult CNS

Myelination continues for at least 6 weeks postnatally in mice and rats, peaking 2 or 3 weeks after birth. However, cells with the antigenic phenotype and morphology of OPCs persist in large numbers in the adult CNS (approximately 4% of all cells). Like their perinatal counterparts, they continue to express both PDGFRA and the NG2 proteoglycan and retain the capacity to generate oligodendrocytes in culture or following experimentally induced demyelination. However, because there has been no compelling reason to think that significant numbers of new

Figure 4 Individual oligodendrocyte lineage cells labeled *in situ* (in 300-μm live sections of postnatal mouse corpus callosum) by microinjection of fluorescent Alexa dye. The myelinating oligodendrocyte (b) was formed between 6 and 8 weeks after birth from a PDGFRA-expressing adult OPC/NG2 cell (a). The long rod-like processes in b are myelin sheaths ('internodes') around nerve axons. Micrographs courtesy of M Rizzi.

oligodendrocytes are needed during normal healthy life, why large numbers of OPCs should survive in the adult has been puzzling.

It has been recognized that OPCs in the adult make contact with nodes of Ranvier (the gaps between adjacent myelin sheaths on an axon), they receive synaptic input from neurons, and they can even fire spontaneous action potentials. This has led to the notion that OPCs participate in the normal physiology of the adult CNS and that their primary role is not necessarily as glial precursors. They have been called 'a fourth glial cell type' (after astrocytes, oligodendrocytes, and microglia), 'synantocytes,' 'polydendrocytes,' or, more commonly, 'NG2 cells.' The physiological role of these cells is under intense scrutiny.

We should not reject the idea that NG2 cells might be needed to generate new or replacement oligodendrocytes throughout life. Cre-lox fate mapping in adult mice (using tamoxifen-inducible *Pdgfra-CreER*^{T2}) shows that they continue to divide and generate significant numbers of new myelinating oligodendrocytes in the corpus callosum of adult animals (Figure 4). Whether this ongoing oligodendrogenesis occurs to replace cells that die through natural turnover or to add extra oligodendrocytes to the existing pool is not known. It is now accepted that new neurons are generated in some parts of the adult brain throughout life; for example, new olfactory interneurons are continuously generated from stem cells that reside in the adult subventricular zones of the forebrain. It is conceivable that some adult-born neurons might need to be myelinated, and this could be one important function of the adult NG2 cells. Alternatively, or in addition, the axonal diameters of some previously unmyelinated neurons might increase during life, taking them over the threshold for *de novo* myelination.

Finally, NG2 cells might have more general cell fate potential. It is known that OPCs in perinatal optic nerve cell cultures can give rise to neurons, astrocytes, and oligodendrocytes if cultured in an appropriate manner. It is therefore possible, though not yet demonstrated, that OPCs in the adult CNS might be able to generate new neurons or astrocytes as well as oligodendrocytes. If so, adult OPCs/NG2 cells would qualify as a type of adult neural stem cells.

Olivocerebellar System

R R Llinas and K D Walton, New York University Medical School, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Morphology

The olivocerebellar system comprises the bilateral inferior olivary nuclei (IO), located in the ventral aspect of the brain stem, and the overlying cerebellum. These two structures are linked through the cerebellar peduncles. Axons from the IO neurons (Figure 1(b)) course up the contralateral peduncle, through the cerebellar white matter, into the cerebellar cortex, where they innervate the Purkinje cells (Figure 1(a), PC). On reaching the Purkinje cell layer, the IO axons establish synaptic contact with single Purkinje cells, forming a one-to-one junction at their soma and extend over the length of their primary and secondary dendrites. These IO afferents were thus named 'climbing fibers' by Ramon y Cajal (Figure 1(a), CF). The climbing fiber–Purkinje cell synapse is the largest synaptic junction in the vertebrate central nervous system. Activation of a climbing fiber elicits an all-or-nothing burst of spikes in the PC, and this stereotypic response is called a 'complex spike' (see Figure 2(c)). There are about ten times more PCs than IO neurons and, on average, each IO neuron generates ten climbing fibers.

The PC axons, the only output from the cerebellar cortex, terminate in the cerebellar nuclei, where they form inhibitory synapses (Figure 3(f), blue). In turn, the axons of the cerebellar nuclei are the only output of the cerebellum. The olivocerebellar axons also contact, via collaterals, the cerebellar nuclei neurons. The axons of half of all cerebellar nuclear neurons return to the contralateral olive as an inhibitory system and terminate in the IO onto structures called 'glomeruli' (Figures 1(a) and 1(d)). Each olivary glomerulus contains approximately five to eight spines (Figure 1(d), ST) from distal dendrites of different IO neurons (Figure 1(d), IOD). The glomeruli contain both excitatory and inhibitory synapses of extrinsic origin. As in other central nervous system structures, gap junctions provide the main communication pathway between the IO neurons (Figures 1(c) and 1(d)). Different types of γ-aminobutyric acid-A receptor subtypes have been identified on the soma and dendrites of IO neurons (Figure 3(f), green). The other half of the cerebellar nuclear system projects as excitatory afferents to the brain stem nuclei, spinal cord, and thalamus, the last as part of the cerebrocerebellar system.

The second major input to the cerebellum is provided by the mossy fibers that innervate PCs through the mossy fiber–parallel fiber system (Figure 1(a)). Activation of this pathway elicits simple spikes in PCs.

Electrophysiology

The function of the olivocerebellar system in motor execution seems to be closely related to so-called physiological tremor. This can be easily observed by measuring the velocity of human finger movements (Figure 2(a)). Vallbo and Wessberg reported that oscillations at 8–10 Hz represent movement steps where their rather stereotyped frequency is close to fixed and is independent of movement speed.

Electrophysiologically, inferior olive neurons are characterized by their ability to generate 'low-threshold' and high-threshold calcium spikes (see Figure 2(d)) as well as spontaneous subthreshold membrane potential oscillations near 10 Hz (Figure 2(b)). These oscillations modulate spike initiation, and so 'spontaneous' action potentials are generated and fire at 1–10 Hz (Figure 2(d)).

Very significantly, the phase of subthreshold oscillations may be influenced by activity, as shown in Figure 2(b) from an *in vitro* experiment. Indeed, extracellular stimulation of the nearby white matter may generate full action potential followed by membrane hyperpolarization (Figure 2(b), boxed area). If it is strong enough, such a stimulus will reset the oscillatory phase, but not the amplitude, of subthreshold oscillations in a large proportion of neurons, and being electrically coupled, they tend toward oscillatory entrainment (Figure 2(c)). Dynamically constrained groups of IO neurons oscillating in phase can synchronously activate a population of PCs and thereby control patterns of synchronous activity in the cerebellar output during motor coordination.

This ability of the olivocerebellar system to generate rhythmic activity has been attributed to the intrinsic oscillatory properties of the IO neurons themselves, and their electrotonic coupling contributes to the synchronicity of activation. Several types of voltage-gated calcium and potassium channels, in addition to those underlying fast action potential generation, enable IO cells to oscillate and fire rhythmically. These include a high-threshold Ca^{2+} channel ($Ca_V2.1$), a somatic low-threshold Ca^{2+} channel ($Ca_V3.1$), a Ca^{2+}-activated K^+ channel ($K_Vx.x$), and a hyperpolarization-activated cationic channel ($K_Vx.x$).

When IO cells fire, the resulting PC complex spikes (Figure 2(e)) display a close to 10 Hz rhythmicity. In fact, *in vivo* simultaneous recordings from many PCs have demonstrated that groups of PCs fire synchronous complex spikes (see Figure 4). Such synchronous activation of multiple PCs by the IO nucleus suggests that clusters of IO neurons fire rhythmically and in unison as expected from the fact that they are electrically coupled to each other.

In fact, the electrotonic coupling has been proposed to play a crucial role both in synchronizing IO oscillations and in generating groups of concurrently oscillating neurons. Modification of this coupling by γ-aminobutyricacidergic terminals is thought to influence the spatial grouping of the PC complex spike activity over the cerebellar cortex. This dynamic modulation of the geometrical distribution of Purkinje cell activation via the climbing fibers was found to be implemented by the inhibitory cerebellar nuclear inputs to the IO that shunt electrotonic coupling at the IO glomeruli. Such inhibitory input can control the degree and distribution of synchronous oscillatory activity in the IO nucleus and cerebellum by uncoupling gap junctions (Figure 1(c)). Cerebellar nuclear cells in turn are also known to have low-threshold calcium-dependent activity that can be modulated at close to 10 Hz.

Voltage-Dependent Dye Imaging

The spatial profile of synchronized IO neuron oscillations has been studied with voltage-sensitive dye imaging (Figure 5(a)), the method of choice for studying the geometrical distribution of activity in large neuronal ensembles (34). The imaging response comprises an initial change in background fluorescence (induced by direct electrical stimulation) followed by several oscillatory waves that spread throughout the IO nucleus (Figures 5(b) and 5(c)). These ensemble IO oscillations were calcium derived and were also observed in concurrently obtained intracellular recordings from IO neurons.

These optically recorded IO oscillations comprised clusters of coherent neuronal activity in which each

Figure 2 (a) Traces showing different degrees of finger movement. Lower traces show electromyograpic recording of muscle showing gradation of activity with finger movement. Plot shows that the frequency of activity is independent of movement amplitude. (b) Intracellular recording of spontaneous oscillations at 2 Hz interrupted by an extracellular stimulus. After extracellular stimulation (marked with an arrowhead), oscillations disappeared for 750 ms (boxed area) and then resumed. The membrane potential was at −60 mV. (c) Left, intracellular recordings of spontaneous (dashed black line) and stimulus-evoked (solid black line) oscillations from the same cell are superimposed. Their corresponding power spectra are shown below. Note that extracellular stimulation modified only the phase of spontaneous oscillations without affecting its amplitude and frequency. Right, six individual intracellular traces of stimulus-evoked oscillations from the same cell are superimposed. Each trace is shown in a different color. Their corresponding power spectra are displayed below. In every recording, the frequency of stimulation-evoked oscillation was the same (2.0 Hz). Note that in each trace, the stimulation-induced shift in the cell's oscillatory rhythm is remarkably similar. Oscillations are clearly seen after the stimulus-induced reset, but they can barely be detected before stimulation. Calibration bar: 1 mV; (b) 500 ms. Calibration bar: 1 mV; B, 1 s; (c), 500 ms. (d) Intracellular recordings of spontaneous activity in an IO neuron. 1, Four spikes are followed by a subthreshold calcium spike; 2, longer burst of spikes; 3, superposition of spikes in two different times, showing that the spike duration progressively decreased until spike generation failed; 4, same as in 2, showing somatic calcium spikes rise from afterhyperpolarization. cluster was a localized functional event (Figure 5(c), second and third image panels). These oscillatory groupings of cells began in several independent regions of the slice, but they had the same oscillation frequency and were phase coherent. Such phase coherence is most clearly observed after the phase reset triggered by an electrical stimulus. These optically recorded oscillations were highly repeatable in

Figure 3 (a–e) Intracellular recordings from cerebellar nuclear neuron in isolated brain preparation showing change in inhibitory postsynaptic potential (IPSP) elicited by white matter stimulation. (a–d) Increasing stimulus strength shows progressive appearance of early excitatory postsynaptic potential (EPSP)–IPSP (arrowhead in (d)) and late EPSP–IPSP (arrow in (d), dots in (c) and (d)). (e) Superimposed responses showing early (arrowhead) and late (arrow) IPSPs. (f) Drawing of olivocerebellar network showing the production of rhythmic activity in the presence of harmaline in Purkinje cells (PC; blue), inferior olivary (IO) cells (red), and cerebellar nuclear cells (green). Rhythmic activity in IO cells is synchronized by gap junctions. This elicits rhythmic and synchronous climbing fiber (CF) activation of PC and collateral activation of inhibitor cerebellar nuclear cells (ICN) and excitatory cerebellar neurons (ECN). PC activation elicits IPSPs in nuclear neurons that are followed by rebound activation. Activation of ECN is transmitted to the rest of the central nervous system through the cerebellar peduncles. Activation of ICN modulates the excitability of IO cells through the γ-aminobutyricacidergic nucleo-olivary pathway. Adapted from Llinas R and Muhlethaler M (1988) Electrophysiology of guinea-pig cerebellar nuclear cells in the *in vitro* brain stem-cerebellar preparation. *Journal of Physiology* 404: 241–258.

time and space; the average of three oscillatory cycles had the same spatiotemporal profile as that of the individual oscillations (compare the second and third image panels in Figure 5(c)).

The frequency of optically recorded clusters, 1.6–6.5 Hz, was within the expected range for intracellularly recorded subthreshold oscillations. The optically recorded oscillatory clusters had a dynamic spatial organization. They changed their size depending on the oscillation phase, so that they embraced the largest area during the upward phase of the oscillations (Figure 5(c), second image panel, third image). Hence, each cluster comprised a core region and the adjoining area. The core region demonstrated a close-to-constant size, but the extent of the adjoining area was phase dependent.

The optical data, therefore, indicate that at the network level, the IO nucleus is organized into functionally coupled activity clusters. Each cluster contains several hundred cells, which may act in unison to simultaneously activate groups of cerebellar PCs, as has been previously observed with multiple electrode recordings. Further, considering the distribution of complex spike activity in the cerebellum cortex, these clusters are very likely responsible for the synchronized activation of the PCs observed in multielectrode experiments (Figure 4). Further, clustering is a direct consequence of the combined electrotonic and intrinsic properties of coupled IO neurons as supported by computational modeling of IO neuronal ensembles.

Figure 5 (a) Drawing showing method for voltage-sensitive dye imaging. (b) A complete time course of optical responses for four pixels. Locations of the pixels are marked with circles of different color in (c). The optical response comprised an initial response to a train of extracellular stimuli (two stimuli at 10 Hz) followed by three oscillatory cycles. The frequency of the optically recorded oscillations was 4 Hz. (c) Several multiframe displays for each of the regions marked in (b). Only the area of the inferior olive (IO) is shown. Position of the stimulating electrode is indicated. The color bar gives the color scale, with dark purple corresponding to lowest fluorescence and red corresponding to the highest fluorescence from 0 to 2.7×10^{-3} $\Delta F/F$. 1, Response of the IO nucleus to the first stimulus. 2, Location and spatial spread of one cycle of the ensemble oscillations. The oscillations emanate from several clusters of closely spaced cells throughout the IO (see the change in amplitude with time). These clusters are highly repeatable from cycle to cycle over an oscillation sequence. 3, An average of three oscillatory cycles further underlines the stability of fluorescent clusters. (d) Frames of imaged ensemble neuronal oscillating clusters in control conditions (left) and after the addition of 20 μm of picrotoxin (right) are shown. Several representative clusters in the lower right part of the IO are outlined in black. Clusters were defined as areas with pixel values above the selected threshold level. After picrotoxin, an additional threshold level of higher value was chosen to delineate the highest areas of activity. (e) Clusters' contours shown within the boxed areas (1 × 1 mm) are enlarged for the control condition (right panel) and after the addition of picrotoxin (middle panel). (Left) Areas shown in right and middle panels are superimposed. Control clusters are shown in blue, picrotoxin clusters of lower threshold are shown in yellow, and those of higher threshold are shaded in red. Overlapping regions of control clusters and picrotoxin clusters of lower threshold are shown in green. Note that picrotoxin significantly increased the size of clusters by activating additional regions and merging several small areas into larger activation areas. (f) Intracellular recording from an IO neuron showing spontaneous subthreshold oscillations before (black) and after (purple) the addition of 20 μmol l^{-1} picrotoxin. Adapted from Leznik E, Makarenko V, and Llinas R (2002) Electrotonically mediated oscillatory patterns in neuronal ensembles: An in vitro voltage-dependent dye-imaging study in the inferior olive. *Journal of Neuroscience* 22: 2804–2815.

Previous *in vivo* multielectrode experiments have shown that synchronized complex spikes are primarily observed among PCs located within the same parasagittal bands. Groups of IO neurons that define such parasagittal bands comprise up to several hundred neurons. Because this number is on the same order of magnitude as the calculated number of cells in our fluorescent clusters, it has been proposed that such optical measurements might reflect the ensemble physiological properties formerly observed with multiple recordings at the PC level. Hence, each IO cluster can control activity of a single parasagittal band in the cerebellum. Simultaneous activation of several IO clusters would result in coherent complex spike activity between different parasagittal bands, as observed during coordinated movements.

In conclusion, dimensions of clusters are probably determined by the IO electrical coupling coefficient and therefore by the magnitude and distribution of the return inhibition from the cerebellar nuclear feedback, as has been demonstrated in previous *in vivo* experiments and supported by mathematical modeling.

Modeling Inferior Olive Clusters

As mentioned above, the IO nucleus appears to play a significant role in the temporal binding of organized movement. The anatomical and physiological properties of these neurons are sufficiently well established to warrant the development of quantitative computer modeling of both single cell and network properties. Nonlinear mathematical analysis of experimental data from single neurons (Figure 6) and from coupled pairs of IO neurons indicates that despite being almost perfectly periodic, IO oscillations have a weakly chaotic nature. This property markedly increases the sensitivity of the dynamics independent of input origin. It is surprising that in this neuronal system, the chaotic degree of the dynamics does not increase (i.e., the Lyapunov spectrum remains practically the same) regardless of the number of elements in the system. Indeed, the synchronization itself was found to belong to a very specific type, known as chaotic phase synchronization and observed in a notoriously robust dynamic system.

That the IO nucleus plays a role in movement coordination is shown by its ability to control functional

Figure 6 Reconstruction of attractor from a time series of membrane potential for a single neuron. The attractor has a structure close to a limit cycle with a regular periodic trajectory. (a) Average mutual information and (b) false nearest neighbors methods were used to reconstruct (c) the attractor and (d) Lyapunov exponents. Exponent values (small positive, 0, and negative) indicate that the system displays low-dimensional chaotic dynamics. Adapted from Makarenko V and Llinas R (1998) Experimentally determined chaotic phase synchronization in a neuronal system. *Proceedings of the National Academy of Sciences of the United States of America* 95: 15747–15752.

parameters in time, locality, and number of degrees of freedom. It has been proposed that to meet these requirements, the IO uses its intrinsic oscillatory properties for temporal organization, that is, its ability to organize, support, and change cluster size and location to control spatial organization. In addition, its weakly chaotic properties exhibit the necessary fluidity to control the number of degrees of freedom by rapidly modulating the phase relation between clusters.

Results from computer simulation of single neurons and a network of a considerable number of neurons support this view of IO functional dynamics. The simulated network of locally coupled neurons demonstrated that clustering had features similar to those observed in the *in vitro* IO studied in brain stem slices with voltage-sensitive dye imaging. The main conclusion from this group of studies is that the IO is a truly integrated system in which the neuronal network and the macroscopic dynamic features (cluster permutation agility) are so well matched that their control properties almost match cellular time constants. This allows the system to effectively control innumerable movements without overloading brain function.

Implications Concerning Olivocerebellar Motor Control

The synchronous, rhythmic firing of the olivocerebellar system has led to the hypothesis that climbing fibers may perform a timing function in motor coordination. Thus, IO activity would provide a timing signal for the motor system by generating synchronous and rhythmic activation of the cerebellar nuclei. The synchronized inhibitory barrage originated by climbing fiber activation of PC complex spikes thus controls the timing of the output of the cerebellar nuclei. Evidence to support the motor timing proposal includes the following: synchronous firing of a population of PCs in anesthetized and awake animals, recordings of rhythmic inhibitory potential in the deep cerebellar nuclei, and temporal correlation between firing of the olivocerebellar system and execution of movements.

To this effect the IO seems to be dynamically organized in clusters of synchronously oscillating neurons that can generate rhythmic and coherent activity of the cerebellar output. Ultimately, as further insight is gained into the oscillatory property of neurons and their relation to macroscopic motor execution and control, a general message becomes apparent: The dynamic properties of single neurons and the channel kinetics that generate them seem to hone the 'impedance matching' from the molecular to the macroscopic levels to the point that our motor timing is nothing other than the echo of our IO oscillation.

Operant Conditioning of Reflexes

J R Wolpaw and X Y Chen, New York State Department of Health and State University of New York, Albany, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Spinal cord reflexes are simple behaviors produced by central nervous system (CNS) pathways that lie entirely within the spinal cord. The sensory afferent fibers that evoke these reflexes enter the spinal cord and activate spinal motor neurons directly or through a chain of one or more spinal interneurons. Although these pathways are entirely spinal, they are affected by descending pathways from the brain, either directly or through other spinal interneurons. Through these descending pathways, the brain exerts both short-term and long-term influence over spinal cord reflex function. In the short term, the brain rapidly adjusts spinal reflexes to suit the needs of different tasks (e.g., standing vs. walking vs. running). In the long term, it gradually shapes spinal reflexes during development, during skill acquisition later in life, and in response to CNS trauma and disease. The long-term changes that the brain induces in spinal cord reflexes involve activity-dependent plasticity in the spinal cord itself.

The spinal cord is the simplest and most technically accessible part of the mammalian CNS. Thus, spinal cord reflexes, the brain's influence over them, and the spinal cord plasticity this influence produces provide the basis of a powerful experimental protocol for studying the mechanisms and substrates of learning. By rewarding a subject (whether monkey, rat, mouse, or human) for a larger or smaller reflex, this protocol operantly conditions the subject to maintain descending influence appropriate to the reward contingency (i.e., descending influence that increases or decreases reflex size). In a laboratory analog of the brain's long-term shaping of spinal reflexes during normal life, the continued maintenance of this appropriate descending influence produces plasticity in the spinal pathway of the reflex and thereby changes reflex size appropriately. According to a standard definition of a skill as an adaptive behavior acquired through practice, the larger or smaller reflex is a simple motor skill, and the plasticity directly responsible for it is located in the spinal cord, where it is accessible to detailed physiological and anatomical analyses.

A lengthy series of studies using this protocol has provided important new insight into the remarkably complex spinal and supraspinal plasticity underlying the acquisition and maintenance of a simple motor skill. Those studies also provide the basis for a promising new approach to restoring effective motor function after spinal cord injury or other trauma or disease. This work has focused on operant conditioning of the simplest spinal cord reflex, the spinal stretch reflex (SSR), and its electrical analog, the Hoffmann (H)-reflex. These reflexes are produced largely by a two-neuron monosynaptic pathway consisting of the primary afferent fiber from the muscle spindle, its synapse on the alpha motor neuron, and the alpha motor neuron. This pathway is shown in Figure 1. In the SSR, the primary afferent is excited by muscle stretch; in the H-reflex, it is excited directly by electrical stimulation of the nerve.

The Conditioning Protocol and Its Results

Figure 2(a) shows the standard conditioning protocol as it is implemented in the rat. The monkey, human, and mouse H-reflex and SSR conditioning protocols are similar. The rat is chronically implanted with fine-wire electromyographic (EMG) recording electrodes in the soleus muscle and a nerve cuff on the posterior tibial nerve (which innervates the soleus). The wires connect through a head-mounted tether and a commutator to an amplifier and stimulator. The tether allows the rat to move freely about the cage and remains connected continuously 24 h day^{-1}. Whenever the ongoing background EMG in soleus remains in a defined range for several seconds, a stimulus through the nerve cuff at M response (direct muscle response) threshold elicits the H-reflex. H-reflex size is measured as EMG in the H-reflex interval (typically 6–9 ms after the stimulus). For the first 10–20 days, data are collected in the control mode to determine the initial size of the H-reflex. Then, the rat is switched to the up-conditioning (HRup)-mode or the down-conditioning (HRdown)-mode, in which a food-pellet reward is given when H-reflex size is above (HRup-mode) or below (HRdown-mode) a criterion value.

This protocol has two crucial features. First, soleus background EMG is stable throughout, so that the background, or prestimulus, level of excitation of the soleus motor neuron pool does not change. Second, the H-reflex is elicited at unpredictable times. Thus, because the H-reflex is the earliest possible CNS response to the nerve cuff stimulus, the rat can change H-reflex size only by being prepared ahead of time, that is, by maintaining mode-appropriate descending influence over the wholly spinal pathway of the reflex. It is this continued descending influence that gradually

Figure 1 Monosynaptic pathway of the spinal stretch reflex (SSR) and its electrical analog, the H-reflex. The pathway comprises the Ia afferent neuron from the muscle spindle, its synapse on the alpha motor neuron, and the motor neuron itself. When the Ia afferent is excited, it excites spinal motor neurons innervating the same muscle and its synergists. If the afferent is excited in the normal fashion, that is, by muscle stretch, the muscle's response is the SSR. If it is excited by direct electrical stimulation, the response is the H-reflex. The SSR and the H-reflex are measured by electromyograph or by their mechanical effects. While their pathway is wholly spinal, both reflexes are affected by descending influences on the Ia terminal (exerted presynaptically) and on the motor neuron, and the SSR is also affected by descending control of muscle spindle sensitivity. As a result of this descending influence and the plasticity it produces in the spinal cord, the brain can gradually modify these spinal reflexes so as to increase reward. From Wolpaw JR (1997) The complex structure of a simple memory. *Trends in Neurosciences* 20: 588–594.

produces the activity-dependent plasticity in the spinal cord that underlies H-reflex change.

The primary observation is that imposition of the HRup- or HRdown-mode changes reflex size appropriately over days and weeks. Figures 2(b) and 2(c) show the progressive SSR or H-reflex increases and decreases as they occur in rats, monkeys, humans, and mice. Reflex change appears to occur in two phases, a small, rapid phase-1 change in the first few hours or days and a much slower phase-2 change that continues for weeks. In Figure 2, this two-phase course is seen most clearly in the monkey SSR data. Phase 1 probably reflects rapid mode-appropriate change in descending influence over the spinal arc of the reflex. This mode-appropriate change in descending influence is operantly conditioned by the reward contingency. In contrast, phase 2 appears to reflect the gradual spinal cord plasticity produced by the long-term continuation of the descending input responsible for phase 1. This spinal cord plasticity survives for some days after removal of all descending influence. This indicates that the conditioning changes the spinal cord.

The Complex Spinal Cord Plasticity Accompanying Reflex Conditioning

H-reflex conditioning is associated with plasticity at multiple sites in the spinal cord. Downconditioning produces a positive shift in motor neuron firing threshold and a reduction in axonal conduction velocity. These two changes together suggest that a positive shift in sodium channel activation voltage occurs throughout the motor neuron soma and axon. As illustrated in Figure 3(a), the change in threshold can account in large part for the smaller reflex. Although activity-dependent synaptic plasticity is often assumed to be the basis of learning, the shift in motor neuron threshold produced by down-conditioning seems to be an example of neuronally based (as opposed to synaptically based) learning. The threshold change could also account for the decrease in motor neuron axonal conduction velocity that is associated with H-reflex down-conditioning (Figure 3(b)). In addition to this neuronal plasticity, H-reflex conditioning modifies Ia afferent motor neuron synapses and several other populations of synaptic terminals on the motor neuron. The effects on GABAergic terminals are particularly striking (Figure 3(c)). Conditioning probably changes spinal cord interneurons as well, either those in di- or trisynaptic pathways that can contribute to the H-reflex and/or those that convey descending influence to the motor neuron. At present, it is most likely that up-conditioning is due to change in oligosynaptic primary afferent input to the motor neuron. Thus, down-conditioning and up-conditioning are probably not mirror images of each other but rather have different mechanisms. In addition to this complex plasticity in the spinal cord ipsilateral to the conditioned reflex, H-reflex conditioning also causes plasticity in the contralateral spinal cord. The precise location and nature of this contralateral plasticity are as yet unknown.

Complex Plasticity Is Necessary and Inevitable

Some of the complex plasticity accompanying reflex conditioning appears to account for the behavioral change, that is, the larger or smaller H-reflex, produced by the conditioning protocol. For example, the positive shift in motor neuron threshold after down-conditioning explains why the H-reflex is smaller. Other changes, however, such as that on the contralateral side of the spinal cord, seem to be unrelated to the behavior, a smaller H-reflex that is the goal and most obvious product of the down-conditioning protocol. Nevertheless, these apparently inexplicable changes are probably both necessary and inevitable.

The spinal cord neurons and synapses affected by H-reflex conditioning support many other motor behaviors, such as locomotion. The plasticity underlying H-reflex conditioning (such as a positive shift in motor neuron firing threshold) is likely to disrupt

Figure 2 The reflex operant conditioning protocol and its results. (a) Soleus electromyograph (EMG) is monitored continuously (24 h per day) in a rat with chronically implanted EMG electrodes and a tibial nerve cuff. The implant wires pass subcutaneously to a head-mounted connector and then through a flexible cable and a commutator to amplifiers and stimulator. The rat is able to move freely about the cage. Whenever the absolute value of its soleus EMG remains within a specified range for a randomly varying 2.3–2.7 s period, a nerve cuff stimulus elicits a threshold direct muscle (M) response and an H-reflex. For the first 10 days, the rat is exposed to the control mode, in which no reward occurs and the H-reflex is simply measured to determine its initial size. For the next 50 days, the rat is exposed to the up-conditioning or down-conditioning mode, in which a food-pellet reward occurs if the H-reflex is above (up-mode) or below (down-mode) a criterion value. Background EMG and M response remain constant throughout. Successful conditioning, defined as a change of at least 20% in the correct direction, occurs in 75–80% of the rats (the remainder change less than 20%). (b) The top graph shows average daily H-reflexes (± standard error) from successful up-conditioned (▲) and downconditioned (▼) rats for the control-mode exposure (i.e., days 10 to 0) and for the subsequent up-mode or down-mode exposure (i.e., days 0 to 50). Under the up-mode, the H-reflex rises gradually to about 175% of its initial value, while under the HRdown mode, it falls gradually to about 55%. The bottom graphs show average poststimulus EMG for representative days from an up rat (left) and a down rat (right) under the control mode (solid) and near the end of up-mode or down-mode exposure (dashed). The H-reflex is much larger after up-conditioning and much smaller after down-conditioning, while background EMG (indicated here by EMG at zero time) and M responses are unchanged. If a rat is switched from the up-mode to the down-mode or vice versa, the H-reflex change reverses in the same gradual fashion. (c) Average results for up-conditioning (▲) and down-conditioning (▼) of (left to right) monkey triceps surae H-reflex, monkey biceps brachii SSR, mouse triceps surae H-reflex, and human biceps brachii SSR. The courses of change are similar to those found in the rat. Error bars = standard error. Modified from Wolpaw JR (1997) The complex structure of a simple memory. *Trends in Neurosciences* 20: 588–594 and Carp JS, Tennissen AM, Chen XY, and Wolpaw JR (2006) H-reflex operant conditioning in mice. *Journal of Neurophysiology* 96: 1718–1727.

Figure 3 Examples of the multisite spinal cord plasticity underlying H-reflex conditioning. (a) Motor neurons on the conditioned side of H-reflex (HR) down-conditioned animals have more positive firing thresholds and slightly smaller Ia excitatory postsynaptic potentials (EPSPs). Together, these two findings can explain why the H-reflex becomes smaller. (b) Distributions of soleus motor neuron axonal conduction velocities in unconditioned (solid) and down-conditioned (dashed) rats. Down-conditioning has a comparable effect in monkeys. The more positive motor neuron firing threshold can explain this drop in conduction velocity. (c) Soleus motor neurons (dashed lines) from an unconditioned rat (top) and a down-conditioned rat (bottom), with arrows pointing to γ-aminobutyricacidergic (GABAergic) terminals on the somatic membrane. GABAergic terminals are detected by glutamic acid decarboxylase (GAD_{67}) immunoreactivity. After down-conditioning, soleus motor neurons have more GABAergic terminals, and these terminals are more densely labeled and occupy more of the somatic membrane. (a) Modified from Carp JS, Chen XY, Sheikh H, and Wolpaw JR (2001) Operant conditioning of rat H-reflex affects motoneuron axonal conduction velocity. *Experimental Brain Research* 136: 269–273. (b) Modified from Carp JS, Chen XY, Sheikh H, and Wolpaw JR (2001) Operant conditioning of rat H-reflex affects motoneuron axonal conduction velocity. *Experimental Brain Research* 136: 269–273.

these other behaviors. Thus, additional compensatory plasticity may be necessary to preserve these previously acquired behaviors in spite of the disruptive effects of the plasticity that underlies the conditioned reflex change. For example, the primary afferent input that produces the soleus H-reflex is a major contributor to the burst of soleus activity that helps support the stance phase of locomotion. As a result, when H-reflex up-conditioning or down-conditioning changes the size of the H-reflex, there are comparable effects on the soleus locomotor bursts: the burst becomes larger after H-reflex up-conditioning and smaller after H-reflex down-conditioning. Figure 4 shows this effect on the locomotor burst. It is likely to disrupt locomotion and thereby induce compensatory plasticity elsewhere in the spinal cord or brain that is necessary to preserve normal locomotion.

Furthermore, the fact that activity-dependent plasticity can occur at many sites throughout the CNS implies that H-reflex conditioning is likely to be associated with additional reactive (or downstream) plasticity. Such reactive plasticity is an inevitable result of the changes in activity caused by the plasticity directly underlying the H-reflex change and/or by compensatory plasticity. In sum, even a skill as simple as a larger or smaller H-reflex is necessarily and inevitably accompanied by a complex pattern of activity-dependent plasticity that goes well beyond the changes accounting for the modified H-reflex.

Supraspinal Control of the Spinal Cord Plasticity

The descending influence that is operantly conditioned by the protocol and changes the spinal cord is conveyed in the corticospinal tract (CST). Although CST transection alone does not have a long-term effect on H-reflex size, CST transection (or ablation of contralateral sensorimotor cortex, which is the origin of the CST) prevents both down-conditioning and up-conditioning.

Figure 4 Soleus H-reflex conditioning affects soleus activity during locomotion. Average right soleus locomotor bursts before (solid) and after (dotted) H-reflex conditioning from an up-conditioned (HRup) and a down-conditioned (HRdown) rat. The insets show the average right soleus H-reflexes elicited during the stance phase of locomotion before (solid) and after (dashed) conditioning. After conditioning, both the stance H-reflex and the soleus burst are smaller in the down-conditioned rat and larger in the upconditioned rat. Primary afferent excitation is a major contributor to the locomotor burst. Thus, the changes in the strength of this excitation that result from H-reflex conditioning affect the size of the burst. EMG, electromyograph; absol val, absolute value. Modified from Chen Y, Chen XY, Jakeman LB, et al. (2005) The interaction of a new motor skill and an old one: H-reflex conditioning and locomotion in rats. *Journal of Neuroscience* 25: 6898–6906.

Transection of other major descending tracts or of the dorsal column ascending tract does not impair conditioning. Furthermore, if the CST is transected in rats in which the soleus H-reflex has already been reduced by down-conditioning, the reflex decrease disappears within 5–10 days. Figure 5 illustrates this effect. It implies that the spinal cord plasticity underlying the smaller H-reflex can survive only a few days on its own.

Down-conditioning also requires the cerebellum. It does not occur in rats in which the cerebellar output nuclei dentate and interpositus have been ablated. The cerebellar contribution is mediated through cerebellar output to cortex rather than to spinal cord, since transection of the entire lateral column (which contains the rubrospinal tract) does not impair conditioning. The cerebellum is also needed for the long-term maintenance of conditioning. If the cerebellar output nuclei are ablated in rats in which the soleus H-reflex has already been reduced by down-conditioning, the reflex decrease persists for about 40 days and then disappears. This remarkable finding implies that the CST activity that maintains the spinal cord plasticity that directly underlies the H-reflex decrease depends on supraspinal plasticity that can survive for 40 days after loss of cerebellar influence, but not longer.

A Hierarchy of Plasticity

Figure 6 summarizes current knowledge and hypotheses concerning the complex multisite plasticity that is produced by H-reflex conditioning. Changes occurring both in the spinal cord and in the brain appear to constitute a hierarchy of plasticity: The reward contingency induces and maintains plasticity in the brain that produces the CST activity that induces and maintains the spinal cord plasticity that directly underlies the acquired skill, that is, a smaller or larger H-reflex. The existence of this hierarchy is revealed by the effects of specific lesions. The brain plasticity responsible for the CST activity that changes the spinal cord can survive 40 days after loss of cerebellar influence, and the spinal cord plasticity that directly underlies the smaller H-reflex can survive only 5–10 days after loss of the CST activity. This simple skill is acquired and maintained through a hierarchy of plasticity in the brain and spinal cord.

Comparable Plasticity throughout Life

The complex spinal cord plasticity associated with H-reflex conditioning is not simply a laboratory phenomenon. Gradual activity-dependent plasticity, driven by descending and peripheral inputs, shapes

Figure 5 The essential role of the corticospinal tract (CST) in maintenance of H-reflex down-conditioning. Average poststimulus electromyograph (EMG) from three rats for representative days: prior to down-conditioning (left); at the end of down-conditioning and prior to transection of the right column (LC rat), the corticospinal tract (CST rat), or the dorsal ascending tract (DA rat; center); and after transection and continued down-conditioning (Condit/Transect/Condit; right). All three rats decreased the H-reflex (H) in response to down-conditioning. LC or DA transection did not affect the H-reflex decrease. In contrast, CST transection led eventually to loss of the H-reflex decrease and to an H-reflex larger than the original, control-mode H-reflex. Background EMG (shown by the EMG at time zero) and muscle response (M) did not change over the course of study. From Chen XY and Wolpaw JR (2002) Probable corticospinal tract control of spinal cord plasticity in rats. *Journal of Neurophysiology* 87: 645–652.

spinal cord function during development and continues to adjust it throughout life. This plasticity establishes and maintains spinal cord pathways in a state that supports effective motor behaviors.

Early in life, descending input to the spinal cord guides the plasticity that leads to an adult spinal cord that has normal reflexes, supports standard motor skills like locomotion, and can also support specialized skills like dancing or playing the piano. Descending inputs and associated peripheral inputs establish normal patterns of spinal proprioceptive reflexes, flexion withdrawal reflexes, and autonomic reflexes. If perinatal supraspinal damage (e.g., cerebral palsy) disrupts descending input, infantile reflex patterns may persist into adulthood and contribute to disability. Figure 7(a) illustrates the effect of neonatal loss of descending input on flexion withdrawal reflexes of adult rats.

Mastery of motor skills later on in life is associated with changes in spinal cord reflexes comparable to those produced in the laboratory. Spinal reflexes are affected by the nature, intensity, and duration of past physical activity and by specific training regimens. SSRs and H-reflexes differ in athletes and nonathletes and among different kinds of athletes. Such differences may contribute to the skills possessed by these different groups. For example, both H-reflexes and disynaptic reciprocal inhibition in the leg are very small in professional ballet dancers. From the perspective of performance, the lessened peripheral influence on motor neurons indicated by the smaller reflexes might increase cortical control and thereby improve the precision of movement.

The impact of specific training regimens furnishes additional evidence of activity-dependent plasticity in spinal cord reflex function. For example, Figure 7(b)

Figure 6 The hierarchy of spinal and supraspinal plasticity underlying spinal reflex conditioning. The shaded ovals indicate the spinal and supraspinal sites of the plasticity associated with operant conditioning of the spinal stretch reflex (SSR) or its electrical analog, the H-reflex. MN is the motor neuron, CST is the main corticospinal tract, IN is a spinal interneuron, and GABA IN is a γ-aminobutyricacidergic (GABAergic) interneuron. Open synaptic terminals are excitatory, solid ones are inhibitory, half-open one could be either, and the subdivided one is a cluster of C-terminals. Dashed pathways imply the possibility of intervening spinal interneurons. The monosynaptic and probably oligosynaptic SSR/H-reflex pathway from Ia and Ib afferents to the motor neuron is shown. Definite (red shading) or probable (pink shading) sites of plasticity include the motor neuron membrane (i.e., firing threshold and axonal conduction velocity), motor unit properties, GABAergic inhibitory terminals, and C-terminals on the motor neuron, the Ia afferent synaptic connection, terminals conveying disynaptic group I inhibition or excitation to the motor neuron, and sensorimotor cortex. The essential roles of the CST (originating in sensorimotor cortex) and of cerebellar output to cortex are indicated. The spinal plasticity that is directly responsible for H-reflex conditioning appears to be induced and maintained by cortical plasticity that itself depends for its long-term survival on the cerebellum. Modified and updated from Wolpaw JR and Tennissen AM (2001) Activity-dependent spinal cord plasticity in health and disease. *Annual Review of Neuroscience* 24: 807–843.

shows that practice of a backward-walking task 15 min daily leads to a gradual change in the relationship between soleus H-reflex size and the time in the step cycle when the reflex is evoked. On the first day, the reflex is large well before the beginning of the soleus burst in the stance phase of the cycle. By the tenth day, the H-reflex is not detectable until the burst begins. the earlier reflex increase on the first day may compensate for uncertainty as to when the stance phase, with its need for greater soleus activity, will begin: the increased sensitivity of the reflex arc promotes rapid excitation by foot contact. The time of contact becomes more predictable as training progresses, so that this compensation is not necessary.

The reflex changes associated with aging are further evidence of adaptive spinal cord plasticity in adult life and in response to specific demands. Age-related alterations in reflex size and task-dependent reflex modulation (e.g., Figure 7(c)) are likely to reflect both the direct and indirect effects of aging; that is, the direct effects of aging on the reflex circuitry itself and the indirect effects of aging due to its effects elsewhere in the CNS or its effects on the peripheral sensory and motor apparatus involved in movement.

Therapeutic Uses of Spinal Reflex Conditioning

Activity-dependent changes in spinal cord reflexes contribute not only to normal motor behaviors but also to the complex motor disabilities that accompany spinal cord injuries and other chronic neurological disorders. Recognition of this additional importance has coincided with and has been encouraged by the energy and optimism now focused on efforts to restore spinal cord structure and function after injury. As described above, an effective adult spinal cord is the result of appropriate activity-dependent plasticity during development and throughout later life. In contrast, a spinal cord that is newly regenerated after injury is likely to display diffuse infantile reflexes and other disordered and ineffective behaviors. As a result, new methods for properly reeducating the regenerated spinal cord to restore more appropriate reflex patterns are likely to be required.

Operant conditioning of the H-reflex can be used to modify the performance of other behaviors that depend on the same pathways. For example, as Figure 4 illustrates, up-conditioning of the right soleus H-reflex increases the amplitude of the soleus locomotor burst during the stance phase of walking, and H-reflex down-conditioning decreases the burst. These effects are consistent with the established importance of primary afferent input in producing the locomotor burst.

Furthermore, H-reflex conditioning can improve locomotion after partial spinal cord injury. Midthoracic transection of the right lateral column (which leaves the CST intact) produces a lasting asymmetry in treadmill locomotion. The right stance phase appears to be abnormally short. As Figure 8 shows, H-reflex up-conditioning, which strengthens the right soleus burst, eliminates this asymmetry. These results suggest that reflex conditioning protocols might improve motor function in people with partial spinal cord injuries. Such protocols could be especially useful

Figure 7 Spinal cord reflexes change throughout life. (a) The direction of limb movements produced by flexion withdrawal responses to painful stimuli in normal adult rats and in adult rats that had undergone spinal cord transection just after birth. The direction of limb movement is almost always appropriate, i.e., away from the stimulus, in normal adults but is often inappropriate in transected adults. Neonatal spinal cord transection prevents descending input from gradually shaping normal (i.e., appropriate) flexion withdrawal responses. Modified from Levinsson A, Luo XL, Holmberg H, and Schouenborg J (1999) Developmental tuning in a spinal nociceptive system: Effects of neonatal spinalization. *Journal of Neuroscience* 19: 10397–10403. (b) Change in soleus H-reflex size as a function of time in the backward-walking step cycle as a human masters backward walking over 10 days. Top: Soleus electromyographic (EMG) activity on day 1 (solid) and day 10 (dashed) just before and after onset of the soleus burst associated with the stance phase of the step cycle. The dotted line shows soleus EMG during quiet standing. Bottom: H-reflex size (as % of size during quiet standing; QS) versus time in the backward-walking step cycle for days 1, 4, 7, and 10 of training. Soleus EMG does not change with training. In contrast, the marked increase in H-reflex size prior to the soleus burst that is seen on day 1 disappears by day 10. Modified from Schneider S and Capaday C (2003) Progressive adaptation of the soleus H-reflex with daily training at walking backward. *Journal of Neurophysiology* 89: 648–656. (c) Soleus H-reflexes in prone (black) and standing (gray) positions from a young person and an old person. In old participants, the H-reflex tends to be smaller and less affected by body position. Modified from Koceja DM, Markus CA, and Trimble MH (1995) Scale: Vertical scale is 2.4 mV for the young subject and 1.2 mV for the old subject; horizontal scale is 16 ms. Postural modulation of the soleus H reflex in young and old subjects. *Electroencephalography & Clinical Neurophysiology* 97: 387–393.

Figure 8 H-reflex conditioning may improve walking after spinal cord injury. The effects of H-reflex conditioning on locomotion in a rat with midthoracic transection of the right lateral column. The traces show the bursts of electromyographic (EMG) activity from right and left soleus muscles during treadmill locomotion before (top) and after (bottom) H-reflex up-conditioning has increased the size of the right soleus H-reflex. The presumed onsets of the right and left stance phases of locomotion are indicated by the solid and open circles, respectively. The short vertical dashed lines mark the midpoints between right burst onsets, which is where the left burst onsets should occur. Before H-reflex up-conditioning, the left burst onset occurs too early; after up-conditioning has strengthened the right soleus burst, the left burst onset occurs on time. Horizontal scale bar: 0.5 s; vertical scale bar: 100 and 150 μV for the right and left bursts, respectively. From Chen Y, Chen XY, Jakeman LB, *et al.* (2006) Operant conditioning of H-reflex can correct a locomotor abnormality after spinal cord injury in rats. *Journal of Neuroscience* 26(48): 12537–12543.

when regeneration becomes practical and precise methods for reeducating the regenerated spinal cord become essential in order to restore effective function. The recent demonstration that reciprocal inhibition can also be operantly conditioned extends the options for using reflex conditioning to improve motor function.

The Opioid System: A Short History

Discovery of the opioid system stems from the use and abuse of opium in ancient history. Opium, extracted from poppy seeds (*Papaver somniferum*; see Figure 1(a)), has powerful pain-relieving properties and produces euphoria. This substance has been used both medicinally and recreationally for several millennia. Morphine, named after the god Morpheus, is the most active ingredient of opium. The compound was isolated in 1805 and rapidly became the clinical treatment of choice to alleviate severe pain. Heroin was synthesized chemically by morphine diacetylation in the late 1800s and was commercialized as the first nonaddictive opiate to treat cough and asthma. The strong addictive properties of heroin were soon acknowledged, and both heroin and opium were prohibited in 1910. Today morphine remains the best pain-killer in contemporary medicine, despite a wide array of adverse side effects (respiratory depression, constipation, tolerance, and dependence). Heroin is a main illicit drug of abuse, and heroin addiction represents a major public health issue. Because of their extraordinarily potent analgesic and addictive properties, opiates have prompted scientists to seek to understand their mode of action in the brain.

In 1973, three independent teams showed that opiates bind to membrane receptors in the brain, and these receptors were named μ, δ, and κ a few years later. In 1975, two pentapeptides, Met- and Leu-enkephalin were isolated as the first endogenous ligands for these receptors. Many peptides followed, forming the opioid peptide family. Three distinct genes encoding the peptides were isolated in the late 1970s and early 1980s; three other genes encoding the receptors were cloned a decade later. In the mid 1990s the entire endogenous opioid system was characterized at the molecular level (Figure 1(b)).

Molecular Components of the Opioid System

The Peptides

Opioid peptide genes encode large precursor proteins, which are further cleaved into shorter peptides. All opioid peptides share a common N-terminal Tyr-Gly-Gly-Phe signature sequence, which interacts with opioid receptors. The preproenkephalin gene encodes several copies of the pentapeptide Met-enkephalin and one copy of Leu-enkephalin. This gene also encodes longer versions of Met-enkephalin. Notably, one of them, the opioid peptide bam22, activates opioid receptors via its N-terminal sequence while activating another receptor family known as sensory neuron-specific (SNS) receptors via its C-terminal part. The preprodynorphin gene also encodes multiple opioid peptides, including dynorphin A, dynorphin B, and neo-endorphin. The preprodynorphin-derived peptides all contain the Leu-enkephalin N-terminal sequence and basic amino acid residues in their C-terminal end. Finally the preproopioimelanocortin gene encodes a single opioid peptide, β-endorphin, among other peptides with nonopioid biological activity. β-endorphin is the longest opioid peptide (31 amino acids) and shows highly potent and long-lasting analgesic properties.

The Receptors

Opioid receptors are membrane receptors with a seven-transmembrane topology that belong to the large G-protein-coupled receptor (GPCR) superfamily. This family comprises several hundred members within the mammalian genome. μ-, δ-, and κ-opioid receptor genes constitute a GPCR subfamily, together with a fourth member encoding the orphanin FQ/nociceptin receptor. The last receptor and its endogenous ligand share high structural homology with the opioid receptors and peptides. However, the receptor does not bind opioids and the peptide orphanin FQ/nociceptin shows no affinity toward μ, δ, or κ receptors. All four receptor genes display similar genomic organization, with conserved intron–exon junctions, suggesting a common ancestor gene. These genes have been characterized throughout vertebrates, but cannot be identified earlier in evolution. The four genes are referred as to Oprm1 (μ), Oprd1 (δ), Oprk1 (κ), and Oprl1 (orphanin FQ/nociceptin) (genomic information is available on the NCBI website). The encoded receptors are classically named MOR, DOR, KOR, and ORL-1, respectively, throughout the literature. A novel nomenclature MOP (μ), DOP (δ), KOP (κ), and NOP (orphaninFQ/nociceptin) has recently been proposed by the International Union of Basic and Clinical Pharmacology (IUPHAR) to unify receptor abbreviations. Many single-nucleotide polymorphisms have been identified in both coding and regulatory sequences of human opioid receptor genes, and large genetic investigations are underway to associate haplotypes with neurological or psychiatric diseases. At present, coding

Figure 1 The opioid system: (a) exogenous opiates activate opioid receptors; (b) the endogenous opioid system. In (a), morphine is the main active ingredient of opium and has strong analgesic and addictive properties, which result from a direct interaction of the drug with opioid receptors. In (b), the endogenous opioid system is a neuromodulatory system. The three opioid receptors naturally interact with a family of opioid peptides, produced by proteolytic cleavage of three large precursor proteins. Receptors and peptides are broadly expressed throughout the nervous system and control nociceptive pathways (pain), mood, well-being (hedonic status), and responses to stress. The system also controls respiration, gastroinstestinal motility, and endocrine and immune functions.

polymorphisms as well as silent or noncoding polymorphisms that may influence receptor expression levels in the brain are under study.

Physiology of the Opioid System *In Vivo*

Opioid peptides and receptors are strongly expressed in the limbic system, as well as in nociceptive pathways and along the hypothalamic–pituitary–adrenal axis. In these neural circuits, the opioid system regulates addictive and emotional behaviors, and controls responses to pain or stress.

Pharmacology

Three decades of pharmacology have demonstrated an analgesic activity for all three μ, δ, and/or κ agonists. Generally, opioid analgesics used in the clinic are μ agonists. These compounds show strongest efficacy in the treatment of severe acute pain, but their activity remains variable in situations of chronic pain. κ agonists are potential candidates in the treatment of visceral pain. Significantly, studies of μ and κ compounds have highlighted opposing activities of μ and κ agonists on mood. μ agonists show potent rewarding properties and abuse liability, whereas κ agonists are strongly dysphoric. The latter activity has hindered the development of centrally acting κ agonists for pain control in the clinic. The pharmacology of δ agonists has shown slower progress. The notion that δ agonists may represent useful analgesics with low abuse liability has been proposed for many years and is currently being explored.

Genetics Approach

For a decade, mice lacking μ, δ, or κ receptors, as well as preproenkephalin, preprodynorphin, or β-endorphin, have been created by gene-targeting (knockout mice). Single mutant mice, or even the triple receptor knockout mice, are viable and fertile and show no obvious developmental deficit, indicating that the opioid system is not essential for survival. These mutant mice have been extensively analyzed either for spontaneous behaviors or in response to opioid and nonopioid drugs. Parallel to the pharmacology, this genetic approach has clarified the specific contribution of each molecular component of the opioid system in opioid-controlled physiology and behaviors *in vivo*. In particular, the comparative analysis of μ, δ, and κ knockout mice has clearly shown very distinct activity patterns for each receptor *in vivo* (Figure 2). Similar comparisons are currently underway for peptide knockout mice. Main conclusions from gene knockout mice are the following.

μ receptors represent the primary molecular target for morphine *in vivo* and mediate both beneficial and adverse effects of the most broadly used opiate. μ receptors also mediate the rewarding properties of nonopioid drugs of abuse including cannabinoids, alcohol, and nicotine or even natural reinforcers such as social interactions. μ receptors therefore represent a key molecular trigger for reward, and most likely contribute to the initiation of addictive behaviors. κ receptors, as predicted by the pharmacology, mediate dysphoric activities of both κ opioids and cannabinoids and oppose μ receptors in regulating the hedonic tone. δ receptors are less directly involved in hedonic control. Very distinct from μ and κ receptors, δ receptors regulate emotional responses and show anxiolytic and antidepressant activity. This specific function of δ receptors is now confirmed both by gene knockout and pharmacological studies using SNC80, the only commercially available highly selective δ compound. Further analysis of δ knockout mice and the development of more selective compounds will probably reveal other activities of delta receptors.

μ, δ, and κ receptor-deficient mice all exhibit enhanced pain sensitivity. This indicates that the three receptors, activated by endogenous opioid peptides, tonically inhibit nociceptive responses. Noticeably,

Figure 2 Physiological role of opioid receptors and peptides *in vivo*. Opioid peptides show some, although weak, selectivity toward μ, δ, and κ receptors. A highly selective exogenous (morphine) or synthetic (SNC80 and U50488H) agonist is indicated for each receptor. The combination of pharmacological studies with gene-knockout approaches (targeted gene inactivation in mice) showed that each receptor controls specific neural responses. μ and κ receptors produce euphoria or dysphoria, respectively, whereas δ receptors control levels of anxiety and depressive-like behaviors (emotional reactivity). The activation of all three receptors inhibits pain (analgesia), but each receptor controls a distinct panel of pain modalities.

the phenotypes of mutant mice differ across pain assays. In models of physiological or acute pain, μ receptors modulate mechanical, chemical, and supraspinally controlled thermal nociception, whereas κ receptors modulate spinally mediated thermal nociception and visceral pain. Again, δ receptors differ from μ and κ receptors in that there is no obvious regulation of acute pain. In contrast, there is evidence for a role of δ receptors in reducing hyperalgesia in situations of inflammatory and neuropathic pain. These data, combined with many pharmacological studies, clearly demonstrate a specific role for each receptor in regulating the broad diversity of pain modalities.

Finally, due to the short half-life and structural similarity of the peptides, identifying a specific role for each endogenous opioid *in vivo* has been difficult. Data from opioid peptide knockout mice do not necessarily follow data from receptor knockouts, consistent with the notion that multiple peptides probably act at each receptor. Although affinity studies and pharmacological approaches suggest a relationship between β-endorphin and μ receptors, enkephalin and δ receptors, and dynorphin and κ receptors (Figure 2), knockout data provide a more complex picture. It is likely that the specific anatomical location of receptors and peptide release largely drive opioidergic synapse functioning.

Receptor Structure

Receptor Binding

Overall μ, δ, and κ receptors show a 60% amino acid sequence identity. Closest homology occurs within the seven-transmembrane helical core, which contains the opioid-binding pocket (Figure 3(b)). Extracellular domains, including three extracellular loops and the N-terminal domain, determine μ, δ, and κ selectivity. These domains differ strongly among receptors and probably act as a gate filtering μ, δ, and κ agonists or antagonists entering the binding pocket. Note that synthetic compounds have been developed with high μ, δ, and κ selectivity, whereas endogenous peptides show limited receptor preference (Figure 2).

Receptor Signaling

As in all GPCRs, opioid receptors convey extracellular signals within the cell by activating heterotrimeric G-proteins, which interact with cytoplasmic domains of the receptor. Agonist binding modifies helical packing of the receptor, and a rearrangement in the positioning of transmembrane domains 3, 6, and 7 has been proposed to drive the transition between inactive and active conformations of the receptor.

Figure 3 Opioid receptors: (a) receptors belong to the G-protein-coupled receptor superfamily with a seven-transmembrane topology; (b) three-dimensional computer model of the human δ-opioid receptor; (c) direct visualization of δ receptors in native neurons. As shown in (a), μ, δ, and κ receptors are highly homologous. Each receptor domain contributes to receptor function, as indicated. Regulation occurs immediately after the receptor is activated by an opioid agonist and includes receptor phosphorylation, uncoupling from the G-protein, and internalization. In (b), the seven-transmembrane helices are shown in red, and portions of extrahelical loops are in white. The binding pocket penetrates halfway within the helical bundle, and side chains of amino acid residues forming the main binding site are shown in blue and green. As shown in (c), hippocampal neurons extracted from a genetically engineered mouse endogenously produce fluorescent δ-opioid receptors. The receptor is observed at the surface of both cell bodies and processes of the neuron (see continuous green fluorescence on the plasma membrane, top). Exposure to the agonist produces receptor internalization, visible under the form of highly fluorescent dots within the neuron. Note the concomitant fading of surface fluorescence (bottom).

This helical movement modifies the receptor's intracellular structure, hence the receptor–G-protein interaction. Intracellular loops of the receptor form a large part of the receptor–G-protein interface. These intracellular receptor domains are almost identical across μ, δ, and κ receptors, consistent with the fact that all three receptors interact with inhibitory G-proteins of the G_o/G_i type. G-protein subunits dissociate from the activated receptor and, in turn, modulate intracellular effectors and pathways.

Several opioid-evoked signaling events have been identified both in transfected cells and native tissues. Opioids inhibit voltage-dependent Ca^{2+} channels or activate inwardly rectifying potassium channels, thereby diminishing neuronal excitability. Opioids also inhibit the cyclic adenosine monophosphate (cAMP) pathway and activate mitogen-activated protein kinase (MAPK) cascades, both of which affect cytoplasmic events and transcriptional activity of the cell. Overall, opioids inhibit neurons by decreasing either neuronal firing or neurotransmitter release, depending on the post- or presynaptic localization of the receptors. Finally, opioid receptors are expressed on both excitatory and inhibitory neurons and can therefore exert inhibition or disinhibition within neural circuits.

Regulation of Receptor Signaling

The C-terminal domain differs largely across opioid receptors. Together with intracellular loops, this receptor domain contributes to receptor–G-protein coupling. Significantly, both the C-terminus and intracellular loops also interact with other cellular effectors following receptor activation. Effectors include receptor-specific (G-protein-coupled receptor kinase (GRK)) or-nonspecific (protein kinase A (PKA) and protein kinase C (PKC)) kinases, arrestins that act as adaptors between the receptor and the endocytic machinery, and other recently identified proteins.

These interacting proteins drive the desensitization of receptor signaling, which typically occurs as an adaptive response after receptor stimulation. Desensitization mechanisms include receptor phosphorylation and uncoupling from the G-protein, as well as receptor endocytosis (Figure 3(c)) and redistribution between the cell surface and intracellular compartments. Largely determined by C-terminal epitopes, these dynamic phenomena differ across μ, δ, and κ receptors. Many studies have addressed the mechanisms of opioid receptor trafficking and desensitization in cellular models and, more recently, *in vivo*. At present, studies on native neurons suggest that agonist-stimulated δ receptors are mainly targeted toward degradation pathways after endocytosis, whereas internalized μ receptors are resensitized in early endosomes and rapidly recycle back to the cell surface. Understanding the dynamic aspects of receptor trafficking to and from the cell surface has become a major field in GPCR research.

Chronic Opiates

Regulatory events that occur at the receptor level, as already described, represent adaptive mechanisms that classically contribute to cellular homeostasis under acute agonist stimulation. Chronic exposure to opiates, however, has long-term consequences, which lead to strong and perhaps irreversible alterations of brain functioning at the cellular, synaptic, and network levels. Behaviorally, these adaptations are manifested by tolerance, defined as a reduced sensitivity to the drug effects, and dependence revealed by drug craving and withdrawal symptoms. Many efforts have been made for several decades to understand the molecular basis of these elaborate responses to chronic opiates. Modifications of opioid receptor-associated ion channels and second-messenger pathways have been demonstrated in several brain areas. Also several protein kinases, including PKA, PKC, and calcium/calmodulin-dependent protein kinase (CaMK)II; glutamate receptors; cytoskeleton proteins or neurotrophic factors are involved. Finally opposing neurotransmitter systems – called anti-opioid systems – are recruited. Integrating these observations into a coherent explanation for tolerance and dependence *in vivo* remains a challenge.

Opioid Receptor Heterogeneity

The Existence of Opioid Receptor Pharmacological Subtypes

Opioid receptor pharmacology is complex and the existence of multiple μ, δ, and κ receptor types has been proposed since the early 1970s. Gene cloning led to the characterization of only three receptor genes, and the molecular basis for pharmacological diversity has long remained a matter of debate. Alternative splicing has been reported, but it has been extremely difficult to establish the biological relevance of these alternative transcripts *in vivo* and to correlate their existence with the multiple opioid receptor subtypes that were described earlier by the pharmacology. Today, it is admitted that the three main Oprm1-, Oprd1-, and Oprk1-encoded receptors are highly dynamic proteins, which may indeed account for the wide diversity of pharmacological subtypes.

Three Receptor Proteins, Many More Cellular Responses

There are several ways to explain pharmacological heterogeneity of opioid receptors. First, increasing evidence supports the notion that μ, δ, and κ receptors may adopt multiple active conformations. Mutagenesis data suggest the existence of multiple binding modes for opioids within the binding pocket. Further, signaling studies in cellular models show that receptor activation and subsequent regulations are strongly drug-dependent. Hence the ligand–receptor complex, rather than the receptor itself, determines the ultimate physiological cellular response. A second source of heterogeneity is the direct cellular environment of the receptor. Heterotrimeric G-proteins differ across cell types, and the number of possible G-protein-associated signaling pathways has expanded dramatically. The variable combinations of G-protein subunits and the nature of associated signaling networks necessarily generate neuron-specific, or even neuron compartment-specific, responses. Also, many regulatory proteins directly interact with the receptor C-terminal tail (as already discussed) and potentially influence opioid-receptor pharmacology, as was demonstrated for several other GPCRs. A third potential receptor modulator is another receptor molecule. The possibility that GPCRs exist as dimeric or oligomeric complexes has gained evidence in the recent years. Co-expression data suggest that the physical association of opioid receptors either as homodimers or heterodimers, or even with other GPCRs, creates novel receptor entities with unique pharmacological properties, which increases opioid receptor heterogeneity. Whether receptor dimerization truly modulates opioid pharmacology *in vivo* remains an important question.

In conclusion, molecular approaches have provided a novel view of opioid receptors. The receptor is now considered a dynamic multicomponent unit rather than a single protein entity. It is likely that the complexity of opioid responses will extend beyond the previously

reported pharmacological subtypes as *in vivo* molecular pharmacology develops. Rational design of opioid compounds that activate a specific subset of μ, δ, or κ receptor-associated signaling pathways is a possible strategy for developing novel drugs of high therapeutic value and low adverse activities, but this still remains a far distant goal.

Conclusion

The last decade in opioid research has led to a better understanding of the genetic basis of opioid-controlled behaviors and physiology. It has also opened avenues toward the development of novel therapeutic opioids in the field of chronic pain, emotional disorders, and addictive diseases. Recombinant technologies have allowed high-throughput screening for novel opiate compounds, the detailed molecular analysis of receptor structure and function, and the identification of associated proteins regulating receptor signaling.

Ongoing studies have returned to analyzing opioid receptor and peptides operating in their physiological environment, using molecular and genetic tools as well as high-resolution imaging techniques. There is a need to identify neural sites where opioid peptide release and subsequent opioid receptor activation controls nociceptive, emotional, and motivational circuits. Also, it is important to characterize signaling pathways that are relevant to specific behavioral or physiological responses to opioids *in vivo*. In addition, novel insights into brain function will arise from understanding the interactions of the opioid system with other neurotransmitter systems. For example, whether the opioid system interacts with the cannabinoid system or anti-opioid systems at the molecular, cellular, or circuit level remains an open question. Last, the elucidation of molecular and network adaptations to chronic opiates will undoubtedly shed light on the general mechanisms of brain plasticity.

What Is Opsoclonus–Myoclonus Syndrome?

Opsoclonus–myoclonus syndrome (OMS) is a rare, unique, and important disorder, affecting children and adults. The following observations are based on the experience and research of the National Pediatric Myoclonus Center, a world center for the evaluation and treatment of children with OMS, and on published literature.

Opsoclonus was described in 1913 and later in 1927 by Orzechowski. The association of opsoclonus and myoclonus as a pediatric syndrome was made in 1962 by Kinsbourne, who also identified adrenocorticotropic hormone (ACTH; corticotropin) as an effective therapy. Although Foster-Kennedy had described a child with probable opsoclonus and neuroblastoma in the early 1900s, it was not until 1968 that Solomon and Chutorian alerted clinicians to the fact that OMS heralds occult neuroblastoma. Since then, over 250 cases have been reported in the literature.

In the typical pediatric case, toddlers acutely develop a constellation of neurological abnormalities, which rapidly progress over days to weeks. Most striking is the gait ataxia or inability to walk. Parents report staggering or a drunken gait, with wide spacing of the legs and falling. The diagnosis is straightforward once opsoclonus, or randomly darting eyes (saccadomania), appears, although this may be one of the later features of the syndrome. This results in a misdiagnosis of acute cerebellar ataxia in the majority of cases. Orzechowski said "the ocular globes are in a state of continuous agitation, being shaken and increasingly displaced by very rapid and unequal movements, which generally take place in the horizontal plane." Opsoclonus may occur in spells or bursts, with eyelids open or closed in sleep. It is increased by saccadic movements or fixation and seldom decreased by fixation. The action myoclonus gives the appearance of tremulousness or quivering, which has been called polyminimyoclonus. The distribution of myoclonus in OMS may include the face, head, and neck; trunk; and limbs, specifically fingers and hands. It is evoked by action and other stimuli, such as noise, light, or visual threat, and is exacerbated by crying, excitement, or stress. Opsoclonus, myoclonus, and ataxia are usually all present in typical OMS, but there may be variability in the proportions of each and the sequence of appearance. The difference in severity between children is remarkable. In atypical cases, either opsoclonus or myoclonus may be absent or so trivial as to be missed. A minority of children, perhaps 5%, have convulsions.

Children with ataxia in combination with either opsoclonus or myoclonus should never be dismissed as having acute cerebellar ataxia. The child's extreme irritability and characteristic age vulnerability should prompt a search of occult neuroblastoma. Besides opsoclonus, myoclonus, and ataxia, the children exhibit rage, fragmented nonrestorative sleep, expressive language impairment (dysarthria to anarthria), and hyperacussis. The keenly observant clinician should be looking for hints of these features in a toddler with acute ataxia. Later sequellae often include obsessive–compulsive disorder, attention-deficit hyperactivity disorder, oppositional defiant disorder, and cognitive impairment, even mental retardation.

In contrast to the neurological disaster, the prognosis for surviving the tumor is excellent in OMS compared to neuroblastoma without OMS. The tumors are neural-crest derived and appear along the sympathetic chains. They may arise in the neck, chest, abdomen, or pelvis in paraspinal, retroperitoneal, or adrenal locations. Thin-cut high-resolution computed tomography (CT) scans probably have the highest diagnostic yield. A nuclear medicine metaiodobenzylguanidine (MIBG) scan is sensitive for neuroblastoma, but has some false negatives and positives. Urine catecholamine screening is only helpful if the levels are increased; the false negative rate is high. Serum neuron-specific enolase or ferritin may be elevated.

Other diagnostic studies are unhelpful. There may or may not be initial cerebrospinal fluid (CSF) pleocytosis, and protein and glucose are normal. Oligoclonal bands are usually absent. Head magnetic resonance imaging (MRI) studies reveal no evidence of any major cerebellar edema or mass lesion, and in most cases are normal. Electroencephalograms are usually normal, but may show nonspecific slowing.

The belief that OMS can be caused either by a tumor or a virus is based on series that show approximately 50% yield in being able to diagnose a neuroblastoma despite using modern imaging techniques. However, recent evidence challenges the idea that there are two different etiologies. First, on the grounds of logic, it is hard to rationalize that an identical syndrome could be produced by such disparate etiologies. Even an experienced clinician would not be able to tell on neurological grounds whether a

Figure 1 Frequency plot of age at OMS onset in all OMS cases according to presumed etiology. The no-tumor and tumor groups were not significantly different.

given child did or did not have a tumor. It is true that some viruses, DNA or RNA, have been documented in children with OMS. However, are they the primary etiologic factors or rather secondary triggers? A viral-like prodrome of vomiting or upper respiratory symptoms usually occurs before OMS, whether or not a tumor is found. Neuroblastoma is notorious for spontaneous involution; no other tumor has such a propensity. The possibility exists, therefore, that children may have already had neuroblastoma by the time their clinical symptoms prompt a look for the tumor. The argument that the tumor may have been eradicated by the immune system is based on the high degree of lymphocytic infiltration in neuroblastomas, especially those that are associated with OMS. Also, the distribution of onset age does not differ between groups (Figure 1). Whether or not a tumor is found does not appear to have a major effect on outcome.

There is also evidence that OMS is not a uniform disease. Subgroups can be defined on clinical and immunological levels. Children with mild presentation and a monophasic course often undergo complete remission with conventional treatment. The more common scenario is the child with one or more relapses, prompted either by infection or attempts to taper steroids or corticotropin. Whether these children have a multiphasic versus a monophasic illness that never was successfully eradicated is unclear. A group of children has relapsing-progressive disease. Mental retardation and significant motor and behavioral/cognitive disability is characteristic of this group.

What Causes the Autoimmune Response in OMS?

In building a hypothesis of etiopathophysiology, one must begin with the tumor – neuroblastoma is the only commonly occurring tumor in pediatric OMS – and work toward the neural targets. The assumption, which is backed by some data, is that an onconeural antigen, found both on the tumor and on embryologically related nerve cells, provokes an autoimmune disorder – a case of 'friendly fire' on the brain.

There may be more than one immunological defect. The tumor escaped immune surveillance; it was allowed to grow. In some children it grows so large that it is inoperable. In other children, however, the tumor may be only a few millimeters in size. Some genetic vulnerability may explain this, but there is no simple Mendelian inheritance. Family members with OMS, including twins, have never been reported. However, complex immunoregulatory gene defects would be more difficult to track down.

A second possible defect is that once the immune system does find the neuroblastoma, there seems to be an overreaction on some level. Fortunately, this is uncommon, occurring in only 3–4% of all neuroblastomas. But in those individuals, immune system dysregulation or a state of autoimmunity occurs. Secondary factors may further promote the development of an actual autoimmune disorder.

The currently favored immunologic hypothesis of OMS is that it is humorally mediated. This is due in part to various putative autoantibodies that have been described, but studies on T cells and other lymphocytes are lacking. Anti-Ri antibodies are associated with breast cancer in women with OMS, but have not been reported in pediatric OMS. Anti-Hu antibodies, found in neuroblastoma with or without OMS, probably do not cause OMS. Both IgM and IgG autoantibodies to high-molecular-weight neurofilament and other smaller antigens have been reported in OMS, but can also be found in some controls. Commercial screening for 'paraneoplastic' autoantibodies by Western blots in children with OMS has not been productive.

When, instead, the powerful new method SEREX (serological identification of antigen by recombinant

cDNA expression library) was employed, various other autoantigens were detected, but no one autoantigen was found in each of the cases of OMS studied. This method utilizes a cDNA library of a brain area to obtain the specific antigens from it. Another new tool, a newly introduced competitive binding assay, demonstrated surface binding of antibodies from OMS sera directed against the same autoantigen in different children with OMS. Autoantibodies bound to the surface of isolated rat cerebellar granular neurons. No study has demonstrated a relation between autoantibody titers and neurological severity. As a result, the intriguing autoantibody hypothesis of OMS is in question.

Although paraneoplastic autoantibodies have been injected into rodents and cavies, no signs of OMS developed – hence, no animal model of OMS. Also, because most children with OMS do not die from their condition, there have been limited postmortem studies. In some cases, there was evidence of brain inflammation; no abnormalities were found in others.

It had been hypothesized that B and T cells enter the brain, once activated by peripherally induced disease induction, and compromise brain function through production of autoantibodies or inflammatory cytokines, or by direct cell-to-cell toxicity. Thereby, normal immune cell trafficking can progress to lymphocyte recruitment. The National Pediatric Myoclonus Center validated this hypothesis in OMS by performing immunophenotyping of CSF lymphocytes through fluorescence-activated cell sorting (FACS), focusing on the same cell types known to infiltrate neuroblastomas and defend against tumors (natural killer cells and $\gamma\delta$ T cells, conventional T cells, and B cells). This was a cross-sectional study, so individuals at any stage in their disease were included. Each of the patients was videotaped, and the videotape was scored by a trained, blinded observer using the OMS Evaluation Scale, a 12-item scale rated from 0 to 3, with a maximum abnormality of 36 (Table 1). This scale is meant to provide an objective documentation of the motor abnormalities of OMS.

CSF exhibited several abnormalities. The frequency of CD19+ B cells was increased significantly. The frequency of CD4+ helper/inducer cells was decreased but that of CD8+ cytotoxic/suppressor T cells was increased. This resulted in a reduction in the CD4/CD8 T cell ratio. In some individuals, this was profound, resulting in a ratio <1:1 instead of the normal 3:1. Using the OMS evaluation scale to assess mild, moderate, and severe levels of abnormality, comparisons were made between the three OMS groups. CD4+ T cells decreased significantly with motor severity while the frequency of CSF B-cells (Figure 2) and $\gamma\delta$ T cells (unconventional T cells) increased with severity. The degree of cellular abnormality was variable. Exploring the B cell hypothesis further, B-cell expansion was more prevalent in acute cases (Figure 3) and tended to decrease over time. In chronic, symptomatic cases, however, the percentage did not return to normal. As to T cell activation in maturation markers, the only abnormality was an increase in HLA-DR+ activated T cells. No other cell abnormalities correlated with severity.

Table 1 OMS Evaluation Scale – motor performance

Item no.	*Description*
1	Walking: side-to-side imbalance
2	Walking: front-to-back imbalance
3	Walking: wide base
4	Instability while standing (feet apart)
5	Difficulty achieving standing position
6	Truncal instability while sitting
7	Targeting difficulty
8	Difficulty grasping with one hand
9	Difficulty with pincer grasp
10	Abnormal eye movements while tracking (fixation)
11	Abnormal eye movements while resting
12	Speech abnormality (dysarthria)

Videotapes were made to include a segment of each item needed for scoring. Each item is scored from 0 to 3 as follows: 0, normal; 1, mild; 2, moderate; 3, severe.

Analysis of different treatment groups yielded novel observations. Conventional immunotherapy, such as with steroids or intravenous immunoglobulins (IVIg), did not result in a statistically significant difference between groups. Children who had been treated previously with cyclophosphamide or multiagent chemotherapy for their tumors did not have a different CSF immunophenotype compared to those who were not treated. These data indicate that while conventional treatments and standard cancer chemotherapy may work by different mechanisms, they have not prevented the persistence of neurological problems. The blood mirrored some but not all of the immunologic abnormalities found in CSF. It reflected the changes in conventional CD4 and CD8+ T cells, but not in B cells. Whether these T cell abnormalities could have some role as treatment markers remains to be demonstrated by longitudinal studies.

Neopterin, a known indicator of cellular immune activation in a variety of disorders, was increased in OMS CSF, but tests are not sensitive enough to allow neopterin to serve as a biomarker of disease activity. Neopterin was more elevated in acute and untreated patients, and the magnitude of the increase was similar to that reported for central nervous system viral infections. No differences were found between the children who did or did not have a demonstrable

Figure 2 (a) Relation of neurological severity to percentage of B cells in cerebrospinal fluid. As an aid to clinical interpretation, neurological severity was defined as mild if the videotape total score was $\leq$12, moderate if 13–24, and severe if 25–36. (b) Relation of syndrome duration to the percentage of cerebrospinal fluid B cells. The syndrome duration category was defined as acute if $\leq$3 months, subacute if 3–12 months, and chronic if $>$1 year. Controls are shown for comparison. Asterisks signify significant difference compared with controls. Crosses indicate significant difference among duration categories, $P < 0.05$ by Duncan test. From left to right, $n = 18$, 8, 10, and 18. As a point of comparison, neurological severity (total score) also varied with the duration of the illness ($F_{2,51} = 4.6$; $P = 0.014$, ANOVA). Scores in the chronic phase (11.8 ± 8.8) were about one-half of those in the acute and subacute phases ($P < 0.05$, Duncan test).

Figure 3 Effects of rituximab on cerebrospinal fluid (CSF) B cells and severity of OMS. Six months after completion of rituximab infusions, CSF (a) and blood B cells (b) were depleted. The total score (c) decreased from the upper limit of moderate to the upper limit of mild categories. Clinical severity was classified as mild if the total score was 0–12, moderate if the score was 13–24, and severe if the score was 25–36.

tumor. Previous studies on CSF neopterin revealed that it rises after allogenic T cell activation, but monocytes and macrophages also can be induced by cytokines to produce neopterin. Elevated neopterin supports the autoimmune hypothesis of OMS.

Neural Targets in OMS

The cerebellum, which contains half of all brain neurons, is a primary target in OMS, but whether it explains all features is less clear. It plays a role in language development and motor learning, and some behavioral or affective symptoms may be cerebellar in origin. An adult with infantile-onset OMS (41 years earlier) exhibited cerebellar vermis atrophy. The patient had gait ataxia as well as truncal and appendicular ataxia. Cerebellar atrophy also was reported in some children with OMS and neuroblastoma, but is not typical. Using conventional proton MR spectroscopy, however, no abnormal cerebellar spectra have been identified.

As to opsoclonus, the consensus is that the mechanisms of saccadic eye movements reside in the brain stem, but the contrary view is cerebellar. Mesencephalic and pontine ocular gaze centers contain burst cells and omnipause cells that control saccadic eye movements. Burst neurons are silent until just before or during a saccade, when they drive ocular motor neurons to create saccades. Omnipause neurons cease firing when burst cells are firing and inhibit burst cells during fixation. Opsoclonus could be due to excessive activity of burst neurons or lack of inhibition.

Myoclonus can originate from cortical and subcortical structures. Limited neurophysiological studies in OMS identified the myoclonus as subcortical in origin, consisting of < 100 ms synchronous discharges without back-average cortical correlate or exaggerated responses to evoked-potential testing or long-latency electroencephalographic/electromyographic responses. In the brain stem, the nucleus gigantocellularis reticularis of the medulla is a critical nucleus for myoclonus. Myoclonus is often associated with ataxia, but most cerebellar disorders are not associated with myoclonus. The special vulnerability of the infant and toddler may relate to parallel, progressive phylogenetic development of the neocerebellum and frontal cerebral cortex, two of the most slowly maturing brain areas. Frontal connections of the cerebellum are crucial for language development. Lesions of the cerebellar vermis in children are associated with mutism (anarthria), irritability, aggressive behavior, poor socialization, language disorder, and possible autistic-like features. Mental retardation is a feature of many pediatric cerebellar ataxias, particularly when vermis foliation is hypoplastic.

It has been proposed that the cerebellum is the seat of motor learning through the mechanism of climbing fiber synapses on Purkinje cells. However, lesions of the inferior olives, from which climbing fibers emanate, prevent motor learning, suggesting that the inferior olives are principally involved. The cerebellum contributes to oculomotor plasticity. There is some evidence that the cerebellum also has a role in cognitive behaviors besides motor learning, for which the repository site of learning may be the cerebellar target areas rather than the cerebellum itself. These behaviors include spatial learning (connections between cerebellum and frontoparietal association cortex, limbic system, and superior colliculus), discrimination learning (projections to cerebellum via pontine nuclei), and emotions such as fear (reticular activating system, limbic system, and hypothalamus). The cerebellum also has a role in language development, as early cerebellar lesions may result in mutism. An active role of the cerebellum in early language development, not just speech articulation, is supported by studies in humans and experimental animals.

How do these structures and their systems interlinkages generate the physiological phenomena that characterize the syndrome? In the absence of functional studies, the answer is unknown. One could speculate that interruptions of cerebellar Purkinje cell firing (whether due to direct immunological assaults on Purkinje cells or other cerebellar neurons, such as granule cells) give rise both to the dyskinesias and ataxia. Concurrent brain stem involvement through cerebellar circuits would explain the opsoclonus. Cognitive impairment, attention deficit disorder, and seizures imply broader cerebral involvement, either as a result of indirect cerebellar-frontal connections, or due to direct effects of the immune system on these more remote sites. Integrating the various phenomena probably requires dysfunction of a diffuse neural network originating in the cerebellum with brain stem and basal ganglia-frontal connections.

In summary, it would seem that a neuroblastoma can result in at least a cerebellar injury, especially involving the vermis, but network failure involving remote neural sites is also likely. Proper functioning of Purkinje cells, the fastest firing brain neurons and main outflow to deep cerebellar nuclei, is requisite to preventing movement disorders.

How Should the Tumor Be Handled in OMS?

Should the neuroblastoma be removed or left alone? Until recently, it has been removed without question. The argument for tumor resection, as opposed to

biopsy, includes reduction of the antigen load that presumably precipitated OMS, and preventing tumor progression. Certain tumors encroaching on spinal foramina or otherwise causing damage present urgent problems and are not at issue. Some parents really want the tumor to be taken out for peace of mind. But children can come to harm as the result of the resection, developing a postsurgical Horner's syndrome (miosis, ptosis, anhydrosis), in the case of chest or neck resections, or plexopathy, neuropathy, or an unstable spine, causing scoliosis.

The argument for leaving the tumor alone is to prevent iatrogenic injury, reliance on scanning to verify gradual tumor involution or absence of progression, and reluctance to perturb the relation of the immune system and the tumor. Also, neuroblastomas in OMS rarely increase in stage. In the International Neuroblastoma Staging System (INSS), they are usually stage 1, sometimes stage 2, and seldom stages 3 or 4. Histologically, they become more mature (ganglioneuroblastoma or ganglioneuroma) over time.

One newer alternative to surgery is the use of radioactive iodine-labeled MIBG to shrink the tumor when it has wrapped around vital structures and is inoperable. Multiagent cancer chemotherapy is the more standard approach. The use of chemotherapy in OMS for neuroblastoma *per se* is also controversial. One view is that the neuroblastoma tends to be more indolent and low-stage tumors do not require chemotherapy.

An important management debate is which should take priority: treating the tumor or the OMS? Because of the devastation caused by delaying immunotherapy for OMS, the National Pediatric Myoclonus Center advocates treatment as soon as the diagnosis is made. For all the reasons previously discussed, the tumor has lower priority. This view can be difficult for oncologists to accept, especially because neuroblastoma without OMS is so aggressive and lethal.

Current Immune Therapies for OMS

Conventional Therapy

The choice of immunologic agents and overall strategy as a treatment remains one of the greatest controversies in OMS. Corticotropin, intravenous immunoglobulins, and corticosteroids are the typical conventional agents. In the experience of the National Pediatric Myoclonus Center, high-dose ACTH is superior to corticosteroids in inducing a neurological remission, but there are no controlled trials. The use of pulse dosing with dexamethasone or methylprednisolone has gained in popularity among steroid prescribers. Having seen the pitfalls of using single or even dual conventional therapies in children with moderately severe to severe disease, the Center no longer accepts them as adequate therapy. Others have had similar negative experiences. This is not to say that corticosteroids, IVIg, or ACTH could not be used alone in the mildest of cases, but moderately severe and severe cases usually require some form of chemotherapy or alternative treatment.

The wait-and-watch approach is popular but dangerous. Sometimes no treatment is started until months after tumor resection, based on the belief that resection alone will stop OMS. Actually, two-thirds of such cases do not improve or get worse after surgery. Then a single agent is initiated; if the child does not do well, perhaps a second conventional agent is added. Some clinicians will consider the use of chemotherapy, but many will not. Children who do not have a tumor are at the highest risk of not being offered chemotherapy for their neurological syndrome. This is unfortunate. Probably, there is a window of opportunity for successfully eradicating the underlying autoimmune disease without allowing permanent brain injury to occur. Once mental retardation develops, it is not reversible.

Newer Approaches

Given the data on various putative autoantibodies and CSF B cell recruitment in OMS, the National Pediatric Myoclonus Center tested the theory of B cell autoaggression in OMS. The first step was to determine whether an anti-B-cell immunotherapy eradicated CSF B cells, and what the effect of such treatment would be on the clinical course. The chimeric anti-CD20 monoclonal antibody rituximab, approved in the United States for the treatment of B cell lymphoma, not only eradicated B cells in blood, as had been known previously, but it significantly lowered the frequency of B cells in CSF. Many patients after treatment had undetectable B cells. A few children did not respond or need retreatment a year later, but for most, rituximab seemed to confer lasting beneficial effect on the frequency of CSF B cells. The relation between clinical and immunological effects was a reduction in total score on the OMS Evaluation Scale (Table 1). Before treatment, the average total score was in the moderate severity range, whereas after therapy, it was in the mild severity category. This will be apparent to the practitioner.

Results of CSF lymphocyte immunophenotyping can be very useful in determining what type of chemotherapy should be given. FACS is available at most major medical centers, therefore the procedure could be adopted widely. If flow cytometry is not available, the clinical rule of thumb is that if a child does not completely return to normal on ACTH therapy, there

is always active underlying autoimmune disease. Because conventional agents do not alter the frequency of pathological lymphocytes in CSF, and presumably brain, the child is at risk for ongoing brain injury and relapse when the conventional agents are tapered or removed. Because no one knows exactly how long the therapeutic window of opportunity is open in OMS, the National Pediatric Myoclonus Center is a strong proponent of front-end multimodality therapy, combining ACTH, IVIg, and rituximab, for example. In the most difficult cases, other agents or approaches may be necessary as well, depending on the initial response.

A protocol that combines cyclophosphamide with oral corticosteroids and IVIg also is being evaluated. However, in a pilot FACS study, cyclophosphamide as add-on therapy did have anti-B-cell properties in the CSF, but did not reduce B cells to normal levels at the doses used in this protocol. This suggests that the combination will be more useful in milder cases. Dose-response studies are needed. Children with the severest disease require the use of multiple types of immunotherapy over a few to several years to put their disease into remission. Mycophenolate mofetil, which has replaced azathioprine in inflammatory diseases, does not reduce the frequency of CSF B cells in OMS. Other agents that have been tried are 6-mercaptopurine, methotrexate, and cyclosporine.

Given the humoral theory of OMS, plasma exchange (PEX) would seem logical. It has been tried empirically; case reports are positive but sparse. A newer strategy is to couple PEX with immunoadsorption, a technique that utilizes a column of staphylococcal A protein, to which IgG binds avidly. Toddlers are not ideal candidates for this procedure because of their lower blood volume – they may need to be transfused – but it can be done safely in older children through a large-bore central catheter in six to eight sessions over several weeks. How PEX works is not well understood, as it does not seem to remove enough Ig to rid the body of autoantigens. It can modify the immunophenotype, as well as render antigen–antibody complexes more vulnerable to immune-mediated destruction.

Future Therapies

Once the responsible onconeural antigen(s) is found, it will be possible to devise specific therapies for OMS, such as a T cell vaccine. Meanwhile, advances in biological response modifiers will probably be used to advantage in OMS. These could include blockers of type 1 T helper cell (Th1) cytokines or treatment with Th2 cytokines. Newer anti-B-cell monoclonal antibodies, with greater efficacy at sanctuary sites, also will become available.

Summary

Many converging lines of evidence support the autoimmune theory of OMS. Cancer-induced immunity cross-reacts with select neural tissues to engender a paraneoplastic syndrome. The multiple immunological abnormalities of OMS involve B and T cells, sometimes persisting for years, and show significant individual variability. CSF B and T cell recruitment is directly linked to neurological dysfunction and disease duration, possibly accounting for relapses and disease progression. As a result, B and T cells are useful biomarkers of disease activity in OMS. The observation that the tumor and no-tumor-found groups were not immunologically different based on the phenotype of CSF lymphocytes suggests a uniform paraneoplastic model of primary disease pathogenesis, with possible secondary provocative roles for viral infections and immunizations. Because OMS is paraneoplastic until proved otherwise, the neurological syndrome should not be treated differently based on whether one does or does not find an underlying tumor. The data also clearly indicate that tumor therapy, including both tumor resection and conventional cancer chemotherapy, usually is insufficient as treatment for this paraneoplastic disorder. As a result, there is a need for more selective and potent immunological agents, which will be the future of OMS therapy.

Optic Nerve, Optic Chiasm, and Optic Tracts

Introduction

The projection neurons of the vertebrate retina are the ganglion cells, which extend axons across the inner surface of the retina in the optic fiber layer and exit the eye via the optic nerve head. These optic axons subsequently course along the optic nerve to the base of the brain at the optic chiasm, where, with optic axons from the opposite nerve, they intermingle and sort to form the optic tracts. The final destination of these axons is the target visual nuclei in the brain (Figure 1). A small proportion of optic axons course in an accessory optic tract posterior to the main optic tract (and innervate a distinct group of accessory optic nuclei), and there exist a small number of centrifugal fibers innervating the retina as well as commissural fibers of the supraoptic tracts. The contributions of the accessory optic, centrifugal, and supraoptic axons vary depending on the species and developmental age (there is also a retino-retinal projection that is entirely eliminated during development), and are not be considered further in this article.

Organization of the Optic Pathway

The retinofugal pathway establishes synaptic connections in both the diencephalon and the mesencephalon, where axons or collateral branches leave the pathway and innervate target visual nuclei. Different optic axon classes, arising from morphologically and physiologically distinct retinal ganglion cell classes and often discriminable by their size, depart the pathway at different locations to innervate distinct targets: for example, the retinal projection to the hypothalamus departs the pathway at the optic chiasm, while the projection to the midbrain extends through a continuation of the optic tract to the superior colliculus (optic tectum). This optic innervation forms a 'retinotopic map' in some of these target nuclei, by which the array of ganglion cells across the retina is faithfully replicated by the order of their synaptic connections within the target. Retinotopic precision in primates is greatest in the projection to the dorsal lateral geniculate nucleus, the thalamic relay nucleus that projects upon the primary visual cortex.

In mammals, many optic axons from the temporal retina do not cross the midline of the optic chiasm but rather turn to project into the optic tract ipsilateral to their origin. The area of the temporal retina giving rise to this nondecussating, or uncrossed, projection varies across species, dependent on the extent of binocular overlap within the visual field and constrained by the position of the eyes in the head. This 'partial decussation' at the optic chiasm enables the binocularly congruent parts of the two retinas to project directly to the same side of the brain, where processing of the two retinal images in the visual cortex mediates stereoscopic depth perception. Mammals with forward-facing eyes tend to have greater binocular overlap though a narrower field of vision relative to those with laterally placed eyes (Figures 2(a) and 2(b)). The balance between these parameters in any species reflects the behavioral ecology of the organism. For example, rodents and rabbits have laterally positioned eyes, enabling a visual field adapted to viewing a broad expanse while monitoring for predators from above and behind (Figure 3). Additionally, in such species, the proportion of cells in the temporal retina giving rise to uncrossed optic axons is as low as 10%. This proportion rises in species with forward-facing eyes, such that virtually every ganglion cell in the temporal retina of primates projects ipsilaterally. The resulting narrower field of vision in primates, on account of having eyes in the front of the head, is partially offset by the ability to turn the head in many directions. The greater proportion of retinal ganglion cells with uncrossed optic axons in the temporal retina in primates, coupled with their smaller receptive fields, renders the population of binocularly driven cortical neurons sensitive to slight retinal disparities, thereby providing the substrate for fine stereoscopic depth perception.

The partial decussation of optic fibers at the chiasm is a feature unique to mammals. In most nonmammalian vertebrates, such as the favorite experimental models of fish and chick, the eyes are positioned laterally, maximizing the breadth of the visual field and minimizing or eliminating regions of binocular overlap. This arrangement of the eyes with respect to the brain results in an optic chiasm with no decussating fibers and a completely crossed retinal projection. Some nonmammalian species with frontally placed eyes, such as owls and frogs, make use of other neural pathways that cross the midline at locations central to the retinofugal targets in order to achieve binocularity.

Figure 1 The optic nerves, chiasm, and tracts are defined by the course of the optic axons as they project from eye to brain. The optic pathway becomes fused with the base of the brain in the region of the optic chiasm (dark stipple, posterior chiasm and tract). The optic nerve (light stipple, anterior chiasm and nerve) comprises the second cranial nerve. Unlike the other cranial nerves, the optic nerve is a part of the central nervous system (as is the retina), being a developmental outgrowth of the ventral diencephalon. Modified from Hoyt WF and Lewis O (1963) The primate chiasm. *Archives in Ophthalmology* 69: 69–85.

Fiber Organization in the Optic Nerve, Chiasm, and Tract

Traditional accounts of the primary visual pathway assumed that optic axons coursed in a retinotopically ordered fashion along the length of the optic nerve, and that axons arising from binocularly conjugate retinal loci were brought together in the optic chiasm to yield a fiber order within the optic tract that accurately anticipated the binocular and retinotopic features of the visual targets. Clinical observations following focal damage to the optic pathway were, however, often incompatible with those traditional accounts: for example, selective impairments of distinct visual functions, affecting binocularly disparate retinal loci, were often a consequence of partial damage to the optic tract, rather than precise, binocularly conjugate, blind fields ('scotomas'), as should be expected from standard textbook accounts of the visual pathways. Subsequently, neuroanatomical investigations in mammals revealed that optic axons are only very coarsely organized into a retinotopic fiber order at the optic nerve head, and that this order deteriorates along the course of the nerve. In particular, the fibers arising from the nasal and temporal half-retinas are intermingled extensively in many mammalian species,

Figure 2 The visual field of mammalian species with frontally facing eyes (a) displays more binocular overlap but a narrower overall field of vision compared to mammals with laterally placed eyes (b) who tend to have a smaller binocular overlap but a wider overall field of vision. Red represents information from the right visual field and blue represents information from the left visual field. Note that both eyes transmit visual information from both visual hemifields; in animals with frontal eyes, this information comes more equally from both eyes, while in mammals with lateral eyes, one eye carries most of the information from a single hemifield. N, nasal; T, temporal. Modified from Jeffery G and Erskine L (2005) Variations in the architecture and development of the vertebrate optic chiasm. *Progress in Retinal and Eye Research* 24: 721–753.

Figure 3 One visual hemifield is shown for the rat, with the binocular portion (dark purple) viewed by the right eye's temporal retina (situated ventrotemporally as a crescent upon the retina) and the left eye's corresponding nasal retina (situated between that eye's temporal retina and the optic nerve head). The remaining portion of the left eye's retina nasal to the optic nerve head views the peripheral (monocular) visual field (light purple). Despite the relatively lateral position of the eyes in the head, the rat's binocular visual field at its widest extent approaches 100°s of visual angle. Modified from Hughes A (1979) A schematic eye for the rat. *Vision Research* 19: 569–588, and from Reese BE (1988) 'Hidden lamination' in the dorsal lateral geniculate nucleus: The functional organization of this thalamic region in the rat. *Brain Research Reviews* 13: 119–137.

Figure 4 Optic axons become segregated by functional class (two of which are indicated here in different colors) as they pass through the chiasmatic region. This is evidenced in all adult mammalian species as a segregation of axons according to their size within the optic tract. Modified from Reese BE and Ho K-Y (1988) Axon diameter distributions across the monkey's optic nerve. *Neuroscience* 27: 205–214.

so that fiber position in the nerve cannot be a basis for the partial decussation at the optic chiasm. Further, an entirely different organizing principle is found central to the optic chiasm: while functionally distinct optic axons are intermingled within the optic nerve, they are partially segregated within the tract (Figure 4). In addition, those distinct axon classes regain some degree of retinotopic fiber order upon entering the tract. Rather than being a passive conduit for bestowing a retinal map upon the visual targets by maintaining precise neighbor relationships, the optic pathway displays conspicuous fiber rearrangements along its length. These observations on the mature visual pathway indicate that optic axons must change their ordering as they navigate a course from eye to brain during development.

Development of the Optic Pathway

Axonal Outgrowth and Optic Nerve Formation

The embryonic retina develops as an out-pouching of the diencephalon, the optic vesicle. This vesicle gradually invaginates to produce the optic cup, the inner surface of which becomes the germinal neuroepithelium producing all of the neurons of the mature retina; the outer surface becomes the nonneuronal pigmented epithelium. The neck of the optic vesicle, the optic stalk, differentiates into the optic nerve as the first postmitotic cells of the retinal neuroepithelium (the ganglion cells) extend axons, which grow among the cells of the stalk within its ventral wall. Those stalk cells, in turn, differentiate into the glia of the developing optic nerve, yielding a mature nerve composed of fascicles of axons and interfascicular astrocytes and oligodendrocytes. Electron microscopic and dye-labeling studies have confirmed that growing optic axons frequently change position between the fascicles, so that neighbor relationships are not maintained along the developing nerve. By the time the growing optic axons arrive at the base of the brain, those from different quadrants of the retina are conspicuously intermingled in the developing rodent and carnivore optic nerve.

Decussation Decisions at the Optic Chiasm

The microenvironment of the developing optic pathway changes dramatically at the base of the brain: axons no longer course in fascicles amid glial cell bodies, but rather course subpially among radial glial processes which extend from somata at the ventricular surface. As the axons from the two nerves meet, those from the nasal retina of each eye cross the midline; those from the temporal retina, by contrast, adopt an uncrossed course. Distinct populations of glial processes and neurons inhabit this 'decision region' prior to and during axonal invasion, and within this region the growth dynamics of newly arriving optic axons change, evidenced by the changing morphology and advance rate of their growth

cones. *In vitro* assays implicate a membrane-bound molecule to which only the temporal retinal growth cones are sensitive, acting as a contact-mediated inhibitory substrate, probably via a receptor–ligand interaction. One such ligand–receptor pair mediating divergence at the optic chiasm has recently been identified as belonging to the Eph/ephrin family, which is known to mediate a number of neuronal and glial interactions in the developing nervous system.

Curiously, a portion of optic axons from the temporal retina of hypopigmented eyes are misdirected at the chiasmatic midline, crossing the midline to project aberrantly into the opposite optic tract, suggesting a reduced sensitivity to the midline signal. Such a reduced sensitivity of axons from temporal retina may also occur during later development in normally pigmented nonprimate mammals, since the later-generated cohorts of retinal ganglion cell in these species extend axons that all decussate, irrespective of retinal locus. The molecular signature of ganglion cells from temporal retina during early development is different from that of their decussating neighbors forming at later developmental stages and contributes to the ability of those later-extending temporal fibers to cross the midline. The transient expression of Zic2, a zinc finger transcription factor, in retinal ganglion cells giving rise to uncrossed axons is necessary to prevent these fibers from crossing the midline at the optic chiasm. Thus, like other neuronal populations in the developing brain and spinal cord, retinal axons are molecularly specified to respond to signals at midline choice points such as the optic chiasm.

With respect to development of the optic chiasm, a unique but experimentally informative species is the frog, which initially has an entirely crossed visual projection. Beginning at metamorphosis, as the eyes shift from the side of the head to the front, the transforming tadpole develops a small ipsilateral component arising from the temporal retinal periphery. This projection is thyroxine dependent and corresponds with the appearance of a thyroxine-responsive stem cell population in the peripheral retina.

Chronotopic Fiber Reordering

The axons of progressively later-generated cohorts of retinal ganglion cells (destined to differentiate into distinct functional classes) grow amid the older optic axons down the nerve, but as they enter the optic chiasm and tract, they become segregated according to their time of arrival, creating a 'chronotopic' map. This is evidenced in electron micrographs by the accumulation of growth cones in the subpial parts of the optic tract, and by the selective labeling of older axons in the deeper parts of the tract. The fiber reordering has been related to the changing glial environment mentioned earlier, and to an associated changing molecular milieu in which proteoglycans create an unfavorable environment for newly arriving axons. This chronotopic reordering of optic axons ultimately yields a mature optic tract in which functionally distinct optic axons, having differentiated into their discriminable size classes, are segregated (Figure 4).

Optic Tract Formation: Retinotopic Reordering and Positioning

As the optic axons enter the tract, they regain a degree of retinotopic order that is not present in the prechiasmatic optic nerve: axons from dorsal and ventral retina are intermingled within the nerve, yet they become segregated across the width of the optic tract, establishing a coarse mapping of this retinal axis. The cause of this retinotopic reordering is unclear, but since the change is relatively sudden, it is likely to be triggered by some changing feature of the immature diencephalon. As this new fiber order, created afresh in the pathway at the base of the brain, presages the orderly termination of axonal arbors in the target nuclei, a role in the formation of retinotopic maps within the targets is suggested.

Independent of signals that reorder the optic axons relative to one another, other cellular and molecular features of the perichiasmatic region may be critical for determining the locus of pathway formation. For example, embryonic neurons in the chiasmatic region may provide a template for the future optic pathway. Ablation of these neurons prevents pathway formation, leaving optic axons stalled within the prechiasmatic nerves. Mutations producing a completely uncrossed optic pathway (shown in both humans and in dogs, in which the optic nerves fail to fuse) may reflect an anomalous specification of these cells or their surface properties that normally defines the characteristic crossing of the retinal axons. Other local features at the surface of the diencephalic neuroepithelium may provide a template for the developing optic tract, defined by both growth-promoting and unfavorable substrates for axonal elongation. These appear to be independent of other fiber tracts in the vicinity (at least in amphibians), since manipulations that allow optic axons to invade a less mature diencephalon, prior to the formation of these other pathways, do not prevent the formation of the optic tract.

Target Innervation

As optic axons invade their targets, their growth rate slows down and the morphology of their growth cones increases in complexity as they begin to form terminal arborizations. The interactions leading

to target recognition, axonal invasion, and synapse formation are still relatively undefined, but are likely to be different in midbrain and thalamus, suggested by *in vitro* studies, transplantation studies, and studies of their normal and abnormal patterns of innervation. Innervation of the lateral geniculate nucleus occurs via collateral sprouting after optic axons have extended within the optic tract beyond the level of the target, suggestive of a precise target-recognition mechanism. Yet, deprived of normal visual targets, optic axons will elaborate axonal arbors and form retinotopically organized synaptic connections in nearby nonretinal targets in the thalamus, provided that those nuclei have been suitably deafferented. Innervation of the optic tectum, by contrast, may be mediated by a longer range diffusible attraction, since transplantation studies have shown that this target can guide optic axons to it via novel (nonoptic) pathways. As occurs at the optic chiasm and in other regions of the central nervous system, receptor–ligand interactions are important for setting up the initial retinotopic map in target regions of the diencephalon. Molecules of the Eph/ephrin family, along with transcription factors, extracellular matrix proteins, neurotrophic factors, and cell death-regulating factors, including gradients of guidance molecules in the target regions responding to corresponding gradients in the retina, all contribute to the process of topographic mapping.

The foregoing developmental considerations are of interest not only because they begin to clarify the mechanisms governing axonal navigation and pathway formation: they also make comprehensible the mature organization of the optic nerve, chiasm, and tract. This in turn provides a fuller understanding of the disorders of vision that result following focal damage to the pathway.

Genetic Mutations in Pigment-Related Genes Reduce Binocular Vision by Reallocating Retinal Fibers at the Optic Chiasm

As mentioned previously, in mammals with reduced pigmentation, such as found in albino species, a portion of the uncrossed retinal projection fails to be inhibited by the midline at the optic chiasm and incorrectly crosses into the contralateral optic tract with the normally decussating fibers (Figure 5). Decades of study have revealed the precise wiring defects that result from the aberrant crossed projection within the lateral geniculate nucleus, as well as the downstream consequences within the primary visual cortex. These studies have determined that the fiber abnormality in hypopigmentation mutants arises from a lack of melanin in the eye rather than being due to any abnormality within the optic nerve or chiasm. Indeed, a study of mouse lines having mutations in genes that decrease pigment specifically in either the retinal pigment epithelium or in the outer choroidal layer of the eye have confirmed that only those with reduced or absent pigment in the retinal pigment epithelium display a smaller uncrossed retinal projection indicative of a fiber misrouting at the optic chiasm.

A number of inherited human diseases affect both pigmentation and vision, on account of absent or abnormally produced melanin in the retinal pigment epithelium. The visual system defects in these individuals include hypersensitivity to light, nystagmus, reduced visual acuity, and reduced binocular vision and depth perception, the last because of the retinal axon misrouting defect, thus leading to severe visual impairment in affected individuals. Similar abnormalities result from mutations in a variety of different

Figure 5 As in Figure 2, information from the right visual field is represented in red while that from the left visual field is depicted in blue. An albino individual from a mammalian species with frontal eyes (b) has reduced binocular vision due to the reallocation of fibers and a misrouting of some normally uncrossed fibers at the optic chiasm (represented by lighter coloring of fibers in the optic nerve, chiasm, and tract). N, nasal; T, temporal.

genes, the common feature of each phenotype being reduced or abnormal melanin in the retinal pigment epithelium. These genetic disorders include the tyrosinase-negative albino, in which no melanin is formed in the skin, hair, or eyes. The albino patient represents the most severe form of oculocutaneous albinism. Mutations in other genes of the melanin synthesis and melanosome biogenesis pathways likewise result in the visual disturbances found in albinism. Hermansky–Pudlak syndrome (HPS) results from mutations in a cluster of genes involved in various aspects of melanosome biogenesis. Ocular albinism (OA1) is yet another melanosome biogenesis disorder that affects vision. While treatment for these disorders is not yet possible, we do have mouse models of each genetic mutation and further research is under way to determine the causes and potential cures.

Optic Tectum: Development and Plasticity

S C Sharma and K A Patil, New York Medical College, Valhalla, NY, USA

Introduction

The term 'optic tectum' is generally used in lower vertebrates to describe the homolog of the mammalian superior colliculus. In fish, amphibians, reptiles, and birds, it is represented by a single pair of dorsally situated dilatations in the mesencephalon, which are their principal visual structure in the brain. The optic tectum contains a visual map that is activated by its principal input, retinal axons. It responds through descending efferent pathways to brain stem and spinal motor areas giving a movement reaction to visual stimuli. At progressive levels of vertebrate phylogenetical transformation, the optic tectum becomes more structurally compartmentalized, giving rise in eutherian mammals to both the inferior and the superior colliculi, the latter maintaining more of the visual functions ascribed to the original optic tectum.

Nevertheless, as the cerebral hemispheres begin to play a more important role in the processing of neural information, the optic tectum is reduced in size relative to the rest of the brain. During the evolutionary process of 'telencephalization,' the cerebral hemispheres are thought to take over several of the visual tasks performed by the primitive optic tectum, and greatly extend the analyses and associative discrimination of visual stimuli. Although simplified, the human superior colliculus still preserves a laminar organization, receiving in its most superficial layers input from the retina and visual cortex, and in its deeper layers input from the auditory and somatic sensory systems. These different types of sensory information are arranged in three separate spatial maps, parallel to the surface of the colliculus, and integrated to direct eyes and head movements toward an external stimulus in a coordinated response. Functions of the superior colliculus also include aspects related to attention and pattern discrimination, working in closer interdependence with the geniculo-cortical system. Thus, in correlation with its physiological importance in the nonmammalian brain, the primal optic tectum shows a higher degree of anatomic complexity than its equivalent, the superior colliculus in the primates. Because of its behavioral relevance, and its convenience in the study of laminar neuronal organization, the optic tecta of fish and amphibians have been popular models in the elucidation of (1) axonal growth and targeting during development and regeneration of the central nervous system; (2) neuronal plasticity following injury; and (3) the neuroanatomic basis for visual-related behavior.

Cytoarchitecture

The optic tectum in lower vertebrates is composed of two prominent structures, which are symmetrically situated along the midline of the brain, and between the olfactory lobes and the diencephalons anteriorly, and the cerebellum posteriorly. It displays a lamination pattern made by a series of alternating layers of neural fibers and cells. Some variations exist in the histological organization of the optic tectum in different species. Here we will exemplify using the optic tectum of teleost fish, although most tecta follow a similar general plan. A commonly accepted nomenclature divides the optic tectum, from surface to depth, into the following: stratum marginale, stratum opticum, stratum fibrosum et griseum superficiale (SFGS), stratum griseum centrale (further subdivided into the inner plexiform layer and the inner gray layer), stratum album centrale, and stratum periventriculare. Each of these layers extends parallel to the surface throughout most of the optic tectum. Information from different regions in the visual field is integrated in different locations along the optic tectum's homogeneous preservation of laminar organization (Figure 1).

The stratum marginale is characteristic of fish and contains three elements: (1) the dendritic trees of pyramidal neurons (their somas are situated in the SFGS), which make synaptic boutons; (2) the marginal fibers originating in the torus longitudinalis, running parallel and laterally among glial elements; and (3) the stratum marginale ascending dendrites, which originate in neurons in the stratum griseum centrale.

The stratum opticum (SO; Figure 1), directly underlying the stratum marginale (SM; Figure 1), contains myelinated axons constituting part of the retinal afferents (contralateral), and large axons of tectal origin. These fibers make synaptic contacts with dendritic arbors from neurons whose somata are located in the stratum griseum centrale, the stratum album centrale, and the stratum periventriculare. They also synapse with dendrites of horizontal neurons whose cell bodies are located within the stratum opticum itself. Horizontal neurons show a spheroidal soma and dendrites that extend horizontally. The next deeper lamina is the stratum fibrosum et griseum superficiale, which is conformed by abundant myelinated

Figure 1 Composite diagram illustrating the principal neuronal types in different layers of the goldfish optic tectum. A, H, and K are pyriform neurons; B and I are pyramidal neurons; C, E, and J are nonoriented neurons; D and G are horizontal neurons; F is a fusiform neuron. SM, stratum marginale; SO, stratum opticum; SFGS, stratum fibrosum et griseum superficiale; SGC, stratum griseum centrale; SAC, stratum album centrale; SPV, stratum periventriculare.

axons and conspicuous cell bodies. Most of these axons are retinotectal afferents, whose terminal arbors synapse with dendrites extended by neurons located in deeper layers, and also with dendrites of pyramidal and bipolar neurons, located within this stratum. The pyramidal neurons are conspicuous in this layer. Horizontal neurons are present in this layer as well. The stratum griseum centrale (SGC; Figure 1) is divided into the outer plexiform layer and the inner gray layer. Most abundant in this lamina are the vertical dendritic arbors of neurons located deeper in the tectum (large piriform and other cells). Also present are the descending axons of pyramidal neurons. Several neuronal types have been found in this stratum: large fusiform neurons, extending dendrites into the SFGS, and an axon which leaves the tectum through the stratum album centrale; small pyriform neurons, giving rise to the stratum marginale ascending dendrites; small multipolar neurons, some of which extend axons that leave the tectum; and horizontal neurons with dendrites arborizing locally. The stratum album centrale (SAC; Figure 1) contains mostly bundles of myelinated axons, although unmyelinated fibers can also be recognized. The majority of these axons are of tectal origin, but some are originated in the contralateral retina, and the ipsilateral and contralateral telencephalon. Neurons here are the ganglionic and the large pyriform types, having large ascending dendritic arbors. Branches of the latter have been shown to be contacted by retinotectal terminals. Nonoriented neurons can be found here as well, representing a less defined type. The deepest laminae are the stratum periventriculare (SPV; Figure 1). It contains the 'periventricular neurons,' which extend dendritic processes into the overlying strata. However, the most characteristic cell type in this layer is the ependymoglial cell, which gives rise to an ascending process that reaches the uppermost aspect of the tectum while extending profuse branches along the way.

Afferents into the tectum are axonal terminals originating from (1) the retina, (2) the telencephalon, (3) the nucleus isthmi, (4) the dorsolateral and dorsomedial thalamic nuclei, (5) several pretectal nuclei, (6) the nucleus preglomerulosus, (7) the torus longitudinalis and the torus semicircularis, (8) the contralateral tectum and the dorsolateral tegmentum, and (9) diverse brain stem cell groups. Fibers originating in the contralateral eye course through the optic nerve, reaching the tectum in a retinotopic distribution. They terminate in the stratum opticum and the SGFS, and scarcely between the stratum album centrale and the stratum periventriculare. They synapse with horizontal neurons, pyramidal neurons, small bipolar neurons, fusiform neurons, and large fusiform neurons. In addition, optic tectum also receives a strong input from the auditory system and contains map of auditory space especially in owl and pigeons.

Tectal efferents originate from (1) the small bipolar neurons of the SFGS, (2) the fusiform neuron in the stratum griseum centrale, (3) the large multipolar neurons of the stratum griseum centrale and the stratum album centrale, and (4) large pyriform neurons of the stratum griseum centrale and the stratum album centrale. Tectal efferents form three efferent fiber groups: (1) the ascending group, running mostly toward the ipsilateral pretectum and thalamus, but some toward contralateral structures (including tecto-ocular fibers); (2) the medial group, coursing toward the contralateral tectum (forming the tectal

commissure, and terminating mostly in the stratum griseum centrale), but a few reaching the torus longitudinalis; and (3) the descending group, which extends into the ipsilateral and contralateral tegmentum and lower brain stem, including the nucleus isthmus (the nonmammalian homolog of the parabigeminal nucleus).

The optic tectum displays visually elicited electrical activity. Discrete areas of the retina receiving light from punctiform stimuli in the visual field project to discrete regions of the contralateral tectum (although species having binocularity project also ipsilaterally, mainly through an isthmotectal relay).The visual projections are arranged in a topographic manner, such that: nasal retina is represented in the caudal region of the tectum, and temporal retina in the rostral region; the dorsal retina projects to the lateral region of the tectum, and the ventral to the medial. This retinotopic organization extends across all laminae of the optic tectum. The topographic organization of axonal terminations is conserved also in the isthmotectal and tectoisthmal projections. There is orderly point to point correspondence between the retina and the tectum. The nasotemporal axis is represented along the caudorostral axis and the dorsoventral retinal axis is represented on the lateromedial axis of the tectum (Figure 2).

The mechanism of retinotectal map formation has been studied in mature fish as their optic nerves have a capability of regeneration. Seminal work was done by Roger Sperry who proposed that during development cells of the retina and tectum acquire cytochemical labels denoting their position within the retina or tectum. The growing retinal axons carrying the unique positional specificity on them are guided toward the tectal cells having corresponding labels; thereby, a selective and appropriate contact is made. By creating retinotectal mismatch or size disparity, Attardi and Sperry showed the regenerating optic axons reached their appropriate terminal sites by passing the inappropriate sites (Figure 3) Further research led to many aspects of neuronal specificity providing evidences of neuronal plasticity in which retinal fibers either 'compress' or 'expand' their projection depending on the available sites. In all such situations one element that remained constant was

Figure 2 (a) Schematic representation of the projection of the retina onto the optic tectum in teleosts, showing the complete crossing of the optic nerves, and the division of the optic tracts into medial and lateral bundles before reaching the tectum. The optic nerve fibers spread in a caudolateral direction across the surface of the tectum from their entrance near rostromedial pole. Nasal retinal fibers (N) terminate in caudal tectum, temporal fibers (T) in rostral tectum, dorasal fibers (D) in lateral and ventral tectum, and ventral fibers (V) in medial tectum. (b) Visuotopic map from a normal left eye to the right optic tectum. Each number in the visual field shows the position of a visual stimulus that gave a localized response at the electrode positions indicated by the same number on the tectum.

Figure 3 Schematic drawings of the regenerated optic fiber patterns observed in the tectum using Bodian protagrol method after optic nerve section and various partial retinal ablations. In each retina diagram, the white area denotes the ablated region. On the retinal diagrams: A, anterior; P, posterior; D, dorsal; V, ventral. On the tectum diagrams: M and L, medial and lateral branches of the optic tract. Redrawn with permission from Dr. RW Sperry.

the order of topography. These and other relevant aspects have been summarized by Sharma and Fawcett.

Retinotectal terminal arborizations show electrophysiological segregation among different tectal layers. While no light-evoked responses have been detected in the stratum marginale, unitary responses are predominantly 'on–off' and transient in the stratum opticum and the superficial-SFGS. Units recorded in the deep-SFGS give sustained responses and are either on-center or off-center type. Electrically active tectal dendritic elements with their highly organized spatial arrangement are an important component of the visual processing apparatus, rather than just relays of action potentials. Similar to the mammalian visual cortex, neuronal elements in the optic tectum display a high degree of specialization for different components in which visual information is separated. Studies of tectal field potentials show a directional selectivity to moving spots of light. Tectal neurons also show velocity sensitivities, since their firing rate depends on the stimulus velocity. There are also specific tectal neurons in fish, which respond only to certain orientations of polarized light, as received by specialized photoreceptors.

There are several neuronal types in the optic tectum, which respond directly to photic stimuli because of direct synapses with retinal ganglion cell axons. Pyramidal cells located in the SFGS, which send dendrites within the SFGS, to the stratum opticum, and to the stratum marginale, have a short latency of response. These cells have strong spontaneous activity, display slow adapting responses with movement directionality, and are perhaps involved in the orientation circuit. Pyriform neurons located in the stratum periventriculare, which send dendritic trees in the upper tectal strata, respond in a delayed form to retinal input, and they are thought to receive direct connections from retinal ganglion cells, via slow conducting fibers reaching the deep tectum. These cells

have a wide range of electrical activity, although smaller pyriform neurons tend to have stronger spontaneous activity and photic responses. Horizontal neurons represent a heterogenous population of tectal neurons arranged in several strata. Their electrophysiological responses have a wide range of variation. Many of them display strong spontaneous activity and short latencies to retinal stimulation, demonstrating their direct connections with retinal afferents.

Multiple types of molecules have been identified in recent years as playing a role in interneuronal communication in the optic tectum of nonmammalian species. Their variety serves as an indication of the complexities of tectal circuitry. Neurotransmitters and neuromodulators that have been shown in tectal neurons include: glutamate, γ-aminobutyric acid (GABA), acetylcholine, serotonin, somatostatin, substance P, neurotensin, neuropeptide Y, gonadotropin-releasing hormones, corticotrophin-releasing factor, and arginine vasotocin. Glutamate-positive retinal fibers terminate in the stratum opticum and the SFGS. Glutamate receptors of different types are present on tectal neuron dendrites. Glutamate is not only necessary for visual information relay, but in addition, *N*-methyl-D-aspartate (NMDA) receptor has been shown to be important in the electrical-activity-driven refinement of the retinotectal terminal arborizations. This process occurs during development and regeneration, and leads to sharpening of the retinotopic map. Glutamate mediates transmission into the tectum by marginal fibers projecting from the torus longitudinalis, and has been found in optic tectum neurons as well, including pyramidal, multipolar, fusiform, large pyriform, and periventricular. GABA, present in neurons and fibers scattered across the frog optic tectum, enhances the excitatory synaptic transmission of optic nerve terminals. Acetylcholine has an important role in the isthmotectal projections and in the intrinsic circuitry of the optic tectum. Cholinergic input modulates the transmission of these fibers via presynaptic nicotinic receptors. Two molecules of interest in the sexual dimorphism that the lower vertebrate brain displays are arginine vasotocin and galanin. They are present in higher levels in the optic tectum (among several brain regions) of male fish, frogs, and newts than in that of females, or sexually unresponsive males.

Development of Tectum and Axonal Guidance

The optic tectum develops simultaneously with the eye. It differentiates from the alar plate of the mesencephalon. Four phases can be considered: cell proliferation; migration; fiber growth and synaptogenesis; and a phase of regressive changes including cell death and neurite pruning. The development of the topographic connection of the retina with the tectum has been a focus of research for many years. In the prospective mesencephalon, the local anterior–posterior polarity is generated through the activity of a long-range signal from the posterior boundary with the rhombencephalon, the isthmus. Many of the successive genetic interactions that determine tectal evolution in the midbrain have been identified at the molecular level.

The development of the ectodermal midbrain/hindbrain organizer is induced by mesoderm. The spatially correct expression of the homeobox genes, Otx-2 (anterior) and Gbx-2 (posterior), is important for the development of the isthmic-signaling region. Otx-2 is expressed in the anterior neuronal tube down to the mid-hindbrain boundary. Gbx-2 is expressed in the rhombencephalon and borders with the expression of Otx-2. Then a diffusible substance, such as fibroblast growth factor 8 (FGF-8), emanating from the organizer determines midbrain polarity. Several genes (including En-1, Otx-2, Pax-2, and Wnt-1) regulate FGF-8 itself transcriptionally. Pax proteins are transcription factors that contain paired box and homeobox DNA-binding domains. Pax-2 covers the whole of the mesencephalon, whereas Pax-5 is expressed in high levels in the isthmic region. Positive inductions by FGF-8, in conjunction with inhibitory influences from the mesencephalic–diencephalic junction, produce a decreasing caudal–rostral gradient of engrailed (En-1 and En-2) expression along the posterior–anterior axis of the midbrain. Eventually, the engrailed distribution determines the positional specificity of tectal neurons. Ephrins and the Eph receptors are among the cell-surface molecules directly responsible for neural guidance of afferent retinal fibers toward specific tectal positions. Ephrin-A5 and Ephrin-A2 are the two molecules shown to be engrailed dependent *in vivo*. They distribute in gradients, increasing from anterior to the posterior poles, with Ephrin-A5 restricted to the caudal half of the tectum. Eph receptors are expressed in gradients across the early retina and on the growth cones of ganglion cells. Eph-A3 is the preferred receptor for Ephrin-A5 and Ephrin-A2. It is present in a retinal gradient, increasing from nasal to temporal. The tectal distribution seems to be a repellent guidance system that stops growing retinal axons at different anterior–posterior positions. Grg-4 is expressed early in the mesencephalon and causes repression of molecules, including FGF-8, Pax5, En-2, and Ephrin-A2. Thus, Grg-4 might contribute to setting the anterior limit of the tectum and its rostrocaudal polarity formation (Figure 3).

The dorsoventral patterning of the mesencephalon is determined by the Shh molecule, which is expressed in the floor plate of the neural tube up to the diencephalon. In the tectum, if Shh is expressed ectopically in the dorsal region, the dorsal tectum receives dorsal retinal fibers, which normally terminate at the ventral tectum. Furthermore, Shh represses the expression of the tectum-related genes (En-1, En-2, Pax-2, Pax-5, and FGF-8) and induces ventral markers, such as HNF3b and ptc. Ephrin-B ligands and their receptors appear to be the guidance cues for spatial segregation along the dorsal–ventral axis. Wnt3 is expressed in a medial–lateral decreasing gradient in chick optic tectum and mouse superior colliculus (Schmitt et al.). Retinal ganglion cell (RGC) axons from different dorsal–ventral positions showed graded and biphasic response to Wnt3 in a concentration-dependent manner. Wnt3 repulsion is mediated by Ryk, expressed in a ventral-to-dorsal decreasing gradient, whereas attraction of dorsal axons at lower Wnt3 concentrations is mediated by Frizzled(s). A classical morphogen, Wnt3, acting as an axon guidance molecule, plays a role in retinotectal mapping along the medial–lateral axis, counterbalancing the medial-directed EphrinB1-EphB activity.

Several molecules known to affect neurite behavior are concentrated in the retinorecipient laminae making them plausible candidates to participate in the regulation of laminar specificity. These include the adhesion molecule SC1/DM-GRASP/BEN, semaphoring/collapsing receptors and ephrin-B2; in addition, N-cadherin is concentrated in the synaptic cleft at retinotectal synapses. N-cadherin and glycoconjugates recognized by the plant lectin Vicia villosa agglutinin-B4 (VVA) guides retinal axons. Versican is an important layer-specific cue for presynaptic maturation of retinal ganglion cells.

Reelin (RELN) is an extracellular matrix protein largely related with laminar organization in several brain areas. In the optic tectum (OT) of trout, as in amniotes, RELN immunoreactivity increases within specific cell layers as lamination proceeds, and decreases when it is complete, except in the stratum opticum (SO), where RELN-immunoreactive cells are observed throughout life. Time-course expression of RELN in the OT suggests a role in the early modeling of synaptic contacts and the accommodation of new retinal arriving axons throughout life.

In summary, the spatial identity of the neurons within the optic tectum seems to be tightly regulated by the graded induction of a series of asymmetric genes, transcriptional factors, and receptors for signal transduction during early development. The exact sequences of different gene activation leading to the formation of adult tectum are not yet clear.

Behavioral Correlates

The optic tectum is involved in (1) perception of form (related to food catching and escape behavior); (2) responses that can be conditioned to visual stimuli; (3) ocular convergence movements; and (4) 'food searching' forward body movements. However, as evidenced in fish, there are visual responses in which the tectum is not directly involved. The optokinetic and dorsal light reflex appear to be mediated by nontectal targets (e.g., diencephalic and pretectal groups), since they persist after tectal ablation. The optic tectum might also be involved in visual memory, as long-term potentiation has been elicited in it. Nevertheless, visuo-spatial conditioning memory involves other brain structures and persists even after abolishing the tectum.

In both fish and frogs, electrical microstimulation of the optic tectum can elicit complex stereotypic body movements. It has been demonstrated that tectoreticular circuit helps in the generation of saccadic eye movements in goldfish. The optic tectum of goldfish, as in other vertebrates, plays a major role in the generation of orienting movements, including eye saccades. To perform these movements, the optic tectum sends a motor command through the mesencephalic and rhombencephalic reticular formation, to the extraocular motorneurons. These motor responses have been studied in the two primary behaviors of vertebrates, feeding and avoidance. Distance of the prey from the eye determines whether frogs will merely fixate on it, or snap at the stimulus. This difference seems to be related to the size of the retinal area stimulated by moving objects. As would be expected, tectotectal connections are involved in behavior involving conjugated eye movements, such as turning toward prey, as shown in studies of the effects of severance of these fibers. In contrast, hemisection of the tectal descending fibers eliminates the frog's ability to snap forward, while preserving that of turning. On the opposite end of the behavioral spectrum, the optic tectum of nonmammalian vertebrates is involved in the avoidance to possibly threatening objects. Both frogs and fish react by jumping or flipping away when they visually spot large dark objects approaching. This behavior is completely eliminated by tectal ablation. Smaller lesions to areas of the tectum abolish the above-mentioned responses to stimuli within specific corresponding regions of their visual field. Stimulation of the rostral tectum induces turns of the head and body toward the frontal field; activation of caudal tectum elicits body orientation toward the rear field.

The primitive optic tectum, like the superior colliculus of primates, integrates other sensory modalities

in addition to vision. In weakly electric fish, electrosensory stimuli (used in the detection of objects in their surroundings) are processed in the tectum. This type of input is directed to areas in the optic tectum in such a way that it overlaps with visual information coming from the corresponding space region. Processed information closes the stimulus-response circuit as the tectum projects to the diencephalic nucleus, which has efferents to the mesencephalic prepacemaker, connecting in turn with the medullary pacemaker nucleus, which finally controls the electric organ discharge (used in interactions with other fish, such as in courtship). In snakes, another sensorial type of information is important. Temperature changes in its surroundings are detected by the heat-focusing pit organ, which connects with the optic tectum to process these stimuli.

In spite of the enormous progress made during the past five decades, our knowledge of the functioning of the optic tectum leaves further opportunities for investigation. Among others, studies are needed to elucidate in further detail the electrochemical features of the tectal circuitries, and to advance our understanding of the integration mechanisms in which the optic tectum accomplishes simultaneous processing of different modalities of sensory information, in order to provide coherent responses to the environment.

Introduction

The vertebrate midbrain consists of three major regions: the caudal isthmus, the ventral tegmentum, and the dorsal tectum (Latin for roof). The tectum can again be differentiated into an auditory center, the torus semicircularis, and a visually dominated center, the optic tectum. This nomenclature is consistent throughout the vertebrates, with the exceptions of birds, in which the auditory center is termed nucleus mesencephalicus lateralis pars dorsalis (Mld), and mammals, in which the optic tectum corresponds roughly to the outer layers of the superior colliculus and the auditory midbrain is called inferior colliculus.

The optic tectum is characterized by several features. First, it is a multisensory center, with a primary visual input and additional input from sense organs that yield a topographic representation of the external world (including auditory, somatosensory, and lateral line, infrared, and electrosensory where present). Second, the sensory input is always organized in the form of maps that are in register with one another, thus forming a coherent spatial representation. And third, the optic tectum is a highly laminated structure, with alternating layers of cell bodies and neuropils, characteristic cell types in the different layers, and a strict separation of input and output structures. Together, these features have rendered the optic tectum one of the best-studied model systems for developmental map formation, the alignment of multimodal maps, plasticity after injury and sensory misalignment, and the cellular processing of sensory input.

The functions of the optic tectum can generally be summarized as being related to spatial orientation. The tectum integrates all available sensory modalities and generates an unambiguous premotor signal which is then relayed to premotor and motor nuclei via descending efferent pathways. This premotor signal aims at aligning the sensory organs to a specific location in space and has led to the notion of the tectum being a visual (or multimodal) reflex center. In the lower vertebrates (i.e., nonmammalian species), the size of the optic tectum suggests that it is the major sensory processing center, a finding that is in line with the idea of mostly reflexive behavior in these animals (Figure 1). In contrast, the relatively small size of the mammalian superior colliculus is often taken as an indication that the telencephalon has taken over most of the tectal functions, thus rendering the superior colliculus a subordinate region under complete control of forebrain efferents.

However, this classic view of the optic tectum can no longer be upheld. The size of the optic tectum is quite variable within a vertebrate class and appears to be dependent on other factors, such as the binocularity of a given species. Also, the optic tectum gives rise to many different projection systems, the largest being the tectofugal ascending pathway that relays information toward the forebrain. Many tectal projections are involved in attentional and integrative networks, thus participating in the general cognitive control of behavior. In addition, a remarkable conservation of cell types and their projections has been found in comparative studies of the vertebrate optic tectum. And finally, physiological as well as lesion studies have shown that throughout the vertebrates the role of the optic tectum is far from being a simple reflex circuit for sensory orientation. Due to the extensive interconnections with many areas throughout the entire brain, the optic tectum is involved in many different behaviors, and likewise exerts its functions only in concert with all other visual and sensory processing areas. This unity of the visual system has to be taken into account when attempting to isolate and analyze functions of any given area in the vertebrate brain.

Cytoarchitecture and General Connectivity

In most vertebrates, the optic tecta can easily be identified as two symmetrical prominent lobes. When sectioned in the transversal plane, these structures display a pronounced pattern of lamination which may be absent only in secondarily simplified brains (e.g., salamanders). These laminae extend parallel to the curved surface of the tectum and may change in their relative thickness, depending on the part of the visual field they are representing. Even though often identical anatomical terms are used, the nomenclature of the alternating cell and fiber layers varies among vertebrate classes and cannot easily be homologized (Figure 2). In general, the optic tecta of fish and amphibia, on the one hand, and reptiles and birds, on the other hand, can be distinguished by the greater differentiation of the laminae in the most superficial layers that are collectively termed the stratum griseum et fibrosum superficiale (SGFS).

For simplicity, the following cytoarchitectonic description focuses on the avian optic tectum (Figure 2(d)). In birds, two nomenclatures for the tectal laminae have been developed. Ramón y Cajal differentiated 15 laminae, starting from the superficial layer. Later, a different

Figure 1 Position and size of the optic tectum (dark gray area) in vertebrates.

Figure 2 Cytoarchitecture of the optic tectum in various vertebrate classes in histological sections: (a) fish, *Carassius auratus*; (b) frog, *Discoglossus pictus*; (c) reptile, *Gecko gecko*; (d) bird, *Gallus gallus*. The layer numbers to the left refer to the original nomenclature suggested by Ramón y Cajal and Pedro Ramón, the acronyms to the right were introduced by various authors. Both nomenclatures can be found in the current literature. EP, ependym; SAC, stratum album centrale; SAP, stratum album periventriculare; SFGS, stratum fibrosum et griseum superficiale; SFP, stratum fibrosum profundum; SGC, stratum griseum centrale; SGFS, stratum griseum et fibrosum superficiale; SGP, stratum griseum profundum; SM, stratum marginale; SO, stratum opticum; SPV, stratum periventriculare. Scale bar = 50 μm (a, b) and 100 μm (c, d). Panel (a) provided by DTT Plachta; panel (c) provided by Y Tang and CE Carr.

nomenclature was introduced that divided the tectum into six layers, five of which are located in the deep tectum and consist of only one cellular or plexiform lamina whereas the intermediate and superficial laminae are subsumed in the SGFS (Figure 2(d)). In the current literature, both nomenclatures are used and often mixed, and some authors subdivide the layers even further. In addition, for developmental studies, a third nomenclature has been established to accurately describe the complex sequence of layer formation.

The different laminae of the optic tectum contain specific cell types. Although earlier studies assumed that each lamina has a characteristic cell morphology and a specific connectivity, it was later found that layers may include cells with comparable morphology but varying connectivity. As an example, the projection neurons of the stratum griseum centrale (SGC) have large somata, large dendritic trees, and distal dendritic specializations, but they receive input from different retinal ganglion cells and project to various target areas. Thus, a complete description of the cell types in the avian optic tectum is not feasible. This article, rather, gives an overview of tectal connectivity pertaining to the laminar organization

Figure 3 Schematic of the connectivity of the optic tectum.

and gives a detailed description only of some well-characterized neurons.

The major sensory input to the tectum originates in the retina. Generally, a large proportion of the retinal ganglion cells project contralaterally into the optic tectum, even in those animals that have a well-developed thalamofugal pathway (the pathway from the retina via the dorsolateral thalamus to the forebrain). Throughout the vertebrates, the degree of ipsilateral projection varies and seems to correlate at least partially with the degree of binocularity in the species. In birds, however, the projection is exclusively contralateral, even in highly binocular species such as owls and even though a transient ipsilateral projection is found during embryogenesis. The topographical projection of the retina produces a map of visual space. Its development during embryogenesis has been studied in great detail as a model system of molecular developmental biology.

In all nonmammalian vertebrates, the optic fibers course over the surface of the tectum, turn sharply inward at their appropriate position, and terminate in the upper layers (2–5 and 7). The retinal afferents from various retinal ganglion cell classes form small terminal fields in individual layers, as determined by immunocytochemical and tracing studies. Additional sensory input is fed into the intermediate and deep layers. The nonsensory input to the tectum is generally not restricted to a single lamina, but can span most of the tectal layers, often in a columnar fashion; however, data on termination zones of specific projections are scarce. It is noteworthy that even in the retinorecipient upper layers, synapses of nonretinal input outnumber the retinal input, emphasizing the point that the optic tectum is not only a visual structure.

The output of the optic tectum is derived from the intermediate and deep layers. The major output is constituted by layer 13, where the ascending tectofugal pathway to the thalamic nucleus rotundus and descending pathways to premotor and motor targets originate. The intermediate layers constitute many projections to other nuclei of the sensory pathways, as well as a prominent reciprocal connection with the isthmic nuclei. In addition to these projections, both Golgi and intracellular studies suggest that many tectal cells have termination zones within the optic tectum, thus constituting a multitude of intrinsic connections which boost the computational capacity of the system. A simplified scheme of tectal connectivity is depicted in Figure 3.

Although it is not the focus of this article, a comment on the comparison between the nonmammalian tectum and the mammalian superior colliculus might be appropriate here. Even though the superior colliculus can also be differentiated into laminae, a direct comparison of laminar cell types and functions is not feasible. As a first approximation, the entire optic tectum of nonmammalian species can be considered homologous to the superficial layers of mammals (including the stratum zonale, stratum griseum superficiale, and stratum opticum), whereas the intermediate and deep layers of the superior colliculus may correlate to subtectal and tegmental areas in nonmammals. However, this rule of thumb breaks down for many aspects; for example, the motor output pathways originate from the deep layers in mammals and from the optic tectum proper in nonmammals. In general, homologies and comparisons between the mammalian and the nonmammalian visual midbrain should be made with great caution to avoid confusion, especially when it comes to functional considerations.

Identified Cell Types

A variety of cell types have been analyzed in such detail that they can be considered an identified cell type, indicating that their morphology, input, projection, and biochemical features are sufficiently documented. This kind of work is fundamental for a deeper understanding of tectal function, a challenge often hampered by the fact that anatomical studies rarely take physiological data into account and that physiological studies

often disregard efforts to ascribe physiological findings to specific cellular circuitry. Therefore, the wealth of data on the optic tectum obtained in anatomical, physiological, and also molecular studies is often difficult to reconcile; however, for some tectal cell types, the integration of the data is possible. Three types of neurons are briefly described here to demonstrate the level of analysis obtainable in this system.

Horizontal Cells of Layer 5

Even in the earliest Golgi studies of the avian optic tectum, horizontal cells were described in various superficial layers. A detailed intracellular study of layer 5 horizontal cells found multipolar cells with rather thick dendrites and arborizations confined to the layer where the soma was located (Figure 4(a)). Dendrites could extend more than 1000 μm in each direction. Because horizontal cells in layer 5 were found to have no axon, their dendrites act as both post- and presynaptic sites. Electron microscopy has shown that these cells receive input from retinal afferents and make connections with dendrites of tectal projection neurons. These local microcircuits are often surrounded by a glial sheet. Intracellular recordings have demonstrated an unusual cell physiology, with an oscillatory response to depolarization. The horizontal cells are immunopositive for calbindin and are likely to form a GABAergic output. On the basis of these features, models have been put forward to explain the contribution of horizontal cells to tectal information processing, an effort also motivated by the finding that horizontal cells with comparable characteristics are also found in the mammalian superior colliculus.

Isthmo-Optic Projection Neurons

The isthmo-optic nucleus (ION) receives a direct input from the optic tectum and constitutes an output to the retina that influences retinal ganglion cell firing rate, thus forming a short feedback circuit to the retina. The tectal neurons that project to the ION have never been observed in Golgi preparations, but have been described in detail with tracing techniques (Figure 4(b)). The somata of these neurons are located in tectal layer 9, close to layer 10, and have a thick axon that projects to the ION via the tecto-isthmal tract. The dendritic arborization has a columnar appearance, with apical dendrites restricted to layer 8 and only occasionally reaching layer 7, and basal dendrites reaching into layers 9–12 where the highest density of dendritic arborization is observed. Because retinal input does not reach deeper than layer 7, direct retinal input is probably not the major input to these cells. The transmitters of the ION-projecting neurons are glutamate and nitric oxide (NO), and the cells have been found positive for the synthesizing enzyme of NO. However, even though the circuit from the retina via the optic tectum and the ION back to the retina is anatomically rather simple, the function of this feedback has not been clearly established.

Figure 4 Identified cell types of the avian optic tectum: (a) horizontal cells in layer 5 of the chick, intracellular fill; (b) neurons of layer 9 that project to the ION in the chick after tracing; (c) SGC neuron in the pigeon, reconstruction of an intracellular fill; (d) detail of dendritic endings. Scale bar = 100 μm (a, b); 200 μm (c); and 20 μm (d).

Projection Neurons of Layer 13

Due to the different nomenclatures, the neurons of layer 13 are often called SGC neurons. These cells constitute the major output of the optic tectum and project bilaterally to the thalamic nucleus rotundus and, in addition, to various nuclei of the tectothalamic tract on the ipsilateral side (nucleus subpretectalis, nucleus interstitio-pretecto-subpretectalis, and nucleus posteroventralis thalami). These projections have been shown to be lateralized (i.e., specific projections differ in strength depending on the side of the brain), with the laterality being introduced by the differential illumination of the eyes during embryonic development in the egg. The output of the SGC is glutamatergic via α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors.

The morphology of SGC neurons is unique in the tectum. All SGC cells are multipolar and have several primary dendrites that course obliquely through the tectum toward the superficial layers, thus constituting very large dendritic fields with spans of several millimeters (covering up to 40° of visual angle in the retinotopic map). At their distal tips, the dendrites show specializations called bottlebrush endings, which consist of many small filiform arborizations (Figure 4(c)). Intracellular work has shown that each SGC neuron has a multitude of these endings, which are located exclusively in a specific tectal layer but are randomly distributed in the lateral domain. On the basis of the position of the bottlebrush endings and the position of the soma, several types of SGC neurons have been differentiated so far that also project to different subdivisions of the nucleus rotundus. In these thalamic subdivisions, various aspects of visual stimuli are represented (e.g., luminance, colour, and motion). Taken together, the tectal SGC neurons form computational channels, sampling information from specific retinal input layers (and thus specific retinal ganglion cell populations) and feeding this information into the functional subdivisions of the thalamic target. In this process, the simple retinotopic organization of the optic tectum is discarded in favor of a complex interdigitating topographic arrangement, in which each point in the nucleus rotundus receives input from a population of cells sparsely distributed throughout the entire tectum. SGC cell types also possess specific physiological characteristics that allow a differentiation of the cells even with extracellular recording techniques. Most remarkable in respect to cellular physiology is the phasic signal transfer from retinal afferent synapses on to the dendritic endings of SGC neurons. Together with the spatial arrangement of the dendritic endings in the visual map of space, simulations have shown that a complex response characteristic is generated, which, for one specific SGC-subtype, results in a differential response to stationary versus moving objects (including second-order motion stimuli).

In addition to these anatomical and physiological characteristics, SGC cell types express specific cell adhesion molecules during development that mediate pathfinding of the axonal projection and, through combinatorial expression in target nuclei, lead to the correct wiring of the output channels. The expression strength of a specific adhesion molecule can be experimentally manipulated, opening the door to manipulations of specific tectal projection systems and thus to the study of, for example, behavioral effects of identified circuitry.

Cells with the characteristics of SGC neurons are found in all avian species examined so far and also in reptiles and mammals, suggesting that basic functions of the optic tectum are performed by these neurons and that these functions appear to have been partially conserved during evolution.

Multisensory Integration in the Optic Tectum

In most vertebrates, the optic tectum is the essential multisensory integration center that enables the animal to orient and interact with its spatial environment. The organization of the visual sensory afferents is essentially topographic, with distortions in the representation of retinal coordinates when retinal specializations (e.g., the area centralis) exist. The retinal topography is transferred to the optic tectum through molecular gradients, which in essence endow each axon with an information about the appropriate position in the tectum it has to project to. In contrast, the integration of additional sensory input to the tectum is much more difficult because spatial information is not necessarily contained in the sensory epithelia. For example, spatial relations in the auditory system have to be computed from binaural cues through a complex circuitry in the brain stem, and space-specific neurons are first found in a subnucleus of the auditory midbrain. From this subnucleus, a topographical projection conveys the information to the intermediate and deep layers of the tectum. The alignment of the two differentially obtained spatial maps in the optic tectum is therefore of critical importance and has to be dynamically regulated because changes in the interaural distance during development, for example, affect binaural parameters and thus the map computation.

The mechanisms of these alignments have been worked out in the midbrain of barn owls in which the

sensory input had been manipulated during development (in the original literature, the auditory midbrain in owls is termed inferior colliculus). In a seminal series of experiments, young owls were raised with prismatic spectacles that displaced the visual field horizontally. Under these conditions, both the visual and the auditory space maps in the optic tectum were found to be shifted relative to the normal situation, indicating that the visual system generates the master coordinate system in the tectum and that the auditory afferents have to find their correct position in this map. Through a combination of anatomical and physiological work, it was shown that the plastic changes occur within the auditory midbrain prior to the subnucleus that projects on the optic tectum. The changes are achieved through axonal outgrowth, the formation of new glutamatergic synapses, and the inhibition of old synaptic connectivity through GABAergic mechanisms. The capacity for huge plastic changes in the auditory midbrain circuitry is most pronounced in young animals, whereas in juvenile individuals the step size for rewiring is drastically reduced. However, there is evidence that in juvenile animals an additional site of adaptive plasticity exists in the optic tectum itself. In experiments with prism attachment to juvenile owls, the auditory map in the superficial layers was found to be shifted further than the auditory map in the deep layers. Likewise, the topography of intrinsic connections between the superficial and the deep layers was found to be systematically modified. Unfortunately, it is difficult to ascribe these changes to specific cell types of the optic tectum because the cellular elements whose responses constitute the bimodal map in the tectum have not been identified. Even though auditory responses can be readily recorded throughout the tectal layers (with the shortest latencies in the deep layers), the dendritic spread of tectal neurons impedes the determination of the cells. The size of the visual receptive fields suggests that a cell type with large dendritic fields (e.g., an SGC neuron) is involved, but the evidence is only circumstantial. This is also a problem for the identification of the neurons that, on mismatch of visual and auditory maps in the tectum, generate the error signal to the auditory pathway that initiates plastic changes. Under normal conditions, this error signal is under GABAergic inhibition and thus not recordable in the auditory midbrain. After the blocking of inhibition in the tectum, a topographic visual signal can be recorded in the auditory midbrain; the cellular origin of this signal in the tectum is, however, still under debate.

The integration of other sensory modalities into the multimodal maps in the optic tectum appears to follow the pattern laid out by the auditory system. In fish and aquatic amphibia, lateral line inputs are computed into a map of hydrodynamic topography, and cells responsive to visual and lateral line inputs are found in the deep layers of the tectum. Likewise, in weakly electric fish the electrosensory afferents are fed into the deep tectal layers where bimodal cells have been recorded. Also, somatosensory and even infrared input is topographically represented in the deep layers. With respect to magnetic input, the literature is ambiguous; although in older studies avian neurons in the superficial and intermediate layers were reported to respond to directional changes in the ambient magnetic field, these data have been questioned and remain an unresolved issue.

Behavioral Aspects

As for any given brain area, the function of the optic tectum can only be completely understood when the integration of this structure into the entire processing circuits of the brain is taken into account. However, much of the research on the tectum has been motivated by the wish to understand a specific behavior on a mechanistical level, and many researchers have thus focused on specific visual functions. Because the prey-catching behavior in anuran amphibia is a famous example for this approach and is often referred to as the defining function of the tectum, a short overview of the research in this field is given next.

The complete sequence of feeding in a toad can be divided into prey recognition, prey localization and distance estimation, prey approach behavior, and prey catching. Because a partial lesioning of the optic tectum resulted in a neglect of prey objects in the corresponding visual field, it was hypothesized that much of the necessary computations take place in the optic tectum. In a series of studies, the response characteristics of many neurons in the retina and the optic tectum were analyzed and classified according to their stimulus preferences. On the basis of these cell classes, a network was proposed that included the various cell types in a hierarchical network. A prey object was thought to excite this network and to eventually lead to the activation of a specific cell type (the famous T 5.2 neuron) that was considered to function as the main tectal output neuron toward premotor and motor areas. Upon activation of T 5.2 neurons in combination with other tectal cell types, various prey-approach behaviors were elicited, until finally the snapping response was activated. Although this concept was very influential, it was criticized in several respects, one being the unnecessary revival of the detector neuron or command neuron concept. More significantly, it was shown that the tectum was not the place where a complete transformation of

visual information into motor commands was performed. Rather, other nuclei in the forebrain, thalamus, and tegmentum contribute to the network activity through interconnections and projections to the premotor areas. Thus, although the optic tectum seems to be the essential area to identify and locate a prey object, the final decision on the behavioral response appears to be made on the level of the premotor and motor nuclei, not on the level of the optic tectum.

The example of the neural control of prey catching in toads again emphasizes the point that brains are highly integrated networks with a massively parallel architecture. At the same time, it highlights the level of analysis obtainable by a thorough analysis of the circuitry and the physiology of a vertebrate optic tectum. This is especially promising because the investigation of the optic tectum's role in more complex levels of brain function is under way. As an example, the tectal contribution to bottom-up attentional mechanisms is being studied in a variety of species. Because the tectofugal pathway conveys information on many aspects of a visual stimulus toward the forebrain and attentional mechanisms are most likely implemented early on to allow for fast analysis and fast responses, tectal circuitry might well turn out to be of fundamental importance. From this circuit analysis point of view, the tectum remains a system of choice, even after more than 100 years of research into the cellular elements and their functions.

Optical Imaging of Intrinsic Signals

N Pouratian, University of Virginia, Charlottesville, VA, USA
S Sheth, Massachusetts General Hospital, Boston, MA, USA

Introduction

Optical imaging of intrinsic signals maps the brain by measuring intrinsic activity-related changes in tissue light reflectance and absorbance. Functional physiological phenomena, such as changes in local blood volume, hemoglobin oxygenation, and light scattering, that are coupled to neuronal activity, result in intrinsic tissue light reflectance changes that are exploited to map functional brain activity. This approach offers a distinct advantage over extrinsic signal imaging, such as fluorescent dye imaging, which may cause phototoxicity in *in vivo* preparations and may therefore alter normal physiology. By not requiring any tissue contact, optical imaging of intrinsic signals is also ideally suited for studying chronic preparations that an investigator may wish to image over days or months or for intraoperative mapping of the human cortex during neurosurgery.

Compared to other neuroimaging modalities, optical imaging of intrinsic signals offers a superior combination of spatial sampling, spatial resolution, and temporal resolution. The spatial resolution of optical imaging is unparalleled among *in vivo* imaging techniques (on the order of micrometers), making it ideal for studying fine functional organization at the level of cortical columns and their supplying microvasculature. Although the temporal resolution of optical imaging is inferior to electrophysiological techniques, imaging is commonly performed at video frame rates (30 Hz), which is more than sufficient for imaging perfusion-related responses, which evolve over seconds.

Intrinsic optical changes were first used to map cortical activity *in vivo* in 1986 by Amiram Grinvald and colleagues. Since this initial report, intrinsic optical changes have been reported in rodents, cats, monkeys, and humans. Because of the advantages it offers, the number of studies using optical imaging of intrinsic signals has grown rapidly.

Sources of Intrinsic Signals and Wavelength Dependency

Rather than directly measuring neuronal activity, optical imaging of intrinsic signals detects hemodynamic events triggered by neuronal activity. An increase in local neuronal activity results in the release of various metabolites and neurotransmitters, including nitric oxide, lactate, adenosine, ATP, calcium, and potassium. Their release in turn triggers a cascade of metabolic and vascular events, including increased oxygen consumption and vasodilation of regional feeding arterioles, resulting in local changes in blood flow, volume, and hemoglobin oxygenation. These events occur over hundreds of milliseconds to seconds following neuronal activation and extend in space over hundreds of micrometers to millimeters from the locus of activity. Functional maps based on hemodynamics are the result of a convolution of neuronal activity with this vascular and metabolic response, and they are therefore spatially and temporally broader than electrophysiologic events. Since optical signals are based on these hemodynamic responses, they must be interpreted appropriately and not accepted blindly as maps of neuronal activity *per se*.

The various components of the hemodynamic response can be selectively imaged by choosing the appropriate illumination wavelength during data acquisition (Figure 1). Each component has its own characteristics, advantages, and disadvantages. The most important contributors to optical signals are changes in blood volume, oxygenation, and light scattering.

Blood Volume Component

Hemoglobin is the most important absorber of light in the visible spectrum. The most prevalent and relevant isoforms are oxyhemoglobin and deoxyhemoglobin. At wavelengths at which the absorption spectra of oxy- and deoxyhemoglobin intersect ('isosbestic wavelengths,' including 550, 569, and 586 nm), light is equally absorbed by these two moieties. Therefore, light absorption is a function of the total hemoglobin content, which is proportional to cerebral blood volume (CBV; assuming constant hematocrit). Optical maps at these wavelengths therefore provide maps of CBV.

Following neuronal activation, relaxation of smooth muscle tone in feeding arterioles produces an increase in vessel diameter and regional CBV. The spatial density of the vascular tone control mechanisms determines the spatial specificity of CBV changes: the higher the spatial density, the greater the specificity. In regions such as primary sensorimotor cortices, regional blood flow is finely regulated at the level of precapillary arterioles resulting in CBV maps with high spatial resolution and the ability to distinguish submillimeter functional columns. The magnitude of CBV signals scales linearly with changes in underlying neuronal activity, enabling accurate quantification of changes in underlying neuronal activity.

Figure 1 Hemoglobin spectra and selection of wavelengths for optical imaging. Different physiological responses can be emphasized by imaging at different wavelengths. The absorption curves for oxy- and deoxyhemoglobin are displayed to highlight how imaging at different wavelengths may emphasize different phenomena.

Oxygenation Component

In the red region of the visible spectrum (>600 nm), deoxyhemoglobin absorbs light several times more than oxyhemoglobin. Reflectance changes in this wavelength band therefore provide estimates of changes in hemoglobin oxygenation. If other components are constant, a relative deoxygenation results in decreased reflectance, and a relative hyperoxygenation results in increased reflectance. This signal is closely related to the blood oxygenation level-dependent (BOLD) signal commonly used in functional magnetic resonance imaging (fMRI).

Within a few hundred milliseconds following neuronal stimulation, the cerebral metabolic rate of oxygen ($CMRO_2$) increases. Because this increase in $CMRO_2$ precedes changes in blood flow or volume, oxygen extraction necessarily increases, resulting in local deoxygenation. This can often be seen as a decrease in the optical signal in the red region of the visible spectrum. This phenomenon is known as the 'initial dip' in the fMRI literature. The subsequent influx of oxygenated blood washes out this effect and tissue oxygenation overshoots the baseline, producing a relative hyperoxygenation and increase in the optical signal that peaks between 3 and 5 s.

Because the initial dip only occurs in the stimulated region, the spatial specificity of the response is high. Its magnitude is small, however, making it difficult to detect and highly susceptible to degradation by vasomotion or other effects of the subject's baseline physiological state. The spatial distribution of the later hyperoxygenation response is biased toward draining veins, which show the largest magnitude hyperoxygenation change. These findings are consistent with BOLD fMRI. The correlation between changes in the magnitude of these oxygenation responses and underlying neuronal activity is less than that of CBV signals.

Light Scattering Component

At long visible or near infrared wavelengths (>670 nm), hemoglobin absorption decreases significantly. In this regime, light scattering becomes an important contributor to the optical signal. Light scattering changes arise from ion and water flux; morphological changes (i.e., expansion or contraction) in vascular, cellular, and extracellular conformations (which may be related to ion and water movement); and blood volume changes. Increased scatter results in decreased reflectance and thus a decrease in the optical signal, typically peaking at 4–6 s after stimulation onset.

Resolving the Components of Optical Imaging Signals

Single-Wavelength Imaging

As alluded to in the previous section, the different components of the optical signal are weighted differentially at different wavelengths. The different hemodynamic signals can therefore be emphasized by imaging at specific wavelengths of light that either accentuate the differences between the chromophores (e.g., at 610 nm, deoxyhemoglobin absorbs significantly more than oxyhemoglobin) or minimize the difference between the chromophores (e.g., 569 nm is an isosbestic point at which oxy- and deoxyhemoglobin absorb equally).

The time course and spatial involvement of optical responses at different wavelengths are unique. For single-wavelength imaging, there are two major patterns of intrinsic signal time courses to physiological cortical activation: monophasic (decreased reflectance) and biphasic (initially decreased reflectance followed by increased reflectance). In the visible spectrum up to ~590 nm, functional intrinsic signal changes monophasically decrease reflectance. Between 600 and 760 nm, a biphasic pattern is observed. Finally, at wavelength greater than 760 nm, a monophasic pattern reminiscent of wavelength less than 590 nm is observed. For monophasic responses, responses generally appear approximately 1 s after stimulus onset, peak 3 or 4 s after stimulus onset, and return to baseline by approximately 8 s. For the biphasic responses, the initial response to stimulation appears within 500 ms, peaks 1 or 2 s after stimulus onset, reverses phases at approximately 2 or 3 s, peaks in the opposite polarity approximately 4 or 5 s after stimulus onset, and returns to baseline by approximately 10 s.

Imaging reflectance changes at a single wavelength provides high-resolution, two-dimensional functional maps. However, single-wavelength imaging suffers from an important shortcoming: ambiguous etiology. Reflectance changes at a particular wavelength emphasize different aspects of the hemodynamic response, but the distinction is not complete. Each component (i.e., blood volume, oxygenation, scattering, and others) contributes to the optical signal at every wavelength to some degree. Cross-talk between the hemodynamic responses can make single-wavelength imaging difficult to interpret.

Optical Spectroscopy

Optical intrinsic signal spectroscopy is a variant of optical imaging designed to better isolate the physiological processes that give rise to the optical signals. Before capturing reflected light on the imaging camera, the light passes through a spectrographic slit. The one-dimensional column of light is then incident upon a diffraction grating that disperses the light into its constituent wavelengths along a second orthogonal axis. This two-dimensional 'spatiospectral' image is then refocused on a second image plane and captured by the camera. The x-dimension of the image represents the wavelength of light at a particular point along the slit, and the y-dimension represents vertical position. Spatiospectral images are taken over time to capture the hemodynamic response, as in other techniques.

This approach essentially sacrifices one dimension of spatial information for an extra dimension of spectral information. The advantage gained is the ability to fit the spectra acquired over time to a model containing physiological parameters that are known to change during the hemodynamic response and affect light reflectance. Optical spectroscopy therefore provides changes in physiologically relevant variables rather than reflectance changes.

Optical Spectroscopic Imaging

Optical imaging offers high spatial and temporal resolution while optical spectroscopy proves more accurate physiologic measures of hemoglobin oxygenation and concentration. Studies combining the advantages of these two techniques are now beginning to emerge. For spectroscopic imaging, full field images are acquired at multiple wavelengths, either in an interleaved manner with a fast filter changer or simultaneously using a beam splitter. The multiple wavelengths at each pixel are then treated as a discrete spectrum, and these pixel-by-pixel 'spectra' are fit to the spectroscopic model to extract value for the physiological parameters at each pixel. This approach produces high-resolution functional maps of hemodynamic responses, permitting the investigation of their evolution within parenchymal, arteriolar, and venous compartments with excellent detail and specificity.

Technique

Selection of Species

Optical imaging of intrinsic signals is done in a variety of species, including rodent, cats, nonhuman primates, and humans. Each offers distinct advantage and drawbacks. The rodent model offers a well-characterized lissencephalic somatosensory cortex with little intersubject variability, the potential to perform population-based studies, and the availability of genetically modified strains. The major drawback of the rodent model is the question of extensibility of results to human subjects. Cats have been used extensively for imaging of intrinsic optical signals, furthering our understanding of both neurophysiology and the organization of the visual cortex. The larger size of the brain relative to the rodent and its greater complexity are both significant advantages of using this subject over rodents. The higher complexity of the cat brain makes it more likely that results can be extrapolated to humans. Although results in primates are most extensible to human subjects, this model is limited by cost and the inability to perform population studies. Furthermore, because of the thickness and density of the cranium and dura, imaging in primates requires craniotomy and removal of the dura. Intraoperative mapping in humans provides an unparalleled opportunity to examine the basic physiology and organization of the functioning human brain. At the same time, intraoperative mapping poses unique challenges for data acquisition, analysis, and interpretation. These include the unique demands of the operating room environment with its physical constraints of sterility and mobility, time constraints, cooperation of awake patients, and other considerations.

Cortical Immobilization

To take advantage of the superior spatial resolution of optical imaging, it is critical that images acquired before and during activation be in identical locations since the former will be subtracted from the latter during analysis. The movement of the brain due to respiration and heartbeat presents a major obstacle. Five different strategies have been devised to overcome this challenge: the cranial window, the thin-skull preparation, stabilization using glass plates, synchronization with respiration and heartbeat, and postacquisition image registration. These approaches are not mutually exclusive, and in several circumstances more than one strategy can be used in a single experiment.

Figure 2 Optical imaging/spectroscopy apparatus. The experimental setup centers on the stereotax, in which the subject's head is immobilized. The cortex is illuminated by a light source, and reflected light is captured by the microscope optics, filtered for wavelength selection, and directed to both an imaging camera and, if desired, a spectrophotometer via fiber optic. Concurrent electrophysiology may be performed by mounting a recording electrode on the stereotax. Reproduced from Sheth SA, Nemoto M, Guiou M, et al. (2004) Linear and nonlinear relationships between neuronal activity, oxygen metabolism, and hemodynamic responses. *Neuron* 42: 347–355, with permission from Elsevier.

Data Acquisition

The imaging apparatus consists of a camera (a photodiode array, video camera, or a charge-coupled device) and an illumination source (voltage stabilized with appropriate filters for wavelength selection). The imaging camera is mounted on a microscope or lens assembly focused on the subject. For spectroscopy, a spectrophotometer and camera are also necessary. These may be directly attached to the microscope, or light may be guided to the spectrophotometer via fiber-optic cables. The latter option is particularly useful when simultaneously combining imaging and spectroscopy (Figure 2).

Once the cortical area of interest has been exposed, the imaging device is positioned appropriately, and images of the cortex are taken at rest and during activation. Analysis of optical images often requires at least one baseline image (i.e., prior to stimulus onset) in order to determine the change in signal from baseline. Most of the components that contribute to intrinsic signals return to baseline 8–10 s after stimulus offset.

Optical Imaging Data Analysis

Analysis of Single-Wavelength Data

For ratio analysis, a reference image is subtracted and divided from all images in a time series on a pixel-by-pixel basis. These ratio images represent fractional change from baseline at each spatial location. The reference image may be a prestimulus baseline image or a so-called cocktail image, which is a sum of multiple individual cortical images under different stimulus conditions, intended to represent the uniformly activated cortex. Using a cocktail blank assumes *a priori* knowledge about cortical functional architecture and neuronal interactions. Subsequent analyses can then be performed to study the spatial and temporal properties of the response, depending on the study purpose.

Analysis of Spectroscopic Data

Optical spectroscopy models are usually based on the Beer–Lambert law, which describes light attenuation in the presence of absorbers:

$$\mathrm{Abs} = \sum_i \varepsilon_i c_i l$$

where ε_i is the extinction coefficient of the ith absorber, c is the absorber concentration, and l is the pathlength through the tissue. In living tissue under normal physiological circumstances, deoxy-(Hbr) and oxyhemoglobin (HbO_2) are the most important absorbers in visible wavelengths. Calculation of attenuation due to absorption requires knowledge of the optical pathlength in the tissue, which is typically much greater than the tissue thickness due to scattering and is wavelength dependent. The pathlength may be calculated using Monte Carlo simulation or measured using a phantom. Attenuation is thus the exponential decrease in light intensity along the nonlinear path taken by the scattered photons:

$$\log\frac{I_0^\lambda}{I(t)} = \left(\varepsilon_{\mathrm{Hbr}}^\lambda \cdot \Delta[\mathrm{Hbr}](t) + \varepsilon_{\mathrm{HbO_2}}^\lambda \cdot \Delta[\mathrm{HbO_2}](t)\right) \cdot l^\lambda + \Delta S$$

where I_0 is the measured prestimulus intensity, $I(t)$ is the intensity time course, $\Delta[\mathrm{Hbr}](t)$ and $\Delta[\mathrm{HbO_2}](t)$ are the time courses of change in absorbers, S is scattering, and superscript λ indicates wavelength dependence. Spectral data are fit to the model using a least-squares analysis to extract the time courses of the model parameters (i.e., Hbr and HbO_2).

Combining Optical Imaging with Other Techniques

Intermodality comparisons are useful because each imaging technique offers different information about the cortical organization, anatomy, and physiology of the cortex of interest. Because each technique offers slightly different information about perfusion responses and holds different assumptions, optical imaging can be combined with electrophysiologic recordings or

other perfusion-related brain mapping modalities to characterize the etiology of perfusion-related neuroimaging signals.

Combining Optical Imaging with Electrical Recordings

Evoked field potential measurement or single-unit recordings can also be performed simultaneously with intrinsic signal imaging since the presence of electrodes does not interfere with optical responses. Such studies have been instrumental for investigating characteristics of neurovascular coupling and corroborating hemodynamic responses with actual measurements of neuronal activity. Optical signals correlate better with field potentials, which measure aggregate input activity in the region, than with spiking activity, which measures neuronal output.

Combining Optical Imaging and fMRI

BOLD fMRI is one of the mostly commonly used perfusion-based brain mapping modalities. Studies comparing BOLD with optical intrinsic signals are particularly advantageous for characterizing BOLD signals because the etiology of optical signals has been well scrutinized. Although many cite optical imaging studies to support the etiology of the BOLD signal, only a few intrasubject comparisons of optical intrinsic signals and BOLD fMRI exist.

A spatial/temporal mismatch has been noted between the early negative 610 nm response (which is attributed to increases in deoxyhemoglobin) and the BOLD signal in response to brief (2 s) somatosensory stimulation. Whereas the BOLD signal is centered on sulci, the negative 610 nm response is centered on gyri. In contrast, the positive 610 nm response and the BOLD signal demonstrate much greater spatial correlation (than the negative 610 nm response and the BOLD signals). Despite the greater spatial correlation, the positive 610 nm response still demonstrates greater gyral activations than BOLD signals.

Comparing fMRI signals, which are tomographic, with optical signals, which are surface signals, presents a challenge. In order to compare mapping signals from multiple modalities within a single subject, the different modalities must be warped into a common space. The common space used is the three-dimensional cortical model of each subject's brain (generated from high-resolution T1-weighted MR scans).

Combining Optical Imaging and Laser Doppler Flowmetry

Laser Doppler flowmetry (LDF) measures cerebral blood flow (CBF) at a single point on the cortical surface using a confocal laser and detector pair. This method can easily be incorporated into the experimental setup to provide information on CBF, a hemodynamic variable not directly assessable by optical imaging. Simultaneous imaging of changes in CBF and hemoglobin oxygenation permits the calculation of $CMRO_2$. Two-dimensional images of CBF can also be obtained by scanning the laser in a raster pattern across the surface or using laser speckle imaging, a related modality that generates two-dimensional CBF maps. When combining LDF with optical imaging, an appropriate filter should be placed in the optical imaging light path to prevent interference between the two. Most LDF devices use a helium–neon laser that operates at 632.8 nm; thus, this wavelength must be excluded both from incidence on the cortex by the optical imaging illuminator and from detection, or at least analysis, by the imaging camera.

Applications

Characterization of Visual and Somatosensory Cortices

The high spatial resolution of optical imaging has made it an ideal modality for characterizing the fine functional architecture of sensory (both visual and somatosensory) cortices on a submillimeter scale. By imaging visual cortex responses to gratings of different orientations, Bonhoeffer and Grinvald demonstrated that neurons responsive to gratings of the same orientation are grouped together and are organized in pinwheel-shaped patterns. This underlying organizational element is consistent in visual cortex orientation domains from cats to primates.

Similarly, optical imaging of intrinsic signals has been used to demonstrate ocular dominance domains in primary and secondary visual cortex of macaque monkeys. Studies in conjunction with single-unit electrophysiology and cytochrome oxidase (CO) histology have better characterized the functional organization within the CO stripes of visual area V2 of primates, detailing previously unrecognized subcompartments within individual CO stripes that are specific for color, orientation, and retinal disparity.

Optical imaging has similarly been applied in human subjects to characterize language and somatosensory (hand and face) cortices. Pouratian and colleagues have studied the organization of language cortices both within and across languages and demonstrated unique spatial and temporal activation patterns of language areas in a task- and language-dependent manner.

Characterization of Functional Perfusion and Neurovascular Physiology

Since perfusion-related imaging techniques (e.g., fMRI and optical imaging) measure hemodynamic

Figure 3 Columnar specificity of optical maps. Columnar specificity of the hemodynamic responses was studied in the rat barrel cortex. Vertical and flat projections of neighboring columns identified by cytochrome oxidase (CO) staining are shown in red and yellow. These projections pass through peak CBV and early deoxygenation responses overlaid on raw images, demonstrating localization of both responses with underlying anatomy. Contours enclosing the peak response area for CBV (green) and early oxygenation (blue) responses are overlaid on CO images. Contours for both responses demonstrate the spatially distinct representations of both hemodynamic responses. Reproduced from Sheth SA, Nemoto M, Guiou M, et al. (2004) Columnar specificity of microvascular oxygenation and volume responses: Implications for functional brain mapping. *Journal of Neuroscience* 24: 634–641, with permission. Copyright 2004 by the Society for Neuroscience.

responses instead of neuronal activity directly, it is imperative to understand the relationship between the two. Several optical imaging studies have investigated neurovascular coupling with simultaneous optical imaging and electrophysiology. Sheth and colleagues showed that the CBV response co-localizes to active cortical columns more precisely than the late oxygenation response, reflecting the fact that blood volume is controlled on a fine spatial scale at the level of precapillary arterioles, whereas hyperoxygenation changes are greatest in downstream draining veins that can be hundreds of micrometers to millimeters from active neurons (Figure 3). In addition, changes in the magnitude of CBV correlate linearly with input synaptic activity, as measured by evoked field potentials. On the other hand, hyperoxygenation changes are nonlinearly related, making their interpretation more challenging.

The degree to which neurons rely on oxidative metabolism has been a topic of controversy for years. Measuring cerebral oxygen metabolism with optical spectroscopy and LDF, Mayhew and colleagues demonstrated that oxygen utilization increases within 1 s of neuronal activity. Sheth et al. additionally found that oxygen metabolism increases linearly with neuronal activity beyond a certain threshold, suggesting the presence of an oxygen buffer or the reliance on nonoxidative respiration for low-level activity.

Imaging Development and Plasticity

Several groups have taken advantage of the ability to use optical imaging for chronic imaging to characterize both developmental and plasticity-related changes in functional architecture and perfusion-related signals. The development of orientation domains has been characterized in ferret visual cortex, from the time that they are first observed postnatally to the time at which they are fully developed. Pouratian and collaborators characterized developmental changes in intrinsic signals in the rodent barrel cortex, showing that whereas some aspects of hemodynamic signals change throughout the developmental period, others remain relatively stable and unchanged throughout development.

Optical imaging has also been used to image neocortical plasticity. Whereas Prakash and collaborators demonstrated rapid representational changes in barrel cortex response after addition of either brain-derived neurotrophic factor or nerve growth factor, others have used optical imaging to demonstrate more long-term changes in functional representations secondary to physical manipulations of the subject. Polley and colleagues showed that long-term whisker removal and differing degrees of environmental stimulation alter neuronal responses in the barrel cortex. While a single whisker's functional representation underwent expansion following innocuous removal of all neighboring whiskers, a contraction could also be induced, using the same manipulation, if the animal was given a brief opportunity to use its whiskers for active exploration of a different environment. Grinvald et al. investigated the stability of ocular dominance columns in macaque visual cortex with chronic optical imaging and found that they remained stable over a period of more than 1 year.

Imaging Disease

Haglund and colleagues were the first to observe optical signals in humans, reporting activity-related changes in cortical light reflectance during cortical stimulation, epileptiform afterdischarges, and cognitive tasks. Large optical signals were found in the sensory cortex during tongue movement and in Broca's and Wernicke's language areas during naming exercises.

Pouratian et al. investigated spatial and temporal properties of hemodynamic responses intraoperatively in sensory, motor, and language cortices. They demonstrated functional segregation of languages in a bilingual patient in expressive language areas

Figure 4 Optical imaging of language representations in a bilingual patient. This Spanish–English bilingual patient was undergoing brain surgery for tumor resection. She was awakened during surgery to map her language function. (a) Map of optical activity observed during English visual object naming. (b) Map of optical activity during Spanish visual object naming. Color bar represent percent optical signal change from base line. (c) Comparison of English and Spanish visual object naming. Optical maps from images shown in (a) and (b) are thresholded and displayed in blue and yellow, respectively. The pink color indicates areas of activation overlap between the two languages tested. (Figure 4). Of clinical interest, these studies evidence a developing role for optical imaging in intraoperative guidance and surgical planning, helping the neurosurgeon delineate eloquent areas that must be spared during the operation.

Conclusions

Optical imaging based on intrinsic signals is unique among functional neuroimaging techniques in that it offers both high spatial (on the order of micrometers) and temporal (on the order of milliseconds) resolution simultaneously with high spatial sampling. The resolution of optical imaging makes it ideal for a variety of experimental investigations, including studying the functional organization of and functional relationships within the brain, characterizing neurovascular physiology, and examining pathophysiological changes due to disease.

Optical Monitoring of Exo- and Endocytosis

Fluorescent Visualization of Synaptic Vesicle Fusion and Recycling

Despite their versatility, electrophysiological methods typically report neurotransmitter release from a population of synapses or release sites. In most cases, unitary quantal transmission can only be detected using recordings of spontaneous neurotransmission or under settings that activate a very small number of synapses. Moreover, these methods usually provide little or no spatial information about the origin of release. Optical experiments using fluorescent probes, on the other hand, report release at the level of individual synapses. These methods either monitor Ca^{2+} influx through postsynaptic NMDA receptors or directly monitor presynaptic properties using styryl dye imaging and green fluorescent protein (GFP)-tagged synaptic vesicle proteins.

NMDA receptor-mediated Ca^{2+} influx provides a valuable reporter of postsynaptic receptor activation in response to presynaptic glutamate release. NMDA receptors have a very high affinity for glutamate ($\sim$1 μM); thus, they can detect even subtle fusion events that may not release sufficient glutamate to activate AMPA receptors. In addition, in response to a single quantal fusion event, postsynaptic NMDA receptors are not saturated, which enables measurements of release with a large dynamic range despite their high affinity. Therefore, this approach has provided evidence of multivesicular release in central synapses. Ca^{2+} indicator dyes with adequate linear response range and affinity can be used to detect Ca^{2+} signal in the single dendritic spine evoked by quantal release events. This method, by its very nature, is limited to glutamatergic synapses or synapses with reliable postsynaptic Ca^{2+} selective channels (e.g., some subtypes of nicotinic acetylcholine receptors or purinergic receptors, such as P2X receptors). Moreover, the properties of neurotransmitter release can only be inferred postsynaptically; therefore, the same caveats that apply to electrophysiological recordings in principle apply to this method as well. However, the ability to monitor neurotransmission at the level of individual synapses and the availability of a wide variety of Ca^{2+} indicators make this a method of choice for the investigation of synaptic activation in intact tissues such as brain slices using two-photon imaging.

In addition to postsynaptic Ca^{2+} imaging, several fluorescence imaging modalities have been introduced which primarily report synaptic vesicle fusion and endocytosis. These methods either take advantage of styryl dyes that can be loaded into recycling vesicles or they utilize exogenous expression of synaptic vesicle proteins tagged with a pH-sensitive variant of GFP at regions facing the vesicle lumen. Styryl dyes, such as FM1-43 and FM2-10, are amphipathic compounds that label recycling synaptic vesicles in an activity-dependent manner. This optical approach is also useful for monitoring the kinetics of replenishment for the release ready pool of vesicles in a synapse. Furthermore, uptake and release of these dyes provides an accurate indication of synaptic vesicle reuse during activity. GFP-tagged synaptic vesicle proteins such as synaptobrevin and synaptophysin, on the other hand, provide a molecularly specific way to examine surface exposure and reinternalization of these proteins during synaptic vesicle exo- and endocytosis.

Functional Analysis of Exocytosis and Vesicle Recycling Using Styryl Dyes

In the past decade, significant advances in our understanding of the dynamics of the synaptic vesicle cycle were made possible by the availability of new optical probes. The first set of probes were the styryl dye FM1-43 and its analogs. FM1-43 is a partially lipophilic dye, which increases fluorescence 100-fold when it partitions into membranes and thus it is virtually invisible in aqueous solution. Because of its chemical structure FM1-43 cannot cross lipid membranes, thus limiting the fluorescence labeling to outer membranes and recycling vesicles (Figure 1). Using this methodology, one can detect activity-dependent vesicular dye uptake and release in synaptic connections in multiple preparations, including central neuronal cultures. Studies using FM dyes have found that activity-induced dye uptake and release operates with high fidelity. Specifically, the extent of fluorescent dye endocytosed during a particular stimulation matches the magnitude of fluorescence loss due to exocytosis in response to the same stimulation. This observation suggests that synaptic vesicles recycle without intermixing with endosomal compartments and thus the fluorescence probes do not get diluted.

The properties of styryl dyes make them useful tools for obtaining quantitative information on vesicular recycling within a presynaptic terminal. These dyes can be inserted into membranes within milliseconds; however, with increasing lengths of their hydrocarbon chains, they have decreasing rates of dissociation from

Figure 1 Optical monitoring of vesicle recycling using FM dyes. FM1-43 and its analogs are partially lipophilic dyes which fluorescence increases almost 100-fold when they partition into membranes. Therefore, they are virtually invisible in aqueous solution. Because of its chemical structure FM1-43 cannot cross lipid membranes, thus limiting the fluorescence labeling to outer membranes and recycling vesicles. During a typical experiment, stimulation in the presence of extracellular dye leads to uptake of dye molecules into vesicles that have undergone exocytosis followed by endocytosis. Subsequent washout of extracellular dye uncovers fluorescent staining specific to actively recycling vesicles during the stimulation paradigm. Consequent stimulation results in fusion of dye-loaded vesicles and loss of fluorescence trapped in synapses. This fluorescence loss is due to departitioning of the dye into aqueous solution or lateral diffusion of dye in neuronal membrane. During kiss-and-run endocytosis, a protein barrier that makes up the fusion pore restricts FM dye lateral diffusion. If vesicle retrieval is faster than the dye departitioning rate, then endocytosed synaptic vesicle may still contain residual dye.

membranes. Previous measurements have shown that FM1-43 departitions from the lipid to aqueous environment with a time constant of 2.5 s, whereas its analogs, FM2-10 and FM1-84, departition with time constants of 0.6 and 4.8 s, respectively. These differential departitioning properties of FM dyes can be exploited to estimate the kinetics of endocytosis in hippocampal synapses. Because of FM2-10's membrane dissociation rate, destaining experiments with the dye provide the closest estimates of vesicle mobilization and exocytosis. In contrast, the same experiments performed with FM1-43 may be vulnerable to dye trapping due to fast endocytosis. Since the introduction of FM dyes, several studies have reported partial release of FM1-43 upon synaptic vesicle fusion during multiple forms of stimulation. In some studies, destaining rates of synaptic boutons stained with FM2-10, FM1-43, and FM1-84 were slower in proportion to the increasing time constants of departitioning. These initial observations were later extended by experiments examining FM dye loss from single vesicle fusion events. The common interpretation of partial FM dye release is the presence of a fast endocytotic mechanism, which preferentially traps the slowly departitioning dyes, FM1-43 and FM1-84, in synaptic vesicles. Partial dye release is only possible if a barrier (presumably a protein-based fusion pore) between the vesicle membrane and the plasma membrane delimits lateral diffusion of FM dye following the formation of the vesicle–plasma membrane interface. However, in other systems such as goldfish bipolar cells, all FM dyes have been reported to laterally diffuse out of fused vesicles and thus lose fluorescence irrespective of their departitioning rates in aqueous solution.

A significant proportion of endocytosis occurs following the cessation of stimulation, albeit on a slower timescale. This slow endocytosis may require formation of clathrin coats, followed by a recycling pathway in which vesicles go through an endosomal intermediate structure and recover all of the necessary molecular components. Alternatively, recycling vesicles can be formed from membrane invaginations called 'cisternae' that develop adjacent to the active zone. Reformation of synaptic vesicles from these endosomal structures requires clathrin and clathrin adaptor proteins that bind to specific synaptic vesicle membrane proteins. Studies of the frog neuromuscular junction have shown that a slow endocytosis pathway, characterized by large membrane invaginations formed in response to prior activity, operates at rest for at least 10 min or more after cessation of exocytosis and selectively traps FM1-43 but not FM2-10. The slowly endocytosed membrane can form synaptic vesicles, which in turn can mix with the reserve pool and become reavailable for release with a delay. FM2-10 uptake, in contrast, occurs in rapidly endocytosing vesicles, which preferentially populate the readily releasable pool (RRP) and give rise to the fast component of destaining.

In a typical experiment to estimate slow endocytosis, one can stimulate synaptic terminals with 10–30 Hz field stimulation for 30–60 s and rapidly perfuse FM1-43 onto the preparation (for 60 s up to 10 min) at gradually increasing delays following the cessation of stimulation. The time course of decrease in the amount of fluorescence trapped within synapses provides an estimate of the time constant of slow endocytosis. This time constant has previously been

shown to slow with increasing extent of depletion of vesicles in the neuromuscular junction. However, in these studies, parallel control experiments are essential to account for the potential effect of changes in the level of exocytosis. Evidence indicates that the number of fused vesicles can regulate the rate of endocytosis. Under the same conditions more rapid endocytosis can be quantified when dye is applied concomitantly during stimulation and washed out rapidly afterwards with no delay. Fast endocytosis is typically tightly coupled to exocytosis, and it is thought to be critical for maintenance of sustained neurotransmission.

The measurement of the size of functionally distinct vesicle pools is critical in linking the structure and function of presynaptic terminals. Styryl dyes are also quite useful in the determination of vesicle pool sizes at the level of individual synapses. For these measurements, it is important to distinguish changes in the Ca^{2+} dependence of the release machinery from changes in numbers and maturational (release competent) states of synaptic vesicles. This distinction can be achieved by using saturating levels of Ca^{2+}-dependent stimulation or Ca^{2+}-independent stimulation, such as by hypertonic sucrose application (typically +500 mOsm), to mobilize vesicles. The recycling kinetics of RRP vesicles can be determined using uptake and release of the styryl dye FM2-10 in response to hypertonic stimulation. To determine the total recycling pool, uptake and release of styryl dyes can be induced by sustained depolarization achieved via application of elevated potassium solution. This strong stimulation can induce mobilization of virtually all vesicles capable of recycling within individual synapses. Comparison of the two fluorescence measurements (RRP vs. the total recycling pool) can reveal critical information regarding the functional allocation of vesicles to a particular pool in given condition.

Detecting the release of FM dyes after their uptake into the synapse is a commonly used method to quantify synaptic vesicle reuse in synapses. In these experiments, FM dye is applied during and/or immediately after stimulation to label endocytosing vesicles. The dye-containing solution is then swiftly washed out to prevent further dye uptake. This dye application stains a number of vesicles depending on the stimulation strength as well as the duration of dye presence. Application of a second stimulation at gradually delayed time points (typically 0–120 s) causes dye loss due to the reavailability of labeled vesicles. However, the proximity of stimulations inducing dye uptake and release makes it difficult to image actual dye loss during the second stimulation because of the high fluorescence background originating from residual dye. This shortcoming is usually circumvented by monitoring the remaining detectable staining at a later time point (typically ~5 min) after complete dye washout. The releasable fluorescence trapped in the synapse gradually decreases following stimulation applied at longer intervals or for longer durations after dye washout. The time course of this decrease in fluorescence provides an estimate of the time constant of vesicular reuse, which is the time it takes for an endocytosed vesicle to become release ready again. This is a very sensitive method for detecting vesicle reuse. As stated previously, the major caveat is the background fluorescence: although usually not sufficient to restain vesicles during stimulation, it makes fast imaging nearly impossible. Because of this problem, the vesicle reuse kinetics is typically reconstructed from a population of synapses rather than from repeated measurements at individual presynaptic terminals.

Detection of Synaptic Vesicle Exocytosis and Endocytosis Using pHluorin Tagged Synaptic Vesicle Proteins

Synaptophluorin (spH) is another fluorescent probe that is commonly used to monitor exocytosis and endocytosis of synaptic vesicles. spH was originally engineered by Gero Miesenbock and colleagues as a fusion construct of the synaptic vesicle protein synaptobrevin (also called vesicle-associated membrane protein) with a pH-sensitive enhanced green fluorescence protein (EGFP) at its C-terminal (located in the synaptic vesicle lumen). Synaptic vesicle lumen normally has an acidic pH of approximately 5.5, at which spH fluorescence is quenched. When vesicles fuse, lumenal EGFP is exposed to the extracellular pH, which results in a marked increase in its fluorescence. Studies using spH have provided valuable information on the tight coupling between exocytosis and endocytosis. One advantage of the spH probe is the molecular specificity of the fluorescence signal since the signal originates from a synaptic vesicle protein as opposed to nonspecific lipid-based fluorescence of FM dyes. Proton diffusion from a synaptic vesicle is not expected to be limited, and the time course of vesicle reacidification is thought to be fast without imposing a significant delay in the fluorescence signal during spH endocytosis. Although most studies have used synaptobrevin as a carrier for the pHluorin tag, recent studies have taken advantage of other synaptic vesicle proteins as pHluorin attachments. Surprisingly, in these experiments, different synaptic vesicle proteins tagged with pHluorin gave different results with respect to their background fluorescence (i.e., surface exposure) and retrieval. For instance, both synaptophysin (a four transmembrane domain synaptic vesicle protein) and the vesicular glutamate transporter reveal very little surface exposure (thus fluorescence) in the absence

of stimulation. Once stimulated, they show a swift increase in fluorescence without significant lateral diffusion upon fusion, which was a salient feature of spH-based measurements. The dependence of the properties of pHluorin-based measurements on the identity of the tagged protein complicates a straightforward interpretation of these experiments in terms of synaptic vesicle recycling. Despite this caveat, these measurements reveal critical information with regard to copy numbers and specific cell biological attributes of synaptic vesicle proteins (Figure 2).

Inhibition of vesicle reacidification by blockers of the vacuolar ATPase is useful for dissecting the kinetics of exocytosis and endocytosis in pHluorin-based measurements. In response to brief field stimulation, synaptophysin-pHluorin (or spH) fluorescence shows a rapid increase and a gradual slow return to baseline, presumably due to slow compensatory endocytosis. However, when the same experiment is repeated in the presence of a vacuolar ATPase blocker (e.g., folimycin), synaptophysin-pHluorin fluorescence shows a larger increase detectable within the first 500 ms. The difference between these two signals can be taken as an indication of endocytosis with the assumption that reacidification of vesicles upon endocytosis proceeds rapidly and requenches internalized pHluorin. However, current estimates of synaptic vesicle reacidification differ widely. According to some estimates, reacidification may take place within 500 ms upon endocytosis. In contrast, findings in hippocampal cultures suggest a relatively slow time course (~5 s). These slower estimates derive from measurements of synaptic vesicle reacidification during delayed endocytosis following stimulation and therefore may not take into consideration a fast component of vesicle reacidification. The vesicles that are endocytosed with a delay after stimulation may end up being slowly reacidified due to slower reassembly of their protein complements, whereas vesicles that are endocytosed rapidly during stimulation may be reacidified rapidly because their protein components (including the vacuolar ATPase) are more likely to be intact.

Figure 2 Synaptophluorin (spH) is a fusion construct of the synaptic vesicle protein synaptobrevin with a pH-sensitive EGFP at its C-terminal (located in the synaptic vesicle lumen). The synaptic vesicle lumen normally has an acidic pH of approximately 5.5, at which spH fluorescence is quenched. When vesicles fuse, lumenal EGFP is exposed to the extracellular pH, which results in a marked increase in its fluorescence. During endocytosis, pHluorin fluorescence is requenched as vesicle lumen becomes acidic. Following fusion, the absence of a diffusion barrier between the vesicle membrane and the plasma membrane may result in lateral diffusion of spH.

Experiments have shown that once the surface fluorescence is quenched, it is possible to monitor single vesicle fusion events using spH as a probe. Using this setting, Gandhi and Stevens detected single vesicle fusion events with square pulse-like rapid alkalinization and reacidification behavior akin to single ion channel openings. These findings suggest that the number of spH molecules per vesicle is preserved during the exocytosis and endocytosis cycle, in a manner consistent with the kiss-and-run hypothesis. However, the same results were not reproducible with a pHluorin fusion construct of synaptophysin, suggesting that rapid reversal of pHluorin signal may be due to lateral diffusion of synaptobrevin because the synaptophysin-pHluorin does not laterally diffuse upon vesicle fusion.

Comparison of Styryl Dye Imaging and pHluorin-Based Visualization of Exo- and Endocytosis

Although FM dyes and spH are commonly used to measure endocytosis and exocytosis, there are advantages and disadvantages to both. FM dye measurements have been instrumental in tracing vesicles during their cycle in the synapse. Using uptake and release of FM dyes, one can obtain results regarding vesicle mixing with endosomal compartments or repeated use of the same vesicles during activity which would be difficult to attain using probes such as spH. FM dyes report lipid cycling; spH reports the fate of synaptic vesicle protein synaptobrevin (or others) upon fusion and endocytosis. Sph is a genetically expressed probe which facilitates more reproducible repeated measurements on the same set of synapses (because it does not require dye uptake). Furthermore, spH can also be transgenically expressed in mice, which makes *in vivo* measurements of synaptic vesicle trafficking possible. However, measurement of endocytosis with spH is confounded by two factors. First, lateral diffusion of vesicular spH following fusion is commonly observed. It is unclear whether reuptake of spH truly reflects endocytosis of vesicles or, rather, reclustering and reinternationalization of synaptobrevin. It is also unknown whether endocytosis of lipid and protein components of synaptic vesicles represents

distinct processes or whether they are coupled. Second, the dependence of endocytosis measurements on vesicle reacidification may delay the fluorescence signal after spH internalization. There are also concerns with regard to using FM dyes. Typically, FM dye measurements suffer from nonspecificity. FM dyes stain the surface membrane indiscriminately; thus, they are less specific to synaptic vesicles. Moreover, changes in FM dye fluorescence typically occur slowly, on the order of seconds, making it difficult to detect events in the millisecond timescale, which more closely matches the time course of neurotransmission. In addition, after FM dye uptake, preparations need to be washed with dye-free solution for a significant period to reduce background fluorescence, which limits the rapid detection of synaptic vesicle reavailability after endocytosis.

In summary, spH provides a molecularly specific probe to monitor the coupling between exocytosis and endocytosis, whereas FM dyes are better at tagging vesicles during their cycling within the synapses. Thus, these two optical probes complement each other in monitoring distinct aspects of the synaptic vesicle cycle.

Optokinetic Eye Movements

General Introduction: Optokinesis and Visual–Vestibular Interaction

Much of vertebrate behavior is dependent on optimal processing of visual information. The image of a stationary or moving object must be maintained relatively stable on the retina if the object is to undergo detailed examination. This is achieved by different motion compensation and tracking systems, including vestibular ocular, optokinetic, smooth pursuit, saccadic, and vergence eye movement systems. Previous studies in humans have shown that retinal image motion speeds greater than a few degrees per second cause degradation in optimal visual performance. Stable gaze during locomotion is necessary to maintain the visual image of an object of interest from slipping on the retina.

The main gaze stabilizing reflex is the vestibulo-ocular reflex (VOR). The VOR generates compensatory eye movements during head movements, allowing viewers to maintain their line of sight, or gaze, on a stationary object. Linear and rotational accelerations of the head are sensed by otolith-related and semicircular canal-related neurons, respectively. Vestibular afferents carry a head velocity signal to central vestibular neurons, which in turn drive oculomotor neurons to produce the rotational and translational vestibular–ocular reflexes (rVORs and tVORs). This simple three-neuron VOR arc can be adjusted by visual inputs traveling in relatively direct and indirect pathways.

The optokinetic system works synergistically with the vestibular ocular system to extend its dynamic range. For example, VOR gain (eye velocity/head velocity) is typically less than 1.0 when measured in darkness. However, in the presence of a visual target, the visually enhanced VOR has gain of 1.0. Visual enhancement of the VOR could be due at least in part to summation of the VOR and visually mediated tracking, including reflexlike optokinetic and volitional smooth pursuit-generated responses to retinal image motion. Such visual following responses support the VOR to maintain clear vision across a broad range of head accelerations. In addition, visual error signals provided by direction- and speed-sensitive neurons of the optokinetic system are essential for adjusting VOR gain in response to physiological or pathological challenges to vestibular–ocular function. Finally, because the adequate stimulus for the VOR is head acceleration, compensation during constant-velocity head movements would fail without the support of the optokinetic system, which produces compensatory eye movements during continuing visual motion. In this article, the focus is on the organization of horizontal optokinetic eye movements and their development.

Optokinetic Eye Movements: Afoveate Mammals

The optokinetic system plays an essential role in stabilizing the visual image on the retina by producing compensatory eye movements in the direction of visual motion. Direction-selective (DS) retinal ganglion cells provide initial visual motion information to nuclei of the accessory optic system (AOS, see later) appropriate for driving slow optokinetic eye movements of afoveate mammals.

The preferred directions for DS retinal ganglion cells of rabbits are aligned close to the activation/inactivation planes of the semicircular canals, facilitating visual–vestibular interaction.

In this article, the focus is on the horizontal optokinetic eye movements. In animals capable of making significant eye movements, large-field visual motion produces reflex following responses of the eyes. Optokinetic eye movements can follow relatively high-frequency oscillation of the visual world, as might occur during head movements associated with locomotion (Figure 1).

During unidirectional large-field visual motion over an extended time, a pattern of eye movements called optokinetic nystagmus (OKN) occurs. OKN is composed of slow, compensatory, following movements in the direction of visual motion and quick resets (Figure 2). An optokinetic response (OKR) has been observed in all vertebrates tested, from fish to humans. Here, the focus is on the OKR of mammals. Mammals lacking a fovea or significant central retinal specialization (e.g., fovea or area centralis), such as mice, rats, guinea pigs, and rabbits, typically have laterally placed eyes with minimal binocular overlap in the visual field representation from each eye. In afoveate mammals the is strongest during low-speed ($<10^\circ\ s^{-1}$) visual motion, directed toward the nose (nasalward).

The major pathway supporting optokinetic eye movements in afoveate mammals involves direct retinal inputs to brain stem nuclei of the AOS. There is little evidence for cerebral cortical control of optokinetic eye movements in afoveate mammals. The adequate stimulus for eliciting an OKR in lower

Figure 1 Examples of optokinetic eye movements elicited during high-frequency (5 Hz), low-amplitude (± 1°) oscillation of either small-diameter (0.1°; left panel) or large-field (± 75°; right panel) visual stimuli. Stimuli were rear projected on a tangent screen 57 cm distant from the eyes. Visual stimuli were moved by driving a galvanometer with a triangle-wave produced by a function generator or computer D/A. Five successive cycles of oscillation are shown. The gain of these eye movements is low (0.1–0.2) for such high-frequency, periodic motion. Traces as indicated in the key. Eye movements were recorded from a mature monkey (*Macaca mulatta*) using an electromagnetic method (CNC Engineering, Seattle, WA) employing scleral search coils.

Figure 2 Example of OKN and after-nystagmus (OKAN) recorded from a mature monkey (*Macaca mulatta*). Rightward continuous visual motion (50° s^{-1}) was projected on a cylindrical screen using a planetarium projector for 30 s. Prior to stimulus onset, the monkey sat in complete darkness with the head held stable. Visual motion commenced after a variable amount of time (arrow, ON) producing a rapid rise in eye velocity followed by a more gradual buildup to visual stimulus velocity. When the visual stimulus was turned off, leaving the monkey in complete darkness, eye movements continue as OKAN. Traces from the top: horizontal eye (HE) position and horizontal eye velocity. Occasional rightward quick-phases have been removed and leftward quick-phases have been clipped for clarity. Vertical dashed lines indicate visual stimulus onset and offset times. Eye movements were recorded with the scleral search coil method.

mammals is large-field visual motion; however, small-field stimuli can also produce optokinetic following movements in frontal-eyed, foveate mammals (Figure 1). The gain of the OKR (eye velocity/visual velocity) approaches 1 for low-speed (e.g., $<10° s^{-1}$) continuous motion in afoveate mammals but can reach much higher speeds ($>100° s^{-1}$) in cats and primates.

Optokinetic Eye Movements: Primates

Primate optokinetic eye movements have similarities to those observed in afoveate mammals, with additional features related to adaptations for frontally placed eyes and foveal vision. For example, to maintain the image of a moving object on the fovea, it may be necessary to suppress the OKR or the VOR. This would occur when an object of interest moves in the direction of head movement. Suppression of OKN or VOR is made possible by extensive descending cerebral cortical projections to specific brain stem nuclei (see later).

During continuous visual motion as might occur during slow head turns, compensation would cease when the eyes reached the limit of rotation. This problem is minimized by insertion of resetting eye movements called quick-phases (Figure 2) that bring the eyes back into a usable portion of the oculomotor

range. Therefore, during unidirectional, constant-speed visual motion a characteristic pattern of slow, conjugate, compensatory eye movements with quick resets occurs; this is called OKN (Figure 2). Quick-phases have amplitude–velocity relationships that fall on the main sequence for saccadic eye movements. The quick-phases are high-velocity (100–800° s^{-1}) resetting movements that play no role in compensation *per se*, other then getting the eye back into a usable portion of oculomotor range. In contrast, the slow, compensatory eye movements of OKN can match visual stimulus velocity over a wide range (e.g., 1–180° s^{-1}) of speeds in macaques. Compensatory eye movements associated with OKN are best illustrated in eye velocity plots where saccades are removed from the records (Figure 3).

An effective method for observing all components of the OKR is to expose an alert viewer to sudden onset of large-field unidirectional visual motion. OKN is induced when the viewer is observing a moving pattern either projected on a screen or placed on the surface or a cylinder rotating around the viewer.

Figure 2 illustrates OKN of a macaque monkey during unidirectional, horizontal visual motion presented on a cylindrical screen 57 cm distant. The gain (measured at steady state) of the OKR is modulated by extent of field stimulated, stimulus contrast, and spatial frequency. To obtain an optimal response, the entire visual surround should contain moving contours and no fixation points, because fixation can stop OKN. In primates, strong optokinetic eye movements can be elicited even when only central 10° of the retina is stimulated, reflecting the foveal/ parafoveal importance in primate vision. To examine the in isolation, the head is held stable. At the start of the experiment, the animal is sitting in complete darkness, when at a random time unidirectional visual motion is provided by a rotating striped cylinder or a pattern projected with an appropriate continuous motion system (e.g., planetarium; Figures 2 and 3) is suddenly illuminated. This produces a rapid rise in eye velocity at 100 to 150 ms latency, followed by a gradual buildup in eye velocity over 4–7 s, until eye velocity matches visual stimulus velocity during steady-state OKN. These two components of OKN are thought to reflect activity in different neural circuits (see later). Compensatory eye speed during OKN saturates at about 180° s^{-1} in macaques and OKN gain is less than 1.0 for greater speeds. The initial rapid jump in eye speed can reach 40–80% of the maximum compensatory OKR and probably reflects contributions from reflex following and smooth pursuit. Eye velocity continues to increase following this initial jump in eye speed, to match visual stimulus velocity. The gradual buildup in eye velocity takes 10–15 s and is due to charging a so-called velocity storage mechanism that is shared between the optokinetic and vestibular ocular systems. This velocity storage system is essential for extending the effective time constant of the vestibular ocular response due to head acceleration or during constant-velocity head movement in the light.

The gain of OKN is affected by the state of the viewer, as demonstrated in testing human study participants. If viewers passively stare at the optokinetic stimulus, gain is less (0.85–0.9) than if they actively track individual stimulus contours, where gain approaches 1.0. It is thought the higher gain during active tracking reflects the addition of volitional smooth pursuit to optokinetically driven eye movements. Such modulation of OKN in frontal-eyed, foveate animals depends on cortical–brain stem pathways (see later).

Optokinetic Eye Movements and Short-Latency Ocular Following Response

As reviewed previously, the latency for eye motion onset with respect to visual motion onset during OKN testing is rather slow (100–150 ms). However, this rather long latency may not capture the actual functional capability of the optokinetic system. A short-latency (50 ms), ocular following response (OFR) can be produced by sudden movement of a large-field visual stimulus presented on a tangent screen in front of the viewer. The OFR stimulus simulates visual motion that occurs during head translation and the tVOR. OFR gain is modulated by viewing distance and retinal image disparity, appropriately supporting the tVOR in gaze stabilization.

The OFR response occurs with maximum gain and shortest latency (50 ms) when the step of visual motion is presented 10–50 ms following a centering saccade. The saccadic target is extinguished before saccade termination, preventing fixation. A major difference between OFR and OKN testing can be found in the method used for delivering the visual stimulus. Typically, OKN is produced by suddenly illuminating a rotating and striped cylinder already moving continuously around the viewer. This sudden onset of the visual surround activates the transient response mechanisms of middle temporal/medial superior temporal (MT/MST) neurons. Subsequently, specific DS mechanisms take over to produce an optokinetic eye movement at longer latency than observed during OFR.

The stereotyped nature of the OFR has proved to be helpful in studying the neural substrate for transformation of visual motion signals into commands for

Figure 3 Immature pattern of horizontal OKN recorded from an infant monkey (*Macaca mulatta*) using the scleral search coil technique. Rightward and leftward visual motion ($55^\circ\,s^{-1}$) was presented sequentially on a cylindrical screen (57 cm distant), using a servo-controlled, planetarium projector. Upward deflection of the shutter trace indicates when the visual stimulus was on (OKN). Following visual stimulation, eye velocity continued as after-nystagmus (OKAN) and reversed direction as OKAAN. When OKAAN eye velocity approached $0^\circ\,s^{-1}$, visual motion was presented in the opposite direction. During binocular viewing (top panel) a 4-week-old monkey produces symmetrical OKN that gradually builds (no rapid rise) to match visual stimulus velocity. During monocular viewing, the 4-week-old monkey shows an immature pattern of OKN with strong nasalward and weak temporalward responses (middle panel). At 6 weeks of age (bottom panel), monocular OKN approaches a mature pattern, with nearly symmetric nasalward and temporalward responses. A rapid rise in eye velocity at the start of OKN is now evident. Eye traces from the top: horizontal eye position and desaccaded horizontal velocity. Horizontal dashed lines indicate the steady-state eye velocity reached during $55^\circ\,s^{-1}$ visual motion.

eye movements. Multivariate statistical and inverse dynamics modeling studies of neuronal response related to retinal image or eye motion (position, velocity, and acceleration) have demonstrated that MST, dorsolateral pontine nucleus (DLPN), and pretectal nucleus of the optic tract (NOT) neurons are best modeled using visual motion parameters. In contrast, ventral paraflocculus (vPF) neuronal response appears to code eye motion *per se*. Therefore, visual motion signals appear to be converted into motor commands for OFR in the vPF of the cerebellum.

Signals carried in the MT–DLPN–vPF pathway (Figure 4) play a role in OFR and smooth pursuit. However, volitional smooth pursuit certainly involves additional pathways, including the frontal eye fields, nucleus reticularis tegmenti pontis (NRTP), and cerebellar vermis. The MST–DLPN–vPF pathway has been considered to be part of the direct or early pathway for producing OFR and a rapid rise in eye velocity during OKN. Pathways traveling from the pretectal NOT and terminal nuclei of the AOS, including the lateral and medial terminal nuclei,

Figure 4 Simplified diagram indicating major sources for visual motion signals that play a role in optokinetic, ocular following, and smooth pursuit eye movements of primates. For example, rightward small- or large-field visual motion leads to rightward optokinetic following movements. Visual motion signal travel in the retinal AOS (LTN/NOT, lateral terminal nucleus/pretectal nucleus of the optic tract) emphasizes the contralateral eye (nasal retina). Visual motion signals also travel in retino-geniculo-striate-extrastriate pathways essential for visual motion processing. The extrastriate visual area (MT, middle temporal) provides binocular, high-speed visual motion information to the AOS/NOT. The distribution of DS visual motion signals is indicated for neurons in the MT, medial superior temporal visual area (MST), dorsolateral pontine nucleus (DLPN), LTN, NOT, and ventral paraflocculus (vPF). The right side of the diagram shows components of OKN, thought to be driven mostly by separate so-called direct and indirect pathways. Direct pathways (solid lines) may serve smooth pursuit and ocular following preferentially, while indirect pathways (dashed lines) have access to the velocity storage mechanism. Production of rightward horizontal optokinetic eye (HE) movements depends on activation of appropriate populations of horizontal (rightward) neurons and inactivation of neurons with other direction preferences. Such signals are found in the NOT/dorsal terminal nuclei-driven and in MT/MST-driven pathways. Signals in the NOT/AOS–dorsal cap of Kooy-inferior olive (dcK) pathway provide visual climbing fiber information that plays a role in visual modification of the VOR Signals in NOT–medial vestibular nucleus (MVN)/nucleus prepositus hypoglossi (NPH) pathways play a role in velocity-storage. Visual motion information in cortico-ponto-cerebellar pathways play a role in all components of the OKR, ocular following, and aspects of smooth pursuit. Floc, flocculus; FTN, flocculus target neurons; INN, internuclear neurons; MN, motor neurons; VI, abducens motor neurons; III, oculomotor motor neurons; LGN, lateral geniculate nucleus; HC, horizontal semicircular canal; type I and type II, neurons in the MVN.

provide major visual afferents for the indirect pathway related to velocity storage. The direct (early) and indirect (delayed) terminology has been helpful in highlighting differences in sources of visual motion information and efferent connections essential for production of reflexlike (OFR, OKR, and OKN) and foveal smooth pursuit (Figure 4).

Development of Optokinetic Eye Movements

The OKR is immature at birth in cats, monkeys, and humans and has some properties that resemble the afoveate pattern of lower mammals. In the adult monkey or human, steady-state OKN gain is symmetric during monocular viewing of a large-field stimulus, moving in either temporalward or nasalward directions. Furthermore, mature OKN in rhesus monkeys includes an initial rapid rise in eye velocity during OKN. OKN immaturity early in life includes a decreased steady-state OKN gain, with increasing visual stimulus velocity or spatial frequency. During the first few weeks of life the monocular OKR is asymmetric, with much higher gain during nasalward compared to temporalward visual motion. In fact, there is little to temporalward response in monkey OKN during the first 2–3 weeks of life.

Examination of Figure 3 shows that immature OKN lacks a rapid rise in eye velocity during OKN, but does show a strong velocity storage component. This is indicated by the gradual buildup in eye velocity during OKN and the presence of after-nystagmus (OKAN). This slow buildup in eye velocity is supported by a velocity storage mechanism, supported in part by activity in the medial vestibular nucleus/nucleus prepositus hypoglossi (MVN/NPH). A more mature pattern of OKN is obtainable by 6 weeks of age in the monkey (6 months in humans). Figure 3 shows the immature OKN response of a 4-week-old rhesus monkey. During monocular viewing of continuous visual motion, there is a strong nasalward response but the temporalward response is just beginning to develop. Another important aspect of immature OKN in macaques is the lack of an early rapid rise in eye velocity during OKN until about 6 weeks of age, when a symmetric monocular horizontal OKN appears.

NOT Binocular Sensitivity and OKN Development

The maturation of the early asymmetric OKR to the mature symmetric pattern is thought to depend on the development of cortical and NOT binocular sensitivity. The best supported hypothesis is that the NOT receives direct retinal input from the contralateral nasal retina at birth. This projection is likely to arise, at least in part, from DS ganglion cells in the gamma class. Postnatal visual experience is necessary to allow development of cortical–NOT pathways representing the ipsilateral eye.

DS retinal ganglion cells could play an important role in cortical–NOT/AOS pathway formation by reinforcing development of cortical neurons with appropriate direction selectivity. For example, even though all directions of visual motion are represented in the MT, only those with ipsiversive direction preference project to the NOT of mature primates (Figure 5). Furthermore, this projection is absent in the first weeks of life, when monocular OKN is still asymmetric.

If coordinated binocular vision is impaired during early life – as occurs in strabismus, anisometropia, or a congenital cataract in one eye (monocular deprivation) – cortical–NOT connections representing the ipsilateral eye may fail to develop, leading to OKN asymmetry. The common underlying deficit is most likely loss of binocularly sensitive neurons in cortex, failure to develop cortical–NOT connections that provide representation for the ipsilateral eye, leading to loss of NOT binocular sensitivity. In addition, cortical–NOT pathways are essential for providing NOT neurons with high-velocity sensitivity, which supports OKN to speeds well over $100^{\circ}\,s^{-1}$. Thus, any disruption of early binocular visual experience might result in the development of asymmetric OKN. This points out the importance of a sensitive period during the first 6 weeks of life in monkeys (first 6 months in humans), when the visual–oculomotor system is most vulnerable to visual experience. The critical period for other visual–oculomotor behaviors may have different time courses.

NOT Direction Selectivity

Decreased binocular interactions early in life disrupt the maturation of cortical–NOT circuits, leaving the NOT driven either exclusively or mostly by the contralateral eye. Such contralateral ocular dominance could help to explain asymmetric, monocular OKN.

Directional mechanisms are certainly important in the development of symmetric monocular OKN and smooth pursuit. Visual motion in the nasalward direction, which produces strong OKN at birth, may initially rely on direct retinal–NOT projections. Such projections have been demonstrated to emphasize the nasal retina, which develops earlier than the temporal retina in primates. Ipsilateral projecting retinal afferents may require longer postnatal development times

Figure 5 Response properties of a representative primate middle temporal (MT) neuron during visual motion testing. (a) The neuronal response during horizontal large-field visual motion presented on a tangent screen while the monkey (*Macaca mulatta*) fixated a stationary target spot. A strong DS response occurs at short latency (50 ms) after the start of leftward visual motion. (b) Left: rasters for successive trials aligned on the start of leftward visual motion and the average firing rate represented as a spike-density function ($\sigma = 10$ ms) for five cycles of horizontal visual motion. Middle: directional tuning data for a representative MT neuron. Large-field visual motion was presented in different directions while the monkeys fixated a stationary target. The average firing rate is indicated at 45° intervals (filled circles), with a curve fit to estimate the direction preference for the unit. The point where the fit curve reached a maximum was taken as the preferred direction for the neuron (arrow). Right: calculated preferred directions for each of 100 MT neurons. MT neurons with ipsiversive direction preference provide visual motion information to the nucleus of the optic tract (NOT). (c) The ipsiversive (leftward) direction response for a NOT unit (left), the direction tuning curve for this neuron (middle), and the calculated preferred directions for a representative population of 50 NOT neurons (right).

than do their counterparts. For example, studies in the kitten reveal that until 3 weeks of age, stimulation delivered to the contralateral eye is effective in driving NOT units, but stimulation of the ipsilateral eye is ineffective, even until about 7 weeks of age, when ipsilateral eye stimulation becomes more effective. There is evidence that sensitivity to the ipsilateral eye is cortically derived, rather than being derived from direct retinal inputs from the ipsilateral eye, because sensitivity to the ipsilateral eye appears at the same time that NOT cells can be orthodromically activated by electrical stimulation of area 17 and area 18 in the cat. It seems likely that a similar pattern of development could be at work in the primates.

Neural Substrate for Optokinetic Eye Movements: AOS

Converging anatomical, single-unit, electrical stimulation and lesion evidence points to the AOS and pretectal NOT as essential sources of DS visual information for optokinetic eye movements and visual vestibular interaction.

The AOS includes DS retinal ganglion cells and their targets the lateral, medial, and dorsal terminal nuclei (LTN, MTN, and DTN, respectively), distributed along the mesencephalic brain stem. All of these nuclei receive a direct input, mostly from the contralateral retina, and indirect inputs from ipsilateral striate and extrastriate visual cortex (Figure 4). Early studies in rabbits identified DS retinal ganglion cells that project to the terminal nuclei; DS ganglion cells are also found in cats and monkeys. Neurons in the LTN and MTN respond preferentially to vertical visual motion while those in the DTN respond optimally for visual motion toward the side of the specific nucleus (ipsiversive).

In lower mammals, the terminal nuclei are easily separated from surrounding structures. In the primate, the LTN is the only consistently demonstrable terminal nucleus, although all divisions of the AOS are probably present. Primate LTN neurons are sensitive to upward visual motion. The DTN is sensitive to horizontal large-field visual motion.

The terminal nuclei and the NOT (see later) provide the only known source of visual motion information to the dorsal cap of Kooy-inferior olive (dcK), thus providing the afferent signals for generation of visual complex spikes in cerebellar Purkinje cells. This activity is thought to play a role in visually guided motor learning in the VOR, especially during high-frequency visual–vestibular interactions. The terminal nuclei and the NOT are reciprocally connected by γ-aminobutyric acid (GABA)ergic neurons, perhaps to improve the efficacy of directional drive for the OKR. Neurons in the terminal nuclei are most sensitive to low visual motion speed ($<5^\circ\,s^{-1}$), especially in lower mammals.

The NOT is often included as a member of the AOS because it has similar anatomical connections and some of its units behave like those of the DTN. However, neurons in the NOT of cats and monkeys often have much wider speed-tuning ranges than do those in the terminal nuclei. In the primate NOT, neurons are sensitive to either large-field or foveal/parafoveal visual motion. These neurons may reflect properties of MT neurons with ipsiversive direction selectivity, which have been shown to project to the NOT. Small-field visual neurons have not been reported in the NOT of lower mammals.

The NOT and AOS can influence smooth eye movements of foveal, optokinetic, or vestibular origin by at least three possible pathways (Figure 4). First, both the NOT and terminal nuclei of the AOS project to the dcK, which in turn provides the sole source of visual climbing fibers to eye movement-associated regions of the cerebellum, such as flocculus, vPF, and vermis. This pathway could play a role in making gradual plastic changes in slow eye movements (e.g., VOR and smooth pursuit) in response to development, aging, and disease. However, it seems unlikely that the NOT projection to the dcK is well suited to support the contribution to the initiation of OKN, ocular following, or smooth pursuit. The low firing rates (<10 spikes s^{-1}) of dcK neurons are consistent with a role related to modulation of ongoing simple spike activity.

Purkinje cells of the oculomotor cerebellum provide essential commands for all components of OKN, OFR, and smooth pursuit. The contraversive visual motion sensitivity of Purkinje cell complex spikes could be derived from DTN and NOT inputs to the dcK (Figure 4). Second, the NOT projects to the NRTP and to the DLPN, which provides visual mossy fiber inputs to the oculomotor cerebellum. These inputs could effect moment-by-moment changes in smooth eye movements of OKN, OFR, or smooth pursuit. Neurons in the NRTP and DLPN of primates discharge during either large- or small-field visual motion over a broad range of speeds and directions. Finally, neurons in both the NOT (and AOS nuclei) project to the NPH and MVN. The NPH is known to contain neurons that participate in all types of horizontal eye movements. In addition, the NPH and MVN are essential for velocity-storage during OKN. Lesions along either direct or indirect pathways produce impairments in different aspects of optokinetic eye movements.

Conclusions

The optokinetic system plays an essential role in gaze stabilization responses during head rotation and

translation. The optimal stimulus for production of an OKR is large-field visual motion, although small-field visual motion may contribute to foveally based tracking systems such as smooth pursuit.

Optokinetic eye movements play a major role in visual–vestibular interactions for gaze stabilization during locomotion and for adjusting the gain of the VOR in response to developmental, age-related, or pathological challenges. The short-latency OFR shares much of the same circuitry as the OKR and may be particularly important in supporting the tVOR.

The OKR of frontal-eyed species (e.g., cats and primates) is strongly influenced by descending visual cortical inputs. These inputs extend the operating range of optokinetic eye movements to include compensation for high-speed visual motion.

The optokinetic system is immature at birth in frontal-eyed animals (e.g., cats and primates) and presents with an OKN pattern similar to that observed in lateral-eyed, afoveate mammals, where temporal–nasal directions of visual motion are most effective. Maturation of the OKR is associated with development of cortical binocularity and motion sensitivity. Appropriate postnatal visual experience is required for this maturation and development of descending cortical connections with the AOS/NOT. Development of cortical binocularity takes place along with development of symmetrical, monocular OKR and improved sensitivity to higher visual motion speeds.

The major visual afferent pathways supporting the OKR comprise both direct retinal and indirect cortical (V1, V2, and MT) inputs to the AOS/NOT. Interconnections between nuclei of the AOS/NOT are mostly GABAergic and could serve to improve directional OKRs. Efferent connections of the AOS/NOT to the dorsal cap of the inferior olive and basilar pontine nuclei (DLPN and NRTP) provide visual climbing and mossy fiber inputs, respectively, to the oculomotor and vestibular cerebellum. Direct AOS/NOT projections to the MVN and NPH may play a role in velocity storage. The optokinetic system plays an essential role in gaze stabilization, visual adjustments to posture, volitional smooth eye movements, and visually guided motor learning.

Orbitofrontal Cortex: Visual Functions

E T Rolls, University of Oxford, Oxford, UK

Visual Inputs to the Orbitofrontal Cortex, and Visual Stimulus–Reinforcer Association Learning and Reversal

Rolls and colleagues have shown that there is a major visual input to many neurons in the orbitofrontal cortex, and that what is represented by these neurons is in many cases the reinforcer (reward or punisher) association of visual stimuli. Many of these neurons reflect the relative preference or reward value of different visual stimuli, in that their responses decrease to zero to the sight of one food on which the monkey is being fed to satiety, but remain unchanged to the sight of other food stimuli. In this sense the visual reinforcement-related neurons predict the reward value that is available from the primary reinforcer, the taste. The visual input is from the ventral, temporal lobe, visual stream concerned with 'what' object is being seen, in that orbitofrontal visual neurons frequently respond differentially to objects or images (but depending on their reward association). The primary reinforcer that has been used is taste.

The fact that these neurons represent the reinforcer associations of visual stimuli has been shown to be the case in formal investigations of the activity of orbitofrontal cortex visual neurons, which in many cases reverse their responses to visual stimuli when the taste with which the visual stimulus is associated is reversed by the experimenter. An example of the responses of an orbitofrontal cortex neuron that reversed the visual stimulus to which it responded during reward reversal is shown in Figure 1. This reversal by orbitofrontal visual neurons can be very fast, in as little as one trial – that is, a few seconds.

These neurons thus reflect the information about which stimulus is currently associated with reward during reversals of visual discrimination tasks – they are reward-predicting neurons. If a reversal occurs, then taste cells in the orbitofrontal cortex provide the information that an unexpected taste reinforcer has been obtained, another group of cells shows a vigorous discharge that reflects the error between the expected reward and the reward actually obtained (see later), and the visual cells with reinforcer association-related responses reverse the stimulus to which they are responsive. These neurophysiological changes take place rapidly, in as little as 5 s, and are presumed to be part of the neuronal learning mechanism that enables primates to alter their knowledge of the reinforcer association of visual stimuli so rapidly. This capacity is important whenever behavior must be corrected when expected reinforcers are not obtained, in, for example, feeding, emotional, and social situations. In that these neurons reflect whether a visual stimulus is associated with a reward or a punisher, they reflect the relative preference for different stimuli. Consistent with this evidence that the responses of some orbitofrontal cortex neurons reflect the learned predictive reward value of visual stimuli, Thorpe and colleagues found that orbitofrontal cortex neurons learned to respond differently to new stimuli that did or did not predict reward. Different neurons in the orbitofrontal cortex are tuned to different learned or conditioned reinforcers, with, for example, approximately 5% responding to visual stimuli associated with taste reward, and 3% to visual stimuli associated with taste punishment.

In the visual discrimination reversal task, a second class of neuron was found that codes for particular stimuli only if they are associated with reward, and not if they are associated with punishment. Such a neuron might respond to a green stimulus associated with reward, after reversal not respond to the green stimulus when it was associated with punishment, and not respond to a blue stimulus irrespective of whether it was associated with reward or punishment. An example is shown in Figure 2. These neurons may be described as conditional visual stimulus-to-taste reward neurons, and may be important in a process by which the rule for which stimulus is treated as being currently rewarded can be reversed in one trial.

This reversal learning found in orbitofrontal cortex neurons probably is implemented in the orbitofrontal cortex, for it does not occur one synapse earlier in the visual inferior temporal cortex, and it is in the orbitofrontal cortex that there is convergence of visual and taste pathways onto the same neurons. The way in which the ventral visual stream builds position, size, and even view invariant representations of objects, as described in *Computational Neuroscience of Vision* by Rolls and Deco, is very important, for it enables brain regions (such as the orbitofrontal cortex) which learn about the associations of objects to generalize to different positions, sizes, and views of the same object when they are seen later.

A possible mechanism for visual-reinforcer learning in the orbitofrontal cortex is associative (Hebbian) modification of synapses conveying visual input onto taste-responsive neurons, implementing a pattern-association network. In this model the unconditioned stimulus forcing the output neurons to respond is the

Figure 1 Orbitofrontal cortex: visual discrimination reversal. The activity of an orbitofrontal visual neuron during performance of a visual discrimination task and its reversal. The stimuli were a triangle (▲) and a square (□) presented on a video monitor. (a) Each point represents the mean poststimulus activity in a 500-ms period of the neuron based on approximately 10 trials of the different visual stimuli. The standard errors of these responses are shown. After 60 trials of the task the reward associations of the visual stimuli were reversed. (+ indicates that a lick response to that visual stimulus produces fruit juice reward; - - - indicates that a lick response to that visual stimulus results in a small drop of aversive-tasting saline). This neuron reversed its responses to the visual stimuli following the task reversal. (b) The behavioral response of the monkey to the task. It is shown that the monkey performs well, in that he rapidly learns to lick only in response to the visual stimulus associated with fruit juice reward. Adapted Rolls ET, Critchley HD, Mason R, et al. (1996) Orbitofrontal cortex neurons: Role in olfactory and visual association learning. *Journal of Neurophysiology* 75: 1970–1981.

Figure 2 A conditional reward neuron recorded in the orbitofrontal cortex which responded only to the green stimulus when it was associated with reward (G+), and not to the blue stimulus when it was associated with reward (B+), or to either stimuli when they were associated with a punisher, the taste of salt (G− and B−). The mean firing rate +/− the SEM is shown. Data from Thorpe SJ, Rolls ET, and Maddison S (1983) Neuronal activity in the orbitofrontal cortex of the behaving monkey. *Experimental Brain Research* 49: 93–115.

(taste) primary reinforcer, and the visual conditioned stimulus becomes associated with this by associatively modifiable synapses. Such a pattern association network could in principle unlearn the association by using associative synapses that incorporate long-term depression (LTD). Although reversal might be implemented by having long-term synaptic depression for synapses that represented the reward-associated stimulus before the reversal, and long-term potentiation (LTP) of the synapses activated by the new stimulus that after reversal is associated with reward, this would require one-trial LTP and one-trial heterosynaptic LTD to account for one-trial stimulus–reward reversal. To implement the reversal learning very rapidly, in as little as one trial after a number of reversals when a reversal learning set has been acquired, a special rule-switching network in the orbitofrontal cortex may be required, and a model of this has been described (e.g., in *Emotion Explained*, by ET Rolls).

Studies in macaques provide evidence on the details of the neuronal representations in the primate orbitofrontal cortex which are essential for building a computational understanding for exactly what information is represented in it and how it is represented, how these representations differ from preceding and succeeding stages, and thus how the orbitofrontal cortex operates computationally. However, the types of visual–reward associations that have been studied in primates (and confirmed as applying in humans) include objects associated with taste rewards or punishers. It has therefore been useful not only to confirm that these concepts do indeed apply to humans, but also to extend the types of visual conditioned reinforcers to quite abstract reinforcers such as monetary reward. In a functional magnetic resonance imaging (fMRI) study, O'Doherty and colleagues used a visual discrimination task in which one stimulus was associated with monetary reward, and a different visual stimulus with monetary loss (punishment). The actual amounts of money won on reward trials and lost on punishment trials were probabilistic. This part of the design, and the fact that unexpected visual discrimination reversals occurred so that there were trials on

Figure 3 Correlation of brain activations with the amount of money won or lost in a visual discrimination reversal task with probabilistic monetary reward and loss, showing the mean percent change in blood oxygen-level-dependent (BOLD) signal from baseline across individuals for six different category ranges of reward and punishment. The signal was averaged across a category range within each individual and then the average signal change from each category was averaged across individuals. This is plotted on the right for voxels in the medial orbitofrontal cortex that significantly correlated with reward, and on the left for voxels in the lateral orbitofrontal cortex that significantly correlated with punishment. The ranges of monetary reward and punishment in each category are shown on the chart and were determined by their relative frequencies, which follow from the experimental design. (Large positive values are large wins; large negative values are large losses.) Adapted from O'Doherty J, Kringelbach ML, Rolls ET, et al. (2001) Abstract reward and punishment representations in the human orbitofrontal cortex. *Nature Neuroscience* 4: 95–102.

which money was lost, showed that the magnitude of the activation of the medial orbitofrontal cortex was correlated with the amount of money won on each trial, and the magnitude of the activation of the lateral orbitofrontal cortex was correlated with the amount of money lost on each trial, as shown in Figure 3.

Another way in which it has been shown that the visual neurons in the orbitofrontal cortex reflect the expected reward value predicted by visual stimuli is by reducing the reward value by feeding to satiety. With this sensory-specific satiety (or reward devaluation) paradigm, it has been shown that the visual (as well as the olfactory and taste) responses of orbitofrontal cortex neurons in the macaque decrease to zero as the monkey is fed to satiety with one food, but remain unchanged in response to another food not eaten in the meal. In that these neurons parallel the changing preference of the monkey for the food being eaten to satiety versus the food not being eaten to satiety, they reflect the relative preference for different visual stimuli.

Error Neurons in the Orbitofrontal Cortex, and Visual Stimulus–Reinforcer Association Learning and Reversal

In addition to the neurons that encode the reward association of visual stimuli, other neurons (3.5%)

Figure 4 Error neuron. Responses of an orbitofrontal cortex neuron that responded only when the monkey licked in response to a visual stimulus during reversal, expecting to obtain fruit juice reward, but actually obtaining the taste of aversive saline, because it was the first trial of reversal. Each single dot represents an action potential; each vertically arranged double dot represents a lick response. The visual stimulus was shown at time 0 for 1 s. The neuron did not respond on most reward (R) or saline (S) trials, but did respond on the trials marked x, which were the first trials after a reversal of the visual discrimination on which the monkey licked to obtain reward, but actually obtained saline, because the task had been reversed. It is notable that after an expected reward was not obtained due to a reversal contingency being applied, on the very next trial the macaque selected the previously nonrewarded stimulus. This shows that rapid reversal can be performed by a nonassociative process, and must be rule based. A model for this has been described by G Deco and ET Rolls. Adapted Thorpe SJ, Rolls ET, and Maddison S (1983) Neuronal activity in the orbitofrontal cortex of the behaving monkey. *Experimental Brain Research* 49: 93–115.

in the orbitofrontal cortex detect different types of nonreward. For example, some neurons respond in extinction, immediately after a lick has been made in response to a visual stimulus that has previously been associated with fruit juice reward, and other neurons respond in a reversal task, immediately after the monkey has responded to the previously rewarded visual stimulus, but has obtained the punisher of salt taste rather than reward (see example in Figure 4).

Different populations of such neurons respond to other types of nonreward, including the removal of a formerly approaching taste reward, and the termination of a taste reward. The fact that different nonreward neurons respond to different types of nonreward (e.g., some to the noise of a switch that indicated that extinction of free licking for fruit juice had occurred, and others to the first presentation of a visual stimulus that was not followed by reward in a visual discrimination task) potentially enables context-specific extinction or reversal to occur. (For example, the fact that fruit juice is no longer available from a lick tube does not necessarily mean that a visual discrimination task will be operating without reward.) Thus the error neurons can be specific to different tasks, and this could provide a mechanism for reversal in one task to be implemented, while at the same time not reversing behavior in another task.

The presence of these neurons is fully consistent with the hypothesis that they are part of the mechanism by which the orbitofrontal cortex enables very rapid reversal of behavior by stimulus–reinforcer association relearning when the association of stimuli with reinforcers is altered or reversed. This information appears to be necessary for primates to rapidly alter behavioral responses when reinforcement contingencies are changed, as shown by the effects of damage to the orbitofrontal cortex. To the extent that the firing of some dopamine neurons may reflect error signals, one might ask where the error information comes from, given that the dopamine neurons themselves may not receive information about expected rewards (e.g., a visual stimulus associated with the sight of food) and obtained rewards (e.g., taste), and would have to compute an error from these signals. On the other hand, the orbitofrontal cortex does have all three types of neurons and the required neuroanatomically defined inputs, and this is an important site in the brain for computing error signals.

In that most neurons in the macaque orbitofrontal cortex respond to reinforcers and punishers, or to

Figure 5 Social reversal task. The trial starts synchronized with the scanner, and two people with neutral face expressions are presented to the individual. The individual has to select one of the people by pressing the corresponding button, and the person will then either smile or show an angry face expression for 3000 ms, depending on the current mood of the person. The task for the individual is to keep track of the mood of each person and choose the 'happy' person as much as possible (upper row). Over time (after between 4 and 8 correct trials) this will change so that the 'happy' person becomes 'angry' and vice versa, and the individual has to learn to adapt her choices accordingly (bottom row). Randomly intermixed trials with either two men, or two women, were used to control for possible gender and identification effects, and a fixation cross was presented between trials for at least 16 000 ms. Adapted Kringelbach ML and Rolls ET (2003) Neural correlates of rapid reversal learning in a simple model of human social interaction. *NeuroImage* 20: 1371–1383.

stimuli associated with rewards and punishers, and do not respond in relation to responses, the orbitofrontal cortex is closely related to stimulus processing, including the stimuli that give rise to affective states. When it computes errors, it computes mismatches between stimuli that are expected, and stimuli that are obtained, and in this sense the errors are closely related to those required to correct affective states. This type of error representation may thus be different from that represented in the cingulate cortex, in which behavioral responses are represented, where the errors may be more closely related to errors that arise when action–outcome expectations are not met, and where action–outcome rather than stimulus–reinforcer representations need to be corrected.

We have also been able to obtain evidence that nonreward used as a signal to reverse behavioral choice to visual stimuli is represented in the human orbitofrontal cortex. Kringelbach and Rolls used the faces of two different people, and if one face was selected then that face smiled, and if the other was selected, the face showed an angry expression. After good performance was acquired, there were repeated reversals of the visual discrimination task (see Figure 5). It was found that activation of a lateral part of the orbitofrontal cortex in the fMRI study was produced on the error trials – that is, when the human chose a face, and did not obtain the expected reward (Figure 6). Control tasks showed that the response was related to the error, and the mismatch between what was expected and what was obtained, in that just showing an angry face expression did not selectively activate this part of the lateral orbitofrontal cortex. An interesting aspect of this study that makes it relevant to human social behavior is that the conditioned stimuli were faces of particular individuals, and the unconditioned stimuli were face expressions. Moreover, the study reveals that the human orbitofrontal cortex is very sensitive to social feedback when it must be used to change behavior.

A Visual Representation of Faces in the Orbitofrontal Cortex

Another type of information represented in the orbitofrontal cortex is information about faces. There is a population of orbitofrontal cortex face-selective neurons that respond in many ways similarly to those in the temporal cortical visual areas. The orbitofrontal face-responsive neurons, first observed by Thorpe and colleagues in 2003, then by Rolls et al. in 2006, tend to respond with longer latencies than do temporal lobe neurons (140–200 ms typically, compared with

Figure 6 Social reversal. Composite figure showing that changing behavior based on face expression is correlated with increased brain activity in the human orbitofrontal cortex. (a) The figure is based on two different group statistical contrasts from the neuroimaging data, which are superimposed on a ventral view of the human brain with the cerebellum removed, and with indication of the location of the two coronal slices (b, c) and the transverse slice (d). The red activations in the orbitofrontal cortex (OFC, red circle; maximal activation: $z = 4.94$: 42, 42, −8; and $z = 5.51$; X, Y, $Z = -46$, 30, −8) shown on the rendered brain arise from a comparison of reversal events with stable acquisition events, while the blue activations in the fusiform gyrus (blue circles; maximal activation: $z > 8$; 36, −60, −20 and $z = 7.80$; −30, −56, −16) arise from the main effects of face expression. (b) The coronal slice through the frontal part of the brain shows the cluster in the right orbitofrontal cortex across all nine individuals when comparing reversal events with stable acquisition events. Significant activity was also seen in an extended area of the anterior cingulate/paracingulate cortex (green circle; maximal activation: $z = 6.88$; −8, 22, 52). (c) The coronal slice through the posterior part of the brain shows the brain response to the main effects of face expression, with significant activation in the fusiform gyrus and the cortex in the intraparietal sulcus (maximal activation: $z > 8$; 32, −60, 46; and $z > 8$: −32, −60, 44). (d) The transverse slice shows the extent of the activation in the anterior cingulate/paracingulate cortex when comparing reversal events with stable acquisition events. Group statistical results are superimposed on a ventral view of the human brain with the cerebellum removed, and on coronal and transverse slices of the same template brain (activations are thresholded at $p = 0.0001$ for purposes of illustration to show their extent). Adapted Kringelbach ML and Rolls ET (2003) Neural correlates of rapid reversal learning in a simple model of human social interaction. *NeuroImage* 20: 1371–1383.

80–100 ms); they also convey information about which face is being seen, by having different responses to different faces (see Figure 7), and are typically rather harder to activate strongly compared to temporal cortical face-selective neurons, in that many of them respond much better to real faces than to two-dimensional images of faces on a video monitor. Some of the orbitofrontal cortex face-selective neurons are responsive to face gesture or movement. The findings are consistent with the likelihood that these neurons are activated via the inputs from the temporal cortical visual areas in which face-selective neurons are found. The significance of the neurons is likely to be related to the fact that faces convey information that is important in social reinforcement, both by conveying face expression, which can indicate reinforcement, and by encoding information about which individual is present, also important in evaluating and utilizing reinforcing inputs in social situations.

Consistent with these findings in macaques and, as previously described, in humans, activation of the lateral orbitofrontal cortex occurs when a rewarding smile expression is expected, but an angry face expression is obtained, in a visual discrimination reversal task. This is an example of the operation of a social reinforcer, and, consistent with these results, activation of the orbitofrontal cortex is found when humans are making social judgments. In addition, activation of the medial orbitofrontal cortex is correlated with face attractiveness. In relation to possible functions in memory of the orbitofrontal cortex, it is of interest that a population of orbitofrontal cortex neurons responds to novel visual stimuli.

Effects of Damage to the Orbitofrontal Cortex on Visual Processing

Consistent with the neurophysiological and neuroimaging results described in this article, lesions in humans and macaques of the orbitofrontal cortex impair visual discrimination reversal. In humans, the ability to identify face expressions is also impaired, though face recognition is not.

Figure 7 Orbitofrontal cortex face-selective neuron as found in macaques. Peristimulus rastergrams and time histograms are shown. Each trial is a row in the rastergram; several trials for each stimulus are shown (the ordinate is in spikes per second). The neuron responded best to face a; it also responded, though less, to face b, had different responses to other faces (not shown), and did not respond to nonface stimuli (c and d). The stimulus appeared at time 0 on a video monitor. From Rolls ET, Critchley HD, Browning AS, et al. (2006) Face-selective and auditory neurons in the primate orbitofrontal cortex. *Experimental Brain Research* 170: 74–87.

Orofacial Motor Control

B J Sessle, University of Toronto, Toronto, ON, Canada

© 2009 Elsevier Ltd. All rights reserved.

Introduction

This article focuses on the brain stem and higher brain center mechanisms involved in the reflex regulation and sensorimotor coordination of the musculature in the orofacial region. Other works may be consulted for the structural and functional features of this musculature and its motor units and muscle fibers and sensory innervation (see the section titled 'Further reading').

Most of the literature on motor control focuses on limb motor control, and reviews of the topic often completely neglect the motor control mechanisms required for orofacial movements, many of which necessitate complex processing to provide for the exquisite motor control that is required for the muscles in the orofacial region. Yet these muscles serve important and diverse functions, some of which are vital for sustaining the life of the organism. In addition, there are unique features of the orofacial motor system that distinguish it from the spinal motor systems. Furthermore, many orofacial movements involve muscles innervated by several different cranial nerves. Given this and the large number of muscles involved, intricate bilateral motor control is essential to ensure that coordinated and appropriate motor patterning is carried out. Some of the muscles are multipennate, and thus the different compartments of these muscles may contribute differentially to the various motor functions carried out by each of these muscles.

Each muscle may be guided in these different functions by sensory inputs to its motor neurons that derive from a large array of different types of receptors. Many of these receptors have features that are similar to those in the spinal motor system, but some are associated with tissues unique to the orofacial region (e.g., tooth, cornea, taste receptors). The orofacial receptors are associated with primary afferents that project to the brain stem. The major sensory nuclei include the trigeminal (V) brain stem sensory nuclear complex (VBSNC), which receives most of the general somatosensory afferent input from the orofacial tissues, and the solitary tract nucleus (NTS), which receives visceral afferents (e.g., those supplying lingual taste buds, laryngeal and pharyngeal taste buds, and mechanoreceptors). The main cranial nerve motor nuclei include the Vth motor nucleus (Motor V), which provides the motor innervation of most jaw muscles; the VIIth motor nucleus, supplying the muscles of facial expression; the XIIth motor nucleus, supplying the intrinsic and extrinsic tongue muscles; and the nucleus ambiguus, which mainly supplies muscles of the palate, larynx, and pharynx.

Types of Motor Functions

The types of movements and other motor functions involving this musculature are also extensive, and some are unique to the orofacial region. They include voluntary movements that are driven by centers in the central nervous system (CNS) and that generally can be refined through sensory inputs to the CNS and reflex circuits. These voluntary movements can range from 'simple' movements involving a limited number of muscles (e.g., jaw opening or tongue protrusion), to the diversity of tongue positions and shapes that some of us can achieve, to the different facial expressions that we can manifest to express our feelings to others, to the complex and sophisticated movements that characterize speech. Reflexes are other types of movements whereby an afferent input to the CNS evokes a rather stereotyped motor response. Again, some of these reflex movements involve relatively simple reflex circuits and are numerous in the orofacial region (e.g., jaw-opening reflex and blink reflex). Other orofacial reflexes are more complicated and involve several motor neuron pools bilaterally (e.g., cough and gag), and others are even more complex and require the activity of numerous muscle groups and highly integrated CNS circuits (e.g., swallowing). Some of these complex motor events may also include a voluntary component as well as a reflex component (e.g., the oral vs. buccopharyngeal phases of a swallow).

Some of the orofacial motor functions may also be cyclic in nature. Chewing is a good example: the cyclic events (e.g., jaw opening and closing) are driven by a CNS program. Nonetheless, these cyclic jaw movements and other associated muscle activities (e.g., of tongue and facial muscles) that characterize chewing are sensitive to afferent inputs acting through brain stem reflex circuits or higher brain centers. Since chewing involves the production of a wide range of bite forces between opposing upper and lower teeth, highly coordinated processes are necessary, on the one hand, for example, to allow for light forces to explore and ascertain the texture of a foodstuff and on the other hand, to allow for the development of large forces that are necessary for biting through tough foodstuffs while avoiding self-injury.

Some of these sophisticated motor functions are laid down at birth, and others develop as the infant matures. Whereas swallowing develops *in utero*, and most mammals are born as suckling and swallowing animals, chewing is a learned motor function. As the infant matures, the rhythmic jaw movements come increasingly under central control and more sophisticated, engaging to a greater degree other muscle groups (e.g., tongue, facial) that allow for more refinement and management of chewing; the postnatal eruption of the teeth in humans provides important sensory inputs from periodontal receptors that also assist in the development of this control. Other highly developed oral functions also appear as the animal matures, the most striking being speech in humans, which involves an elaborate integration of sensory and motor pathways and central programming of muscles of the jaw, face, tongue, palate, pharynx, larynx, and other parts of the respiratory tract. Thus, there is the need for sophisticated neural circuits that allow for integration bilaterally of these diverse and complex motor functions and for coordination with other motor functions, such as respiration. Virtually all these functions of course are not purely 'motor' but indeed are sensorimotor since they depend on or utilize sensory inputs or feedback to initiate or guide them. Furthermore, there are several features that distinguish these functions and their underlying mechanisms from spinal sensorimotor processes and movements. In addition to the large number of muscles that may be involved, often requiring bilateral muscle activities, these features include the arrangement of the various sensory nuclei and motor nuclei into distinct neuronal pools in the brain stem, and unique aspects of the peripheral mechanisms.

Peripheral Mechanisms

Receptors and afferent inputs involved in orofacial motor control will not be considered in detail in this article. Nonetheless, it needs to be pointed out that the numerous orofacial afferent inputs that access the brain stem and are relayed to thalamus and cerebral cortex are involved not only in perceptual processes but may also be involved at each of these levels in sensorimotor integration and control. Furthermore, the distinctive features of some of the receptor systems in the orofacial region need to be kept in mind. These include the unique receptor systems noted above, the limited number of muscles that have muscle spindles and Golgi tendon organs that are so much a feature of limb motor control, and the presence of the primary afferent cell bodies of those jaw muscles that do have spindles (i.e., jaw-closing muscles) within the CNS, in the V mesencephalic nucleus.

Brain Stem Reflex Processes

As noted above, other important sensory and cranial nerve motor nuclei include the NTS, and the VIIth and XIIth motor nuclei, and the nucleus ambiguus. Furthermore, in addition to the VBSNC and NTS, important interneuronal sites include regions immediately adjacent to these sites (e.g., intertrigeminal nucleus, supratrigeminal nucleus), as well as components of the medial and especially lateral reticular formation. These sites receive and integrate afferent inputs from various orofacial tissues and from other brain stem or suprabulbar areas and thereby provide a neural substrate allowing for the initiation or modulation of the brain stem reflexes (e.g., by afferent inputs, descending controls, and conscious state). In addition, they provide some of the neural circuitry and processes that constitute the central programs (pattern generators) that are so crucial in the initiation and control of complex functions such as chewing and swallowing. In addition to the brain stem-based reflex responses evoked by these stimuli, afferent signals are relayed from the brain stem to higher brain centers involved in sensorimotor control of the muscles.

Brain Stem Reflexes

The motor neurons supplying the orofacial muscles receive reflex afferent inputs from the free nerve endings as well as specialized receptors in the orofacial tissues. Thus, the orofacial neuromuscular system can be reflexly influenced by the sensory inputs into the brain stem from receptors that signal pain, touch, joint position, muscle stretch or tension, and so forth. Via their connections with the interneuronal circuits noted above, these afferent inputs can activate or inhibit the cranial nerve motor neurons that supply the orofacial musculature. Brain stem circuits also underlie the reflex changes in heart rate, blood pressure, breathing, salivation, and more complex behaviors that can be evoked by nonnoxious or noxious stimulation of orofacial tissues. On the basis of these various types of responses, several human behavioral paradigms have been developed in order to study the effects of orofacial stimuli in humans; these include changes in autonomic function (e.g., heart rate and salivation), muscle reflexes, and facial expression.

Given the large number of muscles in this region and the diversity of receptors and afferent inputs, the number of reflexes is also immense, and only representative examples are noted below; more extensive reviews should be consulted for more details.

For example, several jaw reflex responses involving brain stem circuits and modulation by afferent and descending influences can be elicited by mechanical stimulation of the jaw-closing muscles. Stretch of these muscles evokes myotatic stretch reflexes through activation of jaw muscle spindle afferents. The primary afferent cell bodies of these spindle afferents are located in V mesencephalic nucleus, from which impulses in their central axons can monosynaptically activate jaw-closing motor neurons in Motor V. Synapses occur on these primary afferent cell bodies, and they and their central axons have intriguing electrophysiological and neurochemical features.

Other well-studied jaw reflexes include the jaw-opening reflex and the reflex effects of stimulation of periodontal receptors around the root of the tooth. A brief excitatory reflex may be elicited under certain conditions, but an inhibitory reflex involving one or more 'silent' periods in the jaw-closing muscles has received particular attention. A protective or regulatory function (e.g., of bite force) during jaw-closing movements is usually viewed as the role of this inhibitory reflex, and even its usefulness has been proposed as a diagnostic tool in certain orofacial pain or motor disorders. It is, however, subject to variation because of several interacting factors, and furthermore, inhibitory periods in the jaw-closing muscles can be induced by stimulation of different types of receptors in various orofacial tissues other than just periodontal tissues. The importance of other inputs is underscored by findings that feed-forward facilitation of masseter muscle activity produced by placing objects of varying hardness between the teeth is dependent on muscle afferent inputs as well as periodontal afferent influences.

Reflex excitatory or inhibitory effects can also be elicited in tongue, facial, and other muscles in the orofacial region. For example, stimulation of receptors in periodontal and other orofacial tissues can elicit reciprocal excitatory and inhibitory reflexes in tongue retrusive and protrusive muscles, and well-studied reflex responses in facial muscles in humans and laboratory animals are the corneal reflex and the blink reflex. It should also be noted that stimulation of many orofacial tissues, including laryngeal and pharyngeal mucosa, can evoke a number of respiratory-related reflexes that facilitate or prevent air intake into the airway (e.g., sniffing vs. coughing). Analogous 'supportive' or 'protective' reflexes exist for the alimentary tract (e.g., swallowing vs. gagging).

In the case of the reflex effects of noxious stimulation of orofacial tissues, brief high-intensity stimulation can elicit a transient jaw-opening reflex in the anterior digastric muscle and reflex activation in other muscles (e.g., tongue, facial); some stimuli can also, or instead, evoke transient inhibitory effects in these muscles. Algesic chemicals (such as hypertonic saline, capsaicin, glutamate, or mustard oil) applied to the temporomandibular joint, muscle, or other orofacial tissues of anesthetized animals can elicit more sustained afferent input into the brain stem that has been shown to activate neurons in subnucleus caudalis or in other components (e.g., subnucleus oralis) of the VBSNC. The activation of these neurons and their connection with the brain stem reflex centers, such as Motor V, can result in prolonged increases in electromyographic activity of both the jaw-opening and jaw-closing muscles, and several chemical mediators and receptor mechanisms (e.g., *N*-methyl-D-aspartate, opioids, γ-aminobutyric acid) in Motor V and interneuronal sites have been shown to be involved. It has been suggested that the cocontraction of these muscles may provide a 'splinting' effect that limits jaw movements in pathophysiological conditions affecting deep tissues such as the temporomandibular joint and muscle. There is, however, no consensus on whether the electromyographic activity of these muscles decreases, increases, or remains unchanged during experimentally induced or clinical orofacial pain in humans, and a number of factors may account for the disparity in experimental and clinical pain data. Influences from brain stem and higher brain centers involved in stress, emotion, alertness, sleep, and wakefulness are examples of other possible contributing factors, and the next sections briefly note some of these circuits and processes. Thus, the issue of how pain interacts with the neuromuscular system is not entirely clear, and theories have been proposed to account for the motor effects of pain that are seen clinically. The vicious cycle theory, for example, proposes that pain can lead to muscle hyperactivity and vice versa, whereas the pain adaptation model proposes changes in agonist and antagonist jaw muscles that allow the masticatory system to adjust to or adapt to the painful condition; most of the limited scientific evidence available favors more the latter concept.

Descending Influences

Many neurons in the VBSNC or NTS that relay to thalamus or other brain regions are subject to segmental (afferent) modulation and to descending modulation from various cortical and subcortical structures. Because many of these neurons also contribute as interneurons to reflex and other behavioral responses evoked by stimulation of orofacial tissues, these responses can also be regulated by these modulatory influences on the interneurons or, in some cases, on the motor neurons themselves that are part of the reflex circuits. These descending modulatory influences include those from the amygdala and other parts of

the limbic system, the lateral hypothalamus, the lateral habenular nucleus, the basal ganglia, the anterior pretectal nucleus, the red nucleus, the cerebellum, the sensorimotor cerebral cortex, the cortical premotor and supplementary motor areas, and the cortical masticatory and swallowing areas. It is through these descending excitatory or inhibitory influences that the higher brain centers can exert control over the brain stem processes and activities of motor neurons supplying the orofacial musculature and thereby initiate, guide, or regulate orofacial motor functions. The next section examines in more detail these higher brain center influences and processes.

Higher Brain Center Processes

Subcortical Processes

As noted above, several areas in the CNS project directly or indirectly to the cranial nerve motor neuron pools and can exert modulatory influences on motor behavior. There are also numerous connections between these areas, and so the neural circuitry involved in CNS control of motor function is extensive and complex. Because of space limitations, it is not possible to review these circuits in detail here. Also, only limited study has been done on these pathways as they apply to orofacial motor control compared with limb motor control, and most of the few studies have focused on the cerebral cortex (see the section titled 'Cortical processes') as well as basal ganglia, amygdala, hypothalamus, and brain stem regions.

In the case of the brain stem, the descending inputs as well as the afferent inputs from peripheral receptors access the reflex interneurons that project to and modulate motor neurons in the cranial nerve motor nuclei and that were noted above. Several of these regions also act in concert to form the neural circuitry of the central pattern generators (CPGs) for chewing, swallowing, and other analogous complex motor behaviors. Most research attention has focused on the CPGs underlying swallowing and especially mastication. The CPG for swallowing (the 'swallow center') appears to involve neurons within and adjacent to the NTS. Collectively, their output provides the time-locked, patterned drive to the different motor neuron pools supplying the muscles that participate in swallowing. While the swallow CPG neurons are triggered into action by sensory inputs, the CPG is nonetheless relatively insensitive to sensory feedback or descending controls once the swallow has started. The masticatory CPG (the 'chewing center'), in contrast, can generate chewing-like movements independent of orofacial sensory inputs. Nonetheless, studies in humans and animals indicate that it can utilize these inputs, especially those from periodontal mechanoreceptors and jaw muscle spindles, in concert with other brain regions accessing it, to provide for modification and guidance of masticatory movements. Thereby, the CPG-dependent stereotyped movements typical of chewing can be varied, and can function in an integrated manner with movements of the cheeks and tongue, to allow for repositioning of the food bolus and for alterations in masticatory force, velocity, and jaw displacement as the food is crushed and manipulated. These features explain how several factors (e.g., number of teeth, food composition and hardness, bite force) can influence the masticatory process and provide for the appropriate reduction of the food to a particular size suitable for swallowing. As part of this process, the CPG can also modulate sensory inputs such that central control can on the one hand mask out undesirable perturbances and reflexes that might disrupt the ongoing masticatory process and yet on the other hand allow nociceptive reflex inputs to access the masticatory motor neurons and thereby provide protection of the masticatory apparatus. One common example of this process in operation is the interruption of chewing by the jaw-opening reflex elicited by a noxious stimulus such as a fish bone piercing the oral mucosa while a person is eating a fish meal.

There are several higher brain centers that access the motor neurons directly or indirectly via the various brain stem interneuronal groups, including the CPGs. A particularly important series of inputs derives from various components of the basal ganglia and substantia nigra, and many cerebral cortical output pathways project indirectly to the brain stem via the basal ganglia (as well as directly to the brain stem). Orofacial motor deficits can arise after lesions of some of these components, and basal ganglia neurons have been recorded (e.g., in putamen and globus pallidus) that show activity during orofacial movements such as chewing, and many of these neurons may receive orofacial sensory inputs. Pharmacological studies have also underscored the relevance of these structures to orofacial motor control. For example, an imbalance in dopamine (e.g., by drugs that alter dopamine actions, such as amphetamines and cocaine) may change basal ganglia functional activities and perhaps be a factor leading to abnormal motor functions such as those seen in oral dyskinesia and sleep bruxism. As in the subcortical processes involved in limb motor control, several other neurochemicals and subcortical structures and interconnecting circuits are involved in orofacial motor control. They include acetylcholine, γ-aminobutyric acid, glutamate, serotonin, vasopressin, catecholamines, and opioids, and the structures include the hypothalamus, amygdala, subthalamic nucleus, red

nucleus, anterior pretectal nucleus, superior colliculus, periaqueductal grey, and cerebellum.

Cortical Processes

Several cortical areas exert descending influences on brain stem and other subcortical regions. Studies using transcranial magnetic stimulation or imaging (e.g., functional magnetic resonance imaging, positron-emission tomography) in humans have revealed that orofacial movements may be associated with activation of the face primary motor cortex (M1), primary somatosensory area (S1), premotor cortex, supplementary motor area (SMA), cortical masticatory area (CMA), insula, and anterior cingulate gyrus, to name just a few. The area(s) activated may vary depending on the type of movement (e.g., swallowing vs. chewing vs. clenching or tapping the teeth together), probably reflecting in part whether the movement involves evoked sensory inputs that project to the cortical area(s). This is consistent with intracortical microstimulation (ICMS) studies in monkeys and subprimates (e.g., rats) revealing evoked movements from only some of these sites and indicating that the pattern of some evoked movements (e.g., mastication) may vary between sites. In addition, the ICMS studies have documented that each orofacial muscle or movement is represented multiple times within M1, indicating that each output zone of M1 control one of the many contextual functions in which a muscle participates. This multiple representation includes ipsilateral and contralateral elemental movements (e.g., jaw-opening, facial twitch, tongue protrusion), as well as complex activities such as mastication and swallowing. For example, mastication or swallowing can be evoked by ICMS, not only from the deep and principal parts of the classical CMA lateral to face M1, but also from within face M1 and even within the face S1 in the monkey, and there is considerable overlap of face M1, S1, and CMA in subprimates. Furthermore, selective cold block or ablation of each of these regions can disrupt chewing and swallowing to varying degrees, indicating that each may be involved differentially in the production and patterning of chewing and swallowing, including the coordination of the tongue, facial, and jaw movements that is necessary for the proper ingestion and transport of food or liquid. It is to be noted also that ICMS-evoked orofacial movements have also been reported for SMA, an area which, like premotor cortex, has been implicated in the preparation for movement. However, little information is available on the role of these regions in orofacial motor control except for recent studies indicating that premotor cortex, as well as other cortical areas (e.g., parietal cortex), may be involved in the preparation and planning for ingestion, visuomotor control, and perhaps even in cognitive functions related to the understanding and communication of ingestive motor actions, facial recognition, and other complex behaviors involving the orofacial region.

Single neuron recordings in monkeys or subprimates have revealed that many face M1 and S1 neurons discharge in relation to chewing or swallowing, but most also discharge in association with more elemental movements, with some active in relation to jaw movements (especially jaw opening) and many others active in relation to tongue movements. These findings are consistent with the above ICMS findings as well as with evidence that ablation or cold block of the monkey's face M1 or S1 disrupts the animal's ability to perform a learned tongue task but causes much less disruption of a biting task. The single neuron recordings in face M1 have also revealed that some neurons are active during preparation for movement, although many more neurons in premotor areas appear to show this feature, at least during visually guided jaw movements, consistent with cortical findings related to limb motor control that have placed more emphasis on cortical (and subcortical) regions other than just M1 in mechanisms involved in motor planning and preparation.

The neuronal and ablation findings noted above also underscore the importance of the somatosensory cortex as well as the motor cortex in the fine motor control of orofacial movements. The face S1 can influence orofacial movements by its projections to face M1 and other cortical areas and to subcortical regions such as the VBSNC, NTS, reticular formation, and even directly into the cranial nerve motor nuclei in primates. The face S1 has a somatotopically arranged array of sensory inputs which are predominantly from facial skin and intraoral structures but may also include some inputs from deep tissues (e.g., muscle). The face M1 and CMA also receive inputs from afferents supplying deep and especially superficial (e.g., skin, mucosa, teeth) tissues of the face, mouth, and jaws. The substantial number of face M1 and CMA neurons that receive bilateral inputs from the orofacial tissues is probably related to the need for bilateral sensorimotor coordination in orofacial muscle function. These inputs may be used by CMA to help guide masticatory-related movements. Face M1 may also use its orofacial afferent inputs for generating and regulating orofacial movements in order to refine ongoing cortical motor activity and shape the appropriate motor response, for example, in the control of voluntary orofacial movements such as the manipulation of the food bolus after it is placed in the mouth, since many face M1 neurons are active

during the food preparatory phase. Sensory inputs from the orofacial regions presumably are utilized by these M1 neurons for this purpose.

Thus, face M1 and S1 may use orofacial afferent inputs to guide, correct, and control movement by the use of sensory cues prior to movement and by using sensory information generated during movement. These processes may involve intracortical processing, cortical gating, and transfer of somatosensory information, as well as corticofugal projections to subcortical sites that modulate and select somatosensory information ascending through subcortical relay neurons in the brain stem (e.g., VBSNC and NTS) and thalamus. These inputs also play critical roles in motor learning and in the motor adjustments or adaptations that take place after a change in the sensory environment. Therefore, this article now turns to a consideration of neuroplasticity, especially as it applies to the cortical mechanisms of orofacial motor control.

Both S1 and M1 have been shown in numerous studies to undergo neuroplastic changes following manipulations of afferent inputs or in association with learning of novel motor skills. While nearly all these studies have focused on limb S1 and M1, as well as some subcortical regions (e.g., basal ganglia), there is some recent evidence that comparable neuroplastic changes may occur in face S1 and M1. For example, dental extraction can lead to the loss of dental representations and an enhanced representation of adjacent orofacial structures in face S1 of the mole rat, and alterations of the dental occlusion can be associated with modifications of the motor representation of jaw and tongue muscles in face M1. These findings suggest that physiological changes occur in face S1 and M1 when the oral environment is altered, and they raise the possibility that such cortical changes reflect adaptive mechanisms that may be crucial in determining how well or poorly a person adapts to such alterations (e.g., dentures, implants, pain, and nerve damage).

A role for face M1 in orofacial motor skill acquisition is also suggested by recent novel findings in monkeys and humans of face M1 neuroplasticity associated with the learning of a novel tongue-protrusion task. No comparable changes were seen in CMA in the monkey study. These studies have underscored that face M1 plays a crucial role in sensorimotor integration and control and that it has a remarkable capacity for neuroplasticity that may reflect dynamic, adaptive cortical mechanisms mediating complex motor and cognitive phenomena related to motor learning and memory. They also suggest that there may be cortical templates for a variety of familiar, learned orofacial motor activities. Speech is one such activity. While its consideration is beyond the scope of this article, cortical mechanisms are clearly crucial to the fine control and coordination of the various muscles participating in voice production and articulation of speech sounds, both when a child is learning to speak and once speech has been learned.

Osmoregulation

A K Johnson, University of Iowa, Iowa City, IA, USA

Introduction

Life began and initially evolved in the sea. The oceans have always been composed of a watery broth of mineral salts, molecules, and dissolved gases. Water and these constituents provide the necessary ingredients for the generation of more-complex molecules and for the reproduction, growth, maintenance, and repair of cells. About 150 years ago, biologists such as the noted French physiologist Claude Bernard first recognized that complex animals had, in essence, internalized the primeval sea in which life evolved. This bodily ocean bathes cells and provides them with an immediacy of ingredients necessary for life. Maintaining a high degree of consistency of the fluids outside of cells (extracellular fluid) is vital and gives advanced organisms the opportunity for life independent of the ancient seas.

In the early twentieth century, Walter Cannon coined the term 'homeostasis' to describe the concerted actions of physiological systems to maintain many physical (e.g., blood pressure) and chemical (e.g., blood pH and extracellular glucose concentration) bodily parameters within relatively narrow limits. Because the viability of cells greatly depends on the constituents of bodily fluids, processes that determine total body water and its distribution are of pivotal significance in the maintenance of virtually all homeostatic processes. Given the importance of body fluid homeostasis, it should not be surprising that there are multiple systems directed at assuring that fluid resources are optimally maintained. Many of these complex physiological mechanisms are related to the process of osmoregulation.

For many neuroscientists and physiologists who study osmoregulation, the concept entails the mechanisms involved in sensing the concentration of extracellular osmoles and the corrective actions taken if the extracellular condition is different from the ideal (i.e., a deviation from a set point). Regulatory responses usually are initiated within a few seconds of detection of an altered osmotic state. In the case of hyperosmolality, provided water is accessible, the compensatory and restorative responses run their course within minutes to at most a couple of hours.

The following review provides a discussion of the nature of osmosensing and a description of some of the cellular and central neural mechanisms found to activate the effector systems responding to a hyperosmotic state. However, it begins with a broader treatment, including important control systems that contribute to more-global aspects of body fluid homeostasis. As an introduction to this topic, it is helpful to gain an appreciation of the nature of body fluids and of the physical determinants of solute and solvent distribution between the key fluid compartments of the body.

Body Fluid Compartments and the Distribution of Water between Them

Approximately 60% of body weight is water. Under normal conditions the totality of water contained in all the cells of the body (i.e., in the intracellular fluid compartment) is about twice the amount of all the water that is outside the cells (i.e., in the extracellular fluid compartment). The 2:1 ratio of intra- to extracellular fluid volume is mainly the result of concentrations of various impermeable ions and molecules located on each side of the cell membrane. The movement of water in and out of cells is largely unimpeded as it can pass through the cell membrane by simple diffusion and is augmented by movement through water channels formed by proteins called aquaporins. Experimentally, it is easy to dehydrate the intracellular compartment by increasing the concentration of impermeable solute in the extracellular space. This generates an osmotic force that initiates the movement of water (osmosis) out of cells, dilution of extracellular solute, and shrinkage of the intracellular space. Using the same principle, it is possible to increase the volume of the intracellular compartment by decreasing the concentration of extracellular impermeable solute, for example by administering into the extracellular compartment water or a hypotonic fluid (i.e., a solution containing a lower concentration of impermeable ions or molecules than found in the extracellular fluid). In this case, water moves down its concentration gradient and enters cells until the extracellular fluid becomes iso-osmotic (isotonic) with the intracellular fluid. Although there are many different types of molecules and ions that do not readily cross cell membranes, ionic sodium (Na^+) is the solute in the extracellular compartment that is the major factor in determining the dynamic apportioning of water between the intra- and extracellular compartments.

The extracellular compartment includes both the interstitial fluid that is located in the space between cells and the plasma of the cardiovascular system. To all intents and purposes, circulating plasma (excluding blood cells and large proteins) is in ready communication with the interstitial fluid, so that a

contraction (e.g., hemorrhage) or an expansion (e.g., plasma transfusion) of blood volume is rapidly followed by a proportional reduction or increase of interstitial fluid. Manipulating blood volume by removing or adding plasma that is iso-osmotic with the intracellular fluid will not immediately change the volume of the intracellular compartment. For example, an acute hemorrhage, which produces an absolute deficit in total body fluid, does not produce a rapid decrease in total intracellular fluid volume.

Responses to Dehydration of the Intra- and Extracellular Fluid Compartments

Under physiological (e.g., exercise, exposure in a warm environment, and normal renal loss) and pathophysiological (e.g., emesis and diarrhea) conditions, animals lose water and Na^+ to the environment. Depending on the cause or type of dehydration accrued, the relative proportion of Na^+ to water loss from the body will vary between a net hypotonic and a net hypertonic fluid loss (Figure 1; note hypertonic fluid loss can occur via the kidneys), and the immediate consequence will be a disproportionate fluid loss from the intra- or the extracellular compartments. Under specifiable experimental conditions, it is possible to selectively dehydrate the intracellular compartment without reducing extracellular fluid volume, and vice versa. Fluid loss from either the intra- or extracellular fluid compartment produces an activation of both reflexive (i.e., autonomic nervous and endocrine systems) and behavioral (i.e., water drinking) responses that serve first to minimize the consequences of dehydration and second to correct such homeostatic disruptions.

Dehydration causes increased activity in the sympathetic nerves innervating the cardiovascular system and the kidneys. The effect of increased sympathetic cardiovascular tone is intended to maintain cardiac output and the perfusion of critical vascular beds (e.g., brain, heart). Sympathetic action on the renal tubules promotes Na^+ and water reabsorption, thereby reducing the rates of the progressing loss of one or both of these substances. The predominant endocrine response to dehydration is the release of the antidiuretic hormone, vasopressin (VP), from the posterior pituitary. This hormone acts on the kidney to promote the reabsorption of water. The initial behavioral response of a dehydrated animal is to seek out and drink water. Such drinking behavior is the result of central nervous system (CNS) activation producing a drive for water (i.e., the motivational state of thirst). Under conditions when there is a loss of Na^+ from the body, such as after the loss of isotonic plasma, a drive to obtain and consume NaCl is activated in conjunction with thirst. This

Figure 1 Physiological challenges and nonrenal loss of water and sodium from the body result in differential dehydration of the intra- and extracellular fluid compartments. The effects of different types of dehydration varying between the loss of pure water to the loss of isotonic body fluid on the intra- and extracellular fluid compartments. The extracellular fluid compartments consist of the fluids in blood vessels and in the interstitial space. The fluids in the vasculature and interstitial space are in ready communication with one another, and the induction of hypovolemia shrinks proportionally the vascular and interstitial volumes. Given sufficient time, renal mechanisms can cause the redistribution of fluid between the extra- and intracellular fluid compartments. GI, gastrointestinal.

motivational state is defined as salt (or sodium) appetite.

Coordinated endocrine and autonomic reflexes and motivated behaviors to cope with dehydration require an exquisite set of integrated physiological responses. The release of VP and sympathetic activation act to reduce the rate of renal fluid loss and to maintain vascular perfusion in the face of moderately reduced fluid resources. These reflexes permit an animal to remain behaviorally competent. Evidence indicates that the threshold for release of VP in response to dehydration is slightly lower than that for activation of thirst-related behaviors. There is probably a similar difference in dehydration thresholds for activating a reflex increase in sympathetic tone versus the mobilization of thirst. The earlier activation of sympathetic and endocrine reflexes allows an animal to continue its normal pursuits (e.g., seeking food or mates, parental care, and sleeping) before thirst and the compulsion to find and consume water are aroused. It should be appreciated that although hormonal and autonomic countermeasures play an important temporizing role in the dehydrated state, it is only through the consumption and absorption of water that homeostasis normally is restored.

It is also worth recognizing that a degree of independence in the control of the rates of renal Na^+ loss versus renal water loss makes it possible, in principle, to partially exchange a state of cellular dehydration for a state of extracellular dehydration or vice versa. For example, if for some reason an animal experiences a pure cellular dehydration (e.g., dogs panting in the heat) but has no access to water, it will over an extended period of time apportion the water deficit between the cellular and extracellular compartments by excreting hyperosmotic urine.

In contrast to dehydration, an excess of Na^+ or water or acute hypertension will activate inhibitory mechanisms. For example, in a hyperosmotic state or under a condition in which blood volume is expanded, NaCl appetite is inhibited, and the release of hormones (e.g., oxytocin in some species and atrial natriuretic peptide) that increase renal Na^+ excretion will be facilitated.

In order to appropriately activate reflexes to minimize the consequences and progression of altered hydration and to mobilize or inhibit homeostatic behaviors, the brain must be informed of the disposition of body fluids. Several types of sensors are involved in detecting the status of total body fluid and the regional distribution of Na^+ and water.

Both mechano- and chemoreceptors have been implicated in the detection of extracellular volume. The most thoroughly studied receptor systems implicated in body fluid and cardiovascular homeostasis are mechanoreceptors, known collectively as vascular baroreceptors (i.e., pressure receptors). There are two subclasses of baroreceptors – one located on the low-pressure side of the circulation in the large veins (e.g., superior vena cava) and cardiac atria, and a second set on the high-pressure side of the circulation in the carotid sinuses and aortic arch. Baroreceptor nerve endings are insinuated into blood vessels, and their membrane potentials change in proportion to the degree of distention of the regions they innervate. Increased deformation of an innervated blood vessel results in an increased frequency of action potentials in these sensory (afferent) nerves. On the venous side of the circulation, with its high degree of compliance, graded increases in blood volume are reflected as increased pressure and stretch in the innervated low-pressure vessels and atria. Because of the low compliance of blood vessels on the high-pressure side of the circulation, arterial baroreceptors are not tuned to sensing small changes in blood volume. However, they do respond when extracellular fluid loss becomes so large that arterial blood pressure falls, such as in the case of hypotensive hemorrhage.

Information from baroreceptors reaches the brain by the IXth and Xth cranial nerves, which synapse in the nuclei of the solitary tract (NTS). When blood volume or arterial pressure falls below normal levels, afferent baroreceptor nerve activity declines and signals the reflex release of VP and sympathetic nervous system activation. With sustained hypotension or hypovolemia, behaviors leading to Na^+ and water intake will be initiated. Alternatively, when blood pressure or blood volume acutely increases above its normal set point, most regulatory endocrine and autonomic reflexes and behaviors are inhibited.

Paralleling neural afferent input reflecting blood volume and arterial pressure are humoral factors that reinforce the neural information entering the CNS. The most thoroughly studied are components of the renin-angiotensin-aldosterone system. In states of hypotension, hypovolemia, or hyponatremia, the enzyme renin is released from the kidneys to trigger a metabolic cascade to ultimately generate the octapeptide angiotensin II (ANG II). ANG II is an opportunistic hormone that acts at innumerable sites and through multiple mechanisms to produce an expansion of blood volume and an increase in blood pressure. Beyond its potent smooth muscle vasoconstrictor actions, ANG II acts to enhance sympathetic nervous system activation by blunting baroreceptor depressor reflexes. This effector peptide also enhances VP release, is a potent dipsogenic and natriorexigenic agent, and a major controller of aldosterone release. The hormone aldosterone acts on the kidney to conserve Na^+, and in many species this steroid also targets the brain to induce salt appetite.

ANG II has a molecular weight of about 1000 Da and does not readily gain access to the brain. Circulating ANG II exerts CNS-mediated effects on autonomic reflexes, VP release, and behavior (i.e., thirst, salt appetite) by acting on a set of small, brain-related structures referred to as sensory circumventricular organs (CVOs). The parenchyma of these regions lacks a blood–brain barrier, and CVOs have been identified as putative receptive sites for various circulating factors. The three sensory CVOs are midline (or near midline) periventricular structures. Two of them, the subfornical organ (SFO) and the organum vasculosum of the lamina terminalis (OVLT), lie, respectively, along the dorsal and ventral aspects of the rostral wall of the third cerebral ventricle. The area postrema (AP), the third sensory CVO, is located on the floor of the fourth ventricle in the caudal medulla. Various lines of evidence indicate that each of the sensory CVOs is responsive to ANG II. The SFO and OVLT are implicated in ANG II sympathetic activation, VP release, thirst, and salt appetite. Results suggest that ANG II action on the AP blunts baroreceptor-mediated reflex depressor responses.

Information about both intra- and extracellular fluid status uses both afferent nerve activity and humoral stimuli as body–brain signaling mechanisms. Input from these two types of sensory modalities enters into an extensive neural network, the visceral neuraxis. This interconnected neural matrix processes information to coordinate and activate regulatory reflexes and behaviors to restore homeostasis. Certain nuclei and brain regions have been implicated as especially critical for maintaining body fluid and cardiovascular homeostasis. Among these are the AP, NTS, caudal and rostral ventrolateral medulla, parabrachial nuclei, raphe nuclei, locus coeruleus, paraventricular and supraoptic hypothalamic nuclei, several nuclei of the extended amygdala, the perifornical region of the lateral hypothalamus, and structures lying along the lamina terminalis.

Counterposed to systems which enhance retention or acquisition of water or Na^+ are systems that inhibit body fluid expansion in the case of overhydration. In rats, in addition to released systemic oxytocin acting to induce natriuresis, oxytocinergic mechanisms also act in the brain to inhibit solute (e.g., Na^+) intake. Other centrally acting factors limiting excess intake of water or Na^+ include brain natriuretic peptide, serotonin, cholecystokinin, corticotropin releasing hormone, and tachykinins. One or the other of these agents has been implicated as acting in periventricular tissues, the parabrachial nuclei, the dorsal vagal complex, or the AP to inhibit sympathetic and fluid retaining hormonal reflexes and prevent excess water or Na^+ intake.

Extracellular Osmoles and the Concept of the Osmoreceptor

An insight into the nature of the stimuli involved in signaling the status of the composition of the extracellular compartment was gained from experiments conducted on thirst in dogs by Alfred Gilman in the mid-1930s. Although it had long been proposed that increased extracellular fluid solute was an adequate stimulus for thirst, Gilman demonstrated that there was an essential property of the solute that was necessary in order to trigger drinking in the dog. Specifically, he showed that for a hyperosmotic solution to be an effective stimulus for thirst, its solute must not readily cross cell membranes. Gilman demonstrated that intravenously infused impermeable solutes, such as NaCl, that dehydrate cells act as excellent dipsogenic stimuli. In contrast, equiosmotic solutions (as measured by either freezing point depression or a vapor pressure osmometer) comprised of solutes (e.g., urea) that pass through membranes will not effectively dehydrate cells, and they do not induce significant thirst.

The nature of the receptors hypothesized to mediate the release of antidiuretic hormone in response to hypertonic solutions was proposed shortly after Gilman by EB Verney. By administering various hyperosmotic agents, Verney came to conclude that antidiuretic hormone (VP) release was mediated by a receptor that was specifically sensitive to stimuli that caused the receptive cells to shrink. He hypothesized that these cells were sensitive to their own volume and coined the term osmoreceptor. It was only a short time until the concept of the osmoreceptor was appropriated to describe the hypothetical sensors that mediate hyperosmotically induced thirst. Within the same period, Bengt Andersson serendipitously discovered that injections of hypertonic saline into the hypothalamus produced avid drinking in goats. Consequently, the brain became the prime focus as the site housing osmoreceptors.

Advances in neuroscience in the 1950s and 1960s and experiments from his own laboratory led Bengt Andersson to propose that the brain osmoreceptor may actually be a Na^+ receptor. He reasoned that in prior experiments in which various hyperosmotic solutes were delivered systemically to induce thirst or VP release, the presence of the blood–brain barrier caused the brain to be dehydrated. In other words, the brain becomes dehydrated and hypertonic because water moves out of the brain more rapidly than does Na^+. The consequence of this unequal movement of water and Na^+ is that brain extracellular Na^+ concentration is increased. Andersson went on to speculate that brain Na^+ receptors are responsible for the activation of regulatory actions to systemic extracellular

hyperosmolality. In response, Michael McKinley and colleagues pointed out that in experiments generating evidence for his hypothesis, Andersson and co-workers had made their hypertonic solutions for central administration by using only sugars (e.g., sucrose) in water. It is possible such infusates produce a dilution of extracellular ions, particularly Na^+, and this may disrupt normal neural function. McKinley's laboratory found that intracerebroventricular infusions are quite effective in stimulating drinking when solutions were made hypertonic by adding impermeable sugars to an artificial cerebrospinal fluid (aCSF; aCSF contains Na^+, among other ions) as a vehicle. One caveat noted by McKinley et al., however, was that solutions made hypertonic by adding NaCl to aCSF are more effective as stimuli than are equiosmolar, sugar-plus-aCSF-constituted hyperosmotic solutions. These findings imply that both osmo- and Na^+ receptors in the brain are likely to be involved in osmoregulation.

The osmoreceptor as a sensor of extracellular osmolality was initially proposed as a hypothetical construct to account for a set of experimentally observed phenomena. However, in 60 years, no one has unequivocally demonstrated a specific cell type, neuron or otherwise, that functions to sense osmolality and trigger increased neural activity in systems controlling thirst, VP release, or sympathetic outflow. However, the concept has engendered productive thought and investigation on issues such as receptor localization and what actually is being sensed (osmole concentration or Na^+ concentration) under physiological conditions.

Although the brain is firmly implicated in the process of maintaining consistency of extracellular osmolality or Na^+, there are also osmoregulatory responses triggered by peripheral mechanisms that almost immediately sense the nature of a given hydrational load. These so-called presystemic sensing mechanisms act to trigger compensatory regulatory actions before there are detectable changes in the osmolality of the systemic circulation or of the brain extracellular fluid. For example, the oral consumption of fluid immediately inhibits VP release and reduces the amount of subsequent drinking in dogs, humans, and other species. Experimental evidence indicates that presystemically signaled regulatory responses to prevent overhydration may derive from different sources and through various mechanisms. These include oropharyngeal monitoring of fluid type and volume, metering of swallowing, detection of gastric volume and/or osmolality, and the sensing of osmolality or Na^+ concentration in the hepatic portal circulation. Undoubtedly, different types of chemo- and mechanoreceptors are involved in these diverse sensory systems. Among the presystemic receptors and sensory pathways most thoroughly studied are the osmo-/sodium receptors in the splanchnic circulation and the afferents from these receptors. Manipulating the osmolality of solutions infused into the hepatic portal vein alters afferent nerve activity, and water is more effective in producing diuresis when it is infused into the portal vein than when infused systemically. Thirst and salt appetite have also been shown to be appropriately facilitated or inhibited by varying the concentration of NaCl in hepatic portal vein infusates. Input from the visceral receptors sensing extracellular osmolality or Na^+ concentration travels in vagal nerve afferents and enters the CNS via the NTS. Although all mammals studied to date have presystemic signaling that contributes to osmoregulation, there appear to be differences in the specific mechanisms a given species employs.

It is likely that there are many sites and cell types in the brain that are osmo- or Na^+ receptive. In the 1950s, Verney and his co-worker, Jewell, speculated that the hypothalamic cells that synthesize VP might themselves be osmoreceptors. Use of *in vitro* intracellular recording methods allowed investigators more recently to demonstrate that increases in extracellular osmolality will depolarize hypothalamic vasopressinergic magnocellular neurons. However, when the hyperosmotic challenge does not exceed physiological levels, the degree of depolarization is not sufficient to generate action potentials. Many investigators believe that magnocellular neurons are likely to receive input from other osmo- or Na^+ receptive regions in the brain or body and that these act to stimulate VP release.

The periventricular tissue surrounding the anteroventral third cerebral ventricle (AV3V) has received significant attention in recent years as a likely site containing osmo- or Na^+ receptors influencing not only VP release but also sympathetic tone and thirst. Awareness was drawn to this region in the mid-1970s by studies conducted in rats that destroyed a small volume of AV3V tissue and resulted in chronic deficits in drinking, VP release, and pressor responses to hypertonic challenges. AV3V lesions that produce these global alterations in behavioral and reflex responses to hypertonic stimuli include the OVLT, the ventral median preoptic nucleus (MnPO; i.e., the MnPO below the anterior commissure), and the preoptic/anterior hypothalamic periventricular nuclei. Functional studies conducted in larger species (sheep and dogs) have suggested that osmoreceptors, as defined by Verney, are likely to reside in one or more of the sensory CVOs.

The OVLT is regarded as a major candidate among the sensory CVOs as a site housing central osmo- and/or Na^+ receptors. However, lesions restricted to the OVLT reduce but do not abolish responses to systemic hypertonic challenges, whereas OVLT lesions that invade the ventral MnPO virtually abolish all

osmotically induced regulatory responses. It has been suggested that the ventral MnPO is osmo- or Na^+ sensitive and that it is a key site for integrating input from osmo- or Na^+ receptors from various regions, including input from the SFO and OVLT, and ascending visceral input from the periphery (e.g., hepatic portal circulation). Recently, lamina terminalis tissues have been the focus of studies using molecular techniques to identify ion channels as candidates for osmo- and Na^+ sensing. Two classes or types of channels, (1) the transient receptor potential ion channel, vanilloid subfamily (TRPV) and (2) the Na_x Na^+ channel, are of particular interest.

The TRPV type 4 (TRPV4) was among the first implicated in osmosensing. TRPV4 is a vertebrate homolog of an osmotically gated ion channel in the worm *C. elegans* and was identified through a candidate gene approach. *In situ* hybridization studies indicate that abundant TRPV4 messenger RNA is found in the OVLT, SFO, and MnPO, as well as in the choroid plexus. When expressed as a homomeric channel in a heterologous system, TRPV4 channels have been shown to be activated by cell volume expansion but not by cell shrinkage. Hence, this type of channel may be ideally suited to activate brain systems that inhibit excess fluid intake or retention. Studies indicate that *trpv4* null (knockout) mice have small alterations in mechanisms both facilitating and inhibiting thirst in hyper- and hypo-osmotic states. Another TRPV channel suggested to be a variant of the TRPV1 channel has recently been implicated in mechanotransduction in supraoptic magnocellular and OVLT neurons. TRPV1 knockout mice are hyperosmotic under basal conditions. Thirst and VP release to cellular dehydration have been reported to be attenuated in *trpv1* null animals.

The Na_x channel is present in the OVLT, SFO, and MnPO (in rat) and has been implicated in the control of salt appetite. Na_x null mice drink large amounts of hypertonic saline under experimental conditions in which salt appetite is normally inhibited in wild-type mice. This response is corrected in rescued mice produced by transducing the SFO with Na_x complementary DNA. The Na_x Na^+ channel involved in salt appetite control has been suggested to be associated with glia.

Recent discoveries that specific ion channels are likely to play a role as osmo- and Na^+ receptors offers great promise for achieving a more thorough understanding of the central mechanisms by which changes in body and brain extracellular fluid osmolality and/or Na^+ concentration are sensed and transduced. Given the likely involvement of many different types of channels and cells, including glia, the classical concept of an osmoreceptor is likely to change.

Summary and Conclusions

Organisms use multiple strategies to maintain consistency of their internal fluid environment. One of the factors carefully regulated by neural and hormonal reflexes and by behavior is extracellular osmolality. Na^+ is the most important extracellular solute, and Na^+ concentration or a suitable proxy (e.g., osmolality or total impermeable extracellular molecules and ions per volume of fluid) is probably sensed by Na^+ receptors or osmoreceptors. Other receptor systems are also linked in important ways to broader aspects of osmoregulation. These include systemic high- and low-pressure baroreceptors and receptors for circulating humoral factors that are released in response to changes in water and sodium balance or distribution and blood pressure changes (**Figure 2**).

Fluid-related information derived from systemic receptor systems converges on the brain through visceral afferent nerves and by accessing parts of the CNS more directly. Body–brain signaling peptides such as ANG II activate central pathways by first acting on brain-associated structures lacking a blood–brain barrier, the sensory CVOs. Afferent signaling molecules that are less impeded by the blood–brain barrier, such as the steroid aldosterone, gain access directly to central neurons to affect osmoregulatory mechanisms by generating a salt appetite. The input arriving in the brain is conveyed into the visceral neuraxis, which is a neural network involved in neural integration of homeostatic information. The result of this central processing of information is the orchestration of a pattern of reflex and behavioral responses appropriate for the animal to deal with the prevailing internal and external conditions and thereby to maximize survival.

Different components of the visceral neuraxis have unique roles in maintaining body fluid homeostasis. Of particular importance are the neural structures lying along the lamina terminalis. The sensory CVOs of the lamina terminalis have been extensively implicated in sensing humoral factors, in particular extracellular osmolality or Na^+ concentration and ANG II. The MnPO processes information from the SFO and OVLT, along with other fluid-related inputs (**Figure 2**). Output from the lamina terminalis structures projects to key premotor nuclei influencing reflexes and behaviors controlling body fluid and cardiovascular homeostasis (**Figure 2**).

Recently, stretch- and ion-gated channels have been identified in cells of lamina terminalis structures, and emerging functional evidence has implicated these in various processes involved in osmoregulation. The development of new methods used to pursue the molecular and cellular nature of osmo- and Na^+ receptors holds great promise for advancing the

Figure 2 A schematic depicting the nature of neural and hormonal inputs into the brain and the central neural pathways that mediate sensory integration of signals for sympathetic and hormonal reflexes and behaviors (drinking (thirst) and sodium ingestion (salt appetite)) which reduce the consequences of dehydration and sodium loss and restore body fluid homeostasis. Both inhibitory and excitatory inputs from the periphery derive from arterial and cardiopulmonary baroreceptors and probably other visceral receptors (e.g., gastric, hepatic, portal, or renal). Information carried in afferent nerves projects mainly to the nuclei of the solitary tract (NTS). Circulating angiotensin II and other fluid-related hormones act on the subfornical organ (SFO) and the other sensory circumventricular organs – the organum vasculosum of the lamina terminalis (OVLT) and the area postrema (AP). Ascending information to the forebrain is carried in from noradrenergic cell groups (e.g., from the locus coeruleus (LC)) in the hindbrain which are activated by arterial and cardiopulmonary receptor input under conditions of hypotension and/or hypovolemia. Centrally generated angiotensin functioning as a neurotransmitter in certain central neural pathways and noradrenergic (NE) inputs act synergistically in the forebrain nuclei (e.g., those nuclei along the lamina terminalis). A hindbrain inhibitory pathway originating in the AP and medial NTS ascends to the lateral parabrachial nucleus (LPBN). This projection uses serotonin (5HT) to guard against excessive sodium and water intake, thereby limiting inappropriate expansion of extracellular fluid volume. Inhibitory input also ascends the neuraxis to act in the forebrain structures. ANG, angiotensin; ANP, atrial natriuretic peptide; FAC, facilitatory; INH, inhibitory; MnPO, median preoptic nucleus; SNS, sympathetic nervous system; JG, juxtaglomerular cells (source of renal renin). Otoacoustic Emissions

D T Kemp, Centre for Auditory Research, UCL EAR Institute, London, UK

© 2009 Elsevier Ltd. All rights reserved.

Otoacoustic emissions (OAEs) are low-level sounds generated by the ear as a natural by-product of the hearing process. The sounds are recordable by means of an ear piece or probe containing a microphone, usually also a means of delivering sound stimulation to the ear. This probe is inserted into the ear canal so as to seal it as in Figure 1. The microphone signal is processed electronically to identify and extract sounds of cochlear origin usually during or following sound stimulation. Figure 2 shows an example of the cascade of sound pressure vibrations typically emanating from a human ear in response to a click stimulus together with its frequency spectra. The emission of a wide range of sound frequencies in response to appropriate stimuli indicates healthy functioning of a set of sensory cells in the cochlea known as the outer hair cells. OAEs also indicate functional integrity of the middle ear since it is the middle ear that conducts the stimulus into the cochlea and then conducts the secondary vibrations from the cochlea to the eardrum to create OAEs in the ear canal. The physical vibration of the eardrum needed to create typical OAEs is less than 0.1 nm, that is, smaller than atomic dimensions.

The outer hair cells of the cochlea (Figures 3 and 4) are the source of OAEs. These cells are uniquely capable of generating sound frequency vibrations. Excitation by mechanical deflection of the stereocilia that protrude from the apex of these cylindrical cells changes their receptor potential and in response the protein prestin in the cell's lateral membrane undergoes a configurational change. This results in a simultaneous length change in the isolated cell while *in vivo* it results in a force being applied to the stiff structure of the organ of Corti in which these cells are embedded (Figure 4). The force is naturally synchronized to the applied mechanical stimulation and this plays an essential role in optimizing the vibratory properties of the cochlea as described below. Normal operation of the mechano-electromotile action of outer hair cells depends critically on the composition and electrochemical status of the endolymph which fills the scala media and bathes the apical faces of both inner and outer hair cells. Inner hair cells also depend on the endolymph to perform their essential role of transducing the sound vibration reaching them and activating the auditory nerve, to initiate hearing. It is the leakage back to the middle ear of some of the vibratory energy generated by the outer hair cells which results in OAEs.

OAE therefore requires healthy status of the middle ear, outer hair cells, and cochlear endolymph. This makes them a valuable tool for the objective detection of a variety of peripheral auditory pathologies. The method is in common use to detect hearing impairment in neonates and for clinical diagnosis. In laboratory applications, emissions are used to monitor cochlear status and to record subtle changes.

Background

The OAE phenomenon was first reported in 1978. Initial observations were on human ears, but the phenomenon of OAE as it is commonly known was subsequently confirmed in a variety of animals. The first reports triggered a controversy which eventually merged with a major reevaluation of peripheral auditory function. At the time of the discovery of OAE, the dominant model of cochlear function was based on the work of the 1961 Nobel prize winner George von Bekesy. His pioneering observations in the 1940s on how sound stimulation vibrated cochlear structures led to the understanding that the spiral elastic basilar membrane of the cochlea (Figure 1(d)), loaded by the fluid filling the cochlea, performed an initial analysis of sound by frequency. This is achieved in a purely mechanical way by the natural formation of a frequency-dispersive, apically traveling, transverse wave. In Bekesy's model when sound energy is introduced into the cochlea by vibration of the stapes in the oval window, the traveling wave transports vibrational energy to specific regions along the tapered basilar membrane determined by the frequencies present in the sound. In this way, high notes become concentrated or focused on sensory cells near to the base, whereas low notes become focused on places near to the apex of the spiral organ as illustrated in Figure 5.

The focusing or concentration of incident sound energy of each frequency on small group of sensory cells serves to concentrate excitation and increase hearing sensitivity. The separation of frequency components across an extended sensory array prior to transduction is valuable for hearing because it permits the detection and subsequent simultaneous neural transmission of multiple frequency-specific channels of sensory information without mutual interference and degradation. This is exploited to maximum advantage in mammals and allows them to detect and perceive the information carried by sounds at frequencies far in excess of the maximum firing rate of auditory neurons. However, the efficiency of this mechanism is severely limited by the natural viscous damping occurring in the small fluid-filled spaces of

the cochlea. von Bekesy's and all subsequent observations of the ear's physical interaction with sound prior to 1978 appeared to show that in practice the process worked too inefficiently to yield the degree of frequency separation (resolution) required to explain the frequency-resolving properties of normal hearing (see Figure 6). An additional unknown mechanism was therefore presumed to act at or after the transduction stage so as to enhance frequency selectivity to the degree that was already known to exist from single-unit auditory nerve fiber studies.

Figure 1 Otoacoustic emissions are recorded by a probe inserted into the ear canal (a) so as to seal it. Stimulation (yellow arrows) is conducted through the middle ear (b) and enters the cochlea (c). It progresses up the spiral basilar membrane of the cochlea (d) propagating in a traveling wave (see Figure 5). This wave mode directs energy at different frequencies to different places on the cochlea's sensory epithelium. The frequency resolution achieved in the process depends critically on the level of viscous damping. Damping is actively reduced by the electromotile action of outer hair cells (see Figure 3) and a by-product of this is the return of sound energy back to the eardrum after a delay. With thanks to M. Robinette and A. Pye for image material.

The discovery in 1978 of sound emissions by the intact healthy ear severely challenged Bekesy's model. The emitted sounds had nonlinear properties indicative of a biological origin. Exploiting this nonlinearity in suppression studies allowed the mechanical frequency tuning of their source to be determined and this was found to be similar to that of auditory nerves. But contemporary cochlear models viewed the cochlea as a passive absorber of sound energy, not an emitter, and they predicted poor frequency selectivity and linear behavior. OAEs on the other hand suggested that the cochlea performed frequency analysis much more efficiently than had been seen in the laboratory and that it did not simply absorb sound but also emitted it. The implications of these challenging observations took some years to be digested. They challenged most previous work on cochlear biophysics. The problem was that no physical mechanism was then known which could account for a reversal of Bekesy's apically traveling wave to cause sound emission into the ear canal. Furthermore, in some ears, sound emission was observed to occur spontaneously at precise frequencies without any stimulation being present at all. No biological mechanism then known had such a capability. This all led to an initial rejection of OAEs as being an epiphenomenon of no relevance to cochlear physiology.

Interestingly, Bekesy's model of the cochlea had been challenged as early as 1948 by Thomas Gold. He reasoned from physical principles that a biological vibration amplifier mechanism was necessary for the

Figure 2 Transient-evoked otoacoustic emission (TEOAE). (a) Left, the sound pressure waveform recorded in a sealed human adult ear canal following a brief click stimulus (top left). The oscillations in sound pressure are the result of vibrations of the eardrum caused by a mechanical response of outer hair cells within the cochlea. The initial 3 ms is blanked out because the recording is overloaded by the click stimulus itself. An eighth octave frequency analysis of this waveform is shown on the right. The upper blue columns indicate the sound pressure level of otoacoustic emission at each frequency for this ear. Both the waveform shape and the spectral intensity structure are highly individual but normally very stable. Sensory hearing loss at any frequency usually abolishes the emission of that sound frequency.

Figure 3 The source of otoacoustic emissions is vibrations from the outer hair cells of the cochlea. In the isolated cell shown, the protruding bundle of stereocilia is just visible on the top left. *In vivo* displacement of the stereocilia by fluid vibration in the excitatory direction opens ion channels in their tips causing a current flow which depolarizes the cell. This causes the cell to shorten. The change is very rapid and generates audio frequency vibration at the stimulating frequency and at distortion frequencies. The electromotility can be demonstrated *in vitro* by applying alternating potential to the cell. Prepared by David Brass.

Figure 4 The sensory hair cells of the cochlea. In the foreground of this longitudinal section of the organ of Corti, the outer hair cell bodies are seen embedded inside the structure. The V-shaped arrays of stereocilia belonging to three rows of outer hair cells are seen above protruding from the apical surface of the organ of Corti. The hairs of the inner hair cells are just visible beneath the tectorial membrane at the top. Hearing occurs only via the inner hair cells which directly synapse onto auditory nerve fibers. Electromotility of the three rows of outer hair cells act as a biological hearing aid, amplifying weak stimulation. Electron micrograph courtesy of A. Forge.

Figure 5 Schematic illustration of the cochlear traveling wave in response to two pure tone frequencies. The dark shaded region indicates the envelope of the wave over time, while the white line indicates (greatly exaggerated) the instantaneous displacement imposed by the wave on the basilar membrane at one arbitrary instant in time. The wave moves from left (base) to right. In this 'low damping' model, there is a sharp peak in the overall envelope for each of the two different frequencies where excitation is maximal for each frequency.

Figure 6 From the same computer model as in Figure 5 and with the same input stimulation, this figure illustrates how the frequency peaks of traveling wave intensity decrease and merge together when substantial viscous damping is present. The traveling waves in this figure represent those in a dead cochlea or one in which outer hair cell motile activity is missing. This corresponds to an ear with sensory transmissive hearing loss.

ear to achieve its remarkable sensitivity and frequency selectivity but that such an active mechanism would obviously not have been operating in the damaged or dead specimens studied in the laboratory. Gold's 1948 model was that biologically derived electrical energy was converted into vibratory energy by some unknown piezoelectric mechanism in synchrony with the incoming sound vibration and was then coupled back into basilar membrane motion so as to replace the energy lost by the viscous drag of the cochlear fluid. With this 'positive feedback,' the cochlea would be able to perform its mechanical frequency separation and focusing role much more efficiently – turning the dull response in Figure 6 into the sharp response of Figure 5.

Gold's hypothesis was generally discounted but the discovery of OAE triggered fresh uncertainty about

the degree to which frequencies where physically separated by Bekesy's traveling wave. This uncertainty was ended in 1982 by new and refined measurements of vibration in undamaged animal cochleae made by Sellick, Patuzzi, and Johnstone. The sharp mechanical frequency tuning they observed in the carefully prepared cochlea matched that seen in auditory nerve fibers. This meant that the healthy undamaged cochlea was somehow able to avoid the previously observed effects of viscous damping, just as Gold had postulated. The discovery in 1983 of outer hair cell electromotility by Brownell provided a suitable mechanism to implement Gold's positive feedback and to generate OAEs. The stimulus-activated electromotility of the outer hair cells is now believed to more than replace the energy lost through viscosity – not exactly by positive feedback as Gold envisaged but by a more subtle interaction with basilar membrane mechanics. This new aspect of cochlea's biophysical function became known as the cochlear amplifier. The cochlear traveling wave amplifier provides up to a 1000 times (60 dB) increase in the level of excitation reaching the sensory inner hair cells over and above that demonstrable in the dead cochlea. OAEs are the result of some of this added energy escaping back to the middle ear, that is, a by-product of the cochlear amplifier.

The output of the cochlear amplification saturates with increasing stimulus intensity so that the gain it provides reduces. This has the effect of reducing the dynamic range of stimulation from over 100 dB (i.e., more than 100 000:1) at the outer ear to maybe 50 dB (~300:1) at the inner hair cells and is valuable in two ways. Weak stimulations receive most amplification to raise them above the relatively high threshold of inner hair cells whereas strong stimuli need no amplification to do that. Also, auditory nerves have a dynamic range in terms of firing rate of only around 40 dB (100:1), and so the compression provided by the nonlinearity of the cochlear amplifier helps the auditory nerve accommodate the full range of environmental sound intensities. The level of stimulus frequency OAE (SFOAE), which is the dominant part of transient-evoked OAE (TEOAE) and SOAE (spontaneous OAE, see below), exhibits a compressive nonlinearity with stimulation level following an approximately 1/3 power law.

OAEs and Hearing Loss

Hearing impairment can take many forms, most of which include an elevation of hearing threshold, that is, a decrease in sensitivity to sound. Sensitivity can be lost due to poor transmission of sound energy though the middle ear to the cochlea (conductive loss), poor transmission and frequency analysis of sound energy through the structures of the cochlea onto the sensory inner hair cells (sensory transmissive loss), poor sensory transduction (sensory transductive loss), or poor transmission of transduced information along the auditory pathways (neural transmissive loss). There are important dimensions to hearing impairment beyond that of simply losing sensitivity to quiet sounds. These arise from degradation of the information extracted from the sound stimulation. Whereas a finite loss of sensitivity can always be completely corrected for by applying external amplification, a loss of information caused, for example, by inadequate frequency separation in the cochlea, by defective transduction, or by impaired neural transmission cannot be corrected for externally. It is therefore of import to ascertain the nature of the loss before prescribing amplification.

Determining whether OAEs are present or absent helps define the nature of a hearing loss. They are absent in the case of sensory transmissive hearing loss due to the failure of the cochlear amplifier through a loss of the electromotile action of outer hair cells. When this happens, the distribution of stimulus sound energy within the cochlea reverts to that seen by Bekesy in dead ears – notably a damping of the traveling wave leading to poor frequency-specific focusing of stimulation onto the sensory hair cell as in Figure 6. There is a loss of sharpness and consequently of the intensity delivered to these cells (compare Figures 6 and 5), and also there is an increase in dynamic range. Loss of outer hair cell function has been shown experimentally to cause up to a 60 dB (50%) loss in hearing. Decreased dynamic range contributes to the clinical symptom of recruitment, and the loss of frequency resolution contributes to poor hearing in noise.

OAEs are absent in sensory transmissive hearing loss because no vibrational energy is being added to enhance the excitatory traveling wave. The prevalence of OAE loss in the entire hearing impaired population with normal middle ear function is very high, leading to the conclusion that loss of outer hair cell function is the major cause of, or is a necessary concomitant of, nearly all nonconductive hearing losses. This empirical fact justifies the widespread use of the technique for newborn hearing screening in those infants without risk of neurological damage and identifies outer hair cells as the most vulnerable component of the auditory system – a fact first learned histologically.

Methods Used to Observe OAE

OAEs are generated when a stimulus of any kind enters the cochlea, but for the purposes of measurement specific types of acoustic stimuli are employed.

Different stimuli emphasize different aspects of outer hair cell function and they also require different signal processing to identify and separate the emission from the incident stimulus.

In the TEOAE technique, a short click sound is delivered to the ear and the probe microphone records ear canal sounds for up to 20 ms afterward (Figure 2). During the first 10 ms in humans and a shorter time in most animals, the stimulation will have propagated as a traveling wave along the entire length of the cochlea. In doing so, the wave will have activated outer hair cells and been strengthened by their electromotile reaction – enhancing the traveling wave and ensuring sharp focusing of each frequency component onto its own frequency place. Natural anatomical or functional irregularities in the system lead to the enhanced traveling wave being partially reflected back to the middle ear and ear canal and so creating an OAE.

The click intensity used to record TEOAEs is typically 50 dB above threshold with a peak intensity of 80–85 dB sound pressure level (SPL). Repeated click stimulation and signal averaging is used to overcome background noise and recover the emission which in human ears ranges from 0 to 30 dB SPL. To avoid including the stimulus or the acoustic response of the middle ear in the measurement, the recording is delayed until several milliseconds after the stimulus. Even so, there is a risk of acoustic oscillations in the ear canal being confused with the cochlear emission. To overcome this, a differential technique is employed in which responses to different intensities of stimulation are subtracted in proportion so as to cancel any linearly proportionate acoustic responses. This leaves only nonlinear signals which are most likely to be of biological origin. TEOAE responses are then analyzed by frequency in order to confirm outer hair cell function along the length of the cochlea. Responses have been obtained between 500 Hz and 8 kHz but the TEOAE technique is most effective over the 1–4 kHz range.

The complex waveform of the response seen in Figure 2 occurs because the various frequency components making up the click take different times to enter the cochlea, to travel to their natural place, and then after reflection to travel back to the middle ear. The delay is frequency dependent and this results in a time dispersion of response components. High frequencies emerge first and low frequencies last. The intensity of each component is irregularly dependent on frequency. Both the delay and intensity profiles are individual and tend to be very stable with time. The TEOAE waveform can be exactly reproduced weeks or even years later, provided there is no damage or deterioration in the cochlea or middle ear. TEOAE is therefore a very sensitive indicator of physiological change in the peripheral auditory system. The technique has been successfully used on other primates and with somewhat greater difficulty on a wide range of other animals including frogs. It is often the method of choice for newborn hearing screening and for research with human subjects, but is rarely used in laboratory research.

A second commonly used method of OAE observation involves measuring distortions produced during stimulation with two pure tones approximately one-third an octave apart. The significance of this separation is that the individual frequency places in the cochlea for such a stimulus just overlap and so compete for the responses of some sensory cells. Due to their nonlinearity, outer hair cells in places which provide amplification to both stimulus frequencies are unable to do so without generating distortion also. This is because the transfer function from mechanical stimulation to amplified mechanical output is nonlinear and saturates at quite low levels. The mechanical force these cells impose on the basilar membrane does not exactly mimic the applied stimulus waveform. Vibrations at new frequency components are generated. For stimulus frequencies f_1 and f_2, nonlinearity of the hair cell's response introduces harmonics distortions at $2f_1$, $3f_1$, $4f_1$, etc., and $2f_2$, $3f_2$, $4f_2$, etc., and also intermodulation distortion products at frequencies of $2f_1 - f_2$, $3f_1 - 2f_2$, $4f_1 - 3f_2$, etc., and $2f_2 - f_1$, $3f_2 - 2f_1$, $4f_2 - 3f_1$, etc. Despite their algebraic complexity, intermodulation distortion actually comprises a simple array of tones, each separated by the stimulus difference frequency $f_2 - f_1$ (f_1 less than f_2) which surround the applied stimuli. It needs to be emphasized that although all these distortion products might be generated at the cell only a few of them escape to form OAEs.

Those distortions that reach the ear canal form distortion product OAEs or DPOAES. DPOAE can be extracted by subjecting the ear canal probe microphone signal to narrow-band frequency analysis and this is illustrated in Figure 7. Because the frequencies of the emitted sounds are absolutely defined by (but are different from) the applied frequencies, any particular distortion product can be readily identified and its intensity measured. DPOAE levels range from −10 up to 30 dB SPL. The measurement of DPOAE is practically limited by the level of background noise present in the duration of the recording. There is also a risk of noise and artifactual distortion generated by the sound delivery and recording systems being mistaken for OAEs. This risk is minimized by making control recordings in an artificial ear canal and by statistical assessment of the signal-to-noise ratio. DPOAEs characteristically emerge after

a b

Figure 7 An example of distortion product otoacoustic emissions. (a) Shows the spectrum of sounds in a human ear canal during stimulation by two pure tones $f_1 = 1420$ Hz and $f_2 = 1500$ Hz, each at 70 dB SPL. The additional blue lines are intermodulation distortion products generated by the nonlinear activity of outer hair cells. The most commonly measured component is at the frequency given by the formula $2f_1 - f_2 = 1360$ Hz in this case. (b) A DP-gram formed by plotting the level of $2f_1 - f_2$ for a series of f_1, f_2 frequency steps across the audio frequency range. The irregularity is quite typical and does not imply a similar fluctuation in hearing. The area shaded red shows the 95 percentile limits of noise recorded during the measurement. In this example, the ratio f_2/f_1 is 1.05, which is well below the optimum value for $2f_1 - f_2$ generation. It has been chosen because this close ratio allows the maximum number of distortion products to escape. This reveals the systematic arrangement of distortion components.

a delay of several milliseconds, and this feature can also be used to discriminate between cochlear and artifactual signals.

For a particular distortion product to emerge from the cochlea to form a DPOAE, there has to be mechanism for its basal propagation. Those with distortion frequencies significantly above the originating place frequency, for example, $2f_1$ and $4f_2 - 3f_1$, cannot propagate at all and also cannot be perceived as their intensity is so much lower than that of the causative stimuli. Those distortions with frequencies lower or slightly above the natural frequency of their place of origin, for example, $2f_1 - f_2$ ($f_1 < f_2$), naturally propagate apically, and these can be perceived as aural combination tones. However, lower-frequency intermodulation products can escape back to the middle ear in at least two ways. First, for values of f_2/f_1 near to 1.2, the spatial distribution and phasing of the $2f_1 - f_2$ distortion produced by each hair cell naturally favors its propagation back to the middle ear which then results in DPOAEs. The ratio 1.2 is the optimum ratio for the creation of DPOAE $2f_1 - f_2$. Different f_2/f_1 ratios favor other lower-frequency distortion emissions. Second, any lower-frequency distortions propagating apically from their site of origin to there own frequency places can be reflected back to the middle ear by the same irregularities which are responsible for the creation of TEOAE and SOAE. Figure 8 illustrates how two stimulus tones introduce a variety of different waves in the cochlea and how they escape to form OAEs.

DPOAEs are a complex phenomenon originating in the mechanical nonlinearity of outer hair cells spread over a significant length of the basilar membrane and emerge by a dual reverse transmission path, which can cause spurious fluctuations of DPOAE intensity with frequency through interference. The intensity of the emission also depends greatly on the stimulus level and on the intensity and frequency ratios of the two stimulus components. Despite this, the technique is valuable in the laboratory and clinic as an indication of outer hair cell function. Typically, measurements of the $2f_1 - f_2$ DPOAE are made over a sequence of f_1, f_2 frequencies and combined to form a DP-gram as shown in Figure 7(b). The method works well up to high frequencies. Stimulation by two equal-intensity stimuli f_2 and f_1 at levels above 70 dB SPL yields DPOAEs related to outer hair cell integrity, providing a psuedo-cochleogram. DPOAEs obtained using lower intensity and unequal stimuli, for example, f_2 55 dB SPL and f_1 65 dB SPL, are more dependent on the functional quality of these hair cells and indicate normal hearing threshold.

A third method of observing OAEs which is mainly employed in specialized research applications involves the application of just one pure tone to the ear. OAEs are created only at the applied frequency due to wave reflection at cochlear irregularities.

Figure 8 Schematic illustration of the cochlear waves that result in the major otoacoustic emissions in response to a two-tone stimulus comprised of frequencies f_1 and f_2. The base (input) and higher-frequency region of the cochlear is left, the apex and lower frequency is right. Stimulation waves move left to right. OAE-generating waves move right to left. Emission waves caused by reflection at a place are called place-fixed emissions. Emissions arising from wave interactions are called wave-fixed or distortion emissions. The most commonly used OAE is the $2f_1 - f_2$ DPOAE which can be seen to have two sources. TEOAEs are composed mostly of SFOAE with some DPOAE.

Separation of the SFOAE from the applied stimulation requires careful processing. As with TEOAEs, a differential technique can be employed whereby responses to high- and low-level stimuli are scaled and subtracted so as to leave only the nonlinear part of the ear canal sound. Alternatively, a second stronger tone is introduced at a nearby frequency to divert outer hair cell activity and so suppress the emission in response to the first tone. Again, a subtraction method serves to remove the unaffected stimulus signal. SFOAEs can be used to monitor cochlear status with time at one selected frequency or they can be measured over a range of frequencies by sweeping the stimulus frequency. The method has the advantage of a greater simplicity of data interpretation but for the most part gives no more information than the TEOAE and DPOAE techniques.

Other techniques need to be mentioned briefly. Observation of SOAEs requires only the narrowband frequency analysis of the ear canal sound. They consist of one or more continuous oscillations at very narrowly defined frequencies – typically of less than 1 Hz bandwidth (see Figure 10). SOAEs are due to the repeated self-stimulation of the cochlea by closed-loop reflections of vibration between the middle ear and the same internal reflecting irregularities that give rise to TEOAEs and SFOAEs.

Each of the stimulated emission techniques reviewed above has variants. TEOAEs, for example, can be derived from stimuli other than clicks and both tone bursts and pseudo-random noise (maximum length sequences) have been successfully employed. DPOAEs can be obtained simultaneously from multiple tone pair stimuli, and also from modulated stimuli. Both techniques have been used for research purposes. DPOAEs have also been obtained in the presence of an additional suppressing tone intended to reduce the reflection component so as to simplify interpretation.

Interpretation of OAEs

As indicated above, the ear emits sound because the healthy cochlea contains an active wave amplifier. Some of the amplifier's energy escapes due to the creation of distortions by nonlinearities in the amplification mechanism. This escape occurs from locations where the spatial phase configurations of the distortion naturally propagate waves back to the middle ear. Other energy escapes because the forward wave propagation characteristics of the basilar membrane and/or the amplification that is present along its length exhibits irregularities (in primates at least), which cause the reflection of both stimulus and distortion waves back to the middle ear. Large numbers of studies in human ears have confirmed that ears with healthy middle ear function but no OAE have a sensory hearing loss typically of 30 dB or more.

OAEs are broadly frequency specific, because failure to exhibit an emission over at least a half-octave frequency range (given suitable stimulation) correlates with hearing loss over a related frequency range. With TEOAEs and SFOAEs, the frequency of hearing loss is the frequency at which OAEs are absent. For $2f_1 - f_2$ DPOAEs, it is the frequency of

f_2 which determines the place in the cochlea being examined, whereas the emission response may emerges about one-half octave below that frequency if the optimum stimulus frequency ratio is used.

However, a direct correspondence of the frequencies of emission loss and hearing loss cannot be totally relied upon. A fine structure of OAE intensity with frequency can exist due to interference between multiple exit routes (see **Figure 8**). Peaks and dips of intensity on a scale smaller than one-half octave are not generally functionally significant. Furthermore, although it is tempting to assume a one-to-one correspondence between frequency and place in the cochlea since, as this is the basis of its function, it is not the case that all emissions originate from the appropriate frequency place. Wave and cell interactions occur over a substantial length of the basilar membrane even for single stimulus frequencies and these contribute to the OAE. Emissions should be regarded as a somewhat spurious by-product of the cochlear amplification and filtering process.

It is also tempting to assume that the intensity of an emission at a given stimulation level, or the lowest stimulus level at which an emission can be detected, will correspond in some way to the sensitivity of hearing. This is partly true. OAE intensity reduces systematically as hearing loss progresses. Many population studies have shown about a 60% correlation between measures of emission strength and hearing threshold sensitivity. This is sufficient to demonstrate the underlying relationship but is insufficient to allow a meaningful prediction of an individual's hearing threshold from OAE measurements. This is not surprising since the cochlear amplifier mechanism feeds but does not involve the transduction process. It is the transduction process that determines the threshold for excitation of the auditory nerve. Furthermore, the transmission of waves back to the middle ear to form OAEs involves the fortuitous escape of energy via mechanisms not related to the hearing process. Even the recording process affects the intensity of emissions recorded. Vibrations of the eardrum driven by waves in the cochlea create measurable emission sound pressures only when the ear canal is sealed by the measurement probe. The volume of air between the probe and eardrum then plays a significant role in determining the sound pressure developed. These cautions raise the following question: what value are OAEs beyond their use for the detection of a loss of outer hair cell function?

The Wider Significance and Importance of OAE

Outer hair cells are known to be the most vulnerable components of the auditory system and their malfunction is implicated in the vast majority of sensory hearing loss pathologies. The stability of hearing sensitivity depends on the mechanisms ensuring the functional homeostasis of the cochlea. The nature of outer hair cells vulnerability and the mechanisms that maintain their optimal function are still inadequately understood. OAEs provide data specific to the functional status of outer hair cells in the intact ear and facilitate direct comparisons between human and animal cochleae. So although quantitative interpretations can be difficult, OAEs have a uniquely important role in auditory research at this time.

The functional mechano-electromotile status of outer hair cells is key to hearing. It can be characterized *in vitro* by their input–output function and operating point. This saturating nonlinear characteristic can be used to predict the pattern of distortion product generated locally but the complexity of the distortion product emission mechanism (see **Figure 9**) prevents the unambiguous determination of the average hair cell input–output characteristics at one frequency region from static DPOAE measurements. On the other hand, changes in OAE level can be readily measured and related to functional change. It is relatively easy to demonstrate the effects of noise and ototoxic trauma and potentially the effects of otoprotective drugs using DPOAE and TEOAE. Long exposures to intense noise can cause permanent hearing loss, abolition of OAE, and even hair cell loss. Lesser exposures cause a temporary threshold elevation and a correlated depression of OAEs. Very short duration exposures (~1 min) can trigger a biphasic alteration in both threshold and OAE which incorporates an enhancement phase. Challenge by even mild overexcitation reveals the characteristics of cochlear control mechanisms (see **Figure 10**).

Changes in OAE intensity can be interpreted as either due to a change in outer hair cell input–output functions or in their operating point. The latter can be experimentally altered by the application of a more intense low-frequency tone, which by delivering a modulated mechanical bias to each hair cell modulates their operating point and consequently modulates OAEs. From this modulation, hair cell characteristics can be deduced. Some pathologies – specifically cochlear hydrops – cause hearing loss by fluid pressure imbalance within the cochlea, and the offset of hair cell operating point can be observed using OAE.

There is extensive evidence for some central control of cochlear status although its function is not well understood. In particular, fibers from the medial olivary complex in the auditory brain stem synapse directly onto outer hair cells and so can alter their operating point and maybe their dynamic function. Excitation of the medial cochlear efferent system has

Figure 9 A DPOAE map of a human cochlea showing a detailed individual structure. This ear has normal hearing. The structure is the result of the complexity of the emission process and interference phenomena. Its broader features probably are related to functionally minor irregularities in cochlear anatomy and physiology which may or may not be predictive of the ear's robustness and genetic factors. The map shows DPOAE intensity against its frequency and stimulus pair frequency ratio obtained by recording DPOAEs at one stimulus pair level for all stimulus frequencies and frequency ratios. Upper and lower panels represent different OAEs.

Figure 10 An example of the cyclic change in cochlear amplification following brief overstimulation as reflected in the intensity and frequency of a spontaneous otoacoustic emission (SOAE).

a small suppressive effect on hearing and on OAEs. As a large proportion of these fibers are activated by input from the contralateral ear, this suppression of activity (called the cochlea reflex) can be most easily demonstrated by applying noise or other fluctuating sound stimulation contralaterally and observing the depression of OAE. This occurs over a timescale of the order of hundreds of milliseconds. There is experimental evidence that a strong cochlear reflex correlates with low susceptibility to overstimulation.

OAEs are a powerful tool for researching the mechanisms that maintain functional cochlear homeostasis. Abnormal malfunction of these mechanisms might be early indicators of pathology or be predictive of individual hypersusceptibility. The absolute intensity of OAEs has not proved to be a valuable measure in itself but the magnitude and time course of changes in OAE intensity seen in response to experimental perturbations of the auditory system are uniquely valuable.

Oxidative Damage in Neurodegeneration and Injury

I G Gazaryan and R R Ratan, Weill Medical College of Cornell University, New York, NY, USA

© 2009 Published by Elsevier Ltd.

Introduction

The etiology of dysfunction and cell death in neurodegenerative diseases remains enigmatic. Most neurodegenerative conditions are insidious in onset and run a gradually progressive and painfully inexorable course for those afflicted and their families. Prototypic neurodegenerative conditions include Alzheimer's disease (AD), Huntington's disease (HD), Parkinson's disease (PD), and amyotrophic lateral sclerosis (ALS). By contrast, acute neurodegenerations are monophasic and characterized by stroke and spinal cord injury. Many neurodegenerative conditions are linked to inherited mutations, resulting in accumulation of the damaged proteins or their wrongly processed variants. Sporadic neurodegenerative conditions are also associated with accumulations of misfolded proteins and their aggregates. Downstream of these events, metal-catalyzed oxidation leading to oxidative stress has been implicated as a common final pathway of injury (Figure 1).

Aging and Neurodegeneration

Mitochondria as a Major Source of Superoxide under Normal Conditions

Neurodegeneration is directly modified by cell aging. Some theories invoke the mitochondria as the major sites of generation of deleterious free radicals that promote aging. The chemistry of reactive species that could result in oxidative damage under normal physiological conditions is the same for any cell. The major species in cells is the superoxide radical, produced as a by-product of the mitochondrial respiration, in particular by complex I and complex III of the respiratory chain. Complex III breaks a two-electron reducing equivalent into two single-electron reducing equivalents inside the membrane (in what is known as the Q cycle), and the resulting quinone radical reacts with oxygen, giving rise to the superoxide radical. This side reaction is known as 'mitochondrial leakage' and comprises up to 3–4% of the total oxygen consumption. If in a lifetime we consume nearly 60 000 l of oxygen per kilogram of body weight, it means that we produce approximately 2000 l of superoxide per kilogram of body weight. What happens to the released superoxide and how does a cell handle the consequent 'oxidative' load?

Antioxidant/Antiaging Mechanisms: Superoxide Scavenging

In both mitochondria and the cytosol, superoxide is scavenged and converted into hydrogen peroxide and oxygen by superoxide dismutase (SOD), although the nature of SOD in mitochondria and the cytosol is different (i.e., MnSOD and CuZnSOD, respectively). The formed hydrogen peroxide is further decomposed into water with the help of catalase or is reduced by the glutathione peroxidase/glutathione system. Very recent studies show that the thioredoxin reductase/thioredoxin system is also capable of reducing hydrogen peroxide to water.

There are a number of theoretical reasons why the nervous system in general and neurons in particular are under the biggest load of oxidative stress under basal conditions. Neurons have a very high metabolic rate in order to meet the demands of electrical signaling. Specifically, our brain uses 20% of the total oxygen consumed, although the brain is only 2% of the body weight. An expected corollary of high oxygen utilization is a tenfold higher level of radical production. Paradoxically, despite higher radical production, catalase is absent in brain mitochondria. This is not the case for heart mitochondria.

Given the higher level of radical production and the absence of catalase in brain mitochondria, what are the mechanisms at play inside neuronal mitochondria to neutralize the formed hydrogen peroxide and keep oxidative damage to tolerable levels? In addition to glutathione peroxidase, the only other known system that neutralizes hydrogen peroxide is that of thioredoxin and peroxiredoxin. Reduced thioredoxin provides peroxiredoxin with reducing equivalents to reduce hydrogen peroxide to water. Oxidized thioredoxin is reduced back by a mitochondrial thioredoxin reductase, selenocysteine flavodithiol oxidoreductase. Why mitochondrial catalase is absent in neurons is not well understood, but could be related to neuronal signaling functions of peroxide that are not necessary in other tissues. The absence of catalase from neuronal mitochondria places the burden of neutralizing hydrogen peroxide generated in mitochondria squarely on the shoulders of the thiol-based detoxification systems, particularly glutathione, thioredoxin, and peroxiredoxin. A causal role for mitochondrial peroxide in aging has been supported by the generation of transgenic mice that overexpress catalase in the nucleus, the peroxisome, and the mitochondria. Significant extension of life span was only seen in the animals in which catalase was overexpressed in the mitochondria. The extension of life span was associated with improvement

Figure 1 Widely accepted hypothetic gain-of-function transformation of cross-linked aggregates of misfolded proteins. Confirmed for AD, PD, and ALS, and supposed for HD. ROS, Reactive oxygen species.

Figure 2 Reactive oxygen/nitrogen species generation and neutralization reactions and systems: Upper level: Superoxide scavenging reactions catalyzed by superoxide dismutase (SOD), catalase, thioredoxin reductase (TR), peroxiredoxin (Prx), and glutathione peroxidase (GPx) and mediated by thioredoxin (Trx) and glutathione (GSH). Center: Oxidation states of cysteine and methionine and their repair; glutathione repairs most of the oxidative modifications by glutathionylation, followed by glutathione removal with the glutaredoxin (Grx) system; methionine is repaired with the methionine sulfoxide reductase (Msr)/Trx system; sulfonic acid modification is irreversible, while sulfinic acid can be repaired with the use of a recently characterized ATP- and Mg^{2+}-dependent enzyme, sulfiredoxin (Srx), which is capable of reducing the sulfinic form of peroxiredoxin. Lower level: Peroxynitrite-generated radicals cause largely nonrepairable damage to proteins, DNA, and lipids.

in cardiac function, decreased development of cataracts, and diminished mitochondrial DNA mutations. It is unclear to what extent the increased life span reflects improvements in brain function.

Antioxidant/Antiaging Mechanisms: Repair of Oxidized Residues

Unscavenged radicals are thermodynamically driven to oxidize cellular constituents, including protein cysteines and methionines. These critical amino acid residues can be subsequently reduced only with the help of specialized enzyme systems (Figure 2). Cysteines are reduced with a glutaredoxin/glutathione system, and methinones are reduced with a methionine sulfoxide reductase (Msr) system. The Msr system includes two enzymes, only one of which belongs to the same enzyme class as glutathione reductase and thioredoxin reductase.

The glutaredoxin/glutathione enzyme system has beneficial effects on functional activity of a number of proteins, including the thiol-containing mitochondrial complex I, the inhibition of which is caused by administration of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a neurotoxin that produces PD-like symptoms in primates, including humans. Interestingly, glutathione depletion is an early feature of

PD and appears to be disease specific. The depletion of glutathione may explain defects in complex I function found in sporadic forms of PD.

Msr, another important enzyme in repair of proteins, is proposed to play a central role in neurodegeneration and aging. Genetically engineered organisms overexpressing the enzyme live longer. On the contrary, the reduced or suppressed activity of the enzyme results in shortened life span, hippocampal degeneration, and increased sensitivity to oxidative stress. The enzyme can repair oxidized methionines and restore the function of many important proteins – for example, calmodulin. Msrs act on oxidized calmodulin and repair all eight methionine sulfoxide residues initially present in the inactive protein.

As mentioned, neuronal mitochondria protect themselves against hydrogen peroxide formed inside the matrix solely with the thiol-dependent enzyme systems. Moreover, repair systems also largely depend on reduced thiols (see earlier). In many cases, the catalytically important enzyme thiols are shown to be protected against oxidative damage by glutathionylation. Glutathionylation is a posttranslational, reversible redox modification of proteins by thiol/disulfide exchange. Indeed, glutathione used to be a dominant theme in brain neurodegeneration, and only recently the significance of thioredoxin-based systems has been fully appreciated. Measurements of reduced nicotinamide adenine dinucleotide phosphate (NADPH)-dependent thiol reducing activity in brain mitochondria show that glutathione reductase and thioredoxin reductase are equally important. Thiol-dependent systems of hydrogen peroxide neutralization and subsequent repair are also targets for oxidative modification (Table 1), and this obviously creates a threshold of oxidative damage that can be handled by neuronal mitochondria. Once reached, it results in mitochondrial failure and subsequent cell death by either apoptotic or necrotic pathways.

The delicate balance existing under normal conditions between oxidant production and antioxidant defensive mechanisms (Figure 3) can either be slowly shifted with aging or disturbed at once upon acute injury to produce oxidative stress. The adaptive response to tissue damage includes the activation of transcription factors such as nuclear factor-kappa B (NF-κB), among others, to switch on the inflammation response to limit damage and promote repair.

Injury and Neurodegeneration

The most common form of neurodegeneration occurs after an acute injury. The causes of neuronal injury are many, and include stroke, epilepsy, trauma, DNA damage from radiation, chemotherapeutic agents, and exposure to environmental neurotoxins. Acute neuronal damage involves a complex combination of processes, including excitotoxicity, inflammation, necrosis, and apoptosis.

Excitotoxicity

Excitotoxicity is a particularly important event that initiates acute neurodegeneration. Accumulation of glutamate within the synaptic cleft leads to Ca^{2+}

Figure 3 Delicate balance between prodeath and prosurvival factors determines the cell fate *in vivo*. For cultured nerve cells, the depletion of intracellular redox potential, shown as that for the glutathione/oxidized glutathione (GSSG/GSH) couple, below a certain level determines whether the cells will differentiate or die. Figure 4 Prosurvival role of nitric oxide (NO): induction of synthesis of heme oxygenase, which provides cells with an antioxidant bilirubin/biliverdin/biliverdin reductase system; synthesis of thioneins, which chelate metal ions and in addition can mediate/enhance methionine sulfoxide reduction by methionine sulfoxide reductase (Msr) and thioredoxin (Trx); and synthesis of heat shock proteins.

influx via hyperactivation of *N*-methyl-D-aspartate receptors, voltage-gated Ca^{2+} channels, and nonspecific cation conductances. The latter nonspecific cation channels are represented by the recently discovered transient receptor potential (melastatin) (TRPM) ion channels, among which TRPM7 and TRPM2, shown to be permeable for Ca^{2+} and inhibited by gadolinium, appear to play a critical role in anoxic cell death.

Excess Ca^{2+} via ionotropic glutamate receptors results in the initiation of neurotoxic signaling cascade by activating calmodulin and neuronal nitric oxide synthase (nNOS). Current opinion holds that the intracellular redox state is the critical factor determining whether in brain cells NO is toxic or protective (Figure 4). NO is known to signal the induction of heme oxygenase-1, which is considered as a prosurvival enzyme. It degrades heme, yielding ferrous iron, carbon monoxide (CO), and biliverdin, which cycles between the oxidized and reduced form, bilirubin. The latter exhibits strong antioxidant properties. Biliverdin reductase is present in brain in large functional excess, suggesting that such redox cycling amplifies antioxidant effects of heme oxygenase expression. On the other hand, NO also reacts with glutathione, generating nitrosoglutathione, which is able to modify and thus inactivate protein thiols. However, the most dangerous species – peroxynitrite – is generated via the direct interaction of superoxide radical and NO, a comparatively stable and harmless molecule. Peroxynitrite is extremely reactive and capable of nitrating tyrosine residues in proteins (Figure 2). A downstream effect of peroxynitrite production is the activation of TRPM channels. Molecular deletion of TRPM2 or TRPM7 channels renders neurons resistant to hypoxia/aglycemia. Whether peroxynitrite induces activation of TRPM channels via nitration of its critical components or some upstream modulatory protein is unclear. Protein nitration has been shown to

take place in brain injuries and in some but not all neurodegenerative diseases.

Superoxide- and especially peroxynitrite-induced modifications of the metallothionein thiols result in the release of zinc. Neurodegenerative diseases are characterized by a mobilization of intracellular zinc. The latter has been shown to mediate NO-induced neuronal death by directly affecting mitochondrial respiration through inhibiting complex III. In addition, it has recently been shown that zinc is capable of entering mitochondria and directly inactivating lipoamide dehydrogenase, the terminal enzyme of major multienzyme energy-producing complexes, as well as glutathione reductase and thioredoxin reductase. The inactivation is irreversible, and only the newly synthesized proteins transported into mitochondria may compensate for the damage (Figure 5). Thus, acute oxidative damage, resulting in massive release of intracellular zinc, will cause mitochondrial failure and cell death.

Inflammation

Oxidative stress can directly or indirectly initiate an inflammatory cascade. Collective evidence from many recent studies suggests that increased phospholipase A2 (PLA2) activity plays a central role in acute inflammatory responses in the brain as well as in oxidative damage associated with AD, PD, and multiple sclerosis (MS). PLA2 contributes to pathogenesis of neuroinflammation by attacking neural membrane phospholipids, to yield arachidonic acid and lysophospholipids. These are subsequently metabolized to a variety of proinflammatory lipid mediators such as prostaglandins, leukotrienes, thromboxanes, and platelet-activating factor. Arachidonic acid metabolism is also one of the major sources of oxidative damage (Figure 6). Arachidonic acid undergoes catalytic oxidation by cyclooxygenases 1 and 2, and, in addition, can react with superoxide or peroxynitrite to generate one of the most potent modifying agents, 4-hydroxy-2-nonenal (HNE). The latter can modify lysine, cysteine, and histidine residues in proteins and can bind to free amino acids and deoxyguanosine. Immunostaining for HNE-modified proteins shows that such modification is characteristic of acute oxidative stress, occurring during brain and spinal cord injury.

Inflammation is characterized with the increased deposition of iron. Iron, especially in the ferrous or unbound form, is able to catalyze the formation of free radicals and could be a cause of neuronal injury. Depletion of antioxidants in the brain, rise in iron-dependent oxidative stress, and monoamine oxidase B (MAO B) activity are key characteristics of aging that contribute to the onset of neurodegenerative disorders. MAO B is a mitochondrial flavin-dependent enzyme that catalyzes oxidative deamination of neurotransmitters and exogenous arylalkylamines. MPTP, an impurity in synthetic heroin, being activated by MAO B, affords a widely used chemically induced model of PD. MPP^+, the toxic product of MPTP conversion, increases superoxide formation by suppressing activity of NADH dehyrogenase (complex I) and increasing leak of electrons to oxygen. Superoxide is then available to attack Fe/S cluster proteins such as aconitase. Destabilization of cytosolic as well as mitochondrial aconitase results in an increase in iron regulatory protein-1 (IRP-1), an RNA-binding protein that signals cellular iron deficiency. This leads to the paradoxical and maladaptive increase in iron in the cell. The mechanisms underlying iron cellular toxicity are only beginning to emerge. A representative trend in neuroprotective drug development is to combine an iron chelator and a monoamine oxidase inhibitor in the same compound (see later). Iron chelators have recently been shown to

have the ability to induce adaptive gene expression via the stabilization of factors such as hypoxia-inducible factor-1 (HIF-1). HIF is a heterodimeric transcriptional complex that mediates the induction of more than 70 genes involved in hypoxic compensation, including those for vascular endothelial growth factor (VEGF) and erythropoietin (Epo).

Activated neutrophils and macrophages generate widespread secondary damage at the traumatic site by releasing cytokines and free radicals. They produce inducible NO synthase and NAD(P)H oxidase (Phox), generating nonmitochondrial superoxide; both enzymes cooperate to generate peroxynitrite and thus expose cells to further oxidative damage. In addition to peroxynitrite, leukocytes possess myeloperoxidase, which generates hypochlorite from hydrogen peroxide and chloride anion. Hypochlorite is a strong oxidizing agent capable of chlorinating protein residues and oxidizing membrane lipids. In all cases of rodent neurodegeneration, medications reducing inflammatory responses were shown to exhibit beneficial effects on the disease progression.

Apoptosis

The discovery that oxidative stress can trigger a program of neuronal cell death with features of apoptosis was significant in several aspects. First, it showed that oxidative stress does not always result in random and disordered cell damage. Second, it demonstrated the possibility of a free radical triggering an endogenous program of cell suicide.

Oxidative stress has been shown to activate a host of downstream signaling pathways leading to apoptosis. In some schemes, the c-Jun N-terminal kinase (JNK) signaling pathway is activated, resulting in Bax translocation, cytochrome *c* release, and apoptosis. In other schemes, Erk activation or poly(ADP-ribose) polymerase (PARP) activation leads to translocation of an apoptosis inducing factor and a caspase-independent cell death. Oxidative stress has been implicated in activation of a cell cycle resulting in cell death, although two studies in which oxidative stress has been induced by downregulating antioxidant defenses failed to demonstrate a protective effect of cell cycle inhibitors.

The superoxide released by mitochondria is directed both 'in' to and 'out' of the mitochondrial inner membrane and, therefore, is capable of damaging mitochondrial DNA, matrix proteins, inner membrane proteins and lipids, and cytosolic proteins and nuclear DNA. With respect to DNA damage, more than 1000 DNA-damaging events occur in each mammalian cell every day, due to replication errors and cellular metabolism. To cope with the deleterious consequences of DNA lesions, cells are equipped with efficient defense mechanisms to remove DNA damage by DNA repair pathways, control cell cycle progression,and eliminate

damaged cells via apoptosis. The complicated network of DNA repair mechanisms includes base excision repair, transcription-coupled repair, global genome repair, mismatch repair, homologous recombination, and nonhomologous end-joining damage. Evolution has overlaid the core cell cycle machinery with a series of surveillance pathways termed 'cell cycle checkpoints.' Checkpoints in proliferating cells tightly control progress through the cell cycle; cells may be arrested at any of the checkpoints, and either DNA will be repaired or cells will die by apoptosis. It appears that apoptosis induced by oxidative damage may be promoted by multiple pathways, both cell cycle dependent and independent. The determining factor for the pathways induced is an area of active exploration (Figure 7).

Nature of Aggregated Deposits in Neurodegenerative Diseases

Alzheimer's Disease

First described by Alois Alzheimer in 1906, AD has two characteristic 'deposits,' tangles and plaques. The latter are found in brain parenchyma and in blood vessels and are formed from amyloid mixed with inflammatory cells. Amyloid presents cross-linked Aβ-peptides formed via wrong processing of amyloid precursor protein (APP). Genetic AD is associated with mutations in APP or in presenilins (1 and 2), the proteins responsible for APP processing. Neurofibrillary tangles can be formed from the oxidatively cross-linked intraneuronal tau protein and occur mainly in large pyramidal neurons. The oxidative stress results in more and more dense plaques and tangles. Once formed, tangles and plaques directly and indirectly enhance the oxidative stress. The direct pathway represents the oxidative activity of metal-bound (Zn^{2+}, Fe^{2+}, or Cu^{2+}) plaques and tangles. The indirect pathway includes the activation of microglial cells, which in turn generate inflammatory messengers, putting the brain on permanent 'red alert.' This indirect pathway had led some to call AD 'arthritis of brain.' Thus oxidative stress may precipitate neuropathological hallmarks of AD or may be a consequence of these neuropathological changes. Disappointing therapeutic results with antioxidants in this disease could reflect an inability to adequately neutralize damaging radicals in all of the cell types and subcellular compartments afflicted in AD.

Parkinson's Disease

PD is a common neurodegenerative disorder affecting 1% of the population over the age of 65 years. The disease is characterized by the loss of dopaminergic neurons in the substantia nigra pars compacta, as well as by the presence of Lewy body inclusions in these cells. Five genes have been identified that are associated with relatively rare familial PD, by either autosomal dominant or recessive transmission. These include genes encoding α-synuclein and dardarin/leucine-rich kinase 2 (LRRK2), which are associated with dominantly inherited PD, and genes for parkin, DJ-1, and pten-induced kinase 1 (PINK1), which cause recessively inherited PD. α-Synuclein readily aggregates and is a major fibrillar component of Lewy bodies.

Figure 7 Cell fate depends on the level of oxidative stress. ROS, reactive oxygen species; MPT, mitochondrial permeability transition; Nrf2, nuclear factor E2-related factor 2; RNS, reactive nitrogen species.

Aggregation of α-synuclein is enhanced with tissue transglutaminase: Lewy bodies in PD patients are positively immunostained with antibodies recognizing isodipeptide bonds, a marker of tissue transglutaminase cross-linking. Phosphorylation also promotes α-synuclein aggregation. Cultured cells overexpressing α-synuclein generate reactive oxygen species (ROS). One mechanism by which aggregated synuclein leads to ROS generation in PD is via trapping trace metals into the aggregates. These metals can then easily accept electrons from reducing substances such as superoxide or glutathione and transfer them to oxygen to form superoxide radical. DJ-1, encoded by a gene that when mutated is associated with autosomal recessive parkinsonism, has antioxidant properties which are lost if the mutation destroys its dimeric structure. The monomer redistributes from cytosol to the mitochondria and nucleus.

Polyglutamine Diseases

Polyglutamine diseases (the CAG trinucleotide repeat/polyglutamine diseases) are characterized by the occurrence of protein aggregates within neurons. The most well characterized among ten known diseases of this origin are HD, dentatorubral and pallidoluysian atrophy (DRPLA), spinal and bulbar muscular atrophy, and multiple forms of spinocerebellar ataxia. Each disease is caused by a distinct gene product with expanded polyglutamine repeats.

Huntington's Disease

The hallmarks of the genetic disorder known as HD are a progressive chorea combined with dementia. Historically, the lurching madness was mistaken for possession by witchcraft (some of the Salem witches burnt in 1693 may have actually had HD). HD is caused by a single, dominant gene (i.e., only one copy is sufficient to cause the disease), unlike most genetic disorders, which are recessive (i.e., two 'bad' copies are needed to cause the disease). The average onset is from 35 to 40 years of age. Huntingtin is a large (350 kDa) protein of unknown function; once the polyglutamine tail crosses the threshold of 38 residues, the mutant begins to form aggregates. The latter precipitate in cytosol and also form nuclear inclusions. The mechanisms by which huntingtin aggregates launch the disease are still disputable. It is supposed to be a gain-of-function event. It is documented that mutant huntingtin can interfere with gene expression that is associated with adaptation to oxidative stress or mitochondrial dysfunction. Thus mutant huntingtin may be directly toxic to mitochondria and this toxicity may be sustained by mutant huntingtin's suppression of compensatory gene expression. While defects in energy metabolism are widely documented in human HD and associated animal models, the only evidence for oxidative stress is oxidative DNA damage.

Amyotrophic Lateral Sclerosis

ALS (Lou Gehrig's disease) is a chronic, progressive disease marked by gradual degeneration of motor neurons. Most incidences are sporadic, with ~10% of cases inherited in an autosomal dominant manner. The cause of ALS is unknown; however, in 2% of all cases (20% of familial disease) the primary cause is a mutation of the CuZnSOD (*SOD1*) gene. Approximately 117 mutations have been identified; they occur on the protein surface and all yield dominantly inherited disease. As in AD and PD, intracellular and extracellular aggregates are present in ALS, and the aggregates are intensely immunoreactive with antibodies to SOD1, supporting the theory that mutant SOD1 is toxic because of aggregation and coaggregation with other essential proteins. Peripherin, a neuronal intermediate filament protein, is associated with inclusion bodies in motor neurons of patients with ALS. Proteomics study has shown the upregulation of peripherin in ALS patients, and the downregulation of mitochondrial membrane transport and respiratory chain proteins. Study of transgenic mice that express the SOD1 mutation has shown that the mutant protein aggregates onto mitochondria only in cells within the spinal cord. This finding explains the selectivity of SOD1 mutations to affect motor neurons. Theories to explain ALS include oxidative and nitrosative stress, aggregation, mitochondrial damage, and glutamate and microglial cell-mediated damage.

Neuroprotection Strategies: Problems and Perspectives

By the time a patient is diagnosed as having a neurological illness, extensive neuronal damage has usually already occurred. Consequently, there is a great need for the discovery of biomarkers that allow early diagnosis and intervention. Common features among neurodegenerative diseases – genetic mutations (SOD1, parkin, huntingtin), protein misfolding and aggregation (Lewy bodies, amyloid plaques, tangles), and mitochondrial dysfunction and apoptosis – have implications for disease prevention and for development of effective therapies. Despite common final pathways, it is unlikely that a single drug or targeting a single mechanism will be sufficient to halt neurodegenerative processes.

Chronic neurodegeneration is age related, and thus delay in biological aging will decrease the occurrence of age-related diseases, with resulting prolongation of a healthy life span. Available evidence suggests that to delay aging one has to maintain healthy mitochondria and reduce oxidative stress. One of the proposed approaches is to maintain or recover the activity of the so-called vitagenes. In this regard, the positive effect of heme oxygenase is linked to the production of bilirubin and biliverdin (see earlier), the administration of which, after the first few weeks of life, in doses slightly above normal levels, results in cytoprotective effects. Also, positive effects of CO administration in doses comparable to that of heavy smoker have been shown in suppression of ischemia–reperfusion injury.

Another approach to activate vitagenes is administration of nutritional antioxidants. Curcumin, the most prevalent nutritional and medicinal compound used by the Indian population, has the potential to inhibit lipid peroxidation and efficiently neutralize reactive oxygen and nitrogen species. It has been recently shown that curcumin inhibits NF-κB activation and induces heme oxygenase-1. Administration of curcumin for 6 months resulted in a suppression of indices of inflammation and oxidative damage in the brain of an AD transgenic mouse model (APPSw). Caffeic acid phenethyl ester, an active component of propolis, has been shown to induce heme oxygenase-1 in astroglial cells. Gene induction in both cases occurs through the antioxidant response element (ARE), and this led to the conclusion that the increased expression of genes regulated by the ARE may provide the CNS with protection against oxidative stress. Indeed, numerous studies have supported a role for ARE activators in the prophylaxis against acute and chronic neurodegenerative conditions.

Anti-inflammatory and anti-apoptotic treatments have also shown benefit for many forms of neurodegeneration, although it is also becoming clear that parts of the inflammatory response must be maintained to facilitate repair. A combinatorial approach that highlights the promise of this strategy is the synergistic neuroprotective effects of minocycline (MC) and glatiramer acetate (GA) in a MS model. MC showed remarkable benefit in animal models of MS, PD, HD, ALS, stroke, and spinal cord injury, and in preliminary clinical data for 36-month human trials of MS. MC has a role in interdicting a host of deleterious pathways, including inhibiting matrix metalloproteases (MMPs), chelating Ca^{2+} divalent metals, and inhibiting p38 mitogen-activated protein kinase (MAPK), reducing microglial activation and inhibiting cytochrome *c* release from mitochondria. GA polarizes T cells toward T helper type 2 (Th2) status. GA-reactive Th2 cells cross the blood–brain barrier, and upon reactivation by myelin antigens, release Th2 cytokines. In the CNS, Th2 cells confer neuroprotection, as demonstrated in animal models of PD, ALS, optic nerve crush, ocular glutamate excitotoxicity, etc.

A recent development in chelators involves the design and synthesis of multifunctional drugs that have the ability to bind iron, inhibit a particular enzyme, and exhibit antioxidant properties (free radical scavengers). Metal (in particular, iron) chelation therapy has been proposed as a way of reducing the level of redox-active metals in neurodegenerative diseases. The green tea catechin epigallocatechin gallate (EGCG; known for its iron-chelating and antioxidant properties), the antibiotic iron chelator clioquinol, and intracerebroventricularly injected desferal (DFO) are potent neuroprotective agents. Obviously, iron chelation targets not only unbound iron and that in the aggregated deposits, but, more significantly, also iron dioxygenases such as HIF prolyl hydroxylase. The latter is an emerging target for neuroprotection, although HIF may not be the only substrate of this enzyme. More than 70 genes of putative nonheme iron oxygenases have been identified in the human genome, but only a number have the physiological functions ascribed. An assumption on the uniqueness of an inhibitory action of a particular drug selected among others may be wrong, if only one enzyme candidate has been tested. The best example is probably EGCG, which targets HIF prolyl hydroxylase, MAO B, and MICAL ('molecule interacting with Cas ligand'), a flavin monooxygenase implicated in axonal guidance and highly homologous to MAO B. The recently discovered M30 as an antioxidant/chelator/MAO inhibitor has also been shown to stimulate neurite outgrowth and thus may actually target MICAL as well.

Conclusions

Therapies targeted at reducing oxidative damage in the nervous system must achieve several goals in order to be effective. First, they must interdict pathological oxidant interactions without affecting physiological signaling by radicals. Over the past two decades, peroxide and nitric oxide have been shown to play the role of messengers in the nervous system. Antioxidants that inadvertently abrogate these signaling functions would not be desirable. Second, antioxidants or, alternatively, effective repair strategies must be augmented in distinct cell types and subcellular compartments. Oxidative and nitrosative stress are not an undifferentiated whole and are mediated by distinct species produced in distinct cellular

compartments and distinct cell types. The great challenge has been to divine a multimodal strategy that inhibits a cassette of targets without the expected toxicity that arises as the specificity of the therapy decreases. We propose that understanding endogenous homeostatic pathways for protecting against oxidative and nitrosative stress is the way forward. These homeostatic pathways involve the activation of preexisting proteins as well as *de novo* gene expression. Small molecules that activate homeostatic responses to oxidant stress are expected to reap large therapeutic benefits. Evidence that such an approach is effective and safe continues to emerge from preclinical studies. The ultimate proof will be the demonstration of neuroprotection in a human clinical trial. Such success will also provide long overdue evidence supporting a role for oxidative damage in human neurological disease.

Oxytocin (Peripheral/Central Actions and their Regulation)

J A Russell and P J Brunton, University of Edinburgh, Edinburgh, UK

© 2009 Elsevier Ltd. All rights reserved.

Oxytocin

Functions

Oxytocin is a neuropeptide hormone produced by neurons in the hypothalamus. Oxytocin secreted from the mother's posterior pituitary gland into the general circulation during birth promotes powerful uterine contractions and hence fetal ejection. It is essential for stimulating milk ejection during suckling in lactation and hence for survival of the young of mammals.

Oxytocin has actions in the brain that complement its peripheral actions: it promotes social interaction and mating behaviors, and it facilitates the rapid expression of maternal behavior after birth. It can also have anxiolytic, stress-reducing, and antinociceptive actions. Both males and females express the oxytocin peptide and receptor genes. In males, oxytocin is involved in the neural network stimulating penile erection.

Oxytocin Peptide and Gene

Oxytocin was the first peptide reproductive hormone to be discovered, in 1906, from its activity in a posterior pituitary extract in stimulating uterine contractions and milk release. In 1953, oxytocin was characterized as a nonapeptide, Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Leu-GlyNH_2, comprising a ring formed by a disulfide bridge between the two cysteine groups, with a three-amino-acid tail, and differing from vasopressin by substitutions at positions 3 and 8. These modifications, from mutations after duplication of a common ancestor gene, result in dramatically different actions of the two peptides.

Essentially, only mammals have an oxytocin gene, which in humans is located on chromosome 20p13 and contiguous except for 3–11 kb with the vasopressin gene, but in opposite orientation. The oxytocin gene codes for a large precursor of 106 amino acids, which includes neurophysin, a larger peptide than oxytocin but without signaling function. The gene has three exons – the first codes for the signal peptide and oxytocin, and the second and third code for neurophysin – and two introns. The oxytocin gene is expressed in distinct groups of neurons in the hypothalamus.

Marsupials may express an oxytocin gene or a similar gene (mesotocin, which is identical to oxytocin except that isoleucine replaces leucine at position 8). Various invertebrates (e.g., earthworm and octopus) have oxytocin-like peptides and receptors in their nervous systems, and these peptides (annetocin and cephalotocin, respectively) promote egg laying.

Regulation of Oxytocin Gene

Regulatory sequences comprise a composite hormone response element (−164 to −145 and −110 to −79 upstream) through which nuclear receptors such as estrogen receptor-β, thyroid hormone, and retinoic acid receptors stimulate, and orphan receptors stimulate (SF-1; TR (testicular orphan receptor)4) or competitively repress (COUP-TF), expression. Control of hypothalamus-specific expression is exerted via the intergenic region between the oxytocin and vasopressin genes.

Progesterone, or its neurosteroid metabolite allopregnanolone, restrains oxytocin gene expression in pregnancy, and a transient postpartum increase in expression follows progesterone withdrawal and stimulation by estrogen. Progesterone action is indirect since oxytocin neurons lack progesterone receptors, but allopregnanolone acts to amplify inhibitory GABA actions via allosteric modulation of $GABA_A$ receptors on oxytocin neurons. Some rostral inputs to oxytocin neurons (in the medial preoptic area and lamina terminalis) contain estrogen receptor-α, indicating an indirect regulation by estrogen.

During lactation, oxytocin gene expression, as reflected in cell body content of oxytocin mRNA, is increased only after 1 week of repeated stimulation by the suckling stimulus, when the posterior pituitary oxytocin store is depleted. Evidently, the level of oxytocin gene expression is set to provide ample oxytocin to meet sustained demand with a wide safety margin for normal reproductive purposes.

Copeptides

Oxytocin neurons also express other neuropeptide genes. Under basal conditions, vasopressin mRNA is expressed in only 1% of magnocellular oxytocin neurons, increasing 17-fold with prolonged stimulation, as in lactation. Proenkephalin-A mRNA expression leads to translation to enkephalins, which have autoinhibitory actions. Other peptides that can be produced include cholecystokinin, corticotropin-releasing factor, and cocaine and amphetamine-regulated transcript.

Neurohypophysial System

Oxytocin Secretion

In parturition and lactation, oxytocin is secreted into the circulation, in pulses a few minutes apart, from

Figure 1 Summary of features of a magnocellular oxytocin neuron. Oxytocin is synthesized in the cell body and transported to the axon terminals in the posterior pituitary; it is secreted by exocytosis when action potentials arrive from the cell body. Some oxytocin is secreted in the median eminence into the hypothalamo-hypophysial portal blood. Oxytocin (OT) is also released from the dendrites in the hypothalamus; this is dependent on Ca^{2+} but not depolarization. Neural stimulation by parturition or suckling causes intermittent high-frequency synchronous discharge ('bursts') of the oxytocin neurons, resulting in secretion of pulses of oxytocin; slow 'continuous' firing is seen in other conditions. Sustained stimulation, as in lactation, increases oxytocin gene expression; estradiol (E) acting via estrogen receptor-β can have a similar effect. +, stimulatory; −, inhibitory. Adapted from Burbach JPH, Young LJ, and Russell JA (2005) Oxytocin: Synthesis, secretion, and reproductive functions. In: Neill JD (ed.) *Knobil and Neill's Physiology of Reproduction*, 3rd edn., pp. 3055–3128. San Diego: Elsevier, with permission from Elsevier.

the millions of axon terminals in the posterior pituitary (neurohypophysis, neural lobe) of the approximately 7000 simultaneously activated neurosecretory oxytocin neurons in the hypothalamus. The cell bodies of these neurons are in the paired supraoptic and paraventricular nuclei in the hypothalamus. These oxytocin neurons are large (20–40 μm in diameter) and designated magnocellular neurons, reflecting their abundant protein synthetic and processing machinery necessary to produce sufficient oxytocin to repetitively attain circulating concentrations high enough to strongly stimulate uterine contractions or milk ejections (Figure 1).

Development

Magnocellular neuron progenitor cells arise at midgestation (embryonic day 10.5 and 12.5 in mouse and rat, respectively) in the neuroepithelium of the ventricular region. Within 4 days, they migrate to form the paraventricular and supraoptic nuclei and then send their axons into the posterior pituitary and begin to express the oxytocin gene. Physiological responsiveness of the oxytocin system develops after birth in the rat. The axons are attracted and guided into the region where the posterior pituitary forms, and they have a trophic effect on the pituicytes, which are modified glial cells. A hierarchy of four transcription factor genes (*Sim1*, *Arnt2*, *Otp*, and *Pou3/2*) is essential for normal embryonic development of oxytocin neurons.

Oxytocin Synthesis and Storage

After mRNA translation on ribosomes in the cell bodies, the oxytocin–neurophysin prohormone is transported through the endoplasmic reticulum, into the Golgi apparatus, and enzymatically cleaved by a prohormone convertase, and the oxytocin now bound covalently to neurophysin is guided into the regulated secretory pathway. The vesicles, or neurosecretory granules, emerging from the Golgi apparatus contain oxytocin and the coproduced peptides, and are continually and slowly transported from the cell bodies within the axons at approximately 8 mm h^{-1}, maintaining a large store of oxytocin in the terminals (Figure 1). A small fraction of the total stored (approximately 4 μg or 2 U, the international unit based on biological activity) is secreted with stimulation (in the rat, approximately 1 mU per milk ejection). During pregnancy, this store is increased 30–50% by decreased release rather than increased gene expression; much of this extra store is secreted during parturition.

Some of the oxytocin–neurophysin-containing secretory vesicles are transported into the dendrites, where

they can release oxytocin by exocytosis. This provides a local feedback mechanism, with possible distant effects of oxytocin diffusing in the brain.

Centrally Projecting System

Oxytocin neurons that project their axons centrally are predominantly in the paraventricular nucleus, with some in the medial preoptic area and bed nucleus of the stria terminalis. These are smaller (cell bodies approximately 10–15 μm in diameter), designated parvocellular neurons, producing and storing less oxytocin to achieve their effects than magnocellular neurons.

Some of these neurons project from the paraventricular nucleus to the brain stem (nucleus tractus solitarii and locus coeruleus) or spinal cord (intermediolateral cell column and dorsal horns), whereas others project to the limbic brain (amygdala and hippocampus), nucleus accumbens, or ventromedial hypothalamic nucleus. In these regions, there is a range of action in appetite control, autonomic regulation, antinociception, anxiety, and sex behavior.

Oxytocin Receptor and Gene

The specific actions of oxytocin depend on its relatively high affinity for the oxytocin receptor and low affinity for the three vasopressin receptors (V1a, V1b, and V2, although the V1b receptor has some affinity for oxytocin), the tissue-selective expression of the receptor, and the pattern of oxytocin secretion.

The oxytocin receptor is a seven transmembrane G-protein-coupled receptor composed of 389 amino acids; in marsupials, the mesotocin receptor is very similar. Only a single oxytocin receptor gene has been identified. The human oxytocin receptor gene is located at chromosomal position 3p25, spans 19 kb, and comprises four exons. The oxytocin receptor gene has evolved from duplication and mutation of an ancestral gene.

Regulation of Oxytocin Receptor Gene

The receptor gene has multiple potential proximal regulatory elements. In general, estrogen upregulates expression and progesterone is inhibitory. The sequence of estrogen and progesterone treatment over several days followed by progesterone withdrawal, mimicking pregnancy levels of these sex steroids, upregulates oxytocin receptor expression in brain regions critical for maternal behavior, which is rapidly induced after birth. In the rat hypothalamic ventromedial nucleus, in which oxytocin promotes female lordosis behavior, estrogen increases oxytocin receptor mRNA expression and acts via protein kinase C to upregulate oxytocin receptor expression. Oxytocin acting in the central amygdala is anxiolytic, and here dopamine regulates oxytocin receptor expression via protein kinase A and an upstream cAMP response element in rats (Figure 2). In contrast, regulation in mice is estrogen dependent, acting via estrogen receptor-α. The oxytocin receptor gene also has interleukin response elements, which may mediate inhibition of expression.

Oxytocin Receptor Distribution in the Brain

The oxytocin receptor is widely distributed, expressed in neurons, notably in olfactory processing regions (olfactory nuclei and piriform cortex), limbic brain structures (including amygdaloid nuclei, septal nuclei, and medial preoptic nucleus), hippocampus, hypothalamus (ventromedial, dorsomedial, premammillary nuclei, and magnocellular nuclei), and brain stem (vestibular nuclei, motor and sensory cranial nerve nuclei regulating face and mouth, and autonomic centers (nucleus tractus solitarii)).

The distribution of oxytocin receptor among brain regions is highly species specific, even between closely related species. In the prairie and montane voles, the different distribution relates to striking differences in social affiliative behavior (Figure 2).

Central Actions of Oxytocin: Receptor Activation

Occupancy of the extracellular binding pocket of the receptor by oxytocin (or agonist derivatives or a nonpeptide synthetic agonist) changes the conformation of the receptor, allowing binding of G-protein ($G_{\alpha q/11}$) to the intracellular domain (Figure 3). This activates phospholipase C, producing inositol trisphosphate (IP_3) and diacylglycerol. IP_3 liberates Ca^{2+}, stimulating exocytotic neuropeptide or transmitter release.

Another pathway leads to prostaglandin and endocannabinoid generation, which mediates autofeedback actions of oxytocin on magnocellular oxytocin neurons. Prostaglandin depolarizes the neurons via extracellular actions on cationic conductances; firing rate is increased by presynaptic inhibition of GABA release. Endocannabinoids are inhibitory via presynaptic inhibition of glutamate and promotion of GABA release (Figure 3).

Oxytocin can excite or inhibit electrical activity of other neurons. Neurons excited by the action of oxytocin on membrane ion channels include those in the bed nucleus of the stria terminalis, the ventromedial hypothalamic nucleus, the dorsal motor nucleus of vagus (parasympathetic preganglionic motor neurons), and spinal cord preganglionic sympathetic neurons. In the spinal cord dorsal horns, oxytocin inhibits pain transmission.

Figure 2 Differential oxytocin receptor expression in the brain. Autoradiographs of coronal hypothalamus sections labeled with oxytocin receptor (OTR) radioligand. (a) Estrogen regulation. Estrogen increases OTR expression in the rat ventromedial hypothalamus (VMH) but not in the amygdala (Amyg). (Bottom) Estrogen regulates OTR expression via protein kinase C (PKC) in the VMH; in the amygdala, dopamine regulates OTR expression via protein kinase A (PKA). In the rat, estrogen is important for oxytocin action on lordosis in the VMH but not for anxiolysis in the amygdala. Adapted from Bale TL, Davis AM, Auger AP, Dorsa DM, and McCarthy MM (2001) CNS region-specific oxytocin receptor expression: Importance in regulation of anxiety and sex behavior. *Journal of Neuroscience* 21: 2546–2552, with permission from the Society for Neuroscience. (b) Species differences. Compared to the female montane vole, in the female prairie vole OTR is strongly expressed in the nucleus accumbens (NAcc) and caudate putamen (CP). Expression is similar between species in the prelimbic cortex (PLC). OTR expression in the CP and NAcc in prairie voles is important in pair bonding and monogamy in this species; montane voles do not form pair bonds. (Bottom) These species differences are due to differences in OTR gene expression. The OTR gene differs only at a few sites (red dotted ovals) in the 5′ flanking region between vole species. Adapted from Lim MM and Young LJ (2006) Neuropeptidergic regulation of affiliative behavior and social bonding in animals. *Hormones and Behavior* 50: 506–517, with permission from Elsevier.

Once released, oxytocin is subject to degradation by placental leucine aminopeptidase (cysteine aminopeptidase–oxytocinase), which cleaves the N-terminal ring structure of oxytocin and is expressed in oxytocin target regions.

Control of Oxytocin Neurons: Electrophysiological Properties

Magnocellular oxytocin neurons have rich excitatory and inhibitory synaptic inputs; there are 37×10^6 synapses/mm^3 in the supraoptic nucleus. Oxytocin neurons, like other neurons, produce action potentials when summation of inhibitory and excitatory postsynaptic potentials depolarizes the cell body above a critical level for action potential generation at the axon hillock (Figure 1). In rats, in which oxytocin is natriuretic, magnocellular oxytocin neurons are directly osmosensitive via stretch-inactivated cationic channels. Such depolarization interacts with excitatory postsynaptic potentials to increase the probability of action potential initiation. Their patterns of firing determine the oxytocin release patterns that are most effective and efficient for the functions of oxytocin. For fetal ejection and milk ejection, brief high-frequency bursts, synchronized among the magnocellular neurons, cause secretion of pulses of oxytocin (Figure 1). Their firing and secretory activity increases slowly and progressively in response to other stimuli, such as systemic cholecystokinin (CCK) administration.

Excitatory Inputs

Noradrenaline The nucleus tractus solitarii (NTS) in the medulla oblongata relays autonomic afferent neural information from the uterus and birth canal during parturition. The NTS contains noradrenergic neurons (the A2 group), which project directly to oxytocin neurons, exciting them via α_1 receptors (Figure 4). Coproduced peptides in these neurons, including neuropeptide Y and prolactin-releasing peptide, supplement excitation by noradrenaline. The NTS also relays information in vagus nerve afferents detecting intra-abdominal CCK and cytokines

Figure 3 Oxytocin actions on neurons: postreceptor signaling. Schematic based mainly on studies of autoregulation of oxytocin neurons by oxytocin (enzymes are italicized). Oxytocin stimulates dendritic oxytocin secretion by exocytosis and the production of prostanoids and cannabinoids, which modulate excitatory and inhibitory amino acid synapses. The oxytocin receptor is a seven transmembrane domain G-protein-coupled receptor. Oxytocin, a nonapeptide (color-coded residues 3 and 6 are different in vasopressin), docks in an extracellular pocket: stars show key residues in domains 1 and 2. Receptor occupancy leads to coupling to $G\alpha_{q11}$ and $G\alpha_i$; this requires the starred residue on the third intracellular loop. Consequent stimulation of phospholipase C (PLC) triggers several pathways. First, PLC catalyzes phosphatidylinositide 4,5-bisphosphate (PIP_2) breakdown to diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). IP_3 triggers Ca^{2+} release from intracellular stores and entry from outside via Ca^{2+} channels. Increased $[Ca^{2+}]_i$ primes oxytocin secretory granules and triggers exocytosis. Second, Ca^{2+} causes phospholipase A_2 (PLA_2) binding to the endoplasmic reticulum; mitogen-activated protein kinase (MAPK) phosphorylates PLA_2, and membrane glycerophospholipid (PL) is broken down to yield arachidonic acid (AA) and prostanoids. Cyclooxygenase 2 (COX-2; induced by MAPK) action forms PGH_2; synthases form PGE_2 or $PGF_{2\alpha}$. Third, oxytocin autostimulates production of endocannibinoids from glycerophospholipid; this is Ca^{2+} dependent via N-acyltransferase/aPLD and PLC/diacylglycerol lipases. Prostaglandins are autoexcitatory by direct effects and by presynaptically inhibiting GABA release. Endocannabinoid can presynaptically inhibit both glutamate and GABA release, with a net inhibitory action. The occupied receptor interacts with G-protein-coupled receptor kinase (GRK), allowing binding to β-arrestin and receptor internalization. Adapted from Burbach JPH, Young LJ, and Russell JA (2005) Oxytocin: Synthesis, secretion, and reproductive functions. In: Neill JD (ed.) *Knobil and Neill's Physiology of Reproduction*, 3rd edn., pp. 3055–3128. San Diego: Elsevier, with permission from Elsevier.

(in rats, signaling satiety or sickness and provoking stress-induced oxytocin secretion); these peptides also activate NTS neurons from the circulation, through the adjacent area postrema.

Suckling stimulus This also acts via brain stem noradrenaline neurons, but the rostral suckling pathway is not fully characterized. The pathway begins with stimulation by the suckled young of somatic sensory nerve endings in and around the nipples. Then, the afferents synapse in the dorsal horn and ascend ipsilaterally, via the dorsolateral funiculi in the spinocervicothalamic tract, into the lateral cervical nucleus and decussate in the lower brain stem. The primary projection from the brain stem to oxytocin neurons is likely direct via the medial forebrain bundle, from noradrenergic neurons (other than A2 neurons in the nucleus tractus solitarii), which also project to regions that regulate nursing behavior.

Glutamate A direct glutamatergic projection from the olfactory bulbs is activated during parturition and may be involved in stimulating oxytocin release into the brain and hence in the initiation of maternal behavior.

A functionally distinct afferent pathway comes from the lamina terminalis, specifically the subfornical organ–nucleus medianus–organum vasculosum lamina terminalis complex. These neurons use glutamate or GABA as neurotransmitter. This input mediates stimulatory actions of circulating relaxin (a pregnancy peptide hormone from the corpus luteum), angiotensin II, and hyperosmolarity.

Inhibitory Inputs

GABA Local GABA neurons around the magnocellular nuclei inhibit oxytocin neurons via $GABA_A$ receptors (Figure 4).

Figure 4 Summary of excitatory and inhibitory inputs to oxytocin neurons and signaling from dendrites that regulate burst-firing. Noradrenaline (NA) is an important transmitter for both inputs from parturition and suckling, and it interacts with local glutamate (Glu) and GABA circuitry to generate bursts. Dendritically released oxytocin (OT) has an essential role in burst-firing: it stimulates its own release and the production of prostaglandins (PG) and endocannabinoid (CB), which presynaptically modulate the glutamate and GABA inputs, thus permitting synchronized burst-firing (see **Figure 3**). Before the end of pregnancy, the activity of oxytocin neurons is restrained by nitric oxide (NO), endogenous opioids (acting centrally and in the posterior pituitary), and allopregnanolone (AP; potentiating GABA action via $GABA_A$ receptors) formed from progesterone. Adapted from Burbach JPH, Young LJ, and Russell JA (2005) Oxytocin: Synthesis, secretion, and reproductive functions. In: Neill JD (ed.) *Knobil and Neill's Physiology of Reproduction*, 3rd edn., pp. 3055–3128. San Diego: Elsevier, with permission from Elsevier.

The neuroactive steroid allopregnanolone, a progesterone metabolite which is abundant until the end of pregnancy, is an allosteric modifier of the $GABA_A$ receptor amplifying the action of GABA by extending the opening time of the Cl^- channel in the $GABA_A$ receptor, prolonging inhibitory postsynaptic currents. This is a mechanism restraining oxytocin neurons from premature excitation near the end of pregnancy.

Opioids κ and μ opioid agonists potently inhibit the firing of oxytocin neurons in rats, even when strongly stimulated. For example, during parturition, morphine, a μ agonist, inhibits oxytocin secretion and stops births. Opioids can act centrally, on inputs to oxytocin neurons or on the neurons themselves, and on axon terminals in the posterior pituitary. Central endogenous opioid inhibition emerges in late pregnancy, as shown by excitatory actions of naloxone. The opioid responsible for this inhibition may be from the brain stem or arcuate nucleus projections to oxytocin neurons. The interruption of parturition by stress involves activation of opioid inhibition of reflex stimulation of oxytocin neurons.

Oxytocin neurons are the only peptidergic neurons that develop opiate (morphine) dependence and tolerance, providing a robust model to study the cellular mechanisms of opiate addiction.

Histamine Oxytocin neurons receive an inhibitory input from histaminergic neurons in the premammillary nuclei. This input may be important during parturition and suckling.

Axon Terminals

Oxytocin and coproduced peptides are released when action potentials arrive at the axon terminals in the posterior pituitary from the cell bodies, traveling at approximately 5 m/s along the unmyelinated oxytocin-containing axons in the pituitary stalk. The arrival of action potentials triggers Ca^{2+} entry into the nerve terminals, leading to exocytosis of oxytocin stored in secretory vesicles, and entry into the systemic circulation via fenestrae in the walls of the adjacent capillaries. Action potentials that are clustered together release more oxytocin. This frequency facilitation results from maintained excitation between spikes due to extracellular K^+ accumulation and depletion of extracellular Ca^{2+} via Ca^{2+} channel activity, both enhancing Na^+ entry.

ATP released by excited terminals initially augments oxytocin release via enhanced Ca^{2+} entry, but the purine adenosine, formed by ATP hydrolysis, then inhibits stimulated oxytocin release by blocking N-type Ca^{2+} channels. These local negative feedback

mechanisms limit release and may contribute to shaping pulses of oxytocin.

Oxytocin release at the axon terminals is modulated by co-released neuropeptides, notably opioids derived from proenkephalin-A, which act on κ or μ receptors on the terminals and inhibit release (Figure 4). This mechanism is downregulated in rats during late pregnancy, enabling more effective control by action potentials from the cell bodies.

Dendrites

The dendrites of supraoptic nucleus oxytocin neurons are broad and bundled together in the ventral glial lamina of the nucleus. Dendrites of magnocellular paraventricular nucleus oxytocin neurons project toward the third ventricle. There are many synaptic boutons on these dendrites. However, the dendrites of oxytocin neurons not only receive signals but also transmit them (Figures 3 and 4). Oxytocin released from the dendrites of magnocellular neurons is an essential component of the mechanism that causes synchronized burst-firing of the neurons during parturition and suckling in lactation, and dendritic oxytocin release is a mechanism of more widespread volume transmission in the brain. Dendritic release of oxytocin can occur independently of initiation of spikes in the cell body, and it is the result of activation of mechanisms that increase intracellular Ca^{2+}; both oxytocin and α-melanocyte-stimulating hormone (from the arcuate nucleus projection) act in this way.

Firing Patterns

Continuous activity Under basal conditions, oxytocin neurons fire action potentials in a continuous irregular manner (at approximately 3 spikes per second); this pattern distinguishes oxytocin neurons from vasopressin neurons, which fire phasically (bursts of activity lasting from a few seconds to minutes with similar silences between bursts). Without parturition or suckling, oxytocin neurons more gradually increase their firing rate, and hence oxytocin secretion, when stimulated.

In this mode of activity, nitric oxide is generated by oxytocin neurons, which express neuronal nitric oxide synthase, and nitric oxide attenuates their responses to stimulation (Figure 4).

Synchronized bursts Magnocellular oxytocin neurons are stimulated during parturition and suckling to fire in brief, intermittent, high-frequency bursts, synchronized among the supraoptic and paraventricular nuclei. This results in secretion of pulses of oxytocin a few minutes apart. This stimulation involves positive feedback mechanisms, such that passage of the fetus through the birth canal (Ferguson reflex) or sucking at the nipples stimulates pulsatile oxytocin secretion, which drives gradual fetal ejection or causes milk ejection and further oxytocin secretion until the feedback loop is broken by birth of the fetus or satiation of the suckled infant (Figure 4).

The mechanism of this synchronized burst-firing of oxytocin neurons has been intensively investigated but is incompletely understood. Burst-firing is a property of the oxytocin neurons but requires synaptic input; it also requires a local auto- or paracrine action of oxytocin released from magnocellular neuron dendrites. This acts back on oxytocin receptors on the oxytocin neuron dendrites, stimulates further oxytocin release, and activates endocannabinoid production, which after release presynaptically inhibits glutamate and GABA synapses (Figures 3 and 4). These presynaptic actions seem to be important in preparing the oxytocin neurons for synchronized burst-firing. Bursts involve drive by a local glutamatergic network but can be evoked by local noradrenaline action. Bilateral projections to oxytocin neurons from neurons in the medulla oblongata may explain the synchronized bursting among the paired supraoptic and paraventricular nuclei during suckling.

Several brain regions facilitate the milk ejection bursts of oxytocin neurons when acted on by oxytocin, including the ventral tegmentum, dorsomedial hypothalamus, and bed nucleus of stria terminalis.

Glia

Oxytocin neuron dendrites in the supraoptic nucleus project into the ventral glial lamina. Here, astrocytic processes are intimately close to the dendrites but withdraw when the neurons are chronically and strongly stimulated, as in lactation. This permits synaptic remodeling, stimulated by 17β-estradiol and oxytocin, with rapidly increased numbers of axon terminal boutons in contact with the dendrites. However, this reversible plasticity is not essential for the burst-firing capacity of the neurons during lactation.

Central Oxytocin Systems

Neurosecretory material was identified in neurons that project within the mammalian brain in 1954, and some of these projections were later shown with immunocytochemistry to contain oxytocin. Further studies since the mid-1970s have shown oxytocin to be an important neurotransmitter or modulator in the brain, coordinating reproductive behavior with the peripheral actions of oxytocin secreted from the posterior pituitary. The central oxytocin system is

separate from the posterior pituitary system so that it cannot be monitored by measuring oxytocin in the circulating blood. Conversely, the blood–brain barrier effectively prevents circulating oxytocin from entering the brain, and oxytocin receptors are not expressed in the circumventricular organs. However, intranasal application of a large dose of oxytocin has effects on the brain, perhaps via the olfactory bulbs or by entering the brain extracellular fluid; this is useful in human experiments (Figure 5). Circulating oxytocin indirectly influences brain function via its peripheral actions in the fetus ejection and milk ejection reflexes.

Oxytocin and Affiliative Behaviors

Oxytocin action in the brain is important in the processes leading to social, mating, or maternal behaviors – that is, motivation, recognition of others, and some degree of bonding.

Motivation to relate Oxytocin promotes male and female mating behavior, social affiliation, and maternal behaviors. It also switches off eating and aggressive behavior and reduces anxiety to favor reproductive and affiliative behaviors.

Female sexual behavior Lordosis (receptive) behavior in rats is promoted by oxytocin acting in the medial preoptic area and the ventromedial nucleus on oxytocin receptors induced by estrogen (Figure 2). In female mice, oxytocin is not necessary for receptive behavior, and in some species (vole and sheep) oxytocin is inhibitory.

Male sexual behavior In rats, erectile function is promoted by oxytocin actions in the paraventricular nuclei on descending projections. However, in male mice with engineered deletion (knockout) of the oxytocin or oxytocin receptor gene, reproductive capability seems normal. In contrast with inhibitory actions of nitric oxide on magnocellular oxytocin neurons, the activity of parvocellular oxytocin neurons involved in penile erection is stimulated by nitric oxide.

Oxytocin secretion from the posterior pituitary is increased in humans with sexual arousal and at ejaculation and female orgasm; this may help sperm transfer.

Memory and recognition The first studies in 1978 of the central actions of oxytocin on memory showed amnesic actions in an avoidance paradigm. It is now clear that oxytocin has a key role in establishing an olfactory memory for a conspecific in rodents and sheep. Unlike wild-type mice, male oxytocin knockout mice fail to remember recent olfactory contact with the same male. Female oxytocin knockout mice have a similar deficit. The olfactory bulb-to-pyriform cortex processing pathway responds normally, and

Figure 5 Oxytocin reduces activation of fear circuitry in humans. Blood oxygen level-dependent functional magnetic resonance imaging of human brain coronal sections in subjects given intranasal placebo or oxytocin. (a) Subject exposed to images of frightened or angry faces or frightening scenes. Activation of the amygdala (red) by viewing the images is greatly reduced by oxytocin. L, left; R, right. (b) Oxytocin reduces coupling of amygdala and brain stem; red/yellow (periaqueductal gray and reticular formation) represent relatively greater brain stem activation after placebo versus oxytocin. Adapted from Kirsch P, Esslinger C, Chen Q, et al. (2005) Oxytocin modulates neural circuitry for social cognition and fear in humans. *Journal of Neuroscience* 25: 11489–11493, with permission from the Society for Neuroscience.

the memory defect is due to failure to activate the medial amygdala; oxytocin injection into the medial amygdala rescues the social memory defect. The medial amygdala is a gateway to a circuit involving the bed nucleus of stria terminalis and medial preoptic area, where oxytocin also promotes social memory. In the mouse (but not rat) amygdala, estrogen receptor-α regulates oxytocin receptor expression, and oxytocin peptide gene expression in the paraventricular nucleus is regulated by estrogen receptor-β. These interacting genes form a four-gene micronet that is important in social recognition; inactivation of any of them impairs social recognition through olfactory cues.

Stress Control and Anxiolysis

Oxytocin is a stress hormone in the rat that is secreted from the posterior pituitary as a result of activation of the magnocellular neuron cell bodies. Oxytocin released by axons of these neurons close to the hypothalamopituitary portal vessel system in the median eminence is transported to the anterior pituitary, where in rats it acts on the V1b receptor on corticotrophs to enhance corticotropin-releasing factor (CRF) action in stimulating ACTH secretion. In humans, oxytocin secretion has the opposite action and may indicate anxiety about social attachment (relational distress).

Stress increases oxytocin release in brain regions that regulate neuroendocrine and emotional stress responses, and it may assist stress coping. In the paraventricular nucleus, oxytocin reduces CRF neuron responses to stress, and in the amygdala it is anxiolytic. In humans, in a controlled stress test intranasal oxytocin interacted with social support to reduce anxiety and cortisol secretion.

Appetite

Oxytocin acts in the brain to reduce salt appetite. Oxytocin knockout mice have an uninhibited salt appetite; they also have an increased appetite for sweet drinks. Hence, oxytocin restricts hedonic appetite. Here, oxytocin action in the nucleus tractus solitarii is important; through this region, oxytocin also inhibits gastric motility. Centrally projecting oxytocin neurons are activated by leptin and cholecystokinin, which reduce appetite and meal size. Hence, oxytocin receptors in appetite-regulating brain regions are potential anti-obesity drug targets.

Bonding

Social Bonding

In prairie voles, which are monogamous and form heterosexual pair bonds after mating, central release of oxytocin during copulation in females leads to bonding (vasopressin has this role in males). Oxytocin receptor expression is essential in the network critical for this behavior (lateral septum, medial preoptic area, bed nucleus of stria terminalis, and nucleus accumbens). Hence, the montane vole, an asocial species that does not bond, is not responsive to central oxytocin and lacks oxytocin receptors in these regions (Figure 2). This different receptor distribution is ascribed to differences in the promoter sequence in the 5′ flanking region in the oxytocin receptor gene. Oxytocin action in promoting pair bonding in prairie voles involves dopamine action in the nucleus accumbens in the mesolimbic reward circuit.

In the rat, activation of oxytocin receptors on GABA neurons in the central amygdala (lateral and capsular divisions) inhibits neurons in the medial central amygdala that project to the brain stem to produce fear responses when excited by vasopressin. Thus, oxytocin opposes fear and anxiety-generating actions of vasopressin in the central amygdala, and it functionally uncouples the central amygdala from the brain stem. This has been shown in human functional magnetic resonance neuroimaging studies after intranasal oxytocin administration, which reduces amygdala activation in response to fear-inducing images (Figure 5). In rats and humans, oxytocin appears to promote social interaction by reducing fear or increasing trust in others.

Maternal Bonding

Female rats and sheep are not spontaneously maternal. In sheep, maternal bonding is a prerequisite for maternal behavior, and bonding depends on rapid formation of an olfactory memory by the ewe selectively for her own newborn lamb, which requires oxytocin action in the olfactory bulbs to engage the memory-forming circuitry. Passage of the lamb through the birth canal reflexly activates brain stem noradrenergic neurons, which excite paraventricular nucleus oxytocin neurons projecting to the olfactory bulbs. Here, prior estrogen exposure upregulates oxytocin receptor expression in the granule layer. Oxytocin establishes olfactory memory by simultaneously promoting noradrenaline release in the olfactory bulb, inhibiting GABA neurons and exciting glutamate glomerular cells, which are coincidentally activated by the odor of the newborn lamb. The subsequent strengthening of the activated synaptic connections, via local nitric oxide generation, represents learning of the lamb odor.

In humans, oxytocin secretion stimulated by vaginal delivery or suckling soon after birth correlates with ease of mother–infant bonding. Visual recognition is important in human mothers; looking at pictures of their children activates brain regions

that express oxytocin receptor and that, animal studies show, are important in maternal behavior.

Maternal Behavior

Initiation Bonding between the mother and individual offspring is not seen in rats or mice, but the initiation of maternal behavior is accelerated by central oxytocin release. This action of oxytocin was first demonstrated in 1979 in virgin rats pretreated with estrogen and progesterone, and it is most important when environmental disturbance impairs maternal behavior. Key sites of oxytocin action in rodents are the medial preoptic area and ventral tegmental area since oxytocin antagonist infused into these areas inhibits the onset of maternal behavior.

Even virgin mice express maternal behavior readily, as do postpartum oxytocin knockout mice. Hence, the central oxytocin system is not essential for maternal behavior in mice; however, detailed studies of oxytocin receptor knockout mice show striking defects in natural maternal behavior toward their newborn. Moreover, oxytocin knockout mice are more aggressive and infanticidal than wild-type mice.

Oxytocin-containing nerve fibers, the release of oxytocin, and oxytocin receptors are all found in the many brain regions that control the different elements of maternal behavior. These regions include the paraventricular nuclei (source of oxytocin); hippocampus (recognition of young); limbic structures – medial preoptic area, bed nucleus of stria terminalis, lateral septum, and medial amygdala (reduced aggression and aversion to the young); mesolimbic reward circuitry – ventral tegmental area and nucleus accumbens (hedonic aspects of maternal behavior); and the medial preoptic area and substantia nigra (control of nursing posture). At these sites, oxytocin modulates the release of GABA, noradrenaline, and dopamine to elicit the components of maternal behavior. Coordination of activity in this network to display the combined elements of maternal behavior is likely achieved via widespread axonal projections of parvocellular paraventricular nucleus oxytocin neurons. However, volume transmission by oxytocin release from dendrites of supraoptic and paraventricular magnocellular neurons, as occurs during parturition and suckling, may be important.

Maintenance Release of oxytocin in the brain has a role in maintaining maternal behavior as well as in its initiation. The quantity of oxytocin receptor expression in regions important for the continued expression of maternal behavior, such as the medial preoptic area, central nucleus of amygdala, bed nucleus of the stria terminalis, and nucleus accumbens, correlates with the quality of maternal behavior. Also, brain regions that are important for maternal behavior are activated by suckling and by oxytocin, suggesting that nursing reinforces maternal behavior via central oxytocin (Figure 6).

Figure 6 Imaging *in vivo* stimulation of brain activity by oxytocin. Blood oxygen level-dependent magnetic resonance image of a coronal brain slice of a lactating rat given oxytocin into a lateral cerebral ventricle. Red/yellow indicate activation versus a control lactating rat given vehicle. Oxytocin activates widespread regions known to express the oxytocin receptor and that are also activated by suckling, evidently by stimulating central oxytocin release. Adapted from Febo M, Numan M, and Ferris CF (2005) Functional magnetic resonance imaging shows oxytocin activates brain regions associated with mother–pup bonding during suckling. *Journal of Neuroscience* 25: 11637–11644, with permission from the Society for Neuroscience.

Disease and Oxytocin System Malfunction

No defined natural disorders are clearly attributable to mutations of the oxytocin or oxytocin receptor genes. Dominant disabling mutations would not be transmissible through the female line, except in humans, since oxytocin is indispensable for milk transfer to the young. There is evidence from animal studies of a potential major impact that reduced receptor expression or impaired function in the brain could have on behaviors in humans. Abnormalities might include impaired affiliative behavior, affecting quality of mothering and sociability, and increased aggressiveness.

The extensive use of oxytocin in obstetric practice to promote birth has led to questioning whether exposure of newborns to oxytocin has long-lasting adverse effects on the brain. Massive doses of oxytocin have been used in published studies on neonatal rats to show enduring changes in the central oxytocin system and related behaviors. The issue assumes more importance with the development of nonpeptide agonists and antagonists which may enter the brain more readily than oxytocin.

Autism

Reduced oxytocin system activity has been implicated in autism, a highly heritable condition. Findings include loss of oxytocin neurons, low plasma oxytocin, and increased precursor level, suggesting abnormal proconvertase expression. Large-scale molecular genetic studies show linkage to the chromosomal locus containing the oxytocin receptor gene (3p25.3), and polymorphisms have been found in noncoding regions and exons in the oxytocin receptor gene in autistic individuals. In autistic adults, intravenous oxytocin infusion may reduce repetitive behaviors and improve processing and retention of social information. However, abnormalities in more than 20 genes or their proteins may underlie different forms of autism.

Prader–Willi Syndrome

This condition (due to deletion of paternally inherited genes on chromosome 15q11–13) involves childhood obesity and insatiable appetite, perhaps due to reduced central satiety action of oxytocin since the number of oxytocin neurons in the paraventricular nucleus is greatly reduced.

The Future

Research on oxytocin systems in the brain is expected to result in targeted treatments in selected cases of autism, obesity due to overeating, aggressive behavior, male impotence, and anxiety.

P2X Receptors

Z Li, S Harris, and T M Egan, Saint Louis University School of Medicine, St. Louis, MO, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

P2X receptors are ligand-gated ion channels that open in the presence of extracellular adenosine triphosphate (ATP). They are found in both simple parasitic organisms such as *Schistosoma mansoni* and more complex animals, such as humans. Activation usually results in a rapid depolarization of the target cell. This occurs as ATP binds to an extracellular site and opens an integral transmembrane pore that allows small monovalent and divalent cations to flow down their electrochemical gradients. At physiological membrane potentials, the overriding effect of activation is an influx of sodium and calcium (Figure 1(a)). The resulting rise in intracellular sodium depolarizes the membrane and renders the cell hyperexcitable. The influx of calcium activates a number of intracellular calcium-dependent processes such as muscle contraction and synaptic vesicle fusion. Some P2X receptors, particularly those expressed in muscle, also have a demonstrable permeability to chloride, although the concurrent influx of sodium still causes depolarization. At times, P2X receptors initiate the movement of larger molecules across the membrane. For example, the release of proinflammatory interleukin-1β from macrophages is stimulated by activation of native $P2X_7$ receptors, and activation of some recombinant receptors (e.g., rat $P2X_2$ $P2X_4$, and $P2X_7$ receptors and human $P2X_5$ receptors) expressed in model cells leads to the opening of membrane pores permeable to the large nucleic acid stains, ethidium and YO-PRO-1 (Figure 1(b)). The original hypothesis that dye uptake reflects a time-dependent dilation of the intrinsic ion channel (also known as the 'pore-dilation' hypothesis) has come under attack. Specifically, recent data suggest that separate pathways mediate the ATP-gated movement of small cations and large dyes; the evidence that supports this claim is discussed in more detail below.

Genes and Gene Products

The first two P2X receptor genes ($P2X_1$ and $P2X_2$) were identified in 1996 by expression cloning from tissues derived from rat. These two then served as templates for the subsequent discovery of five additional rat genes ($P2X_3$–$P2X_7$) by polymerase chain reaction. Orthologous sequences are found in a number of organisms, including trematodes, fish, frogs, chickens, rodents, cows, and humans. Paralogs and splice-variants have also been described. The seven full-length rat genes encode proteins that vary in length from 384 to 595 amino acids and are 40–50% identical in sequence. Functional receptors are oligomeric complexes of three subunits that selectively combine in both homomeric and heteromeric fashions. Each subtype has a phenotype that is defined by (1) the amplitude of the ATP-gated current; (2) the relative permeability of cations and anions; (3) the percentage of the current carried by calcium; (4) the ability to initiate uptake of nucleic acid stains; (5) the rate and extent of desensitization and resensitization; (6) the ability to form heteromeric complexes with other family members; and (7) sensitivity to a range or agonists, antagonists, and allosteric modulators. Six of the seven genes ($P2X_{1-5}$, $P2X_7$) are capable of encoding functional homomeric receptors that mediate ATP-gated transmembrane currents in heterologous expression systems (Figure 1(c) and (d)). The $P2X_6$ receptor is the exception. Biochemical analyses suggest that monomers of this subtype are partially processed and retained by the endoplasmic reticulum. Despite this fact, there are occasional reports of ATP-gated ionic currents generated in cells expressing only the $P2X_6$ gene. These findings are somewhat controversial and may reflect the unintended formation of heteromeric receptors containing recombinant $P2X_6$ and native (but apparently silent) non-$P2X_6$ subunits. This hypothesis is plausible because several laboratories have reported that the $P2X_6$ subtype forms functional heteromeric complexes in a subunit-specific manner when co-expressed with other family members. Indeed, most P2X receptors are capable of forming functional heteromers that display unique phenotypes when expressed in heterologous systems. Although there are numerous examples of functional heteromeric receptors made of two different subtypes, there is no report of a P2X receptor containing three different family members, even though the existence of such a receptor is possible.

Structure and Function

Because the crystal structure of the receptor is unsolved, a range of less direct biochemical and pharmacological approaches was used to develop a preliminary map of the protein as it sits in the membrane. All functional P2X receptors have the following topology: intracellular N-terminus/first transmembrane segment (TM1)/extracellular segment/second transmembrane segment (TM2)/intracellular C-terminus (Figure 1(e)).

Figure 1 (a) P2X receptors are cation channels permeable to sodium and calcium. The traces show total membrane current (black traces) and fura-2 fluorescence recorded from a HEK-293 cell expressing homomeric rat $P2X_2$ receptors. In this experiment, a decrease in fluorescence (excitation 380 nm; emission 510 nm) indicates an increase in intracellular free calcium. An application of 10 μmol l^{-1} ATP (solid black bar) causes an inward current and a decrease in fura-2 fluorescence. The fluorescence was calibrated, filtered, and differentiated to give the ATP-gated calcium current (blue trace). About 7% of the total current is carried by calcium (compare the amplitudes of the blue and black traces). In the inset, the peak currents of the total current and calcium current are normalized to show that their time courses are identical, as expected if all the rise in intracellular calcium comes from the inward flow of calcium current through the P2X channel. (b)YO-PRO-1 uptake. The traces show the averaged data from 45 test (filled black circles) and 12 control (empty red squares) experiments. In the test experiments, ATP (600 μmol l^{-1}) was applied to six to ten HEK-293 cells expressing the $P2X_2$ receptor and a reporter protein (AsRed). The drug was applied 2 min after the start of the recording. YO-PRO-1 fluorescence (491/509 nm) was collected by a photomultiplier. Transfected cells showed little background fluorescence in the absence of ATP but fluoresced brightly during agonist application (solid bar). Control cells expressed only the reporter protein. (c) The traces show ATP-gated currents recorded from seven different HEK-293 cells transiently expressing one subtype of P2X receptor. All the cells except those expressing the $P2X_6$ receptor show inward current in response to ATP. In some cases ($P2X_1$ and $P2X_3$ receptors), the receptors show rapid desensitization during the ATP application. In another case ($P2X_5$ receptor), the size of the current is relatively small compared with the other subtypes. The concentrations of ATP are as follows: $P2X_1$ and $P2X_3$, 1 μmol l^{-1}; $P2X_2$ and $P2X_4$, 30 μmol l^{-1}; $P2X_5$, 100 μmol l^{-1}; and $P2X_7$, 1 mmol l^{-1}. (d) The current traces of (c) are shown at an expanded timescale to show the rate of onset and desensitization of the six functional homomeric receptors. (e) A representation of a P2X subunit. Functional receptors are formed of three subunits; the diagram shows one subunit sitting in the membrane (gray shaded area). Both the N- and C-termini are intracellular. Two transmembrane domains (1,2) span the lipid bilayer, and these are connected by a large extracellular loop (E) that makes up the bulk of the receptor protein. (f) Oligomeric receptors comprise three subunits that form a cation-permeable pore. Although the pore contains parts of both transmembrane domains, TM2 seems to contribute more than TM1 does to the permeation pathway.

Individual subunits are arranged in a head-to-tail fashion so that the TM1 of each subunit abuts the TM2 of its neighbor (Figure 1(f)). The presence of only two transmembrane segments distinguishes P2X receptors from other ligand-gated cation channels, which typically possess three or more. The N-tail is relatively short (about 25 amino acids) and contains a consensus site for protein kinase C-mediated phosphorylation;

removal of this site leads to an accelerated fade in the amplitude of the ATP-gated current of the $P2X_2$ receptor. The C-tail is longer (about 25–250 amino acids) and more variable and contains multiple sites that mediate subtype-specific effects. These effects include receptor desensitization; membrane trafficking; altered permeation; and interactions with proteins, phospholipids, and lipid polysaccharides. $P2X_7$ receptors with their C-tails altered by truncation or site-directed mutagenesis have normal sodium and calcium currents but lose the ability to show a time-dependent increase in the permeability of larger cations like *N*-methyl-D-glucamine ($NMDG^+$). It is interesting that the time-dependent increase in permeability to ethidium and YO-PRO-1 is unaffected by a truncation that obliterates $NMDG^+$ permeability, suggesting that separate pathways underlie pore dilation (i.e., the gradual increase in permeability to $NMDG^+$) and dye uptake (i.e., the gradual increase in permeability to nucleic acid stains).

Both transmembrane segments line the pore and may contain sites affecting channel function. An explicit role for the TM1 has not been forthcoming, although data suggest that it is involved in transducing agonist binding into channel gating. The functional domains of the TM2 are better described. Within the TM2 are specific amino acids that affect the two properties that P2X receptors share with all ion channels, permeation and gating. Further, the TM2 helps direct the assembly of subunits into oligomeric complexes and is partly responsible for determining the rate and amount of desensitization experienced by different family members.

The two transmembrane segments are connected by a long string of amino acids that form the extracellular extent of the receptor. This string contains ten conserved cysteines, some of which participate in disulfide bonds that help define the tertiary structure of the protein. In contrast; disulfide bonds do not form between adjoining subunits; so they are not involved in stabilizing the quaternary structure. The extracellular loop also contains consensus sequences for the N-linked glycosylation involved in targeting the receptor to the cell surface membrane, for agonist and antagonist binding sites, and for intersubunit binding sites responsible for allosteric modulation of the ATP response by hydrogen ions and zinc.

The ATP Binding Site

The ATP binding site resides at the interface of neighboring subunits of the multimeric receptor complex. The negative charge of the phosphate chain of ATP is attracted to the formal positive charge of conserved lysines and arginines located near the TM1 and TM2, and the adenine ring is coordinated by aromatic amino acids. Different family members respond to different agonists. For example, $\alpha\beta$-methylene ATP is a potent agonist at $P2X_1$ and $P2X_3$ receptors but has little or no effect on $P2X_2$, $P2X_4$, $P2X_5$, and $P2X_7$ receptors. Further, the median effective concentration (EC_{50}) of ATP on the $P2X_7$ is much higher than that of all other family members. The differences in agonist (and antagonist) profiles suggest that the structure of the agonist and antagonist binding sites varies in a subunit-specific manner.

Ion Permeation and Gating

P2X receptors are generally classified as ligand-gated cation channels because most of their physiological effects result from the inward flow of cations across the cell surface membrane. However, some subtypes initiate the movement of both cations and anions across cell surface membranes, making the cation channel classification somewhat inaccurate.

Cation Permeability

All P2X receptors are freely permeable to the three most important physiological cations: sodium, potassium, and calcium. Sodium and potassium permeate equally well. Ding and Sachs have suggested that cations interact with an anionic binding site of low to moderate field strength located at about 20% of the electrical distance from the extracellular surface of the channel. If P2X receptors have only two transmembrane segments, then this binding site must be made of parts of TM1 and/or TM2. The only conserved formal negative charge in these domains is an aspartate in TM2 (e.g., Asp^{349} of the $P2X_2$ receptor). Neutralizing Asp^{349} has no effect on cation permeability, making it unlikely that it contributes to regulation of current flow through the channel. Rather, the site may be formed of polar amino acids that reside in a narrow constriction of the pore, although such a model is not applicable to all P2X subtypes (see below). An alternative hypothesis is that other parts of the protein form a reentrant pore loop that forms a selectivity filter in the pore, analogous to the P loop of the potassium-selective KcsA channel or the M2 loop of the glutamate receptor. However, no such reentrant loop has been identified for any P2X receptor to date.

The relative permeability to calcium is higher than that to sodium or potassium and varies in a subunit-specific manner. For example, about 6% of the current through the $P2X_2$ receptor is carried by calcium, and this is large enough to facilitate excitatory neurotransmission onto stratum radiatum interneurons of the

hippocampus. By contrast, the calcium currents of $P2X_1$ and $P2X_4$ receptors are twice as large as those of the $P2X_2$ receptor. The molecular mechanism(s) responsible for the subunit-specific variability are unknown. Two complementary methods have been proposed. First, site-directed mutagenesis of hydroxyl-bearing amino acids within the TM2 of the $P2X_2$ receptor decreases calcium flux, perhaps by interfering with a binding site involved in partially dehydrating permeating ions as they pass through a narrow constriction in the pore. However, the polar residues are missing in some of the subtypes, and therefore hydroxyls are not fully required for calcium flux throughout the family. Second, the COO^- side chains of acidic amino acids found at the extracellular ends of the transmembrane domains may provide an electrostatic force that interacts with calcium in the mouth of the channel pore. Indeed, subtypes that possess these formal charges (i.e., $P2X_1$ and $P2X_4$ receptors) transduce significantly higher calcium fluxes than those that do not (i.e., $P2X_2$ receptors).

Anion Permeability

Hume and Thomas were the first to describe an anion-permeable, ATP-gated ion channel. They measured a shift in the reversal potential of the ATP-gated current of chick skeletal muscle when extracellular chloride was replaced by larger anions. Such a shift suggests that the outward movement of chloride contributes to the ATP-evoked depolarization. The responsible gene was cloned by Soto and others and found to encode a chick $P2X_5$ receptor capable of transducing significant chloride flux in heterologous expression systems. Orthologs have been described in zebra fish, bullfrog, mouse, rat, and humans. Most of these are poorly characterized because their ATP-gated currents are small (e.g., less than 100 pA even at the extremes of physiological membrane potentials), and therefore their anion permeability is unknown. North et al. described a full-length human $P2X_5$ receptor that is different from other $P2X_5$ receptors in that it transduces large (nA) currents in response to ATP. Like the smaller currents of the chick $P2X_5$ receptor, the human ortholog displays a significant permeability to chloride.

Pore Dilation versus Dye Uptake

Sodium, potassium, calcium, and chloride carry most of the ATP-gated membrane current during the first few seconds of application of ATP. Longer applications evoke an additional conductance as the membrane permeability to large organic cations (like $NMDG^+$) gradually increases. The increase in permeability suggests that the narrowest portion of the pore dilates by at least 3 Å from an initial diameter of 9–11 Å. At the same time that the permeability to $NMDG^+$ begins to increase, cells expressing $P2X_2$, $P2X_4$, $P2X_5$, or $P2X_7$ receptors also gain the ability to take up large nucleic acid dyes (i.e., ethidium bromide or YO-PRO-1). A simple hypothesis that could explain both effects is that the P2X pore moves through three states. The first is the nonconducting, closed state seen in the absence of ATP. The second is open in the presence of ATP and permeable to small cations with geometric diameters of $<\sim 11$ Å. The third opens in the continued presence of ATP and with a delay; it occurs when the initial open state widens to a new diameter that is big enough to allow large molecules to pass through the channel. The three-state model is sufficient to explain much of the biophysical data currently available. However, at least in the case of the $P2X_7$ receptor, recent data suggest that the uptake of dye does not occur through the pore of the $P2X_7$ channel *per se*. Surprenant, North, and others have shown that deleting a short stretch of 18 amino acids just intracellular to the end of the TM2 (called the Cys-rich region because it contains many cysteines) prevents the change in $NMDG^+$ permeability but has no effect on the uptake of ethidium. Such an effect is difficult to explain if both molecules use the same pathway to enter the cell. Further, both the Surprenant and Dahl laboratories have shown that RNA interference directed against recently discovered pannexin-1 hemi-channels significantly reduces dye uptake without effecting cation flux through the pore of the $P2X_7$ channel. Thus, it seems that the $P2X_7$ channel uses two different methods to move large ions across the cell surface membrane. The first is a gradual dilation of the integral P2X pore that ultimately results in an increase in permeability to $NMDG^+$. The second is an indirect activation of ethidium-permeable pannexin-1 channels that may result from a protein–protein interaction with the $P2X_7$ receptor. These findings are exciting and novel, but additional experiments are needed to prove the hypothesis they seem to support.

Pharmacology

Although the field has advanced in the past few years, it remains difficult to discriminate among P2X receptors on the basis of pharmacology alone. Gever et al. have provided an excellent review of the recent advances in purinergic pharmacology.

Not only do many of the currently available reagents discriminate poorly among the P2X receptors themselves; these same drugs also act on ATP-gated

metabotropic P2Y receptors. However, a few pharmacological trends do hold true. P2X receptors can be divided into three general classes on the basis of the phenotype of the ATP-gated current and the pharmacology of the receptor. The first class includes the $P2X_1$ and $P2X_3$ receptors. These receptors display agonist-gated currents that desensitize rapidly (<1 s), have a high affinity for both ATP and its analog α,β-methylene ATP (the EC_{50} for both agonists is about 1 $\mu mol\,l^{-1}$), and are blocked by nanomolar concentrations of the purinergic antagonist TNP-ATP. The second class includes $P2X_2$, $P2X_4$, and $P2X_5$. These receptors show a much slower rate of desensitization (tens of seconds), are less sensitive to ATP (EC_{50} about 6–30 $\mu mol\,l^{-1}$), are relatively insensitive to α,β-methylene ATP, and are blocked by micromolar concentrations of TNP-ATP. Heteromeric receptors that contain members of both the first and the second classes generally adopt the agonist and antagonist sensitivities of the first class; that is, they show robust responses to low concentrations of both ATP and α,β-methylene ATP and are readily antagonized by TNP-ATP. The third class is made of the $P2X_7$ receptor alone. This receptor shows the lowest ATP potency ($EC_{50} >$ 100 $\mu mol\,l^{-1}$) and is the only member of the family in which prolonged activation is reported to result in cell vesiculation and death.

Distribution and Physiology

P2X receptors are expressed throughout the body. They are found in a range of tissues, including nerve, muscle, glia, epithelium, bone, and hemopoietic. Most tissues express more than one subtype, and current dogma suggests that the majority of native receptors are heteromeric complexes of two or more subtypes. The $P2X_1$ receptor is predominately expressed in smooth muscle. Genetically altered mice that lack this receptor are infertile because the ATP-mediated contraction of the vas deferens is missing. Further, $P2X_1$ receptors are also widely expressed in the cardiovascular system, where they are found in heart, blood vessels, and platelets. However, no obvious effect on cardiovascular function is found in $P2X_1$-knockout mice, and the role of ATP in these tissues is still unknown. $P2X_2$ and $P2X_4$ receptors are found in neurons and glia throughout the central and peripheral nervous systems, where they facilitate neurotransmission by both presynaptic and postsynaptic actions. In contrast, the distribution of the $P2X_3$ receptor is more restricted. It is predominately found on the sensory afferent neurons of the peripheral nervous system, where it mediates gustation; mechanosensory regulation of urinary bladder function; and transmission of persistent, chronic, neuropathic and inflammatory pain. $P2X_5$ receptors are found in skeletal muscle and may play a role in regulating proliferation and differentiation of tumors. $P2X_7$ receptors are found in mast cells, macrophages, and lymphocytes, where they participate in the immune response.

Presynaptic and Postsynaptic Effects

In general, two separate but related functions are described for these receptors in neurons. First, P2X receptors allow cations to enter the cell, leading to membrane depolarization. Direct somatic depolarization by release of endogenous ATP has been difficult to demonstrate, perhaps because of the rapid degradation of the nucleotide by endonucleotidases. However, good examples exist including depolarization of smooth muscle in the vas deferens and neurons of the celiac ganglia, spinal cord, myenteric plexus, medial habenula, hippocampus, and somatosensory cortex. The outcome of depolarization is the propagation of excitation from one cell to the next. The second effect of ATP is presynaptic. P2X receptors increase intracellular calcium in nerve terminals, both directly, by conducting calcium, and indirectly, by activating voltage-gated calcium channels. In both cases, the rise in intraterminal calcium can lead to an increased probability of neurotransmitter release.

Conclusion

P2X receptors are some of the newest members of the ligand-gated ion channel superfamily. Their unique topology, ubiquitous distribution, high calcium flux, and ability to induce the movement of very large (up to about 900 kDa) molecules across the cell-surface membrane suggest that they play important roles in regulating the homeostasis of a range of organisms. In upcoming years, a high-resolution map of a P2X receptor structure may well be forthcoming; this map, in combination with functional studies, will greatly improve our understanding of the molecular physiology and pharmacology of the receptor. Further, recent studies that demonstrate direct protein–protein interactions of P2X receptors and hemichannels, other ligand-gated channels, and Fe65 suggest that the influence of ATP in the physiology and pathophysiology of humans is underappreciated.

Pain Variability

Chronic pain is an unsolved health problem of major proportions worldwide. Although pain *per se* is rarely life threatening, it takes an enormous toll in quality of life and accounts for huge financial outlays for treatment and compensation. Large surveys indicate that at any given time nearly 20% of adults report suffering from chronic pain of an intensity and duration that embitters their lives, the most common conditions being back pain, arthritis, and headache, including migraine. One of the greatest puzzles concerning pain, both acute pain in response to noxious stimuli and more prolonged pain following injury or disease, is its great variability from individual to individual, even when the provoking stimulus or disorder is essentially identical. A dramatic example is stump and phantom limb pain in amputees. Some amputees report no pain whereas in others severely disabling pain lasts a lifetime, even when the level of the amputation is the same. The fact that re-amputation usually fails to relieve phantom limb pain points to factors associated with the patient rather than the surgery as the underlying cause. Variability is also the rule in the day to day. A slap in the face that provokes sobs in one person will be laughed off by another. We each have a different pain threshold.

Variability in pain expression has traditionally been attributed to psychosocial and cultural factors – personality and upbringing. It is also irrevocably entangled with the question of how much the outward expression of pain actually reflects the pain felt by the individual, inside. In some societies, for example, people do not hesitate to express their pain, whereas in others children are taught to be stoical. Even for a given individual and a stimulus of fixed intensity, pain expression may vary wildly with the circumstances. Did that slap in the face indicate a challenge or an insult, or did the tears come just because it hurt? In most cultures, there is a dramatic sex difference in the degree to which pain expression is sanctioned. Boys are taught not to be cry babies, but girls are expected to show tears. Does the resulting difference in outward pain behavior only reflect social norms, or is there also a real difference in the amount of pain felt among boys and girls in response to identical painful stimuli? A large body of evidence indicates that women are much more likely than men to suffer from a variety of chronic pain conditions and that women are less tolerant of noxious stimuli when tested in laboratory experiments. To what extent does this reflect pain expression as opposed to pain experience? Is it possible that the socialization of boys and girls actually alters the amount of pain experienced later in life and not just how pain is expressed?

Pain is inherently a private sensory and emotional experience. It cannot be shared. It is felt in the first person (I) and can only be inferred by outward behavior and language in the second and third persons (you and he or she). This fact of life is likely to remain with us for the foreseeable future. There is no method on the horizon that will permit me to crawl into your brain and sample your pain experience. However, advances in noninvasive brain imaging may soon make it possible to know whether someone is faking his or her tears because the amount of neural activity in certain parts of the brain tends to correlate with reported pain experience. Moreover, these brain activations increase and decrease when the amount of pain felt in response to a fixed stimulus is altered by factors such as anticipation, hypnosis, and the presence of analgesic drugs.

Heritability of Pain

In addition to socialization and other psychosocial and environmental factors, variability in pain response is also due to differences in the wiring of our individual brains as determined by our genes. The first solid indications of this comes from rare familial disorders inherited by certain family members, but not by others, in which pain is either absent (e.g., congenital insensitivity to pain with anhydrosis (CIPA)) or excessive (e.g., Fabry's disease or familial hemiplegic migraine (FHM)). Such conditions can usually be traced to disease-causing mutations in specific genes. Evidence for heritability is also available from the study of twins. Pain as a normal trait (e.g., in response to noxious heat and cold) and the presence of common painful conditions such as backache and sciatica are more concordant in identical than fraternal twins. The idea here is that identical twins share all their gene variants whereas fraternal twins share only half. Recently, investigators have begun to undertake studies using modern genetic methodologies aimed at actually identifying the specific genes that control normal pain sensitivity and the likelihood of suffering pain in response to injury or disease.

Basically, all biological traits are determined by genes, environment, and interactions between genes

and environment. Why should we be surprised to learn that pain susceptibility is affected by nature as well as by nurture? The short answer is that we should not be. Nonetheless, because of the overwhelming influence of environment on both the clinical manifestations of pain response in patients and in our day-to-day experience of pain, the emergence of an important genetic component took many people by surprise.

Beyond the simple knowledge that pain response is in part heritable, the new awareness of pain genes has at least two important implications. First, contemporary biology has powerful new ways of exploiting this knowledge in the interests of improving our understanding of pain mechanisms and ultimately improving diagnosis, prognosis, and treatment. Second, knowledge that there are pain genes has immediate implications for pain patients here and now. People who report having more pain than is expected from easily observable signs of injury and disease are often stigmatized as complainers and malingerers. Sometimes they are even suspected of being outright liars, trying to cheat the system and obtain undeserved benefits from insurance companies, employers, or caring family members. The knowledge that pain is variable and that one person may have much more pain than another for genetic reasons, through no fault of his or her own, may provide some comfort. Of course, the fact that pain genes exist does not mean that malingerers and cheats do not.

Pain Genes

What are pain genes? Genes are parts of DNA molecules that encode for proteins. Genes do not encode for sensory and emotional experiences such as pain. Only a conscious brain can experience pain. But this does not mean that all of the 25 000-odd genes that are required to make a human body are pain genes. A pain gene is a gene with a polymorphism (i.e., a variation in the sequence of DNA base pairs) in a region that encodes for a protein that affects pain susceptibility. Sequence variations can also affect pain if they occur in a region that regulates the expression of pain genes. For most of our genes and regulatory regions (99.9%), the base pair sequence is identical from one person to the next and the proteins that genes yield are no different in the way that they work. For some genes, however, there are rare variants (mutations) or common variants (polymorphisms) that do affect the functioning of the proteins encoded. Sequence variants of a given gene are called 'alleles' of the gene. For most genes with functional variations among people, there are only a few common alleles. What makes us genetically different from one another is the mix-and-match combination of alleles that we carry.

At present, we have no idea how many genes there are in which allelic variation affects pain response. The question "How many pain genes are there?" is not even well defined. Some gene variants may have major effects on pain, whereas others may have subtle effects. Polymorphisms in some genes affect pain only if accompanied by polymorphisms in others, such that pain sensitivity is determined by a combination of alleles, not by just a particular one. Some pain genes may have no effect on pain at all except under unusual environmental circumstances (e.g., at high altitudes, or if your sister-in-law made you particularly exasperated). This is a gene–environment interaction.

An essential distinction needs to be made between alleles that cause (or increase the predisposition to) diseases that may be painful and alleles that predispose to pain in the presence of identical injury or disease. An example of a disease-susceptibility gene is a gene that increases the likelihood of developing diabetes, a metabolic condition that often leads to pain-provoking nerve injury (diabetic neuropathy). Indeed, quite a large number of genetic mutations have been identified that cause various types of inherited peripheral neuropathies, and some of these conditions are associated with pain. A prominent example is the $Thr^{124}Met$ base pair substitution that causes painful Charcot–Marie–Tooth (CMT-2) neuropathy. In each of these neuropathies, there is visible damage to nerve fibers in affected patients, although this in itself does not explain why some of these conditions are painful and others are not. A far less obvious example of genetic variation that predisposes a person to experiencing pain is the alleles associated with risk-taking behavior. The more risks you take, the more likely you are to suffer from a painful injury. Like pain, there are no genes that encode for risk-taking behavior. But there may be a chain of causality from gene to protein to behavior – for example, an allele that encodes for muscle proteins may make a young man tend to be more attractive and athletic, more outgoing, more likely to engage in risky sports, more likely to be hurt playing football, and hence more likely to suffer pain.

Disease-susceptibility genes that affect pain directly are of obvious medical importance, and even the ones that affect pain indirectly, like risk-taking genes, may have more than simple entertainment value. But if our aim is to better understand the neural mechanisms that determine pain intensity and to facilitate the development of better analgesic drugs, pain-susceptibility genes are of more immediate interest than disease-susceptibility genes. For example, it is possible that pain-susceptibility genes determine which amputee will have severe phantom limb pain and which, with the same amputation level (the same disease), will have none. Identification of the gene variants that make the

difference might point directly to the neurobiological processes that are responsible for phantom limb pain in the first place. Among the various possibilities is that an amputation pain-susceptibility gene might determine to what extent sensory neurons that have been damaged as a result of the amputation generate spontaneous abnormal electrical impulse discharges. Alternatively, the critical genetic polymorphism may have nothing to do with primary sensory neurons but, rather, affect amplification mechanisms within the spinal cord. Either type of effect, and many others, could account for the difference in pain between the suffering and the pain-free amputee. And knowing which could lead scientists to new and better pain relievers.

Finding Pain Genes

How do we find pain-susceptibility genes? The search for pain genes, like the search for genes that control any other inherited trait, begins by comparing the genetic makeup of individuals or groups with contrasting pain phenotypes (i.e., pain responses). For example, which alleles in which genes are identical in amputees with phantom pain and different from amputees without pain? It is relatively straightforward to identify a Mendelian gene, a gene that affects a pain phenotype so powerfully that its alleles alone determine whether you will have pain or not. The approach, linkage analysis, involves studying families in which some members carry the mutation (and have the painful condition) and others do not. Genetic differences are identified which correlate with the pain phenotype of the individual family members. Nearly all medically important disease-susceptibility genes identified to date were identified by tracing linkage in large families. This is also true of conditions that are painful. A striking example is FHM, for which specific mutations have been found in four separate genes (in different FHM families), all of which cause the painful migraine with hemiplegia characteristic of this disease. Another example is erythermalgia, an inherited condition associated with red warm hands and/or feet and severe burning pain. The cause in all families studied to date is a rare mutation in a single gene. Interestingly, in both conditions, the mutated genes encode for proteins whose function is known and makes sense in terms of current pain physiology. There is also the anticipation that this line of work might uncover genes never before linked to pain. Such information might open up new chapters in pain physiology.

An important limitation to linkage analysis in the search for pain genes in families is that it only works for traits that arise spontaneously, such as migraine headache and erythermalgia. Many chronic pain conditions, phantom limb pain in amputees, for example, result from acquired injuries or disease. It is exceedingly unlikely that we will ever find large families in which all the members have had a below-the-knee amputation or suffer from a uniform degree of diabetic neuropathy. In addition, susceptibility to chronic pain is likely to be affected by several genes and to be further modified by environmental factors. Linkage analysis in families works efficiently only for genes of major effect. The alternative is to compare genetic makeup in matched groups of patients, with and without pain, who are not related. This is called an association study. In a typical association study, we compare the genomes of two unrelated groups of individuals that differ in the trait of interest but that are as similar as possible with regards to other parameters, such as environment and ethnicity. Because of the much greater variability in genetic background among people who are unrelated, the number of people who must be tested is much larger. The specific number required depends on how strong an effect the gene(s) in question has in determining the trait. For a Mendelian gene, a few dozen samples may be sufficient. However, in the more common situation in which any given gene has only a partial effect in determining the trait, hundreds or even thousands of individuals need to be included in each group. Due to practical (often budgetary) constraints, association studies are frequently conducted with smaller sample sizes than necessary. The reliability of results obtained from such studies, as assessed by successful replication, is often disappointing. An example is an early report that the $Val^{158}Met$ polymorphism, a simple base pair substitution in *COMT*, the gene that encodes for an enzyme (catechol-*O*-methyl transferase) involved in noradrenaline synthesis, greatly increases pain susceptibility. A number of attempts to replicate this finding have obtained a much weaker signal or none at all. Single nucleotide polymorphisms (SNPs) of this sort have also been reported to affect pain in osteoarthritis, low back pain, postherpetic neuralgia, and other common medical conditions.

A potential alternative to association analysis in humans, actually a complementary approach, is to begin by carrying out linkage analysis using an animal model of a human pain trait. Such studies are almost always done in mice because of the superior experimental resources available for genetics studies in this species (**Figure 1**). The hope is that, after identifying a pain-susceptibility gene in mice or a modest number of gene candidates, we might succeed at finding important polymorphisms in the homologous human gene(s) using patient cohorts of manageable size. The mouse study tells us in which part of the human genome to look. An interesting example is the 2004 work by Seltzer and colleagues, who used

Figure 1 Graph of pain sensitivity in the neuroma model of neuropathic pain in 12 different inbred mouse strains (all males). The most sensitive strains are C3H/HeN and CBA/J, and the least sensitive strains are C58/J and AKR. Individual mice within an inbred strain are genetically identical to one another. Therefore, trait variability within each strain (column error bars) gives an indication of the effect that environmental factors had on the animals' response, whereas variability among strain means gives an indication of the degree to which the pain trait is heritable. SD, standard deviation. Data from Mogil JS, Wilson SG, Bon K, et al. (1999) Heritability of nociception, I: Responses of 11 inbred mouse strains on 12 measures of nociception. *Pain* 80: 67–82.

the recombinant inbred approach (a variant of family linkage analysis) in the mouse neuroma model of neuropathic amputation pain. This analysis identified a region in the mid-part of mouse chromosome 15 that apparently harbors a gene of major effect for this pain trait. Seltzer was then able to focus his attention on the corresponding region of the human genome, chromosome 22, in DNA samples from a cohort of limb amputees and women who had undergone mastectomy, some of whom had chronic pain and some of whom did not. This strategy has yielded a promising pain gene candidate, but verification is still needed.

Pharmacogenetics and Other Applications

Another example of the mouse–human comparison approach illustrates the newly emerging field of pharmacogenetics. Mogil and colleagues (2003) found that contrasting sensitivity to κ-opioid-type pain relievers in females (but not males) of two inbred mouse strains is due to an allelic difference in a genetic region close to *Mc1r,* the mouse melanocortin-1 receptor gene. Allelic variation in the human homolog of *Mc1r* was previously known to occur in light-skinned redheads. Putting one and one together, they found that redheaded women are much more sensitive to κ-opioid analgesics than are men or women who are not redheads. Common base pair substitutions in *OPRM1,* the gene encoding for the human morphine receptor, and in *CYP2D6,* the gene that encodes for a liver enzyme that metabolizes codeine, have an important influence on the efficacy of morphine and codeine as pain relievers in people who carry different alleles of these genes. One of the first clinical applications of pain genetics is likely to be arrays (gene chips) that will indicate which drugs, including pain relievers, might be particularly effective, or toxic, for a given patient.

Genetic linkage analysis and association studies may point to a region of DNA that harbors many genes, with more than one being an attractive candidate for the gene responsible for the trait in question. We still need to chose which is the gene that really counts. And even when a polymorphism in a particular gene is indicated, it is wise to verify that we have indeed found the target gene using an independent methodology. A variety of methods are available to do this, mostly using animal models. Pharmacological reagents, agonists or antagonists, are sometimes helpful. Drugs, however, often interact with molecular targets in addition to the intended one. A more specific, although resource-intensive approach, is to knock out the gene in question using the method of homologous recombination, so that its protein product is not expressed in any cell in the body (global knockout) or in a particular class of cells (conditional knockout). The key question is whether this knockout will duplicate the phenotype attributed to the candidate gene being tested. For example, will the knockout mouse have more pain sensitivity than normal littermates? Particular genes can likewise be expressed in excess, leading to the prediction that this will cure the

pain phenotype. Another approach is to use antisense oligonucleotides or small inhibitory RNA (siRNA) molecules to block the transcription of the target gene into messenger RNA and hence to prevent the expression of the gene's protein. Specific antibodies can also be used to neutralize the protein product itself. Such ablative procedures can, in principle, form the basis of new pain therapies. Therapeutic antibodies for pain control in certain conditions have recently become available, and there is optimism that siRNA technology will also prove its practicability. Further down the road are proposals to develop gene therapy for pain control. For example, a patient's cells could be altered genetically so that they express endogenous morphine-like protein pain-relieving molecules specifically in body locations where they are required. More speculatively, it might be possible in the future to actually repair mutated genes in patients or insert altered, or even completely novel, genes using viruses as carriers (vectors) of genetic information. Genetic engineering is fast becoming a medical reality.

Finally, there are a variety of ways in which genetic thinking can be applied to the discovery of pain mechanisms that do not involve actually identifying pain genes. For example, in 1990 Devor and Raber applied selective breeding to a pain phenotype in outbred rats. Hindlimb nerves were injured to induce experimental neuropathic pain, and individual male and female rats that showed high pain sensitivity were then interbred, as were males and females that showed low pain sensitivity. First-generation offspring did not show much of a change in pain phenotype. But after selection pressure had been applied for five successive generations, nearly all offspring of pain-sensitive animals were pain sensitive and nearly all offspring of pain-resistant animals were pain resistant. These high and low pain-prone rats could then be used to see what other traits co-selected with pain. Because the animals are alike genetically except for genes that affect the pain response, it is likely that any behavioral or neurophysiological characteristic that contrasts between them is determined by the same genetic variants that are responsible for the difference in pain sensitivity. A related approach, correlational analysis, does not require genetic selection lines. In this approach, 10–15 strains of inbred mice are graded on a particular trait (**Figure 1**), say sensitivity to heat stimuli applied to the paw. If another trait, say neuropathic pain, shows the same rank order of sensitivity across strains, it can be concluded that these two traits are controlled by similar genes and hence probably share a common underlying physiological mechanisms. Unlike gene knockout, gene-based pharmacological approaches, and genetic engineering, information on how the pain system works can be gleaned from linkage analysis, association studies, genetic selection, and correlational analysis without prior knowledge, assumptions, and hypotheses.

The genetic revolution has only just started to impact on the field of pain science and medicine. There is well-founded optimism about the potential power of linkage analysis and association studies, particularly when undertaken using the mouse–human comparison approach, to generate new knowledge. The payoff in terms of new therapeutic options is likely to be not too far down the road.

Introduction

Nociceptor and Nociceptive Pain

During evolution, living organisms develop a specialized apparatus to sense their immediate environment in order to protect themselves from potentially hazardous situations. This special apparatus is called nociceptor, which can detect noxious stimuli from the environment. Intense stimulation of high-threshold nociceptors will elicit a pain sensation, through a pathway that is initiated from the action potential generated in the peripheral nociceptor terminal, conducted via thin unmyelinated C fibers and myelinated Aδ fibers to the spinal cord dorsal horn in the central nervous system (CNS), finally projecting to the cortex via a relay in the thalamus. This acute 'ouch' pain is called nociceptive pain or physiological pain, and it has a protective role that warns of potential tissue damage. Many pain transduction molecules have been identified, such as the thermal receptor transient receptor potential (TRP) ion channel family. Whereas TRPV1 and TRPV2 detect heat stimuli, TRPA1 and TRPM8 may sense cold stimuli. Activation of TRPV1 after a heat stimulus (>42 °C) generates inward currents in the nociceptor peripheral terminal and results in action potentials in the nociceptor axon, leading to the sensation of pain.

Nociceptive Sensitization and Clinical Pain

A further evolution of the early pain system was the development of the capacity to produce increases in sensitivity after injury, termed nociceptive sensitization. This sensitization results in hyperalgesia, an increased responsiveness to noxious stimuli, and allodynia, a painful response to normally innocuous stimuli. Nociceptive sensitization was found even in simple organisms such as *Aplysia*, in which an intense noxious stimulus can produce a long-lasting sensitization of the gill withdrawal reflex due to increased synaptic strength. The persistence of a heightened responsiveness of the nervous system after a brief noxious stimulus has clear parallels with memory, where information needs to be stored and retrieved. Although the gill withdrawal reflex in *Aplysia* could be used as a model for nociceptive sensitization, it has been accepted as a model for learning and memory since many synaptic mechanisms that work in this model also apply to learning and memory behaviors in rodents.

Whereas nociceptive pain is typically transient, clinical pain or pathological pain is characterized by persistent pain hypersensitivity. Clinical pain is often associated with either peripheral tissue damage/inflammation (inflammatory pain) or lesions to the nervous system (neuropathic pain), and it is typically characterized by hyperalgesia and allodynia, as well as by spontaneous pain – pain experienced in the absence of any obvious peripheral stimulus. Animal models of inflammatory pain are usually produced by injection of irritative substances such as formalin, carrageenan, and complete Freund's adjuvant (CFA) into a hindpaw or joint of rats and mice, and this pain lasts from hours to days or weeks. In animal models, neuropathic pain is often induced by lesion to a peripheral nerve (e.g., partial lesion of the sciatic nerve and its branches in rats and mice), and this pain can last for many weeks to several months. In addition, animal models are also developed for cancer pain and postoperative pain (e.g., pain after incision), which share some features with inflammatory and neuropathic pain but also have distinct characteristics. Long-term exposure of opioids such as morphine, a traditional analgesic, may also produce clinical pain symptoms. Pain hypersensitivity is not only produced in the injured tissue or territory (innervated by the injured nerve) but also spread to the adjacent noninjured regions or the extraterritory. Current drugs have had only limited success in treating some clinical pain, such as neuropathic pain, in part due to our incomplete knowledge about how nociceptive sensitization is produced and maintained. It is generally believed that persistent pain or clinical pain is an expression of neural plasticity, which can occur in both the peripheral and the central nervous system.

Neural Plasticity in the Peripheral Nervous System: Peripheral Sensitization

Tissue injury such as that caused by surgical incision produces inflammation and heightens the pain experience. This arises from the production and release of inflammatory mediators such as prostaglandin E_2 (PGE_2), bradykinin, ATP, protons, and nerve growth factor (NGF) from nonneuronal cells (e.g., fibroblasts, mast cells, neutrophils, and platelets) and from primary sensory terminals. After nerve damage, proinflammatory cytokines such as tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) are released from enclosing Schwann cells and damaged axons. The soma and axons of primary sensory

Figure 1 Induction of peripheral sensitization in nociceptor neurons. Peripheral tissue injury or nerve damage leads to the production of various inflammatory mediators, such as TNF-α, PGE_2, bradykinin, and NGF, which are released and stimulate the appropriate receptors on terminals, axons, or the cell body of primary sensory neurons. TNF-α is known to activate p38 MAPK in DRG neurons. Stimulation of G-protein-coupled receptors (GPCR) by PGE_2 activates adenylate cyclase through G_s and subsequently stimulates PKA. Other GPCR such as bradykinin B2 receptor activate phospholipase C-β (PLC-β) through G_q, thus increasing intracellular Ca^{2+} and leading to the activation of ERK and PKC. Stimulation of the tyrosine receptor kinase A (TrkA) receptor by NGF results in an activation of ERK, PI3K, and PLC-γ signaling pathways. Activation of PLC-β or PLC-γ results in the hydrolysis of plasma membrane lipids and activation of PKC, both proposed to enhance TRPV1 function. In particular, NGF can rapidly increase membrane expression of TRPV1 through PI3K. PI3K activates Src that binds to and phosphorylates TRPV1, leading to membrane insertion of TRPV1. As a consequence of these regulations, the threshold for the activation of TRPV1 is reduced so that lower temperature (e.g., body temperature 37 °C) can activate the receptor following tissue injury. In addition, activation of PKA, PKC, p38, and ERK results in potentiation of TTX-resistant sodium channel (TTX-R, including $Na_v1.8$ and $Na_v1.9$). Hyperactivity of TRPV1 and TTX-R causes increased sensitivity of primary sensory neurons at the peripheral terminals, axons, and cell bodies, termed 'peripheral sensitization.'

neurons contain receptors for these inflammatory mediators, and activation of the receptors leads to the activation of multiple intracellular signaling pathways, increasing the sensitivity and excitability of nociceptors (Figure 1). This sensitization in the peripheral nervous system (PNS) is called peripheral sensitization. Several ion channels are essential for the generation of peripheral sensitization. Posttranslational regulation of these channels can occur within minutes by phosphorylation, which is responsible for the induction of peripheral sensitization. However, transcriptional regulation of these channels takes hours to manifest, leading to persistent peripheral sensitization. In addition, regulation through transcription-independent translation or axonal transport can also change the sensitivity of nociceptors.

Peripheral sensitization produces increases in pain sensitivity restricted to the site of tissue injury. An example is heat pain after sunburn; a normally warm shower now feels burning hot.

Onset of Peripheral Sensitization

Various types of ion channels, such as TRPV1, TRPV2, TRPM8, P2X3, acid-sensitive channel ASIC, and tetrodo toxin (TTX)-resistant sodium channels (TTX_R, including $Na_v1.8$ and 1.9), are expressed in primary sensory neurons of the dorsal root ganglion (DRG) or trigeminal ganglion. The sensitivity of these channels can be regulated by inflammatory mediators. Current studies focus on two molecules – TRPV1, a transduction molecule that can convert extracellular stimuli into electrical activity on the membrane, and TTX_R, a conduction molecule that is important for the conduction of action potential to the spinal cord. TRPV1 is specifically expressed in C-fiber nociceptive neurons and is required for the generation of heat hyperalgesia. Inflammatory heat hypersensitivity following bradykinin, NGF, CFA, and carrageenan is almost abolished in TRPV1 null mice. TTX_R sodium channels are also expressed in nociceptors and crucial for the generation of hyperexcitability of sensory neurons. Knockdown of $Na_v1.8$ with antisense oligodeoxynucleotides results in decreased inflammatory pain and neuropathic pain. It is generally believed that hypersensitivity of TRPV1 and TTX_R underlies the induction of peripheral sensitization. Several protein kinases, such as phospholipase C, PKC, phosphatidyl inositide-3 kinase (PI3K) and extracellular signal-regulated kinase (ERK), are implicated in TRPV1 sensitization (Figure 1). In particular, the PI3K pathway may contribute to peripheral sensitization by inducing rapid trafficking and membrane insertion of TRPV1. Activation of PKA, PKC, and p38 mitogen-activated protein kinase

(MAPK) is also involved in regulating the sensitivity of TTX_R (Figure 1). A membrane translocation of PKC-ε appears to be important for its activation of TTX_R.

Persistence of Peripheral Sensitization

Tissue and nerve injuries induce gene transcription and protein synthesis in primary sensory neurons contributing to persistent pain hypersensitivity. Although NGF is required for the survival of sensory neurons during fetal development, it is not necessary for the survival of mature sensory neurons. Rather, it maintains the phenotype of nociceptive sensory neurons in the adult and is thus required for the continued expression of many genes. C-fiber nociceptors in the DRG are roughly divided into two subsets, NGF-responsive and glia-derived growth factor (GDNF)-responsive, despite the fact that there is a significant overlap between these two subsets of nociceptors. NGF is absolutely critical for gene activation in tyrosine receptor kinase A (TrkA) expressing C-fiber nociceptors. Many nociceptive genes, such as those encoding for substance P, calcitonin gene-related peptide (CGRP), brain-derived neurotrophic factor (BDNF), TRPV1, and $Na_v1.8$, are induced by NGF in DRG neurons. Therefore, an increase in NGF levels in DRG neurons after peripheral inflammation leads to an upregulation of these nociceptive genes. In contrast, a decrease in NGF levels in DRG neurons results in a downregulation of these genes in axon-injured neurons, which can further be rescued by NGF. It has been shown that GDNF family member artemin is also produced in inflamed tissue, which can induce TRPV1 expression in DRG neurons through the GFRα3 receptor. The GFRα3 receptor is coexpressed with TrkA, thus enhancing the function of NGF.

Target-derived NGF is retrogradely transported to the cell body in the DRG, where it activates p38 MAPK, leading to an upregulation of TRPV1 and other nociceptive genes (e.g., BDNF, substance P, and TRPA1, a receptor required for cold allodynia). Therefore, the active form of p38 (phosphorylated p38) is coexpressed with TRPV1 and inhibition of this kinase suppresses heat hyperalgesia (Figure 2). It remains to be investigated whether artemin also activates this kinase to induce TRPV1 expression. Apart from p38, ERK/MAPK is also activated by NGF in DRG neurons and involved in NGF induction of nociceptive genes. Activation of the transcription factor cAMP response element binding protein (CREB) could be downstream to MAPK activation. The CREB binding sites (CRE) are found in nociceptive genes that encode BDNF, substance P, and CGRP in sensory neurons.

In addition to transcriptional regulation, MAPK also mediates gene expression via translational regulation. Peripheral inflammation and NGF induce an increase in TRPV1 protein levels but not in TRPV1 mRNA levels in the DRG. This nontranscriptional regulation of TRPV1 is mediated by p38 in a NGF-dependent way. Finally, increased axonal transport of nociceptive proteins also contributes to persistent pain hypersensitivity. For

Figure 2 Regulation of TRPV1 expression and persistent heat hyperalgesia by p38 MAPK activation in primary sensory neurons. In normal conditions, TRPV1 is synthesized in the cell body of primary sensory neurons in the dorsal root ganglion (DRG) and transported to both peripheral terminals in the skin/muscle and central terminals in the spinal cord. After peripheral tissue inflammation (e.g., arthritis), NGF is produced in inflamed tissue. NGF is also produced by Schwann cells after peripheral nerve damage. Upon release, NGF is taken up by intact peripheral nerve terminals and axons and retrogradely transported to the cell body in the DRG. NGF in the cell body activates p38, which in turn increases TRPV1 translation. Furthermore, increased TRPV1 is anterogradely transported to peripheral terminals, producing persistent peripheral sensitization (heat hyperalgesia). Adapted from Ji RR, Samad TA, Jin SX, Schmoll R, and Woolf CJ (2002) MAPK activation by NGF in primary sensory neurons after inflammation increases TRPV1 levels and maintains heat hyperalgesia. *Neuron* 36: 57–68, with permission from Elsevier.

example, inflammation increases TRPV1 axonal transport from the DRG cell body to peripheral nerve terminals after inflammation (Figure 2).

Neural Plasticity in the CNS: Central Sensitization

Tissue and nerve injuries produce plastic changes in the pain pathway not only at the peripheral sites but also at the central sites. An important advance in pain research is to establish that activation of peripheral nociceptors by high-threshold and persistent noxious stimuli (heat, mechanical, and electrical) or by inflammatory mediators (chemical stimuli) also results in an activity- or use-dependent neuronal plasticity in the CNS. This plasticity modifies the performance of the nociceptive pathway by enhancing and prolonging the responses to subsequent peripheral stimuli. These changes in the spinal cord, as well as in the brain, are defined as central sensitization. Although central sensitization is often but not always induced by peripheral sensitization, it is responsible for the pain, after injury, by normally innocuous low-threshold afferent inputs (mechanical allodynia) and the spread of hypersensitivity to regions beyond injured tissue. The behavioral consequences of central sensitization can be readily detected in human psychophysical experiments. For example, intradermal injection of capsaicin, the pungent ingredient in chili peppers that activates the TRPV1 receptor, produces an intense but transient burning pain. This is followed by heightened sensitivity outside of the primary region of the capsaicin injection to high-threshold pinprick (secondary mechanical hyperalgesia) and to low-threshold brush (secondary mechanical allodynia), both of which are induced by central sensitization. Clinically, central sensitization contributes to pain hypersensitivity in the skin, muscle, joints, and viscera, such as in patients with fibromyalgia. Neuropathic pain after spinal cord injury is called 'central pain,' in which peripheral sensitization may not be robust and central sensitization can be self-maintained.

Current studies on central sensitization focus on dorsal horn neurons, the first-order relay neurons in the pain pathway. Small nociceptive fibers from primary sensory neurons mainly project to the superficial dorsal horn (laminae I–II), as well as lamina V, whereas large myelinated fibers terminate in the deep dorsal horn (laminae III and IV). Primary afferent inputs to dorsal horn neurons are excitatory, which is primarily contributed by glutamate. The dominant type of inhibitory synaptic transmission in the dorsal horn is mediated by γ-aminobutyric acid (GABA) and glycine receptors, which are ligand-gated Cl^- channels. In normal conditions, the inhibitory control on the pain system is very powerful, serving as a 'gate control.' Disturbance of the balance between excitatory and inhibitory synaptic inputs will lead to abnormal pain sensitivity. For example, there is a reduction of inhibitory synaptic transmission but an enhancement of excitatory synaptic transmission in the dorsal horn following peripheral nerve injury.

Pain and memory are often associated in daily life. Persistence of a heightened responsiveness of the nervous system after noxious stimuli or injuries has clear parallels with memory. Studies on neural plasticity in the hippocampus reveal that long-term potentiation (LTP) – a brief tetanic electrical stimulation that induces long-term enhancement of synaptic transmission in hippocampal neurons – underlies the generation of memory. LTP is also induced in dorsal horn neurons. It is not only induced by nerve stimulation at high frequencies (100 Hz) but also may be induced by nerve injury or even by low-level activity in nociceptive nerve fibers after inflammation. However, LTP is more difficult to induce in dorsal horn neurons than in hippocampal neurons. Therefore, central sensitization is a broader phenomenon, including LTP (homo- or heterosynaptic), wind up (homosynaptic, a transient synaptic plasticity during a noxious stimulus), and activity-dependent classic central sensitization (heterosynaptic, a synaptic plasticity induced by low-threshold Aβ stimulation, which outlasts initial C-fiber stimulation) and other forms of hypersensitivity of CNS neurons. Whereas long-term memory and the late phase of hippocampal LTP require gene transcription, short-term memory and early phase LTP require only posttranslational modifications. This same dichotomy appears to apply to central sensitization and pain hypersensitivity: the induction of central sensitization and pain hypersensitivity appears to require only posttranslational processes, whereas their maintenance seems to depend on changes in gene transcription. Although neural circuits in the spinal dorsal horn and hippocampus are quite different, glutamate is the predominant neurotransmitter in both circuits and activation of NMDA receptors is essential for the plasticity of both dorsal horn and hippocampal neurons. The activity of NMDA and AMPA receptors can be regulated by several protein kinases through posttranslational regulation. Moreover, the ERK-CREB pathway might be critical for the transcriptional regulation of genes in both the dorsal horn and the hippocampus that maintain central sensitization and LTP.

Onset of Central Sensitization in the Spinal Cord

Mild noxious stimulation generates fast excitatory postsynaptic potentials (EPSPs) lasting milliseconds.

This fast synaptic transmission is mediated by ionotropic glutamate receptors, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and kainate receptors. Another type of ionotropic glutamate receptor, the *N*-methyl-D-aspartate (NMDA) receptor, contributes little to the EPSPs or action potentials under normal conditions due to Mg^{2+} blockade of the channel. However, this receptor contributes importantly to the onset of different forms of central sensitization after removal of Mg^{2+} blockade via depolarization. In addition to glutamatergic synaptic transmission, intense noxious stimulation also releases neuropeptides, such as substance P, producing slow postsynaptic responses via G-protein-coupled natural killer (NK)-1 receptors. Also, C-fiber stimulation can release the neurotrophin BDNF. Like substance P, BDNF is located in large, dense-cored vesicles. Inflammation not only increases the synthesis of substance P and BDNF in primary sensory neurons but also increases the expression of their receptors (NK-1 and TrkB) in postsynaptic spinal neurons. Both increases would enhance the responses of the receptors because the spontaneous activity that is generated in axons and cell bodies of primary sensory neurons after injuries will cause more release of neurotransmitters.

Activation of protein kinases and intracellular signaling cascades is required for the development of central sensitization. Protein kinases can phosphorylate NMDA and AMPA receptors via posttranslational regulation, enhancing synaptic transmission and producing central sensitization (**Figure 3a**). For example, a PKC-mediated phosphorylation of the NMDA receptor in dorsal horn neurons removes its voltage-dependent Mg^{2+} block, enabling glutamate to generate a greater inward current through the NMDA ion channel at resting membrane potentials. Tyrosine kinase Src enhances NMDA current via phosphorylation of the NR2A/B subunit of the NMDA receptor, increasing channel open time and kinetics. Noxious simulation, inflammation, as well as stimulation of TrkB receptor induce the phosphorylation of NMDA receptor subunits in the dorsal horn neurons.

NMDA receptor-mediated activation of CaMKII is critical for the induction of hippocampal LTP. CaMKII not only phosphorylates GluR1-containing AMPA receptor subunits on Ser831, enhancing the single channel conductance of synaptic AMPA receptors, but also induces rapid trafficking and incorporation of GluR1 into hippocampal synapses as well as docking of NMDA receptors to postsynaptic sites in dorsal horn neurons. Painful stimulation was also shown to induce CaMKII phosphorylation and membrane insertion of GluR1 receptor subunits in spinal cord neurons.

In addition to enhanced excitatory synaptic transmission, suppression of inhibitory synaptic transmission also plays an important role in the generation of central sensitization. PGE_2, an inflammatory mediator strongly implicated in peripheral sensitization, also contributes to central sensitization by suppressing glycine currents in dorsal horn neurons via activation of PKA (**Figure 3(a)**). BDNF has been implicated in disinhibition via modulation of chloride influx and alternation in anion reversal potentials.

In particular, ERK is specifically activated in superficial dorsal horn neurons by nociceptive inputs (**Figure 3(b)**). Activation of NMDA and TrkB receptors, as well as metabotropic glutamate receptors, results in ERK activation, which is required for behavioral manifestation of central sensitization. ERK can suppress the activity of $K_v4.2$ potassium channels, increasing the excitability of dorsal horn neurons. Also, ERK may phosphorylate NMDA receptor in dorsal horn neurons and mediate membrane insertion of AMPA receptors during synaptic plasticity.

Persistence of Central Sensitization in the Spinal Cord

Pain and memory also share mechanisms for long-term changes in synaptic plasticity. In particular, the transcription factor CREB plays an essential role in persistent neuronal plasticity in both hippocampal and dorsal horn neurons and is required for both long-term memory and persistent pain (e.g., neuropathic pain). CREB is known to regulate the expression of numerous genes that are important for plasticity, cell survival, and synaptic formation. Noxious stimulation induces a rapid phosphorylation of CREB in dorsal horn neurons. Persistent CREB phosphorylation was also shown in the spinal cord after inflammation and nerve injury. CREB may maintain central sensitization by inducing the transcription of immediate early genes (e.g., c-*fos*, *Zif268*, and *Cox-2*) and later response genes (e.g., *NK-1*, *TrkB*, and *prodynorphin*). Importantly, these genes are induced in the dorsal horn following intense noxious stimulation, or inflammation and nerve injury, and they all contain CREB binding sites (CRE) in their promoter regions. Although multiple signaling cascades are implicated in CREB activation, the ERK pathway appears to be critical for this activation. Phosphorylated ERK (pERK) is colocalized with pCREB in dorsal horn neurons following noxious stimuli. Upon activation of ERK, pERK is translocated to the nucleus, activating the CREB kinase RSK2 (**Figure 3(c)**). Since multiple signaling cascades, such as PKA, PKC, PI3K, and Src, can cause ERK activation, they should also converge on CREB phosphorylation. Central sensitization is maintained not

Figure 3 Mechanisms of central sensitization induction and maintenance in spinal cord dorsal horn neurons. (a) Induction of central sensitization. Following tissue or nerve injury, there is increased release of the neurotransmitters glutamate, substance P, and BDNF from the central terminals of primary afferents in the spinal cord. Activation of postsynaptic NMDA receptors and Ca^{2+}-permeable AMPA receptors in the spinal cord leads to Ca^{2+} influx. Stimulation of mGluRs (e.g., group I) and NK-1 receptors activates PLC and stimulates Ca^{2+} release from intracellular stores. The increase in intracellular Ca^{2+} activates CaMK, PKC, and ERK. Activation of TrkB leads to the activation of the Ras-Raf-MEK-ERK pathway as well as Src, which is also activated by PKC. Activation of these protein kinases increases the function of NMDA and AMPA receptors. In addition, ERK activation suppresses the activity of the $K_V4.2$ potassium channels, increasing the excitability of dorsal horn neurons. PGE_2 is also released in the spinal cord under pain conditions; activation of its EP receptor reduces the function of glycine receptors via PKA. Collectively, these posttranslational steps result in enhanced excitatory synaptic transmission and reduced inhibitory synaptic transmission, contributing to an overall increase in dorsal horn neuron sensitivity that generates central sensitization. (b) Activation of ERK in superficial dorsal horn neurons following a noxious stimulation. Injection of a C-fiber activator capsaicin into a hindpaw of rats produces intense burning pain. It also rapidly (within minutes) phosphorylates ERK, as shown by pERK immunofluorescence, in the medial superficial spinal cord, where C-fiber primary afferents from a hindpaw terminate. However, pERK-labeled neurons are not found in the nonstimulated spinal cord (e.g., contralateral side). (c) Maintenance of central sensitization. Activation of ERK in dorsal horn neurons after injury leads to a nuclear translocation of pERK, activating the transcription factor CREB via RSK2. CREB activation results in increased transcription of many dorsal horn genes such as *NK-1*, *Cox-2*, c-*fos*, *TrkB*, and *prodynorphin*. Persistent activation of these genes maintains heightened excitability and synaptic responsiveness and thus supports central sensitization and persistent pain. Scale bar = 50 μm (b).

only by an upregulation of gene expression but also by a downregulation of gene expression. For example, a reduction of spinal glutamate transporters (e.g., EAAC1 and GLAST1) following nerve injury will decrease the uptake of glutamate, leading to sustained glutamate activation in synapses and enhanced excitatory synaptic transmission.

In addition to persistent change in excitatory transmission, peripheral nerve injury also produces long-term changes in inhibitory transmission. For example, nerve lesion induces a rapid downregulation of the potassium chloride cotransporter KCC2 in dorsal horn neurons, leading to an accumulation of intracellular chloride that can convert inhibitory inputs of GABA and glycinergic interneurons into excitatory ones. Furthermore, there might be a delayed but permanent loss of inhibitory neurons in the dorsal horn after nerve injury.

Glial Regulation of Central Sensitization in the Spinal Cord

Studies on pathological pain primarily focus on the responses of the neurons and neural circuits. There is accumulating evidence indicating a role of spinal glial cells in persistent pain. In particular, microglia in the spinal cord are strongly implicated in the genesis of neuropathic pain. Microglial markers such as CD11b are rapidly induced in spinal cells after nerve injury.

Nerve injury also produces robust morphological changes of microglia, from resting status (with ramified processes) in the normal conditions to hypertrophy status (with thick and short process) after lesion. Upon activation, microglia become a major source of inflammatory mediators, producing proinflammatory cytokines (TNF-α, IL-1β, and IL-6), PGE_2 (synthesized by the enzymes COX-1 and COX-2), and NO (synthesized by the enzyme iNOS). Nerve lesion elevates the levels of these cytokines and enzymes in the spinal cord. BDNF is also produced in cultured microglia, although it is barely detected in spinal microglia *in vivo* under normal or injury conditions. Upon release, all these substances are neuroactive. Although PGE_2 and BDNF have been implicated in central sensitization, little is known about the central effects of proinflammatory cytokines. IL-1β appears to enhance excitatory postsynaptic transmission in dorsal horn neurons, in addition to its transcriptional regulation of COX-2. The involvement of microglia and inflammatory mediators in central sensitization is also supported by behavioral studies: spinal injection of glial toxins (e.g., fluorocitrate), microglial inhibitor (minocycline), and inhibitors of proinflammatory cytokine pathways and COX has been shown to reduce neuropathic pain. In addition, several receptors, such as ATP receptor P2X4, chemokine receptors CCR2 and CX3CR1, and probably Toll-like receptor (TLR-4), are induced in spinal microglia after nerve injury; blocking these receptors results in reduced neuropathic pain.

Signal transduction in spinal microglia begins to be revealed. Nerve injury induces a very robust activation of p38 MAPK exclusively in spinal microglia. Furthermore, intrathecal injection of p38 inhibitors attenuates nerve injury-induced neuropathic pain. p38 activation in microglia is known to induce the synthesis and release of multiple inflammatory mediators in the spinal cord, enhancing and prolonging spinal sensitization (**Figure 4**). It is generally believed that spontaneous electrical activity produced in the axons and cell bodies after nerve injury is essential for the genesis of neuropathic pain. This activity also appears to be important for microglial activation of p38. Therefore, nerve conduction blockade proximal to nerve injury prevents spinal p38 activation. TNF-α is also implicated in p38 activation. In particular, the chemokine fractalkine (CX3CL1) plays an important

Figure 4 Glial regulation of spinal sensitization following peripheral nerve injury. After peripheral nerve injury, hyperactive primary sensory neurons or spinal neurons can release neuromodulators such as substance P, ATP, and fractalkine (CX3CL1), leading to the activation of the MAPK (p38 or/and ERK) signaling pathway in spinal microglia. The activated microglia synthesize and release multiple inflammatory mediators, such as IL-1β, TNF-α, IL-6, nitric oxide (NO), and PGE_2, as well as the neurotrophin BDNF. These mediators serve as diffusible neuroactive substances, acting on postsynaptic dorsal horn neurons, enhancing the function of NMDA and AMPA receptors or reducing the function of GABA and glycine receptors. These mediators can also act on presynaptic sites, leading to increased release of neurotransmitters (e.g., glutamate and BDNF). Moreover, these mediators will act on surrounding glia (microglia or astrocytes), causing further activation of glia. Taken together, a positive feedback loop between neurons and glia in the spinal cord enhances and maintains central sensitization and neuropathic pain.

role in mediating neural/glial interaction for several reasons. First, fractalkine is produced in neurons (including both primary sensory and spinal neurons). Second, CX3CR1 is the sole receptor for fractalkine and this receptor is only expressed in spinal microglia. Finally, nerve injury induces a marked upregulation of CX3CR1 in spinal microglia. Activation of CX3CR1 also results in p38 activation, and CX3CR1/p38 cascade in spinal microglia is essential for the development of neuropathic pain. In addition to p38, ERK is also activated in spinal microglia by nerve lesion, which is essential for neuropathic pain sensitization.

Apart from a rapid activation of spinal microglia, nerve injury induces a delayed but more persistent activation of astrocytes. Interestingly, c-Jun N-terminal kinase (JNK)/MAPK is persistently activated in spinal astrocytes and contributes to late maintenance of neuropathic pain. Since astrocytes have more close contact with synapses, they should regulate spinal neuron sensitivity via different mechanisms than microglia.

Central Sensitization in the Brain

Activity-dependent central sensitization is extremely robust and has been reported in rodent, cat, and primate dorsal horn neurons, including spinothalamic neurons. A central sensitization-like phenomenon can also be generated in neurons in other parts of the pain system, such as the rostroventral medulla (RVM), anterior cingulate cortex (ACC), and amygdala, following tissue injury. Several symptomatic features of headache reflect central sensitization produced in trigeminal nuclei within the brain stem. For example, inflammation induces phosphorylation of AMPA receptor (GluR1) in the RVM, which may regulate descending facilitation. Calcium-dependent adenylate cyclase AC1 and AC8 are highly expressed in the ACC, and inflammatory pain is attenuated in mice lacking AC1 and AC8. The action of AC1 and AC8 appears to be mediated by the cAMP-PKA-CREB pathway. Neuronal activity in the ACC could influence spinal nociceptive transmission by activating the descending facilitatory system.

Pain consists of different components. In addition to a sensory-discriminative component that describes the quality, intensity, and spatiotemporal characteristics of the sensation, pain experience also includes an emotional-affective component, referring to the unpleasantness or aversion of sensation. Emotional distress could be the most disruptive and undesirable feature of painful experiences. ACC also plays an important role in pain affect. Noxious stimulation (e.g., formalin)-induced conditioned place avoidance (noxious conditioning) has been established as an animal model to examine affective pain. Lesions of the ACC produce severe deficits in avoidance conditioning. Furthermore, the PKA/ERK pathway in the ACC is also involved in affective pain. Therefore, neural plasticity also plays an important role in the generation of affective pain.

Summary

Under normal conditions, pain is acute and protective, manifested as responsiveness to noxious stimuli. However, after tissue or nerve injury, pain often becomes pathological and chronic, with increased responsiveness to noxious stimuli and even becoming responsive to innocuous stimuli. Pain hypersensitivity following intense nociceptive input or injuries results from neural plasticity that occurs both in the peripheral nervous system (e.g., primary sensory neurons), termed peripheral sensitization, and in the central nervous system (e.g., dorsal horn neurons), termed central sensitization. Activation of several intracellular signal pathways in nociceptive neurons leads to both induction and maintenance of both types of sensitization. Furthermore, activation of spinal glial cells following injuries can enhance and prolong central sensitization by producing inflammatory mediators centrally. Current treatment for clinical pain is not very effective, in part due to a focus on nociception. Development of drugs that suppress signal transduction pathways in neurons and glia may offer new therapies for chronic pain by normalizing neural plastic changes in the pain pathway.

Pain and the Sympathetic Nervous System

W Jänig, Christian-Albrechts-Universität zu Kiel, Kiel, Germany

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The autonomic nervous system is by definition an efferent system that is involved in the regulation of a variety of target cells, such as vascular and nonvascular smooth muscle cells, cardiac muscle cells, and secretory epithelia. Based primarily on anatomical criteria, we distinguish parasympathetic, sympathetic, and enteric nervous systems. Primary afferent neurons with small-diameter myelinated (Aδ) or unmyelinated (C) nerve fibers that also innervate the autonomic target cells (e.g., blood vessels in somatic tissues or viscera) and have their cell bodies in the dorsal root ganglia, trigeminal ganglia, or ganglia associated with vagal afferent neurons (inferior, or nodose, and superior, or jugular, ganglia of the vagus; petrosal ganglion) are not called autonomic (sympathetic or parasympathetic) afferent neurons. We have no anatomical, histochemical, functional, or other criteria (e.g., distinct central synaptic connectivity of these afferent neurons) to classify visceral afferent neurons as autonomic. Afferent neurons of the enteric nervous system which have their cell bodies in enteric ganglia are called intrinsic primary afferent neurons. This conceptual distinction between efferent sympathetic or parasympathetic neurons and afferent neurons that innervate autonomic target cells does not collide with the notion that these afferent neurons are functionally closely associated with autonomic regulation in the sense that they monitor the inner state of the body.

Any noxious (tissue-damaging or potentially tissue-damaging) event within the body or impinging on the body affects the sympathetic nervous system and neuroendocrine systems and leads to integrative responses that further healing and recuperation. These responses are orchestrated by the brain, the level of integration occurring in spinal cord, brain stem, and forebrain (hypothalamus and cerebral hemispheres) (Figure 1). The integrated responses during pain and nociception involving the sympathetic nervous system have to be distinguished from the role of the sympathetic nervous system in the generation or enhancement of pain. This aspect appears to be, at first sight, rather unconventional, since it assigns to an efferent system, which is normally involved in regulation of autonomic target cells, functions that may lead to activation or sensitization of the nociceptive system and therefore to pain. This article is restricted to this point, arguing that the sympathetic nervous system may be involved in the generation of pain.

Conceptual Background

Table 1 lists the different functions of the sympathetic nervous system related to the generation of pain. Some of these functions may be relevant under biological conditions and others only under pathobiological conditions. They involve primarily peripheral mechanisms. However, the functional relevance of these peripheral mechanisms will only be revealed when the central mechanisms are taken into account (Figure 2).

Whether explicitly formulated in the literature or not, the centerpiece of the models behind all descriptions of the putative role of the sympathetic nervous system in the generation of pain is a positive feedback pathway from the spinal cord to the periphery of the body via the sympathoneural or sympathoadrenal system. Figure 2 illustrates in which context this efferent loop has to be seen. Peripheral inflammation leads to nociceptor sensitization, followed by central sensitization of second-order neurons (e.g., in the spinal or trigeminal dorsal horn), with an amplification of the transmission of nociceptive impulses. Peripheral nerve lesion is followed by generation of ectopic impulses in nociceptive and nonnociceptive primary afferent neurons leading to central hyperexcitability. Both chronic pain states are accompanied, in the periphery and in the central nervous system, by plastic changes of the nociceptive system (and other neural systems). These plastic changes are expressed in biochemical, morphological, and functional changes of the neurons and neuron circuits. Depending on the time after trauma, changes associated with peripheral inflammation are probably reversible, and those being associated with nerve lesions not. Both categories of pain states (i.e., inflammatory pain and neuropathic pain) are expressed in spontaneous and evoked pain as well as possibly other somatosensory abnormalities and autonomic, somatomotor, and possibly endocrine responses. An important but still not well-defined component in this concerted action of the brain is the role of the sympathetic nervous system in initiation and maintenance of the pain states via the efferent feedback to the peripheral tissues (red in Figure 2). This function of the sympathetic nervous system may be relevant under pathophysiological conditions but less so under physiological conditions. The idea about the involvement of the sympathetic

Figure 1 Spinal cord, brain stem, and hypothalamus contain neuronal circuits (red shaded area) that modulate nociceptor sensitivity, inflammation, and ectopic activity in lesioned afferent neurons in the periphery of the body via the sympathoadrenal (SA) system, the sympathoneural (SN) system, and the hypothalamic–pituitary–adrenal (HPA) system. Feedback information from the peripheral inflammatory process occurs via nociceptive primary afferent neurons and cytokines. Abdominal vagal afferents signal events from the inner defense line of the body (gut-associated lymphoid tissue) to the lower brain stem (NTS, nucleus tractus solitarii). The telencepalon controls inflammation and sensitivity of nociceptors via the circuits in the spinal cord, brain stem, and hypothalamus (shaded arrows).

nervous system in the generation of pain is based on various clinical observations as well as on animal experimentation.

In the following sections, the focus is on the different modes of sympathetic–afferent coupling in the periphery of the body (as outlined in the top half of Table 1); these are believed to be the basis of sympathetically maintained pain. The roles of the sympathetic nervous system in inflammation and hyperalgesia, briefly outlined in the lower half of Table 1, will not be further discussed.

Sympathetically Maintained Pain: Clinical Background

Pain that is dependent on activity in sympathetic neurons is called 'sympathetically maintained pain' (SMP). SMP includes generically spontaneous pain and pain evoked by mechanical or thermal stimuli. It may be present in the complex regional pain syndrome (CRPS) type I and type II and in other pain syndromes. The concept of involvement of the (efferent) sympathetic nervous system in the generation of pain is based on various clinical observations that have been documented in the literature for decades. Representative of these multiple observations on patients with pain in which the sympathetic nervous system is causally involved are the following groups of experimental and clinical findings involving patients who had SMP:

- Blockade of impulse transmission in sympathetic paravertebral ganglia may relieve spontaneous pain as well as mechanical and cold allodynia in patients with CRPS.

Table 1 Sympathetic nervous system and the generation of pain

Sympathetic–afferent coupling in the periphery[a]
• Coupling after nerve lesion (noradrenaline, α-adrenoceptors)
• Coupling via the micromilieu of the nociceptor and the vascular bed
• Sensitization of nociceptors mediated by sympathetic terminals, independent of excitation and release of noradrenaline
• Sensitization of nociceptors initiated by cytokines or nerve growth factor and mediated by sympathetic terminals
• Sympathoadrenal system and nociceptor sensitization
Role of the sympathetic nervous system in inflammation and hyperalgesia[b]
• Complex regional pain syndromes and sympathetic nervous system
• Immune system and sympathetic nervous system
• Rheumatic diseases and sympathetic nervous system
• Systemic chronic pain and sympathetic nervous system (e.g., fibromyalgia)

Figure 2 Concept of generation of peripheral and central hyperexcitability during inflammatory pain or neuropathic pain involving the sympathetic nervous system (CNS, central nervous system; PNS, peripheral nervous system). The pain is always associated with motor, autonomic, and endocrine responses. The upper dashed arrow indicates that the central changes are generated (and possibly maintained) by persistent activation of nociceptors with unmyelinated (C) fibers (e.g., during chronic inflammation), called here 'central sensitization,' or after trauma with nerve lesion by ectopic activity in myelinated (Aδ, Aβ) and C-afferents and other changes in the lesioned afferent neurons, called here 'central hyperexcitability.' The lower dashed arrow, in red, indicates the efferent feedback via the sympathetic nervous system (including the sympathoadrenal system). The transmission of nociceptive impulses is under multiple control of the brain (clear arrows, upper right). Primary afferent nociceptive neurons (in particular those with C-fibers) are sensitized during inflammation. After nerve lesion, all lesioned primary afferent neurons (unmyelinated as well as myelinated ones) undergo biochemical, physiological, and morphological changes, which become irreversible with time. These peripheral changes entail changes of the central representations (of the somatosensory system), which become irreversible if no regeneration of primary afferent neurons to their target tissue occurs. The central changes, induced by persistent activity in afferent nociceptive neurons or after nerve lesion, are also reflected in the sympathetic efferent feedback system that may establish positive feedback loops to the primary afferent neurons.

- Long after limb amputation, injection of adrenaline or physiological doses of noradrenaline around a stump neuroma may be intensely painful, compared to saline injection.
- Intraoperative electrical stimulation of the sympathetic chain may increase pain in patients with CRPS type II but not in patients with hyperhydrosis.

- In patients with CRPS or posttraumatic neuralgias, intracutaneous application of noradrenaline in a symptomatic area rekindles spontaneous pain and dynamic mechanical and cold allodynia that has been relieved by sympathetic blockade. This supports the idea that human nociceptors, after partial nerve lesion, develop noradrenergic sensitivity which can be maintained over several years.
- Some patients with postherpetic neuralgia experience increased spontaneous pain and mechanical hyperalgesia/allodynia after intracutaneous injection of adrenaline or phenylephrine (an α_1-adrenoceptor agonist).
- Patients with CRPS type I and SMP experience more spontaneous pain and mechanical allodynia when sympathetic cutaneous vasoconstrictor neurons are activated by cold stress.

These findings on patients with SMP are interpreted as follows (Figure 2): primary afferent nociceptive neurons are excited or possibly sensitized by noradrenaline released by sympathetic postganglionic fibers; these nociceptors may have expressed α-adrenoceptors, or their increased excitability may be generated indirectly – for example, by decrease of blood flow and subsequent ischemia or by other components modulated by sympathetic fibers. However, the mechanisms underlying SMP in the patients with nerve lesion could be rather different. In these patients, following nerve lesion (whether induced mechanically, metabolically, or by a virus), the lesioned primary afferent neurons and corresponding central representations (e.g., in the dorsal horn, thalamus, and cortex) may undergo dramatic biochemical, morphological, and physiological changes. Sympathetic coupling to afferent neurons with large-diameter axons may now be important, since activity in these neurons could generate central hyperexcitability and feed into central circuits that have changed as a consequence of the peripheral nerve lesion.

SMP following Nerve Lesion Simulated in Behavioral Animal Models

In animals (rats), signs of pain are measured by quantifiable behavioral components; examples of such behaviors include paw withdrawal latency in reaction to thermal noxious stimulation (heat, cold), frequency and threshold of paw withdrawal in reaction to mechanical stimulation, degree of self-mutilation (autotomy), or spontaneous lifting and licking of paws. These reactions are interpreted as equivalent to mechanical or thermal hyperalgesia or allodynia or spontaneous pain in humans. Behavioral models allow to test whether the sympathetic nervous system contributes to these hyperalgesic/allodynic behaviors or to spontaneous pain behavior. Animals are given clinically relevant nerve lesions, and behavioral experiments are performed before and after interventions aimed at targeting the sympathetic supply of the affected extremity. The strengths of these models include the range of possible experimental manipulations performed at the sympathetic nervous system and the ability to use different strains of animals or transgenic animals. Quantitative data obtained in these behavioral experiments lead to the formulation of hypotheses that can be tested in reduced experiments *in vivo* and *in vitro* using various methodical approaches.

Several rat models of neuropathic pain involving controlled nerve lesions have been used to determine the contribution of the sympathetic nervous system to neuropathic pain (Table 2). The interventions included surgical or chemical sympathectomy; systemic or local application of adrenoceptor blockers, including phentolamine (α_1, α_2), prazosin (α_1), or yohimbin (α_2), or of adrenoceptor agonists, including phenylephrine (α_1) or clonidine (α_2); and intraperitoneal application of guanethidine, which is taken up by the noradrenergic terminals and depletes noradrenaline.

Overall, the results obtained using these rat behavioral models of nerve injury were somewhat disappointing and disconcerting, since they did not lead to straightforward answers. The controversial results from these models provide conflicting evidence on the role of the sympathetic nervous system in generating pain behavior, indicating that behavioral animal models must be designed with utmost care. Small changes in the experimental procedures may create major behavioral changes. Behavioral testing should be performed in a blinded fashion if possible, and the models must be designed in close association with the clinical situation to be certain to test what is intended to be tested. The results of systemic pharmacological interventions (e.g., application of adrenoceptor agonists or antagonists, guanethidine, or chemical sympathectomy with 5-hydroxydopamine) do not necessarily allow functional interpretations, partly because of the widespread systemic effects of these agents. Finally, the controversial results obtained from the animal behavior models may argue that the models do not reflect SMP as defined clinically.

This controversial situation does not mean that behavioral animal models are useless and cannot simulate the clinical situation. On the contrary, there are good reasons to assume that we are dependent on the design of these animal models if we want to unravel the mechanisms behind the different types of pathological pain in which the sympathetic nervous system is involved. However, a single model

Table 2 Nerve lesion animal (rat) models to study sympathetically maintained pain[a]

Model	*Nerve lesion*	*Behavioral measurements*	*Intervention at the sympathetic supply*	*Results*

cannot be expected to represent SMP in different groups of patients. Furthermore, the animal models so far tested are related to nerve lesions. Rat models simulating SMP in patients with pain states developing after trauma without nerve lesion (see Table 1) practically do not exist (e.g., for patients with CRPS type I).

Effects of Sympathetic Postganglionic Neurons on Afferent Neurons

Physiologically sympathetic postganglionic neurons do not directly excite primary afferent neurons innervating skin or deep somatic tissues. Some small effects may occur indirectly (e.g., via the vascular bed and subsequent changes of blood flow). The situation may change under pathophysiological conditions: excitation of sympathetic neurons may activate or sensitize afferent neurons. Furthermore, sympathetic postganglionic terminals may mediate sensitization of nociceptive afferents for mechanical stimulation during inflammation. Finally, the sympathoadrenal system may be involved in the sensitization of nociceptors for mechanical stimulation. The ways of sympathetic–afferent coupling discussed in the following sections are schematically illustrated in Figure 3.

Coupling between Lesioned Postganglionic and Afferent Nerve Terminals

Subsequent to nerve section or ligation, a few afferent myelinated and unmyelinated nerve fibers ending in a neuroma can be excited following electrical stimulation of the sympathetic supply or by noradrenaline or adrenaline injected systemically. The coupling occurs in young neuromas but less so in old ones, weeks and months after nerve lesion. The frequency of electrical stimulation, applied to the sympathetic trunk, necessary to excite the lesioned afferent nerve fibers is high. Physiologically sympathetic neurons do not discharge at these frequencies. Clinically, neuroma

Figure 3 Ways hypothesized to couple sympathetic and primary afferent neurons following peripheral nerve lesion (a) or during inflammation (b–d). (a) These types of coupling depend on the activity in the sympathetic neurons and on functional adrenoceptors expressed by the afferent neurons, or are mediated indirectly via the blood vessels (blood flow). Coupling can occur in the periphery (1), in the dorsal root ganglion (3), or possibly also in the lesioned nerve (2). (b) The inflammatory mediator bradykinin acts at B_2 receptors in the membrane of the sympathetic varicosities or in cells upstream of these varicosities, inducing release of prostaglandin E_2 (PGE_2) and sensitization of nociceptors. This way of coupling is probably not dependent on activity in the sympathetic neurons. (c) Nerve growth factor released during an experimental inflammation reacts with the high-affinity receptor TrkA, in the membrane of the sympathetic varicosities, inducing release of an inflammatory mediator (or mediators) and sensitization of nociceptors. This effect is probably not dependent on activity in the sympathetic neurons. (d) Activation of the adrenal medulla by sympathetic preganglionic neurons leads to release of adrenaline, which generates sensitization of nociceptors. The question mark in (b) and (c) indicates that PGE_2 or other inflammatory mediators may be released by cells other than the sympathetic varicosities. Adapted from Jänig W and Häbler H-J (2000) Sympathetic nervous system: Contribution to chronic pain. *Progress in Brain Research* 129: 453–470.

pain is usually not dependent on sympathetic activity. Histological observations show that catecholamine-containing axon profiles are rare within the neuroma and for several centimeters proximal to it. The coupling is chemical and occurs via noradrenaline acting on α-adrenoceptors, although other mediator substances may also be involved. Ephaptic coupling between sympathetic fibers and afferent fibers has so far not been observed in a neuroma.

The situation is different when afferent and sympathetic fibers are allowed to regenerate to the target tissue. This has been shown experimentally for the chronic situation more than a year after cross-union of nerves (e.g., adaptation of the proximal stump of the sural or superficial peroneal nerve to the distal stump of the tibial nerve, in the cat) and after reinnervation of appropriate and inappropriate target tissues. In these cases, unmyelinated afferent fibers may be vigorously excited by electrical low-frequency stimulation of the sympathetic supply. This excitation is adrenoceptor mediated (Figure 4). It can be mimicked by adrenaline or noradrenaline and blocked by α-adrenoceptor blockers (e.g., phentolamine).

Coupling between Unlesioned Postganglionic and Afferent Nerve Terminals following Partial Nerve Lesion

Intact C-fiber polymodal nociceptors in skin may develop sensitivity to catecholamines following partial nerve injury. Sympathetic nerve stimulation and noradrenaline may excite the polymodal nociceptors or sensitize them for heat stimuli. The activation and sensitization are already seen 4–10 days after partial nerve lesion and are maintained for at least 150 days. This sympathetic–afferent coupling apparently involves the nonlesioned polymodal nociceptive afferent axons that project through the lesion site, and nonlesioned postganglionic axons. It is suggested that the unlesioned unmyelinated afferents develop hyperreactivity to catecholamines following degeneration of the sympathetic postganglionic axons. Expression of adrenoceptors in afferent fibers may be triggered by collateral sprouting of both afferent fibers and postganglionic fibers in the target tissue. However, activation or sensitization of nociceptors via sympathetic–afferent coupling requires sympathetic stimulation at high non-physiological frequencies.

Coupling in the Dorsal Root Ganglion and Collateral Sprouting following Peripheral Nerve Lesion

Chemical sympathetic–afferent coupling following peripheral nerve lesion (e.g., of a spinal nerve, the sciatic nerve, or another limb nerve) may occur proximally to the injury site in the nerve or in the dorsal root ganglion (DRG; Figure 3(a), site 3). Sympathetic postganglionic fibers reach the spinal nerves via gray rami. Most of these fibers project distally to

Figure 4 Sympathetic–afferent coupling after nerve lesion, with subsequent fiber regeneration. Excitation of unmyelinated afferent fibers by electrical stimulation of sympathetic fibers following nerve injury. Unmyelinated primary afferents were recorded in cats 11–20 months after the central cut stump of the sural or superficial peroneal nerve (both skin nerves) had been adapted to the distal stump of the transected tibial nerve (mixed nerve). This preparation was designed to mimic the consequences of lesion of a mixed nerve. A 'neuroma-in-continuity' at the lesion site was present, and cutaneous nerve fibers had regenerated into skin and deep somatic tissue supplied by the mixed nerve. (a) Experimental setup. Post, postganglionic; pre, preganglionic; stim, stimulation; rec, recording; LST, lumbar sympathetic trunk. (b) The afferent fibers were identified as unmyelinated by electrical stimulation of the neuroma with single pulses. The signal indicated by the red dot was recorded from the same afferent fiber as in (c) and (d). (c) Record from a single unmyelinated afferent fiber. Supramaximal stimulation of the LST with trains of 30 pulses at 1–5 Hz (trains and stimulation artifacts indicated by bars). Note that the afferent fiber had some low rate of ongoing activity (impulses before the trains at 1 and 4 Hz) and a second fiber was activated at 5 Hz stimulation (marked by an asterisk). (d) Adrenaline (5 μg, injected intravenously) activated the fiber. Angiotensin (0.2 μg, injected intravenously) generated a large increase of mean arterial blood pressure but did not activate the afferent fiber. (e) Stimulus response curves for the single afferent fiber (□) and four filaments containing two or three (●,▲/▼) and more than five (■) afferent fibers. Ordinate scale is the total number of impulses (imp) exceeding ongoing activity in response to variable stimulation frequency of the LST. Adapted from Häbler H-J, Jänig W, and Koltzenburg M (1987) Activation of unmyelinated afferents in chronically lesioned nerves by adrenaline and excitation of sympathetic efferents in the cat. *Neuroscience Letters* 82: 35–40.

peripheral target cells; some project proximally (e.g., to the DRG) and are normally found along blood vessels. After an experimental nerve lesion (e.g., transection and ligation of the sciatic nerve in rats), many perivascular catecholamine-containing axons of the unlesioned proximally projecting neurons start to sprout in the DRGs which contain somata with lesioned axons. The extent of this collateral sprouting increases with time after nerve lesion. For more than 70 days after nerve lesion, some somata are partially or almost completely surrounded by varicose catecholaminergic terminals, and the frequency of these catecholamine-fluorescent structures increases. The noradrenergic axons sprout preferentially to axotomized large-diameter afferent cell bodies.

Afferent neurons projecting in the lesioned nerve can be excited or depressed in their activity via the DRG by electrical stimulation of sympathetic neurons and by catecholamines:

1. In the first 2–3 weeks after nerve lesion, most A-fiber neurons with spontaneous activity and only very few silent A-fiber neurons are excited, yet the spontaneous activity is not maintained by

activity in sympathetic neurons. The sympathetically evoked activity in afferent neurons probably is partly mediated indirectly by ischemia in the DRG. When the catecholaminergic sprouting in the DRG is more prominent at later time periods, most spontaneously active A-fiber neurons are inhibited during stimulation of the sympathetic supply, but are rarely excited.
2. Only very few afferent neurons with unmyelinated axons respond to electrical stimulation of the sympathetic trunk; most of them are inhibited in their activity.
3. The coupling from sympathetic postganglionic fibers to afferent cell bodies in the DRG occurs only to spontaneously active muscle afferent neurons with Aδ-fibers.
4. Activation of the afferent neurons, via the DRG, requires high-frequency stimulation of the sympathetic neurons at 5–20 Hz, discharge rates that occur rarely or not at all physiologically.
5. Noradrenaline and preferentially α_1-adrenoceptors are involved in sympathetic–afferent coupling in the DRG.
6. Mechanical allodynic/hyperalgesic behavior shown by rats with L5 spinal nerve injury (transection and ligation) is not dependent on the innervation of the DRG by sympathetic neurons.

The mechanism leading to the collateral sprouting of postganglionic noradrenergic fibers in the DRG is possibly related to neurotrophic signals (and their receptors), generated by afferent cells with lesioned axons in the DRG and the surrounding satellite glia cells. Whether these aberrant pathological connections can account for spontaneous pain and allodynia in some patients after peripheral nerve lesions awaits further investigations.

Indirect Involvement of the Sympathetic Nervous System in the Generation of Pain

Modulation of Excitability of the Nociceptive Afferent by Its Micromilieu

Nociceptive afferents are embedded in a complex micromilieu (Figure 5). The state of this micromilieu surrounding the receptive terminals depends on mediator substances, released during inflammatory processes following trauma, from nonneural cells such as mast cells, polymorphonuclear leucocytes, macrophages, fibroblasts, endothelial cells, or other cells. The microcirculation is under neural control of sympathetic vasoconstrictor neurons. Activation of subgroups of nociceptive primary afferents not only causes orthodromic impulse traffic but also arteriolar (precapillary) vasodilation and (in most tissues, but not in human skin) venular plasma extravasation by release of neuropeptides from the receptive terminals (e.g., substance P and calcitonin-gene-related peptide). Both afferent-induced changes are called collectively 'neurogenic inflammation.' This shows that there are possibilities for indirect coupling between sympathetic and afferent nerve terminals:

1. Vascular perfusion of the micromilieu surrounding the nociceptors after nerve trauma may change as consequences of denervation and reinnervation by postganglionic vasoconstrictor neurons and afferent nociceptive neurons.
2. Hyperreactivity of blood vessels to activity in sympathetic neurons or circulating catecholamines may develop.
3. Blood vessels exhibit changes in vasodilation in response to antidromic activation of reinnervated peptidergic unmyelinated afferents. Thus, after a nerve lesion, reinnervated blood vessels may be under stronger than normal vasoconstrictor influence, which can no longer be counteracted by an afferent-mediated vasodilation. *In vitro* investigation of the rat tail artery has shown that the functional recovery of neurovascular transmission is permanently compromised after nerve lesion.
4. Nociceptors may be sensitized by inflammatory mediators such as prostaglandins and interleukins, the release of which from nonneuronal cells of the micromilieu may be mediated by noradrenergic nerve terminals.

Sensitization of Nociceptors Mediated by Sympathetic Terminals Independent of Excitation and Release of Noradrenaline

Following a single intradermal injection of the inflammatory mediator bradykinin into the dorsal skin of the rat paw, the withdrawal threshold to mechanical stimulation of the rat hindpaw decreases dose dependently for more than 1 h. This type of mechanical hyperalgesic behavior is mediated by the B_2 bradykinin receptor. In normal rats, bradykinin-induced hyperalgesic behavior is blocked by the cyclooxygenase inhibitor indomethacin and therefore is mediated by a prostaglandin (probably prostaglandin E_2) that sensitizes nociceptors for mechanical stimulation.

The decrease in paw withdrawal threshold in response to mechanical stimulation generated by intradermal injection of bradykinin is significantly reduced after surgical sympathectomy. Decentralization of the paravertebral sympathetic ganglia (denervating the postganglionic neurons by cutting the preganglionic sympathetic axons) does not abolish the bradykinin-induced mechanical hyperalgesic behavior (Figure 6). This indicates that the sensitizing effect

Figure 5 (a, b) The micromilieu of nociceptors. The microenvironment of primary afferents is thought to affect the functional properties of the receptive endings of myelinated (Aδ) and unmyelinated (C) afferent fibers with nociceptive function. This has been particularly documented for inflammatory processes. The vascular bed consists of arterioles (directly innervated by sympathetic and afferent (Aδ and C) fibers), capillaries (not innervated and not influenced by nerve fibers), and venules (not directly innervated, but influenced by nerve fibers). The micromilieu depends on several interacting components. Neural activity in postganglionic noradrenergic fibers (1) supplying blood vessels (3) causes release of noradrenaline (NAd) and possibly other substances causing vasoconstriction. Excitation of primary afferents (Aδ- and C-fibers; 2) causes vasodilation in precapillary arterioles and plasma extravasation in postcapillary venules (C-fibers only) by the release of substance P (SP) and other vasoactive compounds (e.g., calcitonin gene-related peptide). Some of these effects may be mediated by nonneuronal cells, such as mast cells (MC; 4) and macrophages (MP; 5). Other factors that affect the control of the microcirculation are the myogenic properties of arterioles (3) and more global environmental influences, such as a change of the temperature and the metabolic state of the tissue. Hypothetical relation (shown in b) between sympathetic noradrenergic nerve fibers (1), peptidergic afferent nerve fibers (2), blood vessels (BV; 3), and macrophages (4). The activated and sensitized afferent nerve fibers activate macrophages (via substance P release). The immune cells start to release cytokines, such as tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1), which further activate afferent fibers by enhancing sodium influx into the cells. Substance P (also calcitonin gene-related peptide; not shown) released from the afferent nerve fibers reacts with neurokinin-1 (NK) receptors (calcitonin gene-related peptide receptors) in the blood vessels (arteriolar vasodilation, venular plasma extravasation; neurogenic inflammation). The sympathetic nerve fibers interact with this system potentially on three levels: via adrenoceptors (mainly α) on the blood vessels (vasoconstriction), via adrenoceptors (mainly β) on macrophages (further release of cytokines), and via adrenoceptors (mainly α) on afferents (further sensitization of these fibers). Adapted from Jänig W and Baron R (2003) Complex regional pain syndrome: Mystery explained? *Lancet Neurology* 2: 687–697.

of bradykinin is not dependent on activity in the sympathetic neurons innervating skin, and therefore also not on release of noradrenaline, and that bradykinin stimulates the release of prostaglandin from the sympathetic terminals or from other cells in association with the sympathetic terminals in the skin (Figure 3(b)). Mechanical hyperalgesic behavior generated by intracutaneous injection of bradykinin, with its dependence

Figure 6 Mechanical hyperalgesic behavior and sympathetic innervation. Cutaneous nociceptors on the dorsum of the paw are stimulated by a linearly increasing mechanical force. Paw withdrawal threshold is defined as the mean (+S.E.M.) minimum force (in grams, ordinate scale) at which the rat withdraws its paw. Abscissa scale: log dose of bradykinin (in nanograms) injected in a volume of 2.5 μl of saline into the dermis of the skin. Decrease of paw withdrawal threshold in response to mechanical stimulation induced by intradermal injection of bradykinin in sham-sympathectomized (control) rats (●, six hindpaws), in surgically sympathectomized rats (lumbar paravertebral ganglia L2–L4 removed 8 days before; □, 12 hindpaws), and in rats with decentralized lumbar sympathetic chains (section of white rami with preganglionic axons to paravertebral ganglia L2 and L3 and chain rostral to ganglion L2 8 days before; ◆, ten paws). Sham sympathectomy and sympathetic decentralization were both significantly different from sympathectomy groups at doses of bradykinin of 10^2 and 10^3 ng (Δ, $P < 0.01$). Adapted from Khasar SG, Miao FJ-P, Jänig W, et al. (1998) Modulation of bradykinin-induced mechanical hyperalgesia in the rat skin by activity in the abdominal vagal afferents. *European Journal of Neuroscience* 10: 435–444.

on the sympathetic innervation of the skin, is an interesting phenomenon. However, the idea that it is due to prostanoids sensitizing nociceptors (since indomethacin prevents it) appears to be too simple. The reasons for this are that (1) sympathetic fibers mediate this hyperalgesia, independent of neural activity and release of noradrenaline; (2) indomethacin does not block this behavior under certain conditions (e.g., when the adrenal medullae are activated after vagotomy or after sound stress); (3) sensitization by bradykinin of nociceptive afferents innervating deep somatic tissues, in response to mechanical stimulation, has been demonstrated in neurophysiological experiments in the cat, yet not in humans, for cutaneous pain; and (4) in skin, there is a spatial dissociation between afferent nociceptive fibers and sympathetic fibers, many of the former ending in the epidermis and subepidermal plexus, whereas most of the latter terminate in deeper dermal layers, raising the question as to the nature of the interaction between both groups of fibers.

Sensitization of Nociceptors Initiated by Nerve Growth Factor or Cytokines, Possibly Mediated by Sympathetic Terminals

Based on behavioral and pharmacological experiments it has been deduced that nociceptive afferents can be sensitized by nerve growth factor (NGF) or proinflammatory cytokines involving noradrenergic sympathetic postganglionic fibers. The underlying mechanisms of such interactions are largely unknown and have to be worked out by recording the activity of nociceptor neurons with electrophysiological techniques.

NGF Systemic injection of NGF is followed by a transient thermal and mechanical hyperalgesia in rats and humans. During experimental inflammation (evoked by Freund's adjuvant in the rat hindpaw), the concentration of NGF increases in the inflamed tissue, paralleled by the development of thermal and mechanical hyperalgesia. Both are prevented by anti-NGF antibodies. The mechanisms responsible are sensitization of nociceptors via high-affinity NGF receptors (TrkA receptors) and an increased synthesis of calcitonin-gene-related peptide (CGRP) and substance P in the afferent cell bodies; the latter is induced by NGF being taken up by the afferent terminals and transported to the cell bodies. The NGF-induced sensitization of nociceptors, or part of it, also seems to be mediated indirectly by the sympathetic postganglionic terminals. In rats, heat and mechanical hyperalgesic behavior generated by local injection of NGF into the skin are significantly reduced after chemical or surgical sympathectomy. These experiments suggest that NGF released during inflammation by inflammatory cells acts on the sympathetic terminals via high-affinity TrkA receptors, inducing the release of inflammatory mediators (the source of which is unknown) and subsequently the sensitization of nociceptors for mechanical and heat stimuli (Figure 3(c)). It is unclear whether this sensitization of nociceptors mediated by terminal sympathetic nerve fibers is dependent on or independent of neural activity in the sympathetic neurons, release of noradrenaline, and adrenoceptors expressed in the nociceptive afferent neurons.

Proinflammatory cytokines Tissue injury, injection of the bacterial cell wall endotoxin lipopolysaccharide,

Figure 7 Long-term enhancement of bradykinin(BK)-induced mechanical hyperalgesia after activation of the adrenal medullae (by vagotomy) and its disappearance after denervation of the adrenal medullae (AM). (a) Decrease of paw withdrawal threshold in response to mechanical stimulation of the dorsum of the rat hindpaw induced by BK injected intradermally (BK-induced behavioral mechanical hyperalgesia), in sham-vagotomized rats (●, $n = 18$), in vagotomized rats (Δ, $n = 16$; 7 days after subdiaphragmatic vagotomy), in rats with denervated adrenal medullae (■, $n = 6$), and in vagotomized rats with denervated AM (□, $n = 6$) (for details, see **Figure 6** caption). (b) Total change of paw withdrawal threshold (baseline plus BK-induced) in response to intradermal injection of 1 ng of BK in rats before and 7–35 days after sham vagotomy (●, $n = 8$), before and 7–35 days after vagotomy (Δ, $n = 6$), and in rats whose AM are denervated 14 days after vagotomy and for measurements taken up to 35 days after initial surgery (▲, rats tested after vagotomy and denervation of the AM, $n = 6$; ▼, rats only tested after additional denervation of the AM, $n = 4$). Note that 1 ng of BK injected intradermally does not significantly change the paw withdrawal threshold in rats with intact vagus nerves (see a); *, $p < 0.01$, ▲/Δ vs. ● on day 7; +, $p > 0.05$, ▲/▼ vs. ● on days 28 and 35; #, $p < 0.01$, ▲/▼ vs. Δ on days 28 and 35. (c) Schematic diagram showing the proposed spinal cord and brain stem neural circuits which modulate nociceptor sensitivity via the sympathoadrenal system (adrenal medulla). Sensitivity of cutaneous nociceptors for mechanical stimulation is modulated by adrenaline released by the AM. Activation of the AM increases the sensitivity of the nociceptors. Activity in preganglionic neurons innervating the AM depends on activity in vagal afferents from the small intestine; this activity has an inhibitory influence on the central pathways to these preganglionic (preggl) neurons. Thus, interruption of the vagal afferents leads to activation of the AM. It is hypothesized that these neuronal (reflex) circuits in the brain stem are under the control of upper brain stem, hypothalamus, and telencephalon. Dotted lines indicate axons of sympathetic premotor neurons in the brain stem which project through the dorsolateral funiculi of the spinal cord to the preganglionic neurons of the AM; NTS, nucleus tractus solitarii; +, excitation; − , inhibition. Adapted from Khasar SG, Miao FJ-P, Jänig W, et al. (1998) Vagotomy-induced enhancement of mechanical hyperalgesia in the rat is sympathoadrenal-mediated. *Journal of Neuroscience* 18: 3043–3049.

or injection of carrageenan (a plant polysaccharide) stimulate tissue inflammation and lead to a sensitization of nociceptors that is reflected in mechanical or heat hyperalgesia. Systematic pharmacological interventions using blockers or inhibitors of the various mediators demonstrate that the proinflammatory cytokines tumor necrosis factor-α (TNF-α) and interleukins (IL-1, IL-6, and IL-8) may be involved in this process of nociceptor sensitization. Pathogenic stimuli activate resident cells, with release of inflammatory mediators, including bradykinin. Activation of macrophages, monocytes, and other immune-related cells leads to release of TNF-α. Nociceptors are believed to be sensitized by two possible pathways: (1) TNF-α induces production of IL-6 and IL-1β by immune cells. These interleukins stimulate cyclooxygenase-2 and the production of prostaglandins E_2 and I_2 (PGE_2, PGI_2), which in turn react with the nociceptive terminal via E-type prostaglandin receptors. (2) TNF-α induces the release of IL-8 from endothelial cells and macrophages. IL-8 reacts with the sympathetic terminals that are supposed to mediate sensitization of nociceptive afferent terminals by release of noradrenaline, to act via β_2-adrenoceptors. These two peripheral pathways by which nociceptive afferents are hypothesized to be sensitized involving cytokines are under inhibitory control of anti-inflammatory interleukins (e.g., IL-4 and IL-10) and circulating glucocorticoids.

Sympathoadrenal System and Nociceptor Sensitization

Activity of the sympathoadrenal system (adrenal medullae) is regulated by central circuits that are different from those regulating other sympathetic systems. Activation of this system (Figure 7(c)), but not of the sympathoneural system, generates mechanical hyperalgesia and enhances bradykinin-induced mechanical hyperalgesia (decrease of paw withdrawal threshold in response to mechanical stimulation of the skin; compare • and Δ in Figure 7(a)). Both develop slowly over 7–14 days during continuous activation of the adrenal medullae (AM; e.g., induced by subdiaphragmatic vagotomy) and are maintained over the 35-day test period (Δ in (Figure 7(b)). In rats with denervated AM (adrenal nerves with preganglionic axons innervating the cells of the AM sectioned; (Figure 7(c)), subdiaphragmatic vagotomy has only a small effect (□ and ■ in Figure 7(a)), generated by removal of inhibition of nociceptive impulse transmission in the spinal dorsal horn (Figure 7(c)). Denervation of the AM, 14 days after vagotomy, when the decrease of paw withdrawal threshold is maximal, is followed by a slow increase of paw withdrawal threshold, taking more than 3 weeks (▲ and ▼ in Figure 7(b)). Thus, the decrease of paw withdrawal threshold following vagotomy is reversed after denervation of the AM. Application of adrenaline through a minipump for 3–14 days slowly enhances the development of mechanical hyperalgesia induced by bradykinin injected intradermally. Continuous application of a β_2-adrenoceptor blocker over 7–14 days by way of a minipump prevents the enhancement of this hyperalgesic behavior generated by activation of the AM.

The results of this experiment imply that adrenaline released by persistent activation of the AM sensitizes cutaneous nociceptors for mechanical stimuli. This sensitization of nociceptors and its reversal are slow and take days to develop. The slow time course implies that the nociceptor sensitization cannot be acutely blocked by an adrenoceptor antagonist given intracutaneously or systemically. Adrenaline probably does not act directly on the cutaneous nociceptors but instead acts on cells (e.g., mast cells, macrophages, or keratinocytes) in the microenvironment of the nociceptors. These cells then release substances that induce slow changes, generating nociceptor sensitization. Change in the sensitivity of a population of nociceptors, generated by adrenaline released by the AM, regulated by the brain, would be a novel mechanism of sensitization, different from mechanisms that lead to activation and/or sensitization of nociceptors by sympathetic–afferent coupling, as discussed earlier (Figure 3(d)).

This peripheral mechanism of pain and hyperalgesia involving adrenaline released by the sympathoadrenal system and acting on nociceptors may operate in ill-defined pain syndromes such as irritable bowel syndrome, functional dyspepsia, fibromyalgia, and chronic fatigue syndrome. Conclusions about long-term sensitization of nociceptors for mechanical stimulation by adrenaline fully rest on behavioral experiments. Neurophysiological experiments *in vivo* on primary afferent nociceptive neurons are required to test directly whether all or only a subpopulation of nociceptors are sensitized.

Pain Management

Introduction

Advances in neuroscience and psychology over the past 30 years have revolutionized our understanding of the reasons for the variability and complexity of pain and have provided new evidence-based treatment options. Pain is now viewed as a complex perception associated with an array of interactions at the level of the peripheral and central nervous systems, involving sensory, emotional, cognitive, and environmental factors. Instead of treating pain report in isolation, there is a range of treatment options available to the multidisciplinary pain management team, targeting relevant outcomes such as function, mood, quality of life, acceptance of pain, and optimal adjustment to persisting pain. A number of key events in the evolution of pain management as a specialty should be noted. The establishment of the first multidisciplinary pain clinic in Seattle at The University of Washington in 1960 by Professor John Bonica led to widespread recognition of this approach. The publication of the 'gate control' theory of pain in 1965 by Melzack and Wall was significant for two reasons: it recognized the role of the spinal cord in modulation of signals from both nociceptors in the periphery and descending pathways and highlighted the potential role of psychological factors in activating descending pain-inhibitory pathways. Since the establishment of the International Association for the Study of Pain in 1974, this organization has attracted over 6000 members from a range of disciplines in more than 80 countries. Chronic pain has been described as the 'hidden epidemic' affecting one in five adults, up to 80% of patients with advanced cancer, and in AIDS the estimated prevalence is 30–80%. Based on the wealth of scientific research available, it has been proposed that persistent pain is a disease entity and warrants the same health focus as other major diseases such as diabetes and cancer. Linked to this is the call to recognize evidence-based treatment of pain as a basic human right, as studies consistently show that pain is often undertreated even when resources are available.

Acute Pain

'Everyday' acute pain is associated with stimulation of nociceptors, which are peripheral sensory receptors on Aδ and C-fibers. Other Aδ and C-fibers, called 'silent nociceptors,' are only activated by noxious stimuli in the presence of tissue damage. Nociceptors convert a range of noxious environmental stimuli (thermal, mechanical, and chemical) into action potentials that reflect the intensity and duration of the insult. The effect on nociceptors is mediated through a wide range of inflammatory mediators, including ATP, bradykinin, prostinoids, serotonin, histamine, and hydrogen ions (tissue acidosis). Nociception is not pain, as pain can only be experienced by the conscious brain. Diagnosis is usually straightforward in acute pain, as there is usually broad concordance between symptoms, physical signs, and pathology; however, there is no direct relationship between the amount of tissue injury and pain. Acute pain is typically dull and aching and anatomically related to the area of pathology. Acute pain usually resolves in a predictable period once the noxious stimulus is removed and normal healing progresses. Multimodal analgesic and interventional techniques which target different mechanisms contributing to the pain are recommended for moderate to severe pain to reduce side effects associated with individual drugs, in particular opioids. Options include drugs such as nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, ketamine, gabapentin, wound infiltration, regional local anesthetic blocks and spinal opioid administration. Uncontrolled acute pain should rarely be a clinical problem except in special cases, such as the patient with previous trauma to the tissues (e.g., surgery or injury), incomplete healing, persistent inflammation, or nerve injury (either peripheral or central), and those on large doses of opioid medication, or if there is a history of substance abuse. In these cases factors such as peripheral and central sensitization and tolerance may either singly or in tandem result in the heightened experience of pain, and nonstandard analgesic regimes such as a subcutaneous or systemic infusion of ketamine and lignocaine (singly or in combination) may be required.

Chronic or Persistent Pain

Chronic or persistent pain refers to the pain that a significant proportion of patients will continue to experience despite appropriate medical or surgical assessment and intervention. For epidemiological purposes a period of 3 months is taken, but in practical terms chronic pain may be present as early as 2 weeks. Epidemiological studies in different countries are remarkably consistent. Approximately 20% of the population will experience persisting pain, with about half of those patients distressed and disabled.

There are three main categories of factors contributing to chronic pain: nociceptive, neuropathic, and psychological/environmental. Nociceptive pain refers to the pain associated with ongoing tissue damage that can last long after the initial noxious stimulus. Components of this type of pain are involved in the pain of osteoarthritis, rheumatoid arthritis, unhealed fractures, and chronic infections.

A different clinical presentation is associated with neuropathic pain, which is due to damage, disease, or section of the peripheral or central nervous system. Pain descriptors include a range of dysesthetic sensations such as burning, shooting, or electric shocks. The topographical distribution of neuropathic pain tends to be regional rather than dermatomal. For example, in a variant of neuropathic pain, complex regional pain syndrome (CRPS), the dysesthetic pain may occupy the whole of the upper limb following a trivial injury to the hand. Common associated phenomena are allodynia (pain experienced after a nonpainful stimulus – e.g., touching sunburned skin), hyperalgesia (severe pain experienced after a mildly painful stimulus), abnormal motor responses, and disturbance of sympathetic activity such as sweating, swelling, and color change. In the case of persistent low back pain, there may be neuropathic, nociceptive, and psychosocial components contributing to the pain experience. In many cases there will be no evidence of nerve or tissue damage – for example, in CRPS type 1, where ongoing pain is considered to be due to dysfunction of part of the nervous system.

Neuropathic components of pain may be classified according to the etiology of the pain, the anatomical site, or a mechanism-based classification. Such systems have been of variable utility clinically, as it is likely that multiple pain mechanisms are operating simultaneously. Also, as plasticity is an inherent feature of animal and human sensory pathways, neuronal systems involved in the experience of pain may alter over time.

The biomedical model is generally inadequate in cases of persisting pain. The biopsychosocial model proposed by Engel has been widely accepted, as it provides a better analysis of all of the factors contributing to persistent pain. Figure 1 shows the typical factors that inadvertently cause an increase in suffering.

The biopsychosocial model requires that the bio- (medical), psycho- (psychological), and social (environmental) factors are assessed so that all treatable

Figure 1 When chronic pain becomes a problem. Reproduced with permission from MK Nicholas, Pain Management and Research Centre, Royal North Shore Hospital, St. Leonards, NSW, Australia.

factors are identified. A diagnostic formulation and treatment plan are then arrived at after a 'round table' interdisciplinary meeting. A diagnosis may result from the medical assessment, but a formulation looks at the impact of the patient's pain and possible modulating factors. The importance of a formulation lies in the fact that a patient may have the same diagnosis, but the impact in terms of mood, function, and quality of life may be very different.

An important concept is that persistent, physical pain changes the nervous system, and adverse psychological/environmental adaptations become self-sustaining; this process represents a disease entity. Patients with persisting pain should be referred to a pain center as early as possible. Figure 2 is a suggested algorithm.

Cancer Pain

Pain is experienced by approximately 60–80% of patients with advanced cancer. Nociceptive and neuropathic components of pain occur either singly or in combination, as in chronic pain. However, the underlying disease process is usually progressive, resulting in the need for regular reviews and adjustments of the analgesic regime. Analgesic titration is further compounded by drug interactions with other therapeutic agents and by symptoms such as fatigue, constipation, dyspnea, and impaired cognitions. By tailoring multimodal analgesic drug therapy to each patient's needs, at least 85% of patients should experience effective pain relief. Other options include chemotherapy and radiotherapy, which are also associated with pain relief by reducing tumor bulk. Biphosphonates produce morphological change and apoptosis of osteoclasts which are responsible for osteoclast-induced skeletal metastases. Pinning or surgical treatment of fractures may be required, as up to 30% of patients with bony metastases develop long bone fractures.

Breakthrough pain is a heterogeneous group of complaints related to spontaneous neuropathic components, incident pain associated with movement, and pain secondary to fluctuations in analgesic levels. Distinction between these causes is important, as treatment will be different. For incident pains such as associated with dressing changes, a preemptive dose of an opioid, such as immediate-relief morphine, should be taken.

Approximately 10% of patients do not experience adequate pain relief. Therapeutic options must take account of prognosis, location of pain, type of pain, coexistent disease, and psychosocial factors. Traditionally neurolytic blocks were favored but increasingly spinal drug administration is used, which may vary from a percutaneous intrathecal or epidural catheter to an implantable programmable pump. Outcome studies have shown that intrathecal morphine administration is associated with improved pain control, reduced side effects, less use of adjuvant pain medications, and improved survival in a cancer pain population, as compared to standard medical management.

Pharmacological Treatments

The application of evidence-based medicine, the introduction of novel analgesic agents, and the publication of a range of guidelines (e.g., Oxford League Tables) have resulted in a more rational approach to prescribing. A commonly used tool to describe analgesic efficacy is numbers needed to treat (NNT). This is defined as the number of patients who need to receive an analgesic, for one patient to report a predetermined level of pain relief (usually 50%) more than the placebo group. While being a useful tool, few studies provide a cohort of the more than 500 patients needed to calculate a credible NNT. An analgesic with high efficacy has an NNT of 2–3. The flip side is that these measures are not only drug, dose, and context specific but also do not reflect minor and major adverse events (expressed as numbers needed to harm (NNH)).

Acetaminophen

Acetaminophen is one of the most commonly used analgesics worldwide. This drug is available as an oral, rectal, and intravenous preparation. Its mode of action remains undefined. Hypothesis suggest an action on a number of systems, including inhibition of central cyclooxygenases COX-2 and COX-3, modulation of descending serotoninergic pathways, action on the *N*-methyl-D-aspartate (NMDA) receptor, or an action related to nitric oxide. The evidence for the clinical efficacy of acetaminophen is good and it is usually recommended as a first-line analgesic in mild to moderate acute and cancer pain, and as part of a multimodal approach in severe pain. It is regularly combined with other analgesics, such as codeine. It is well tolerated and side effects are rare, except for liver failure associated with an overdose.

NSAIDs

The introduction of a number of selective COX-2 inhibitors (coxibs), in addition to aspirin and the traditional nonselective (COX-1 and COX-2) NSAIDs, has provided a range of new treatment options but has also highlighted a number of concerns over this drug class. All NSAIDs have analgesic, anti-inflammatory,

Figure 2 Algorithm: who and when to refer to a pain clinic. Adapted from Nicholas MK (2004) When to refer to a pain clinic. *Best Practice & Research Clinical Rheumatology* 18(4): 613–629.

and antipyretic actions which result from their action in reducing prostaglandin concentrations both peripherally and centrally. The mechanism of action also explains the range of adverse events witnessed clinically. The principal COX-1 side effects are gastrointestinal (GI) ulceration and bleeding (COX-1 is involved in the production of prostaglandin E_2 and prostacyclin, which have a protective action on the gastric mucosa) and a platelet-inhibiting effect (COX-1 has a role in the production of thromboxane A). The latter

'side effect' is used therapeutically to reduce platelet aggregation and the risk of stroke and myocardial infarction.

Coxibs have the same clinical efficacy as do traditional NSAIDs but are associated with significantly reduced risk of GI complications, although the same renal precautions apply. While they do not interfere with the action of thromboxane A in platelets, the inhibition of prostacyclin in the endothelium may explain the high incidence of thrombogenic adverse events observed with rofecoxib that led to the withdrawal of this drug worldwide. This raised the question as to whether this was a class effect of coxibs. Rofecoxib (methyl sulfone) has a chemical structure different from that of the other coxibs (arysulfonamides), which may explain the clinical differences. Coxibs are still represented in the market by celecoxib (oral preparation) and parecoxib (intravenous administration).

Antidepressants, Systemic Local Anesthetics, and Anticonvulsants

The increasing evidence base showing improved pain control with tolerable side effects has resulted in the antidepressant, systemic local anesthetic, and anticonvulsant groups of drugs being accepted as specific analgesics for neuropathic pain. Most studies have been in painful diabetic neuropathy (PDN) and postherpetic neuralgia (PHN), as these are common neuropathic pain conditions. Use of these drug classes for other neuropathic pain syndromes is on the presumption that similar neurobiological processes are involved, although it is almost certain that a number of mechanisms underlie the majority of neuropathic pain syndromes and that more than one drug may be required. At present there are no widely accepted drug administration algorithms for neuropathic pain and few studies comparing one drug with another or the outcomes associated with multiple drug use.

While almost all studies with tricyclic antidepressants (TCAs) have shown that their use is associated with pain relief, their clinical use is limited by the frequency of associated side effects, which includes dry mouth, constipation, blurred vision, urinary hesitancy, and postural hypotension. This has led to studies on the newer antidepressants, which have a more favorable side effect profile. These include the selective serotonin reuptake inhibitors (SSRIs) and those that inhibit the uptake of both serotonin and noradrenaline (SNRIs). To date the results have not been clear-cut but more evidence is accumulating to support their use.

Anticonvulsants and systemic local anesthetics are drugs which have the ability to suppress ectopic neuronal activity. Initially their use was an extension of their established role in epilepsy but now they are considered as specific analgesics for chronic pain; also more recently a role in acute pain has been identified. Their main action is to differentially suppress spontaneous ectopic neuronal activity at drug concentrations that do not block normal neuronal conduction (approximately 3 times less). In broad terms this effect may be achieved either by drugs such as carbamazepine, lamotrigine, mexiletine, and lignocaine, which block sodium channels, or gabapentin and pregabalin, which also bind to the $\alpha_2\delta$ subunit of the voltage-gated calcium channel. A variety of side effects have been reported, ranging from lightheadedness and dizziness to ataxia, severe skin rashes (lamotrigine), and arrhythmias (mexiletine).

Opioids

Opioids are the mainstay of management of moderate to severe acute pain. In most cases the opioid acts through the μ receptor, which is similar among species, permitting extrapolation from animal studies. Attempts to clinically target the δ receptor, κ receptor, and opioid-like receptor (ORL1) have been largely unsuccessful.

Although morphine has been the traditional first-line drug, there is now a range of opioids available with differing pharmacokinetics and pharmacodynamics. These include fentanyl, codeine, meperidine, oxycodone, hydromorphone, buprenorphine, and methadone. Fentanyl is a synthetic opioid which is up to 100 times more potent than morphine and has rapid onset and offset due to high lipid solubility. Codeine may be administered orally or intramuscularly or in tablet form combined with paracetamol or an NSAID. Meperidine is a synthetic opioid that has a short half-life and is being used less due to problems with addiction and the risk of convulsions with normeperidine, the major metabolite. Oxycodone and hydromorphone are useful alternatives to morphine. Hydromorphone has approximately seven times the potency when given spinally. Methadone is a synthetic opioid with a long and variable half-life. It has been used increasingly in chronic pain management due to an action on the NMDA receptor.

The usual routes of administration are oral or parenteral (subcutaneous, intramuscular, or intravenous). As there is a wide variation in opioid requirements, patient-controlled analgesia (PCA) devices are often used postoperatively to allow patients to titrate opioid doses to their needs. Increasingly the benefits of epidural and intrathecal opioid administration are being recognized.

Side effects of opioids include respiratory depression, nausea, vomiting, endocrine abnormalities, and bowel dysfunction, in particular constipation.

Ziconotide

This peptide is a selective for the N-type calcium channel and is approved by the US Food and Drug Administration (FDA) for intractable pain in those for whom intrathecal infusion is appropriate and who have failed to respond to more conservative measures and intrathecal morphine. This drug has a narrow therapeutic index with side effects such as dizziness, nystagmus, confusion, gait disturbance, and urinary retention.

Ketamine

Glutamate acting through the NMDA receptor in the dorsal horn is associated with amplification and prolongation of nociceptive input, termed 'wind-up.' Central hypersensitivity that results is implicated in persistent pain states. NMDA receptor antagonists, including ketamine, dextrometorphan, and memantine, have been successful in treating clinical pain conditions with significant components of hyperalgesia and allodynia. Ketamine is the most widely used drug in this group and has been used orally, subcutaneously, and intrathecally. Because of actions at other NMDA receptors, particularly in the CNS, side effects are common and include somnolence and dysphoria. Although it has been used intrathecally, concerns have been raised about neurotoxicity.

α_2 Agonists

Clinical efficacy has been demonstrated for α_2 agonists given spinally in nociceptive and neuropathic pain. Although used orally and topically, clonidine is most commonly administered intrathecally, usually in combination with an opioid. Side effects include sedation and hypotension.

Methods of Drug Delivery

Studies have shown that the delivery of both established and new drugs by modern drug delivery devices and novel routes of administration are often associated with improved analgesic outcomes. In a particular patient, contemporary multimodal acute pain management may involve many routes, such as oral, intravenous, and intraspinal drug administration. Although in persistent pain management there is a greater focus on contributing psychosocial aspects, it is important to minimize side effects associated with analgesic therapy so that function can be promoted. Oral administration is recommended if bowel function is normal, or parenteral (subcutaneous, intramuscular, or intravenous) if it is impaired, such as postoperatively. Other routes are generally indicated to shorten the onset of action (e.g., transmucosal or nasal fentanyl), to address concurrent medical problems such as fentanyl patches in short bowel syndrome, to target specific sites (e.g., topical lignocaine patches in postherpetic neuralgia), or to access specific analgesic receptors, such as peripheral or spinal opioid receptors. Low-dose buprenorphine patches, changed every 7 days, provide long-duration, well-tolerated analgesia, particularly in the older age group.

Invasive Treatments

Peripheral Nerve Stimulation

The technique of peripheral nerve stimulation, which is thought to activate large, low-threshold afferent fibers, may be considered when persistent pain is well localized and lead placement in the region of the pain is technically feasible. Drawbacks are that the leads may displace or break. An increasingly common indication is headache due to occipital neuralgia, postherniorraphy nerve pain, and other types of postoperative neuropathic pain. This technique should be avoided where there is a significant central component to the pain.

Spinal Cord Stimulation

Highly sophisticated systems are now available to electrically stimulate parts of the spinal cord and brain. The proposed mechanism of action of spinal cord stimulation (SCS) is a combined activation of descending inhibitory pathways and release of a cascade of neuroactive substances in the region of stimulation, particularly γ-aminobutyric acid (GABA). Nociceptive pain is poorly responsive to SCS, but conditions such as neuropathic pain, ischemic limb, cardiac pain, and CRPS are accepted indications. There is a significant incidence of complications, in particular infection, lead breakage, and electrode movement.

Deep Brain and Motor Cortex Stimulation

Deep brain stimulation and motor cortex stimulation have been used for pain that has been unresponsive to all other therapeutic modalities. Deep brain stimulation usually involves stimulation of the sensory thalamic nuclei, which target neuropathic pain, and the periacqueductal gray, which is effective for certain types of nociceptive pain. Motor cortex stimulation shows promise for severe 'central pain.'

Intraspinal Drug Delivery

Modification of spinal function by epidural and intrathecal drug administration depends on administration of either local anesthetics which block neuronal sodium channels in spinal nerve roots or drugs which

act at a spinal cord dorsal horn level on other receptor systems (e.g., opioid receptors). Local anesthetics have a rapid onset, as they block nerve roots which pass through the epidural or intrathecal space. Drugs targeting spinal cord μ or GABA sites have a slower onset, as they need to target receptors on primary afferent endings or at supraspinal sites. Epidurals are widely used for the management of labor pain and postoperative pain management, particularly in patients with potential respiratory compromise. Larger volumes of local anesthetic are required to achieve sensory blockade as compared to intrathecal analgesia.

Spinal drug administration also has an established role in both chronic noncancer and cancer pain. Up to 10% of patients experience severe cancer-related pain despite optimal medical management. Many patients with nonmalignant pain also fail to report benefit with oral or parenteral medication or experience unacceptable side effects. Intraspinal drug delivery should be considered in these patients, as a range of spinal and supraspinal receptors can be targeted which may be associated with improved analgesia and a reduction in side effects associated with systemic administration. Delivery may be epidural, intrathecal, or intracerebroventricular through either an externalized system or a fully implanted system. Currently a range of battery-powered or gas-driven implantable infusion systems are available and also a complementary hand-held device with the facility to deliver bolus doses as needed. Equivalent analgesia may be obtained with epidural administration at one-tenth of the parenteral morphine dose and intrathecally at one-tenth of the epidural dose. Intraventricular, compared to intrathecal, administration requires smaller doses. Although currently at least 16 drugs have been used intrathecally, only morphine sulfate, ziconitide, and baclofen have been approved by the US FDA for intrathecal use. There is concern over the long-term safety of many of the other compounds and drug mixtures used. Spinal drug administration may be associated with a different spectrum of side effects. For example, intrathecal morphine may be associated with the growth of catheter tip inflammatory masses. Outcome studies have shown that intrathecal morphine administration is associated with improved pain control, reduced side effects, less use of adjuvant pain medications, and improved survival in a cancer pain population as compared to standard medical management. This approach can also be of benefit in carefully selected patients with severe and disabling chronic nonmalignant pain. Combination of these approaches with an intensive cognitive behavioral pain program may produce a better outcome than either treatment alone.

Neurodestructive

Although neurodestructive techniques are used in certain chronic noncancer conditions such as trigeminal neuralgia and spinal medial branch rhizotomy, they are to be avoided in most other cases due to the high incidence of deafferentation pain. Neurolytic procedures using phenol or alcohol, which permanently interfere with the function of nerves, are usually reserved for well-localized cancer-related pain, in patients with a short life expectancy. Common clinical examples include celiac plexus block for pancreatic cancer, and subarachnoid neurolytic blocks for pelvic pain and for unilateral chest wall pain associated with mesothelioma.

Radiofrequency

Radiofrequency techniques have been used for over 25 years to interrupt nerve transmission at various anatomical points. Most commonly the medial branch of the posterior primary division supplying the affected spinal segment (sacral, lumbar, thoracic, or cervical) is targeted after selection on the basis of concordant relief, with injection of one or more different local anesthetics or saline onto the medial branch or into the facet joint. Up to 80% of patients experience initial relief, with a variable period of sustained benefit from weeks to over 1 year. The dorsal root ganglion, the cervical spinothalamic tract in the treatment of cancer pain (known as a cordotomy), and the lumbar sympathetic chain are also potential targets for this technique. The role for these techniques is not clear, but they are relatively simple and well tolerated.

Treatment of Psychological and Environmental Factors

Psychosocial Assessment and Management of Pain

Psychosocial assessment, which includes assessment of psychological and environmental factors, is widely accepted as an essential part of the evaluation of persisting pain conditions. The assessment aims to identify the main presenting problems and the contributing somatic, psychosocial, and demographic factors. A formulation of relevant domains is then presented at a multidisciplinary conference and targets are identified for intervention. Typically a series of validated self-report questionnaires covering the relevant domains such as mood, function, coping strategies, pain behaviors, self-efficacy, and tendency to catastrophize are also completed by the patient. These can also be completed after treatment and should give a reliable indication of change and act as a check on patients' verbal reports.

Interventions can be delivered either serially (over weeks or months), as part of an intensive pain program, or as a component of a coordinated management plan (e.g., spinal cord stimulation and pain program). As these treatments are aimed at helping the patient to live with their pain, it is recommended that all medical and surgical treatments targeting pain relief are completed before commencing the program. Most evidence is for multidisciplinary treatments that are delivered according to cognitive behavioral principles, whereby patients learn a set of active pain management skills, which replace other unhelpful strategies. Treatments have to be tailored to the individuals needs and also integrated with the workplace if return to work is a goal. In general terms there is a dose-related response such that the more disabled patients do better with more intensive treatment. Significant improvements in pain, mood, function, and quality of life have been shown. Inevitably some patients do not benefit from this approach. Possible reasons are inadvertent reinforcement of passivity, lack of acceptance of persisting pain, poor patient compliance, and conflicting treatment advice. Such patients may seek further treatments targeting pain reduction after a pain program, and the risk is that further passive approaches will be introduced, reinforcing disability. In such cases individual sessions with a clinical psychologist may be appropriate.

Introduction

In spite of the tremendous progress made over the course of human history in the understanding of the sensorium, the concept of pain as a unique and separate sensation has only been appreciated within the past half century. For the most part, it was generally thought that pain did not arise from specific nociceptors but that the temporal patterns of sensory inputs from sensory fibers led to the interpretation of the inputs as being painful. Although a specific pattern had been suggested, its acceptance was hampered by the fact that the correlation between stimulus intensity and pain perception is quite variable. Moreover, individuals with an injury or inflammation report pain arising from normally nonnoxious stimuli (allodynia) or as being much more intense than is normally experienced by a given noxious stimulus (hyperalgesia). A veritable explosion of studies aimed at understanding the mechanisms of pain over the past four decades has led to our understanding of not only specific pain receptors (nociceptors) and pain pathways but of pain regulatory systems in the central nervous system (CNS) that serve to both inhibit and augment pain perception. A key moment in the history of pain research was the 1965 publication of the 'gate control theory' by Melzack and Wall. This theory is considered to be the first attempt to provide a coherent mechanism describing an endogenous mechanism through which the CNS can modulate pain. Further studies clearly demonstrated the existence of brain regions that can be activated to produce a complete blockade of responses to noxious inputs, providing compelling evidence of an endogenous pain-control system. This concept was bolstered by the discovery of selective stereospecific receptors for opioids and by the discovery of endogenous peptidic ligands for these receptors. These discoveries spurred an intense and growing field of neuroscience dedicated to the investigation of pain-control mechanisms. We now understand not only that the brain receives nociceptive inputs from the periphery, which are interpreted at cortical sites as pain but that there also exist complex interactions among several regions of the brain that result in activation of descending modulatory systems that both inhibit and facilitate pain. The balance among these opposing modulatory systems can produce either analgesia or an enhanced pain state.

Ascending Noxious Inputs to the Brain Yield Pain

It has been well appreciated over the past 100 years that noxious inputs from the periphery enter the CNS through synaptic contacts between the peripheral nerves and second-order neurons of several ascending projections. One of the most prominently considered tracts is the spinothalamic tract (Figure 1), which transmits sensory inputs from the spinal cord to the distinct thalamic nuclei, including the posterior part of the ventromedial nucleus, ventroposterior nuclei, and ventrolateral nucleus. The spinothalamic tract consists predominantly of projections from lamina I of the spinal dorsal horn; it also includes projections from laminae IV to V and from laminae VII to VIII. The parabrachial nucleus receives inputs from laminae I and laminae V through the parabrachial tract and transmits these inputs to more rostral sites, including the amygdala, hypothalamus, and thalamic nuclei. Nociceptive inputs from the spinal dorsal horn are also transmitted to the noradrenergic pontine nuclei, which include the locus coeruleus (A6), the subcoeruleus and Kölliker–Füse nuclei (A7). These regions modulate cardiovascular, respiratory, and autonomic functions in addition to nociception and may participate in the integration of pain with contextual and situational cues. The ascending pain pathways also project to the reticular formation, including the raphe nuclei, and to the ventrolateral periaqueductal gray (PAG). Ultimately, the ascending nociceptive sensory inputs are integrated with nonnociceptive sensory inputs from other regions of the CNS and are projected to cortical regions, most notably the somatosensory cortex and the anterior cingulate cortex (ACC), where nociception is interpreted as pain, including its emotional context. These regions give rise to caudally projecting pathways to medullary and spinal sites, through which further noxious inputs may be either inhibited or facilitated, and thus serve as a complex endogenous pain modulatory system.

Descending Inhibition of Pain

The Periaqueductal Gray

The PAG is one of the first brain structures that was recognized as playing an important role in pain and analgesia. Tsou and Jang, working in Shanghai in 1964, reasoned that because morphine blocks pain at doses that do not affect other sensory modalities, it probably worked through a site specific for pain control. They either applied morphine directly onto the surface of the brain, injected it into the cerebral

Figure 1 Schematic representation of pain modulatory circuitry. Ascending sensory pathways are shown in green, descending pain inhibitory pathways are shown in blue, and descending pain facilitatory pathways are shown in red. Noxious stimuli applied to the free nerve endings (nociceptors) of peripheral afferent fibers are transmitted to the central nervous system through synaptic transmission with second-order neurons in the dorsal horn of the spinal cord. The ascending fibers of the spinothalamic tract (STT) neurons transmit sensory inputs to the thalamus, which relays the sensory signals to nuclei of limbic structures, including the amygdala and to cortical sites, where the pain experience is interpreted in the context of environmental and other cues. Collateral projections from the ascending tracts innervate the parabrachial region (PB), the mesencephalic reticular formation, and the periaqueductal gray (PAG) as well. The ascending nociceptive inputs activate a cascade of descending pain inhibitory (blue) and facilitatory (red) circuits that modulate further noxious inputs. The somatosensory cortex, thalamus, and limbic regions communicate with one another, and with the PAG, which is a predominant pain-inhibitory locus with reciprocal communications with the rostroventromedial medulla (RVM). Inhibitory signals are also elicited from noradrenergic nuclei, including the A7, A5, and locus coeruleus (LC), which may project directly to the spinal cord or through the RVM. Descending pain facilitatory signals may arise from the anterior cingulate cortex (ACC), which communicates with limbic structures as well as the RVM. The parabrachial region (PB) and the dorsal reticular nucleus (DRT) also activate pain-facilitatory signals, either directly to the spinal dorsal horn or via synaptic transmission in the RVM. The RVM acts as a final relay for the integration of descending pain modulatory systems. It receives inputs from rostral structures and possesses both pronociceptive facilitatory and antinociceptive inhibitory projections to the spinal dorsal horn. The predominant net effect either inhibits further noxious inputs, thus serving as an endogenous antinociceptive system, or facilitates nociceptive inputs, thus acting as a pronociceptive modulatory system that promotes states of enhanced pain. DRG, dorsal root ganglion.

ventricles, or microinjected it into discrete brain regions and discovered that it produced a powerful antinociceptive effect when microinjected into the PAG. This discovery led to a rapid succession of mapping experiments in which opioids were microinjected or electrical stimulation was applied to discrete loci about the PAG, identifying the ventrolateral aspect of this region as the pain modulatory site. In one study, electrical stimulation of the PAG produced antinociception of such intensity that it was possible to perform a laporotomy on a conscious rat without producing overt signs of behavioral distress. Electrical stimulation of the PAG was rapidly adapted to relieve intractable cancer pain in humans, and it is commonly cited as one of the most rapid applications of an experimental finding to clinical application. Although PAG stimulation has been largely discontinued because of other side effects, such as anxiety and distress, deep brain stimulation aimed at other regions remains an important means of controlling otherwise intractable pain. Significantly, antinociception produced by electrical stimulation of the PAG or microinjection of morphine produced antinociception that lasted much longer than the stimulus application, suggesting that an endogenous analgesic system was being activated. Analgesia produced by electrical stimulation of the PAG is blocked by opioid antagonists, showing that an endogenous opioid system mediates this antinociceptive effect. Further mapping experiments demonstrated that there is considerable overlap between PAG sites that produce antinociception in response to electrical stimulation and those that are responsive to morphine microinjection. It is now known that several neurotransmitter systems are capable of activating pain modulatory circuitry from the PAG. Activation of the CB1 cannabinoid receptors in the PAG is believed to underlie opioid-independent stress-induced analgesia. Other studies demonstrated that agonists acting at metabotropic glutaminergic receptors; *N*-methyl-D-aspartate (NMDA) receptors; and receptors for neurotensin, substance P, calcitonin gene-related peptide

(CGRP), or neuropeptide Y also produce varying degrees of antinociception when microinjected into the PAG. The PAG receives inputs from central sites that receive nociceptive projections from the periphery, including the thalamus, hypothalamus, parabrachial regions, cortical regions, and the limbic system (Figure 1), and it may be a site where nociceptive signals are integrated with autonomic and stress-mediated responses. In spite of its prominent role in the modulation of pain, the PAG has few direct projections to the spinal cord. Rather, the PAG possesses reciprocal connections with medullary sites that project to the spinal cord. It is suggested that these caudal projections from the PAG are diffuse, rather than discrete, because a single midline injection of local anesthetic into the rostral medulla failed to abolish antinociception from electrical stimulation of the PAG, whereas stimulation-produced antinociception was blocked by local anesthetic microinjected into the midline and lateral aspects of the rostral medulla. It is now recognized that the PAG mediates its antinociceptive effect through medullary relays with spinal projections that inhibit further nociceptive inputs at the level of the spinal cord.

Noradrenergic Inhibition of Pain

Early investigations found that antinociception mediated from stimulation of the PAG, either electrically or by microinjection of morphine, could be attenuated by the spinal injection of α-adrenergic blockers. Other studies demonstrated that the spinal administration of α-2 adrenergic agonists acts synergistically with opioids to enhance antinociception. These studies indicated that the endogenous pain-control mechanisms depend, at least in part, on a noradrenergic system. Consistent with this hypothesis, it was found that several noradrenergic sites, the A5 (locus coeruleus), A6, and A7 (Kölliker–Füse) nuclei, possess communications with the PAG and contribute to its antinociceptive actions. Critically, the locus coeruleus is the major source of noradrenergic projections to the spinal cord, and the A7 is also an important source of noradrenergic projections to the superficial laminae of the spinal dorsal horn. These noradrenergic spinopetal projections may inhibit the response of second-order neurons of the spinal dorsal horn. In addition, the A7 projections may also attenuate the activity of primary afferent nociceptors through activation of the α-2 adrenergic receptors residing on the nerve terminals. Several studies showed that electrical or chemical stimulation of these noradrenergic regions produced antinociception sensitive to blockade by spinally administered adrenergic antagonists. Electrical or neurotoxin lesions of the noradrenergic nuclei attenuate the antinociceptive effect of opioids and enhance the sensitivity of dorsal horn neurons to noxious stimuli. The noradrenergic regions also receive inputs from structures related to the pain-processing pathways, including the parabrachial region, and send projections to other sites, including the nuclei of the rostral ventromedial medulla (RVM). This region is generally regarded as the final relay in the modulation of pain.

Descending Inhibition from the Rostral Ventromedial Medulla

The RVM is defined as the medulla ventral to the nucleus gigantocellularis and extending between the caudal facial nucleus and the inferior olivary complex, and it includes the serotonergic nucleus raphe magnus (NRM) and the nucleus gigantocellularis pars α and the surrounding reticular formation. The RVM exhibits reciprocal connections with the PAG as well as inputs from the A5 and A7 noradrenergic nuclei, parabracial region, and limbic and hypothalamic sites (Figure 1). Early studies aimed at determining the antinociceptive pathways linked to the PAG found that electrical stimulation or morphine microinjection into the RVM produced behavioral signs of analgesia and inhibited dorsal horn neuronal responses to noxious stimuli. Local anesthetic block of the RVM or electrolytic or chemical lesions of the RVM abolished antinociception arising from stimulation of the PAG. The RVM is a major source of bulbospinal projections that terminate in laminae I, II, and V of the spinal dorsal horn, where they can form synapses with second-order neurons and terminals of primary afferent nociceptors, thus inhibiting further nociceptive inputs.

Extensive studies have been performed over the past three decades to characterize the neurons of the RVM. Based on the response characteristics to noxious heating of the tail and measured by electrophysiological methods, there are three classes of neurons within the RVM. The on cells were so named because of a marked acceleration of firing rate that occurs just prior to the nociceptive tail-flick reflex. The off cells cease firing immediately prior to the nociceptive tail-flick reflex. The changes in firing rate were related to the nociceptive reflex and not to the intensity of the stimulus, indicating a physiological connection between the neuronal responses of these cells and behavioral signs of nociception. The third class of cells, the neutral cells, do not demonstrate any consistent changes with noxious stimuli and might be related to physiological processes other than modulation of nociception. Doses of morphine that produce behavioral signs of analgesia or inhibit dorsal horn responses to noxious stimuli given

either systemically or microinjected into either the PAG or RVM result in increased off cell activity and the suppression of on cell activity. Further studies established that the suppression of the off cell pause is necessary for the antinociceptive effect of opioids, whereas the inhibition of on cell activity is not necessary for antinociception to occur. Doses of opioid antagonists that abolish the antinociceptive effect of opioids also restore the cessation of the off cell activity. It is generally accepted that the activation of the descending projections of the off cells block nociceptive transmission at the level of the spinal cord and thus moderate the input of pain signals to higher centers of the brain. Descending inhibition from the RVM off cells is a key component of endogenous pain-control systems.

Pain Facilitation from Supraspinal Sites

Until the early 1990s, the main focus of studies of the role of the RVM was related to its inhibition of spinal nociceptive inputs. However, as studies of this region progressed, it became clear that a dual function may be evoked from the RVM. That is, stimulation of the RVM was found to either produce antinociception or to actually facilitate responses to noxious stimulus, indicating a pronociceptive effect. Electrical stimulation applied to the RVM at low intensities (e.g., 5–25 μA) facilitated the nociceptive tail-flick reflex in anesthetized rats, whereas higher intensities of stimulation (50–100 μA) inhibited the response. Likewise, the electrophysiological responses of dorsal horn neurons to noxious stimuli were facilitated by low-intensity stimuli applied to the RVM and inhibited by higher-intensity stimulus. Chemical stimulation of the RVM by the microinjection of excitatory substances such as glutamate or neurotensin produced a similar biphasic effect. Lower doses facilitated behavioral and electrophysiological responses to noxious stimuli, whereas higher doses inhibited the same responses. The microinjection of a neurotensin antagonist into the RVM also elicited a biphasic effect related to dose, leading to the conclusion that endogenous neurotensin in the RVM mediates the facilitation of nociception and, to a lesser extent, inhibition, which is masked under normal conditions.

Just as the off cells mediate descending inhibition, there is sufficient evidence to support the concept that the on cells mediate a descending facilitation of pain. The electrophysiological characteristics of the on cells are consistent with a pronociceptive function because they become active after a noxious stimulus is applied. Moreover, manipulations that facilitate responses to nociceptive stimuli also increase on cell activity For example, prolonged delivery of a noxious thermal stimulus facilitated the tail-flick reflex to noxious heat and also caused an increase in the firing rate of the on cells. This facilitated response was abolished by the microinjection of the local anesthetic lidocaine into the RVM. Withdrawal from opioids and the subdermal injection of formalin into a hindpaw of a rat both produced exaggerated behavioral responses to noxious stimuli, and both provoked increased responses of on cells of the RVM.

Whereas the concept of endogenous systems that inhibit pain was readily accepted and well studied, the concept that endogenous mechanisms promote nociception may at first appear to be counterintuitive. However, enhanced sensitivity to pain (hyperalgesia) may serve as a protective mechanism. The enhanced pain state may be beneficial to healing after an injury. For example, the inflammatory response and hyperalgesia accompanying a broken limb discourage its use during the healing process. Considerable evidence has recently been generated to point to the RVM as a principal contributor to the maintenance of enhanced pain states, and it may be responsible for the maintenance of chronic pain states. More recent studies have postulated the existence of a spinal-bulbo-spinal loop that may be important to the development and maintenance of exaggerated pain behaviors associated with chronic pain states.

Descending Facilitation from the Rostral Ventromedial Medulla Mediates Chronic Pain States

Considerable evidence shows that descending facilitation arising from the RVM maintains enhanced pain states. Hyperalgesia elicited by formalin injection into the hindpaw or by electrical stimulation of the RVM were both blocked by the spinal administration of methysergide, which blocks the facilitatory serotonergic projections from the RVM. Neurogenic inflammation caused by the application of mustard oil produced facilitation of dorsal horn neurons in response to noxious peripheral stimuli that was abolished by microinjection of lidocaine into the RVM. Neurotoxic lesions of the RVM also abolished behavioral signs of pain facilitation in animals with inflammation of a hindlimb. The microinjection of lidocaine into the RVM of rats with experimental nerve injury abolished hyperesthesias to sensory stimuli. Strong circumstantial evidence suggests that the population of RVM neurons that express the μ-opioid receptor corresponds to the RVM neurons that drive descending facilitation and correlate to the function of on cells. By using the μ-opioid receptor as a portal of entry into these pain facilitatory cells, it was

possible to selectively destroy a large part of this neuronal population. The ablation of this population of RVM neurons, presumed to correspond to on cells, abolished behavioral signs of enhanced pain in animal models of neuropathic pain.

Enhanced abnormal pain associated with peripheral nerve injury has been linked to the enhanced release of excitatory neurotransmitters from primary afferent neurons, which appears to be secondary to neuroplastic changes that include enhanced descending facilitation from the RVM. The stimulated release of neuropeptides from spinal cord preparations or cultured dorsal root ganglion (DRG) neurons has emerged as a useful tool for assessing the function of primary afferent nociceptors. Chronic pain states, both inflammatory or neuropathic, are associated with enhanced capsaicin-evoked release of substance P or CGRP. The disruption of descending facilitation from the RVM, through either physical ablation of the descending projections from the RVM in the dorsolateral funiculus (DLF) or by selective ablation of the pain facilitatory neurons of the RVM, abolished behavioral signs of neuropathic pain as well as the enhanced capsaicin-evoked release of peptidic transmitters from primary afferent nerve terminals. It is now hypothesized that persistent or repetitive input of noxious stimuli elicits supraspinal neuroplastic changes that results in the activation of a descending pain facilitation from the RVM. This spinopetal pain facilitatory process serves to promote additional release of excitatory neurotransmitters from primary afferent terminals, which in turn promotes the maintenance of the tonic descending facilitatory system, thus perpetuating a chronic pain state.

Descending Pain Facilitation Can Be Elicited by Neuroplastic Changes in the Rostral Ventromedial Medulla

Although the role of descending pain modulatory systems has been extensively studied, the role of the ascending inputs from the periphery to the brain in triggering this process is less clearly understood. In the normal state, acute nociceptive inputs are relayed to supraspinal sites, in part through the spinothalamic neurons of the superficial lamina of the spinal dorsal horn that express the neurokinin (NK-)1 receptor. These neurons are the primary targets of peptidergic primary afferent nociceptors and account for more than 77% of the nociceptive-responsive cells of lamina I. These lamina I projection neurons send terminations to thalamic nuclei, which integrate sensory inputs and serves as a relay to the somatosensory cortex, insular cortex, and amygdala. There is also a significant projection from lamina I to the parabrachial region, which receives sensory and nociceptive inputs from mechanical, thermal, and cold stimuli and which may act as a site of integration and discrimination of noxious inputs that are then passed on to the hypothalamus and amygdala. These projections lead to the activation of descending processes from the cortical and limbic regions to stimulate the PAG and ultimately the RVM, the final relay in processing of descending control of nociceptive inputs The selective ablation of the spinal neurons expressing the NK-1 receptor abolished behavioral signs of enhanced abnormal pain in rats with peripheral nerve injury or inflammation of the hindpaw, but it did not alter responses to acute nociceptive stimuli. Likewise, the augmented electrophysiological and neurochemical responses of dynamic wide-range neurons to peripheral stimuli were abolished by ablation of the NK-1-expressing neurons. It is now hypothesized that the activation of this ascending limb relays persistent nociceptive messages to the parabracial and thalamic regions, which ultimately communicate with the RVM. Persistent noxious inputs result in neuroplastic adaptations within the RVM to induce an activation of descending pain facilitatory systems from this region.

The RVM and surrounding region include the nuclei of prominent spinopetal serotonergic projections that constitute both inhibitory and facilitatory projections from this region. It has also recently become evident that spinal serotonin (5-HT)1A receptors mediate the inhibition of pain transmission, whereas the 5-HT3 receptors facilitate pain transmission in the spinal cord. Persistent noxious stimulation evoked the expression of the protooncogene product Fos, which is a neurochemical marker for neuronal activation, in the nucleus raphe magnus (NRM). Furthermore, double-labeling studies revealed that a subpopulation of these neurons also expressed serotonin, indicating that nociceptive inputs indirectly activate descending serotonergic fibers. Accordingly, the spinal administration of the 5-HT3 antagonist ondansetron mimicked the behavioral and electrophysiological consequences of ablation of the spinal neurons that express the NK-1 receptor in animal models of inflammation and of nerve injury. Genetically altered mice that do not express the 5-HT3R-A subunit demonstrate normal responses to acute nociceptive stimuli, but demonstrate significantly reduced behavioral and electrophysiological responses to inflammatory pain. It has been suggested that descending serotonergic facilitation of nociception mediated through the 5-HT3 receptor becomes active during conditions of chronic pain. Taken together, these studies provide growing evidence that chronic pain states are maintained by a spinal-bulbo-spinal excitatory system, in which incoming

pain causes supraspinal neuroplastic changes that, in turn, serve to facilitate further nociceptive inputs, thus maintaining a condition of enhanced pain.

Other Pain Facilitatory Sites

Anterior Cingulate Cortex

The anterior cingulate cortex (ACC) is recognized as an important cortical center of integrations of pain with emotional and situational cues. The ACC has reciprocal connections with the medial and ventrolateral thalamic nuclei, and it receives input from the hippocampus, amygdala, and hypothalamus. The ACC, together with these limbic regions, encodes emotional and autonomic responses to pain. The ACC sends projections to the PAG and the RVM, regions known to participate in the modulation of pain.

Electrophysiological recordings have shown that neurons within the ACC are activated in response to noxious stimulation. Recordings performed in monkeys suggest that the ACC may encode the anticipation of pain because they may be activated by conditioned aversive stimuli. Stimulation of the ACC enhanced the activity of spinal dorsal horn neurons that are responsive to noxious stimuli, and lesions of the ACC or lidocaine microinjection into this region resulted in decreased responsiveness of these neurons. Electrolytic lesions or microinjection of lidocaine into the ACC reduced behavioral responses to acute noxious stimuli as well as measures of enhanced pain in animal models of inflammation. Behavioral studies suggest that ACC lesions may block the aversive component of pain rather than modulating the response to pain intensity. Avoidance of noxious stimuli was attenuated by lesions of the ACC. In humans, brain imaging studies show that the ACC is activated by acute painful stimuli as well as by pain conditions such as headache and neuropathic pain. Functional magnetic resonance imaging (fMRI) studies also indicate that the ACC responds in anticipation of pain. Patients with lesions of the ACC demonstrate a reduced affective response to chronic pain states. Based on such observations, it is believed that the ACC is integral in the integration of the motivational and affective components of pain. This region integrates inputs from the limbic, sensory, and motor regions to perform a global assessment of situational cues along with the noxious inputs and to form the interpretation of the quality of pain.

The ACC may facilitate pain in part though the activation of the pain facilitatory neurons of the RVM because microinjection of lidocaine or an α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)/kainate receptor antagonist into the RVM blocked the facilitation of nociceptive reflexes produced by electrical or chemical stimulation of the ACC. Other studies suggest that pain facilitation from the ACC is processed through the medullary dorsal reticular nucleus (DRT).

Dorsal Reticular Nucleus

The DRT is found in the dorsal caudal – most portion of the medulla. This region has reciprocal connections with the spinal dorsal horn, and its spinopetal projections are consistent with the laminar distribution of nociceptive-encoding neurons. The DRT also communicates with the PAG, the nuclei of the RVM, the locus coeruleus, and the A5 and A7 noradrenergic nuclei as well as with thalamic and limbic structures. These connections implicate a role in the pain-processing pathways. Electrophysiological studies have demonstrated that the DRT is a pain facilitatory site that forms a spinal-bulbo-spinal feedback amplification loop that enhances nociceptive input. The neurons of the DRT appear to be excited almost exclusively by noxious stimuli. Stimulation of the DRT facilitates behavioral responses to noxious stimuli and enhances electrophysiological and neurochemical responses of dorsal horn neurons to nociceptive stimuli. In contrast, lesions of the DRT increase pain thresholds and result in reduced responses to nociceptive stimuli. Inflammation is associated with increased activity of the DRT, and lesions of the DRT attenuate augmented responses to noxious stimuli in animal models of inflammation. Lesions in or lidocaine injection into the DRT blocks enhanced responses to nociception produced by stimulation of the ACC. This nucleus provides an additional mechanism through which the enhancement of nociception and production of hyperalgesia in chronic pain states may be maintained.

Conclusion

Tremendous progress in our understanding of the mechanisms that modulate pain have been made over the preceding half century since pain research came into its own. Many exciting discoveries were made that established the existence of endogenous mechanisms that inhibit the expression of pain. The characterization of the pain-inhibitory pathways, along with the discovery of opioid receptors and the endogenous opioid peptides, not only enhanced our understanding of the mechanisms through which opioid analgesics may produce their therapeutic effects but also revealed the existence of dedicated pain-control circuitries. The system that is best characterized at the present time is the PAG-RVM-spinal pathway. The PAG appears to be a central collection and processing site for nociceptive inputs from caudal and rostral sites, where a pain-modulatory message

might be transmitted to the spinal cord through intermediate relays. Cortical regions integrate sensory, affective, and motivational inputs and may activate both inhibitory and facilitatory systems; this may partly explain the observations that environmental, psychological, and emotional cues alter pain responses. The RVM is capable of relaying both inhibitory and facilitatory signals to the spinal cord. The relative strength of these opposing signals influences the intensity of further incoming pain signals at the level of the spinal cord. Activation of pain-facilitatory systems from the RVM and the DRT also provides a mechanism through which chronic pain states may be maintained. Increasing evidence suggests that pain facilitation may serve a protective role in wound healing but that it may also become maladaptive, permitting long-lasting, abnormal pain that persists as neuropathic or other chronic pain states.

Introduction

Definitions

The International Association for the Study of Pain (IASP) has defined central pain as pain caused by a lesion or dysfunction in the central nervous system (CNS); nowadays central pain is often referred to as 'central neuropathic pain.' Note that, according to the IASP definition, the cause shall be a primary process in the CNS. Thus peripherally induced pain with central mechanisms is not central pain, even if the central mechanisms are prominent.

The term 'thalamic pain' is often used in a general sense for all central pain, and the expression 'pseudothalamic pain' is sometimes used for central pain caused by extrathalamic lesions. The term 'dysesthetic pain' is also sometimes used for central pain in general. Dysesthetic pain can have either central or peripheral causes. It is recommended that the general term, central pain, be used in most instances, and that only central pain caused by lesions in the thalamus should be labeled thalamic pain.

The term 'anesthesia dolorosa' has chiefly been used for head and face pain, and in particular for the neuropathic pain after destructive surgery or nerve blocks to treat neuralgias. The term 'deafferentation pain' is used for similar conditions, but it is more commonly used in patients with lesions of spinal nerves.

Historical Perspective

Central pain is puzzling for patients and their friends and families, but also for personnel in the health care system – doctors, nurses, and others who provide care for patients. It seems strange to the patient that that there is apparently nothing wrong in a leg or arm, but that it hurts so badly and feels so peculiar that it is difficult to find words to describe how it feels. It is also puzzling for the research worker, because it is difficult to find a plausible explanation for many of the features of central pain.

Knowledge about central pain in the late 1930s was summarized in an impressive series of publications in 1938 by Riddoch, who added observations of his own. Many of Riddoch's ideas about central pain showed considerable foresight in the light of today's view of the clinical features of patients with central pain. For instance, he discussed the difference between unpleasant and painful sensations, the presence of both spontaneous and evoked pain, the diversity in the quality of central pain, the overreaction to somatic stimuli, the many kinds and locations of CNS lesions that can cause central pain, the uncertainty of the role of autonomic dysfunction, and the role played by the capacity to cope with the disability central pain causes. Regarding the pathophysiology of central pain, he supported Head and Holmes' original idea that the crucial lesion is one of the dorsal column–medial lemniscal pathways, which we now know to be incorrect. A historical review of the literature was provided by Boivie in 2005.

With modern techniques and methods much new knowledge has been acquired, but there are still aspects of central pain that remain unknown, the most important one being our lack of knowledge about the underlying cellular mechanisms. One reason for this is the lack of experimental models for central pain caused by brain lesions. Experience from techniques to produce experimental lesions in the spinal cord gives hope that the use of this model will lead to new insights into central pain.

Historically, central pain appears to have first been knowingly described as early as 1883 by Greiff in a patient who developed lasting pain following cerebrovascular lesions. The lesion included the thalamus. Due to the description from 1906 by Dejerine and Roussy of the thalamic syndrome, including thalamic pain, this pain has remained the best known form of central pain, but only a minority of central pains are related to thalamic lesions.

In the oldest literature many fascinating detailed descriptions of the symptoms and signs are found, but no systematic studies were done contemporaneously. Many of the published descriptions show that the character of this pain can vary considerably from patient to patient and that central pain can be excruciating. They vividly illustrate how individuals interpret this kind of pain: as a crushed feeling, as a scalding sensation, as if boiling water was being poured down the arm, as if the leg was bursting, as if something was crawling under the skin, as pain pumping up and down the side, as if the painful region was covered with ulcers, as if pulling a dressing from a wound, as if a log of wood was hanging down from the shoulder, like a wheel running over the arm, and as a cold stinging feeling. As a result of descriptions such as these, central pain has commonly been thought of as being excruciating pain with bizarre character, and covering large areas of the body. This is only part of the truth, however, because central pain can appear in many guises. It can have a trivial

character and be restricted to a relatively small area, such as distal pain in one arm, or in the face. Central pain is mostly severe in the sense that it causes the patient much suffering, even though its intensity may be relatively low, because it is commonly irritating and constant.

Epidemiology

There are large differences in the prevalence of central pain among the disorders that may lead to such pain. The highest prevalences are found with traumatic spinal cord injury (SCI), multiple sclerosis (MS), stroke, and syringomyelia (Table 1). The latter is a rare disease with a very high incidence of central pain.

Two prospective epidemiological studies have been published, one of central poststroke pain and the other on pain following SCI. In the stroke study an incidence of 8.4% was found during the first 12 months, and in the spinal cord study 41% developed at-level pain (at least to some extent central pain) and 34% developed below-level pain (certain central pain) during the 5 years the patients were followed. Among the stroke patients with somatosensory deficit (42% of all stroke patients) the incidence of central pain was 18%. The corresponding figure in a mainly retrospective study of central pain in 63 patients with brain stem infarct was 44%, with an overall incidence for central poststroke pain (CPSP) of 25%.

A recent study of the prevalence of central pain in 364 patients with MS has found that 28% of patients experience, or have experienced, central pain. The prevalence of central pain in MS has not been specifically investigated in the previous studies of pain in MS, but the information given in some of the studies support the conclusion that the prevalence is in the order of 25–30%. Trigeminal neuralgia occurs in 5% of MS patients.

The highest prevalence of central pain is found in syringomyelia. It appears to be in the order of 67–75% of all patients. It has been suggested that this high incidence depends on the fact that the syrinx directly injures the dorsal horn of the spinal cord, where processes that are of fundamental importance in pain mechanisms reside.

Table 1 Estimated prevalence of major disorders with central pain and calculated number of patients per 10 million inhabitants

Disease	*Patients with CP (no.)*	*Patients with CP (%)*
Spinal cord injury	3200	35
Multiple sclerosis	2800	28
Stroke	6800	8.4

Lesions That Cause Central Pain

Many etiologically different lesions in the brain and spinal cord can cause central pain (Table 2). These lesions and dysfunctions are due to many different disease processes. The macrostructure of the lesion is probably less important than its location as regards the probability that it will induce central pain. This does not mean that the structure of the lesion has no significance, because it is conceivable that the microstructure of the lesion in some instances is critical, but there is to date no information from research on this matter. Lesions include both rapidly and slowly developing ones. There appears to be no correlation between the tendency to cause central pain and the speed with which they develop.

The role of thalamic lesions is one of the recurring questions in discussions regarding the location of the lesions that cause central pain. In their prospective study, Andersen et al. had 25% thalamic involvement among the 191 CPSP patients (as assessed by computed tomography scans), but in a study of 70 patients using the more sensitive method of magnetic resonance imaging (MRI) it was found that about 60% had lesions involving the thalamus.

The importance of the location of the lesion within the thalamus was elucidated in a study of thalamic infarct. The results showed that only patients with lesions including the ventroposterior thalamic region developed central pain. Many studies have shown that the first requisite for a disease process to produce central pain is that it affects structures involved in somatic sensibility, which is not surprising, since pain is part of somesthesia. Abnormalities in somatic sensibility are actually the only symptoms and signs besides pain that are present in all patients with central pain.

The dominating features of the sensory abnormalities are abnormal sensibility to temperature and

pain, and hyperesthesia. The results from studies on patients with central pain following stroke, MS, SCI, and syringomyelia, employing quantitative methods to assess the sensory abnormalities, form the basis for the hypothesis that central pain only occurs after lesions that affect the spinothalamic pathways (i.e., the pathways that are most important for temperature and pain sensibility). If this hypothesis turns out to be correct it means that lesions of the dorsal column–medial lemniscal pathways are not necessary for the occurrence of central pain, but many patients also have such lesions and they certainly affect sensibility. Likewise many patients have severe deficits in temperature and pain sensibility and yet they do not develop central pain.

There is a large variation in the spectrum of sensory abnormalities among patients with central pain. It ranges from a slightly raised threshold for one of the submodalities, to complete loss of all somatic sensibility in the painful region. Hyperesthesia to touch, moderate cold, and heat; allodynia to touch and cold; and hyperalgesia to cold, heat, or pinprick are common in many central pain conditions, and often coexist. For instance, some stroke patients with severely decreased tactile sensibility, even with total loss, have tactile allodynia. Head and Holmes, as early as 1911, claimed that overreaction to somatic stimuli was the most typical sign of central pain.

Neurophysiological Examinations

Because of the fact that the sensory disturbances in central pain indicate that the lesions affect the spinothalamic pathways, it is of interest to study somatosensory evoked potentials (SEPs) evoked by peripheral stimulation of afferents that activate the spinothalamic pathways. This can be done by using lasers to stimulate cutaneous heat receptors. Studies using this technique on patients with CPSP have shown that abnormalities in the laser-evoked cortical potentials, which have a long latency, correlate well with abnormalities in the sensibility to temperature and pain, but not to touch and vibration.

Pain Characteristics

Pain Location

In stroke about 70% of patients have hemipain, which in a minority affects the face (see Table 3 and Figure 1). In MS central pain dominates in the lower extremities (87%), and occurs over the upper extremities (31%). About 5% have trigeminal neuralgia. Central pain is experienced as superficial or deep pain, or with both superficial and deep components, but the high incidence of cutaneous hyperesthesia contributes to the impression that superficial pain dominates, although deep pain is also common.

Lower half of the body
One leg
At the level of injury

Quality of Pain

No pain quality is pathognomonic for central pain. Central pain is thus not always burning or 'dysesthetic.' In fact, central pain can have any quality, and the variation among patients is great, although some qualities are more common than others (Table 4). Another basic feature is the presence of more than one pain quality in most patients. Different pains can coexist in a body region, or may be present in different parts of the body. One would expect the location of the lesion to be a deciding factor regarding the quality of pain. This appears to be partly true, but it is also apparent that similar lesions can lead to different pain qualities.

Intensity of Pain

The intensity of central pain ranges from low to extremely high. However, even if the pain is of low or moderate intensity, the patients assess the pain as severe because it causes much suffering, due to its irritating character and constant presence.

Central pain usually has a relatively constant intensity, but in some patients the intensity varies. These variations seem to occur spontaneously or under the influence of external somatic stimuli or psychological stimuli, or due to internal events, such as cutaneous stimuli, body movements, visceral stimuli, emotions, and changes in mood. It is also common that patients with central pain experience an immediate increase in pain after sudden fear, joy, loud noise, or bright light. Experience from clinical practice indicates that central pain is as affected by psychological factors, as other pain conditions (i.e., anxiety and depression) aggravate central pain.

Figure 1 Pain drawings of 23 patients with central pain. Sex (W, female; M, male) and age in years are shown for each patient. From Österberg A and Boivie J, unpublished results.

Temporal Pattern of Pain

Central pain may start almost immediately after occurrence of the lesion, or it may be delayed for up to several years. By its nature it is often not possible to define this in disseminated or slowly progressive disease such as MS or syringomyelia. Delays are well known in stroke. This delay may be as long as 2–3 years, but in most patients the pain starts within a few of weeks of the stroke. Most spontaneous central pain is present constantly, with no pain-free intervals. Unfortunately, central pain is usually permanent, but it may remit completely. CPSP may successively decrease and cease completely, but usually continues throughout life. A few cases have been reported in which a new supratentorial stroke abolished the pain.

Pathophysiology

The pathophysiology of central pain can be summarized as follows:

1. The disease process that causes central pain involves the spinothalamic pathways, including the indirect spino-reticulo-thalamic and spino-mesencephalic projections or their trigeminal equivalents, as indicated by abnormalities in the sensibility to pain and temperature. Thalamocortical lesions are also able to precipitate central pain.
2. The lesion probably does not have to involve the dorsal column–medial lemniscal pathways to elicit central pain.
3. The lesion can be located at any level of the neuraxis, from the dorsal horn to the cerebral cortex.
4. Many etiologically diverse processes may cause central pain, but the probability of central pain occurring varies greatly between these diseases, from being rare to occurring in the majority of patients.
5. As yet no single region has been shown to be crucial in the processes underlying central pain, but three thalamic regions have been focused upon – namely, the ventroposterior, reticular, and medial/intralaminar regions. The role of the cerebral cortex in central pain is unclear.
6. The pain and hypersensitivity experienced by central pain patients are believed to result from increased neuronal activity and increased neuronal reactivity along the somatosensory pathways, and decreased inhibitory mechanisms.
7. The cellular processes underlying central pain are still unknown, but processes involving excitatory amino acids, and in particular *N*-methyl-D-aspartate (NMDA) receptors, have been implicated.

Hypotheses Concerning the Mechanisms Involved

Disinhibition by lesions in the medial lemniscal pathways The notion that central pain is caused by lesions in the dorsal column–medial lemniscal pathways was one of the most favored hypotheses in the first half of the past century. The crucial physiological consequence of the lesions was thought to be a disinhibition of neurons in the pain-signaling system.

Lesion in the spinothalamic pathway In the past two decades most investigators have found evidence suggesting that the spinothalamic system is affected in the majority of central pain patients (see earlier). This is the basis for the currently favored hypothesis that central pain only occurs after lesions affecting the spinothalamic system. In many patients the lemniscal pathways are also affected, but this does not appear to be necessary for the occurrence of central pain. It even appears possible that involvement of the lemniscal pathways does not affect the character of the pain. Based on results from research on patients with central pain following spinal cord injuries, it has been concluded that spinothalamic tract lesions are necessary for the development of central pain, but that some other kind of perturbations may also be necessary for its development.

Disinhibition by removal of cold-activated spinothalamic projections The most recent hypothesis is that of Craig. He proposed that "central pain is due to the disruption of thermosensory integration and the loss of cold inhibition of burning pain." This disruption is, according to the hypothesis, caused by a lesion somewhere along the spinothalamic projections to the thalamus.

Treatment

General Aspects

Treating central pain is no easy task, because there is no universally effective treatment. This means that one often must try various treatment modalities to get the best results (Table 5). Treatment usually reduces the pain, rather than giving complete relief, but relatively small decreases in pain intensity are often highly valued by the patients.

One of the similarities between central pain and peripheral neuropathic pain is type of treatment. In both pain categories antidepressants and antiepileptic drugs are the most frequently used drugs, and have the best documented effects and are the only drug types tested in well-conducted clinical trials. They are the first-line treatments, together with transcutaneous electrical nerve stimulation (TENS). There is a body of literature containing thorough discussion of the treatments of neuropathic pain; here only some brief comments are made on this subject.

It is conceivable that treatment affects some aspects of central pain but not others. Therefore it would be desirable to assess the effect of treatment on each pain

Table 5 Treatment modalities used for central pain

Pharmacologic

Spinal cord stimulation
Deep brain stimulation
Motor cortex stimulation
Neurosurgery
Dorsal root entry zone lesions

modality separately, in accordance with ideas about mechanism-based treatments of pain. Another important but still largely unanswered question is whether the different central pain conditions respond differently to a particular treatment. This has not been systematically studied, but such differences appear to exist. From the literature and from clinical experience, one gets the impression that central poststroke pain, as compared to central pain in spinal cord injury (SCI) and MS, responds better to antidepressants. Conversely, paroxysmal pain in MS seems to respond much better to antiepileptic drugs than do other kinds of central pain. It is still uncertain to what extent patients with central pain benefit from the use of strong analgesics. The conclusion is that some, but only a minority, of the patients experience sufficient relief to continue long-term treatment with analgesics. Many of the other treatments listed in Table 5 are more of an experimental character, although some of them are used quite frequently.

Electrical stimulation of the spinal cord or the brain is an exclusive mode of treatment that should be reserved for particularly severe and treatment-resistant pain conditions. The exquisite pain suffered by many central pain patients fulfills such a criterion. From a review of the literature, and based on experience with his own patients, Tasker concluded that spinal cord stimulation is not effective enough in central pain to be recommended, a view shared by Gybels and Sweet, Nashold, and Pagni. Instead Tasker favors deep brain stimulation (DBS) or motor cortex stimulation (MCS). In recent years the focus has been on surface stimulation of the motor cortex, with several groups reporting good effects, particularly on CPSP.

Many different surgical lesions have been tried to provide relief of central pain, but no particular lesion has been found that reliably results in successful outcome. Dorsal root entry zone (DREZ) lesions have gained interest over recent years for the treatment of central SCI pain, but so far results have not been consistent.

Antidepressants Table 5 presents the first-line drugs for central pain. Controlled trials have been done with antidepressants (ADs) only on CPSP (15 patients) and the central pain in SCI, with conflicting results. In the CPSP study there was a statistically significant reduction in pain as compared to placebo. The number-needed-to-treat (NNT) value for amitriptyline was 1.7 (1.1–3.0). These results contrast with those from a controlled study of amitriptyline on central pain in 44 patients with SCI in which no significant effects were found, compared to active placebo, but the doses were relatively low, judging by the plasma concentrations.

Antiepileptic drugs An effect on central pain has only been demonstrated for the antiepileptic drug (AED) lamotrigine in central poststroke pain. Gabapentin has been recommended for the treatment of neuropathic pain. Several case reports describing successful treatment of central pain have been published, but so far no good controlled studies on central pain have been published. Recently pregabalin, closely related to gabapentin, was shown to give good relief of central pain in a trial on 137 patients with SCI. In trigeminal neuralgia it is clear that the pain-relieving effect of carbamazepine is strongly correlated with the plasma concentration, as in epilepsy. It is not known weather this is also the case with AEDs in central pain. No such correlation was found in the study on CPSP.

Like the antidepressants, the AEDs have a tendency to cause troublesome side effects, and must therefore be managed with caution. It is possible that some groups of patients are more amenable to the side effects than are other patients with neurological diseases, because many neurologists have the impression that carbamazepine, and possibly also other AEDs, cause more problems in MS patients than in patients with idiopathic trigeminal neuralgia or epilepsy. This could be explained by the fact that carbamazepine has effects on cerebellar centers for the coordination of movements, which are frequently affected by the disease process in MS.

Many AEDs might cause allergic reactions, mainly in the skin. The most serious reactions occur in rare instances with the use of lamotrigine. The best way to prevent this is to increase the dose slowly.

Analgesics, cannabinoids The question of whether central pain responds to analgesics is still controversial. The results from acute, single-blind tests of opioids, as well as a controlled clinical trial with the potent μ-opioid agonist levorphanol on patients with CPSP, indicate low sensitivity to opioids. This is similar to the experience of many patients with central pain who undergo operations and receive opioids

postoperatively – namely, that they have a good effect on the pain related to the operation, but no effect on the central pain.

In a study on five patients with stroke and ten with spinal cord injury, intravenous morphine did not give significant pain relief, but there was a strong tendency to obtain better pain suppression by the morphine, compared to placebo. However, in the open posttrial oral medication period, only three patients (= 17%) continued with morphine for at least 12 weeks. The others stopped before that, because of side effects and/or poor relief. The conclusion was that opioids may be useful for a minority of patients with central pain, and that the effect is modest in most of these. This is in accord with common clinical experience.

For many years the use of cannabinoids in neuropathic pain has been discussed. Two controlled clinical trials on central pain in MS have now been reported. A weak but significant pain-relieving effect by oral dronabinol was found in 24 patients during 3 weeks of treatment. In the second study on 64 patients (34 took a whole-plant based spray for 5 weeks) a clear significant pain relief was recorded.

The identification and characterization of brain mechanisms involved in the processing of pain is essential for a better understanding of the complex phenomenon that is the pain experience. Although many advances have been made in the understanding of central nervous system mechanisms involved in pain processing, delineating the roles of the supraspinal structures in pain has been a difficult task, in part because of the complexity and multiplicity of mechanisms supporting this essential sensory experience. For example, lesions of the cerebral cortex rarely produce a complete loss of the capacity to experience pain. Furthermore, pain is only rarely reported in response to direct electrical stimulation of the cerebral cortex in unanesthetized patients undergoing neurosurgery. These two classic findings have led to the long-held view that the cerebral cortex is not substantially involved in the processing of pain. Yet modern research employing single-neuron recording techniques in animals has identified several cerebral cortical regions that appear to be involved in pain processing. How can this apparent paradox be resolved to better understand the contribution of the cerebral cortex to the pain experience?

The answer lies in the possibility that simultaneous activation of multiple regions distributed throughout the brain may be necessary for many aspects of pain perception. Testing this hypothesis, however, is not feasible with the traditional single-neuron recording techniques that permit investigation of only small numbers of neurons in discrete brain regions. Other methodological approaches which can evaluate the responses of many brain regions simultaneously are needed to assess the extent and distribution of activation that may be evoked during the pain experience. To these ends, functional imaging techniques have been successfully employed to map the responses of multiple cerebral cortical and subcortical areas to pain.

To date, the most effective imaging techniques used to study pain have been positron emissions tomography (PET) and functional magnetic resonance imaging (fMRI). Both techniques typically examine changes in cerebral blood flow (CBF). CBF has long been known to be correlated with neuronal activity and, in many studies of cognitive tasks, has proven a reliable index of activity. Furthermore, this approach has the particularly powerful advantage that human subjects can be studied without anesthesia and can undergo multiple scans without significant radiation exposure. Autoradiographic techniques using similar indices of activity are employed effectively in animal studies as well.

Since 1991, a number of functional imaging studies have examined the processing of pain by the human brain and, despite the use of different painful stimuli and different experimental conditions, have produced a remarkably consistent map of brain regions involved in pain processing. Many investigations have now identified pain-induced activation of a number of brain regions which, together, appear sufficient to support the complex sensory, affective, autonomic, and motor components of the pain experience. These regions and their possible roles in the pain experience are detailed next.

Overview of Brain Regions Active during Pain

Thalamus

A substantial portion of nociceptive information entering the brain from the spinal cord is received by a number of nuclei in the thalamus. These include lateral thalamic nuclei, such as the ventroposteriolateral and the ventroposteriomedial nuclei, and medial thalamic areas, such as the intralaminar nuclei and mediodorsal nucleus. Neurons responsive to painful stimuli have been identified in both the lateral and medial thalamic nuclei – those in the lateral thalamic nuclei generally have unilateral receptive fields representing only a portion of the body, whereas neurons in the medial thalamic nuclei generally have large bilateral receptive fields. Neurons in both regions have been demonstrated to encode pain intensity with an accuracy sufficient to support behavioral discrimination. Accordingly, most functional imaging studies of acute pain in normal subjects have detected significant activation in the thalamus. This activation is typically located contralateral to the stimulated area, but may become bilateral if stimuli are sufficiently intense (**Figures 1(c) and 1(d)**). Determining exactly which thalamic nuclei are activated remains a difficult issue because neither PET nor fMRI offers sufficient spatial resolution to easily distinguish among the small, tightly packed nuclei of the thalamus.

Primary Somatosensory Cortex

Neurons in the lateral thalamic nuclei constitute the bulk of subcortical input to the primary somatosensory cortex (SI), a functional region consisting of Brodmann's areas 3, 1, and 2 of the postcentral gyrus.

Figure 1 Distributed processing of pain intensity by the human brain: (a) activation of primary somatosensory cortex (SI); (b) activation of secondary somatosensory cortex (SII); (c) activation of thalamus (Thal) and cingulate cortex; (d) activation of Thal and insular cortex. Multiple regression analysis of positron emission tomography (PET) data revealed statistically reliable relationships between perceived pain intensity and activation of a functionally diverse group of brain regions, including those important in sensation, motor control, affect, and attention. Pain intensity-related activation occurred bilaterally in the cerebellum (Cb), Thal, insula (Ins), anterior cingulate cortex (ACC), and SII; contralaterally in the SI and supplementary motor area (SMA); and ipsilaterally in the frontal operculum (FrOp). Statistical maps derived from functional PET data (color) are superimposed on structural magnetic resonance images of brain structure (gray). The color scale denotes the regression coefficient of brain activation, which exhibited a statistically reliable relationship with subjective ratings of pain intensity. Modified from Coghill RC, Sang CN, Maisog JM, and Iadarola MJ (1999) Pain intensity processing within the human brain: A bilateral, distributed mechanism. *Journal of Neurophysiology* 82: 1934–1943, used with permission from The American Physiological Society.

Although SI has long been known to play a key role in the processing of innocuous stimuli, its role in the processing of pain has until recently been controversial. Classical studies of patients with brain lesions identified few disruptions of pain when the postcentral gyrus was damaged. Electrical stimulation of this area rarely led to the subjective experience of pain in conscious patients during neurosurgery. However, neurons responsive to painful stimuli have been identified in this area and exhibit a somatotopy similar to neurons that process exclusively innocuous stimuli. Nociceptive neurons in SI are notoriously difficult to identify and generally represent only a small portion of neurons encountered during recording sessions. Functional imaging studies by different groups have now demonstrated significant activation of SI during pain (Figure 1(a)). This activation is almost always contralateral to the stimulated region and occurs in areas consistent with the known somatotopy of SI. This region is activated in a fashion that is dependent on the perceived intensity of pain. The somatotopic focus of pain-induced activation in SI, combined with limited observations that lesions of SI disrupt the ability to extract some of the sensory features of painful stimuli, suggests that this region makes an important contribution to some of the sensory-discriminative aspects of the pain experience. Given the equivocal stimulation and lesion results in humans, it appears that although this region may contribute to pain perception, other regions must necessarily be activated to appreciate the full experience of pain.

Secondary Somatosensory Cortex and Posterior Insular Cortex

Other cerebral cortical areas probably involved in processing some of the sensory-discriminative aspects of pain include the secondary somatosensory cortex (SII) and related somatosensory fields of the posterior insula. These areas receive input from the SI, but also, in primates, receive direct input from thalamic regions likely to be involved in pain processing. Nociceptive neurons with large, typically bilateral receptive fields have been identified in these regions. Unilateral lesions of this area elevate pain thresholds and degrade tactile discrimination abilities, but do not produce a complete elimination of pain sensibility. Functional imaging studies frequently identify bilateral activation within the SII and adjacent areas (Figure 1(b)). Like the SI, the magnitude of this activation is also significantly related to the perceived intensity of pain. Functional imaging studies have also identified multiple and complex somatopically organized body representations in multiple subregions of the SII.

Cingulate Cortex

The cingulate cortex (Figures 1(c) and 2) is one of the most consistently activated regions during functional imaging studies of pain. Classic studies of chronic pain patients who have undergone transection of the cingulum bundle, a white matter pathway through which much input and output of the cingulate cortex travels, have led to the idea that the cingulate cortex plays a role in the processing of pain-related affect. Multiple functional imaging studies have shown that this area is involved with processes related to general affect and to pain-related affect. In humans, selective hypnotic amplification of the unpleasantness, but not the intensity, of pain has been shown to increase activation within this region, indicating that

Figure 2 Pain-induced activation of the anterior cingulate cortex (ACC; upper orange blob) and thalamus (Thal; lower orange blob) displayed on a volume rendering of a human brain: (a) high-sensitivity individuals; (b) low-sensitivity individuals. SI, primary somatosensory cortex.

it is involved the processing of the negative emotional aspects of pain. However, this region also responds in a graded fashion to progressive increases in nociceptive stimulus intensity, indicating that it has access to and can use intensity-related information.

On the basis of both anatomic and functional criteria, this complex structure has been subdivided into the anterior cingulate cortex, midcingulate cortex, posterior cingulate cortex, and retrosplenial cortex. In studies of pain, regions of the anterior and midcingulate cortex in Brodmann's area 24 (typically referred to as the anterior cingulate cortex) are most frequently activated. Portions of this structure receive direct nociceptive input from the medial dorsal nucleus and intralaminar nuclei of the thalamus and have extensive connections with the amygdala, prefrontal cortex, and anterior insular cortex. Although nociceptive neurons have been identified in the cingulate cortex, this region is by no means exclusively involved with pain processing. It appears to be important in analgesia. The cingulate cortex has high concentrations of opioid receptors and is also active during placebo analgesia. Consistent with a role in analgesia, but in contrast to classic lesion studies in chronic pain patients, lesions of the anterior/midcingulate cortex and cingulum bundle increase responses to acute pain in nonpain patients.

The anterior cingulate cortex is involved with autonomic regulation and processing of emotional memories. This portion of the cingulate cortex is also frequently activated in functional imaging studies with high attentional demands and appears to be involved in avoidance learning. The midcingulate cortex is involved in reward-based decision making as well as response selection. Anterior portions of the midcingulate cortex have cortico-spinal projections and may play a role in some of the motoric responses to pain and other somatosensory stimuli. All these diverse functions are important for the processing of pain, and many careful investigations will probably be needed to fully characterize the multiple roles of the cingulate cortex in pain.

Anterior Insular Cortex

Similar to the cingulate cortex, the anterior insular cortex probably plays multiple complex roles in the processing of pain (Figure 1(d)). This region is frequently activated during functional imaging studies of pain and exhibits monotonic increases in activity as perceived pain intensity increases. The anterior insular cortex is reciprocally connected with anterior portions of the cingulate cortex and similarly receives direct nociceptive input from the thalamus. Like the cingulate cortex, it is connected with the amygdala and prefrontal cortex. However, it is highly connected with the posterior insular cortex, which, in turn, is connected with the SII. As such, it has been proposed to serve as a cortico-limbic pathway for somatosensory information. Limited stimulation and lesion studies support anatomic evidence for this region's serving to link somatosensory and limbic processes. Lesion patients have been reported to have altered affective responses to noxious stimuli, whereas nonpain patients undergoing stimulation of this area report feelings of fear. Functional imaging studies indicate that this region is not exclusively involved in unimodal somatosensory processing but responds in a multisensory fashion to visual, auditory, and tactile stimuli. This area, thus, may be critical for integrating ongoing afferent information with memory, allowing a full appreciation and evaluation of the meaningfulness of multidimensional aspects of the stimulus in light of previous experience.

Prefrontal Cortex

The prefrontal cortex is heavily connected with both the anterior cingulate cortex and the anterior insular cortex. This region has been thought to be involved in aspects of pain since the prefrontal lobotomy studies in the late 1940s. Patients with prefrontal lobotomies still experience pain and, in some cases, have been reported to have decreased thresholds for acute pain. However, during chronic pain, these patients exhibit disrupted pain affect and appear to have difficulty understanding the meaning and future implications of their pain. The prefrontal cortex is frequently seen to be activated in functional imaging studies of pain. In some instances, activation of this region is related to perceived pain intensity, particularly when analyses are weighted toward individual differences in subjective reports of pain. In other studies, prefrontal activation appears to be related to the cognitive difficulty of generating a rating of the stimulus. Such roles are not mutually exclusive because the

prefrontal cortex is extremely important in attention, affect, working memory, future planning, and decision making. It is clearly activated during the evaluation of stimuli of multiple sensory modalities. The prefrontal cortex is heavily connected with the amygdala and hippocampus and, as such, is well positioned to integrate information from the anterior cingulate and anterior insular cortices with both historical autobiographical information and information from the environmental milieu. All these processes are probably important in the evaluation of afferent sensory information as well as the application of a meaning and future significance to this information.

The prefrontal cortex also appears to be important in the modulation of pain. Studies of expectation and anticipation indicate that prefrontal activation prior to the stimulus can influence the subjective experience of the stimulus. Such roles of expectation are crucial elements of the placebo response. Consistent with this functionality, the prefrontal cortex is significantly involved in placebo analgesia.

Supplementary Motor Cortex and Motor Processing

A number of other brain regions are activated during the pain experience. Such areas include regions thought to be important in motor processing, such as the cerebellum, putamen, and supplementary motor cortex (Figures 1(a) and 1(c)). Escaping from and/or orienting to a painful stimulus is a critical response necessary to minimize possible injury and identify the cause of pain and is a key component of the pain experience. Given that subjects do not generate actual movements during the scanning period, activation in these motor-related areas has been postulated to reflect the neural infrastructure that processes movement preparation or suppression. The supplementary motor cortex is thought to be important in internally directed motor planning, timing, sequencing, and action retrieval. All these processes are probably engaged when a conscious human subject actively suppresses withdrawal responses while simultaneously considering how to escape from a noxious stimulus if the pain becomes intolerable.

Basal Ganglia

Typically, the functions of the basal ganglia are discussed in terms of motor processing. However, the basal ganglia are involved in numerous other processes and are frequently activated during pain. Of the basal ganglia, the putamen is most frequently activated during pain. Nociceptive neurons have been identified in this region as well as the caudate nucleus. Both the caudate and putamen represent important structures for cortical input into the basal ganglia. Much output of the basal ganglia is sent back to the same cortical region (via the thalamus) as the input. This loop architecture may provide a substrate for sequential evaluation of sensory information. In addition, the basal ganglia are known to play important roles in reward and reinforcement and to respond robustly to novel and behaviorally salient stimuli. All these processes are highly relevant to pain.

Cerebellum

Much like the basal ganglia, the cerebellum is typically associated with motor processing; its role in pain remains poorly explored and poorly understood. Both the cerebellar vermis and the cerebellar hemispheres are activated frequently in functional imaging studies of pain (Figure 1(c)). Much like the basal ganglia, the cerebellum is connected with the cerebral cortex in a loop architecture. Projections from the cortex synapse on pontine neurons, which in turn project to the cerebellum. The cerebellum then projects back to the same cortical region via the thalamus. These loops involve the motor and premotor cortices, as well as the prefrontal cortex. The cerebellum is frequently activated in cognitive studies that do not involve movement, and lesions of the cerebellum have been reported to disrupt affect. Thus, at least some of the cerebellar activation observed during pain may be related to cognitive and affective processes involving the prefrontal cortex.

Brain Regions Deactivated during Pain

As already discussed, numerous brain regions exhibit increased activity while subjects undergo noxious stimulation. However, several brain areas appear to be less active during pain than during rest or during nonpainful stimulation. These regions include the posterior cingulate cortex and the adjacent precuneus (Figure 1(c)), as well as the ventromedial prefrontal cortex. Similar deactivations are seen during a wide variety of experimental tasks that do not involve pain. Interpretation of these consistently deactivated areas has remained limited due to the difficulty of designing appropriate control conditions and the lack of fully quantitative assessments of brain activation. However, emerging evidence suggests that these areas are highly active during the rest condition when conscious subjects are frequently allowed to think in an unconstrained fashion. Then, when subjects are engaged in a task, these random thoughts are terminated and produce an apparent deactivation.

Brain Activation during Chronic Pain

When pain is evoked by normally nonpainful stimuli in patients with chronic pain, brain activation patterns are generally similar to those produced by acute pain in healthy subjects. However, during some forms of

chronic neuropathic pain, patterns of cerebral blood flow are markedly different than those seen in healthy subjects. During resting pain, patients with complex regional pain syndrome exhibit paradoxically low cerebral blood flow in the thalamus that is contralateral to their affected limb. The physiological significance of this unusual pattern of cerebral blood flow is unclear. It may reflect alterations in metabolic activity that result in perturbed relationships between neural activity and blood flow. Alternatively, it may represent a loss of inhibition, such that afferent nociceptive information is minimally modified before being distributed to the cerebral cortex.

Brain Mechanisms Supporting Individual Differences in the Subjective Experience of Pain

Pain is a profoundly individualized experience. Some individuals are highly sensitive to pain, whereas others are surprisingly insensitive. Prior to the advent of functional imaging, developing an understanding of these individual differences in the subjective experience of pain remained difficult due to the challenges of separating interindividual experiential differences from interindividual differences in the reporting of pain to a third-person observer. However, functional imaging studies of individuals reporting vastly different pain from a standardized heat stimulus indicate that, consistent with their subjective reports, highly sensitive individuals exhibit significantly more frequent and significantly greater activation of the primary somatosensory cortex, anterior cingulate cortex, and prefrontal cortex (Figure 2). In contrast, sensitive and insensitive individuals exhibit roughly similar levels of thalamic activation, suggesting that experiential differences emerge once afferent information has traveled beyond the suprathalamic levels.

Interindividual differences in the experience of pain may arise from a convolution of an individual's past history, present environment, and perceived future implications of a stimulus with incoming afferent information. The delineation of mechanisms by which these factors influence afferent processing has been accomplished, in part, by examining the effects of learned expectations on pain. Expectations are future predictions of the nature of an experience that are derived from previous experience with a stimulus as well as the present context in which the stimulus is presented. Brain regions including the prefrontal cortex, anterior cingulate cortex, and anterior insular cortex are activated in a manner that is proportional to expected pain, indicating that they are involved in the construction of a mental representation of an impending stimulus. All these regions are also activated during the actual experience of pain and, as such, can provide a substrate for the integration of expected information and afferent information. This convergence appears to be critical in the elaboration of the pain experience because reduced expectations of pain result in reduced reports of pain as well as reduced pain-related brain activation. Accordingly, expectations may provide a sensory set that substantially influences how afferent information is processed.

Distributed versus Parallel Processing of Pain

The multiple brain areas activated during functional imaging studies of pain reflect the complex mix of sensory, emotional, attentional, and motoric components of the experience that we know as pain. Although each region mentioned may be preferentially involved with some specific processing task, the number of different brain regions activated by painful stimulation and the high degree of connectivity among these areas strongly suggest that pain is processed by complex distributed cortical and subcortical networks. Furthermore, many of these networks are not only involved exclusively with the processing pain but are also probably involved in the processing of innocuous stimuli and in processes underlying cognitive evaluation of the situation within our environment.

A distributed system of pain processing explains the difficulty in eliciting painful sensations by cortical stimulation because simultaneous activation of several brain regions could be necessary for pain. Similarly, a distributed pain system explains why discrete cortical lesions seldom lead to a complete reduction in pain but may alter certain aspects of the pain experience, and why chronic pain may initially be alleviated by lesions at different levels of the neuraxis but usually returns after a period of months. This resiliency of chronic pain may involve a plasticity of networks involved in the processing of pain, whereby functions usually performed by one region are taken over by another. Such resiliency is of obvious evolutionary value because the ability to detect, understand, and escape pain is essential for survival. Future studies in this rapidly advancing field of functional imaging will probably provide a better characterization of the complex processes that underlie the pain experience.

PANDAS (Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infections)

P J Hoekstra, R B Minderaa, and C G M Kallenberg, University of Groningen, Groningen, The Netherlands

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The acronym PANDAS stands for 'pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections.' The notion that tics may be associated with infections was raised by the German psychiatrist Erwin Straus in 1927, and 2 years later by the American neurologist Laurence Selling, but subsequently faded into oblivion. In the mid-1990s, however, several case studies entered the literature, describing children who suddenly demonstrated severe tics and obsessive–compulsive symptoms that appeared to be temporally linked to streptococcal infections. Confronted with a failure of conventional treatment approaches, the authors of those studies described the successful application of immune-based treatments in some of these cases, consisting of therapeutic plasma exchange, intravenously administered immunoglobulins, or simple use of antibiotics to treat the infectious process. In some cases, streptococcal reinfections were associated with the reinduction of symptoms.

There also was the notion that patients with Sydenham's chorea, which has a well-established link to group A streptococcal infections, often show behavioral symptoms, including obsessions, compulsions, marked irritability, and emotional lability, and a substantial number of children with obsessive–compulsive disorder (OCD) were reported to show choreiform movements or tics. Furthermore, a study had suggested the presence of autoantibodies reacting with brain tissue in the serum of patients with tics and/or OCD. These observations led researchers at the National Institute of Mental Health to formulate clinical criteria for a putative subgroup of children with OCD and/or a tic disorder, designated PANDAS; in these children, symptom exacerbations were abrupt, dramatic, and temporally related to group A beta-hemolytic streptococcal (GABHS) infections. The concept of PANDAS strongly centers on Sydenham's chorea as a putative disease model, including the suggested pathogenic role of autoantibodies that cross-react with basal ganglia antigens as a hypothesized consequence of structural homology with streptococcal antigens. Research criteria were outlined for the PANDAS subgroup (see Table 1). What percentage of children with a tic disorder and/or OCD meet criteria for PANDAS is unknown. Although PANDAS criteria require prepubertal symptom onset, cases with adult-onset symptoms that otherwise meet PANDAS criteria have been described.

PANDAS is not an established clinical entity nor enlisted in formal disease classifications. Indeed, the very idea that tics or OCD symptoms might be related to autoimmunity remains, as yet, controversial, even when and if there is an established association with infections. Moreover, some of the criteria for PANDAS have been criticized for being vague and insufficiently operationalized. Especially, it is hard to say when precisely the criterion of a temporal association between GABHS infections and symptom onset and exacerbations has been met. Interestingly, in Sydenham's chorea, a latent period as long as 6 months, between onset of symptoms and the preceding GABHS infection, is not uncommon. GABHS infections are fairly common in children in general, as are remissions and exacerbations in children with tic disorders. Another criterion for PANDAS, the presence of an episodic course of symptom severity with explosive exacerbations and remissions, is not easy to apply either. An episodic course of symptoms is characteristic of pediatric tic and OCD symptoms in general, but it is hard to say when exacerbations can exactly be called explosive.

A more fundamental concern regarding the concept of PANDAS is the risk of circularity. From a scientific perspective, research that attempts to define the extent of immune involvement in neuropsychiatric disorders should better preclude the *a priori* selection of cases that, by definition, demonstrate a temporal relationship with streptococcal infections. Indeed, much of the evidence supporting a possible role for autoimmunity in tic disorders and OCD has been based on unselected individuals. Findings in unselected cases and in cases fulfilling criteria for PANDAS have been similar in magnitude. Still, introduction of the concept of PANDAS has certainly done much to stimulate research and clinical interest in the potential relevance of immune factors in tic and related disorders. In the following sections, after outlining the main clinical features of PANDAS, we present an overview of findings supporting, as well as challenging, the immune hypothesis of tic and related disorders.

Clinical Features

The first PANDAS criterion requires the presence of a tic disorder and/or OCD, two clinical entities that are generally regarded distinct in phenomenology and

Table 1 Criteria for diagnosis of PANDAS

Presence of obsessive–compulsive disorder and/or a tic disorder
Pediatric onset
Episodic course of symptom severity
Association with group A beta-hemolytic streptococcal infection
Association with neurological abnormalities

presumed etiology. Involuntary, rapid, recurrent, nonrhythmic motor movements and/or vocalizations are the defining features of tic disorders. Common motor tics include eye blinking, neck jerking, shoulder shrugging, and facial grimacing, whereas typical examples of vocal tics are throat clearing, barking, sniffing, and hissing. Tic intensity can vary substantially, ranging from barely visible or audible tics to extremely forceful or loud expressions. Quite often, tics are mild, in which case they may hardly attract attention from others and may not interfere with everyday life at all. However, powerful and frequent tics may severely interfere with everyday activities, including speech, driving, and walking. In exceptional cases, tics may lead to physical injury, including joint dislocation and other tissue damage. Tics usually start around the age of 6 years, are often transient, and tend to improve after adolescence, but may persist into adult life. Frequently, tic disorders are associated with a wide variety of emotional disturbances, especially obsessional phenomena, sometimes justifying a comorbid diagnosis of OCD. OCD is characterized by recurrent and persistent thoughts (obsessions) and/or repetitive behaviors (compulsions) that the person feels driven to perform in response to an obsession, or according to rules that must be applied rigidly. Only a subgroup of pediatric OCDs may be etiologically related to tic disorders, characterized by a family history of tics, a more familial subtype in general, male preponderance, association with disruptive behavior and developmental disorders, and a less striking association with mood disorders. The predominant phenomenology of obsessions/compulsions also differs between tic-related and non-tic-related OCDs. Presence of hoarding/symmetry and sexual and aggressive symptoms predominates in the former, whereas in non-tic-related OCD symptoms of contamination/checking prevail. In tic-related OCD, compulsions do not generally appear to be anxiety driven, but rather could be phenomenologically regarded as complex tic behaviors. It is well known that so-called mental tics form a part of tic symptomatology, and in some cases certain obsessions and compulsions could be better conceptualized as mental and complex tics, respectively. Thus, it may well be that the presence of tics – or, more generally, a movement disorder, in contrast to anxiety-driven obsessions and compulsions – forms the distinctive feature of those neuropsychiatric disorders which may be related to autoimmunity.

The PANDAS criterion of an episodic course of symptom severity refers to a clinical course characterized by the abrupt onset of symptoms or by dramatic symptom exacerbations. Typically, the onset of a specific symptom exacerbation can be assigned to a particular day or week, at which time the symptoms seemed to 'explode' in severity. Symptoms usually decrease significantly between episodes and occasionally resolve completely between exacerbations. Symptom exacerbations must be temporally related to GABHS infection (i.e., associated with positive throat culture and/or elevated anti-GABHS antibody titers). The temporal relationship between the GABHS infection and the symptom exacerbation may vary over the course of the illness, with recrudescences following the GABHS infections at much shorter intervals, often with a time lag of only several days to a few weeks, than are seen in first episodes. Because fever and other stressors of illness are known to increase symptom severity, the exacerbations should not occur exclusively during the period of acute illness. Finally, common examples of the required association with neurological abnormalities include motoric hyperactivity and adventitious movements (including choreiform movements or tics).

Laboratory Abnormalities

The diagnosis of PANDAS is made on clinical criteria alone. There are no laboratory tests that can diagnose PANDAS. Still, a number of the laboratory findings that have been reported in tic disorders and/or OCD may support the involvement of immune dysregulation. These include the presence of serum autoantibodies reacting with basal ganglia, increased streptococcal antibody titers, alterations in T and B cell subsets, and changes in levels of cytokines and adhesion molecules. It should be noted that these laboratory measures have virtually no place in the clinical management of patients with a tic disorder, OCD, or suspected PANDAS, perhaps with the exception of streptococcal antibody titers.

Antineuronal Antibodies

The presence of autoantibodies against basal ganglia in the peripheral blood of patients with tics and/or OCD is potentially a strong line of evidence in favor of the autoimmune hypothesis of these disorders, and has been repeatedly reported by several research groups. Results, however, have been partially conflicting, and relatively high levels of antineuronal staining have been found in sera from healthy controls. It is unclear how to interpret this overlap between patients and controls. It

raises suspicions of methodological flaws, suggesting rather high levels of nonspecific binding, albeit not necessarily, given that autoantibodies in healthy individuals have repeatedly been reported. Unfortunately, as yet, no accepted standardized methodology of assessing anti-basal-ganglia antibodies is available. Rather, different research centers have all used different methods, which makes results difficult to compare. Varying substrates of brain tissue have been utilized across studies, ranging from immortalized neuronal cell lines to animal and human brains, and have, moreover, been prepared in different ways. Also, methods of assessing antibody binding to brain tissue have differed from center to center. Early studies used immunofluorescence microscopy, which implies that assessment of presence of antibody binding depends on subjective human judgment, whereas more recent studies have made use of enzyme-linked immunosorbent assays (ELISAs), which is a more objective and quantitative method.

Assessed with an indirect immunofluorescence technique, autoantibody binding to human caudate tissue in patients with tics and/or OCD has been reported in 44–50% of tic disorder patients versus 21–24% of healthy controls. Subsequent studies using ELISA techniques against either an immortalized neuronal cell line, human basal ganglia, or rat brain in general have confirmed the increased levels of serum antineuronal antibodies in patients with tic disorders.

An important consideration when interpreting studies regarding anti-basal-ganglia status is whether observed antibody–antigen bindings are truly specific antineuronal bindings. Brain tissue contains a host of antigens which are not exclusively neuronal. The technique of Western blot, which separates proteins according to molecular weight, facilitates the identification and subsequent sequencing (molecular characterization) of specific candidate autoantigens. Common binding to basal ganglia antigens of 40, 45, and 60 kDa has been observed; these autoantigens have been identified as neuronal glycolytic enzymes (i.e., aldolase C, enolase, and pyruvate kinase M1, respectively). Neuronal glycolytic enzymes are multifunctional proteins that are expressed intracellularly as well as on the neuronal cell surface. On the neuronal plasma membrane, these enzymes are involved in energy metabolism, cell signaling, and synaptic neurotransmission. Interestingly, antibodies to pyruvate kinase have been found to also react strongly with surface antigens of infectious strains of *Streptococcus*, and conversely, antibodies to streptococcal M proteins react with pyruvate kinase.

The mere presence of autoantibodies does not necessarily imply a causal involvement of autoimmunity. Autoantibodies against a range of tissue antigens are normally present in healthy individuals, probably as part of the immune system's ongoing process to discriminate between self and non-self. Whether these autoantibodies cause damage and, thus, may have pathological significance is what counts, not the presence *per se*. Autoantibodies are also found when tissue damage is caused by trauma or infection. In other words, autoantibodies can result from, rather than be the cause of, tissue damage. Currently, the pathogenetic meaning of antineuronal antibodies in tic disorders and OCD is unclear. Some support for the direct involvement of antineuronal autoantibodies in the disease process stems from two different research findings. First, intravenously administered immunoglobulins and therapeutic plasma exchange were reported to be effective treatments in cases fulfilling PANDAS criteria. These treatment modalities are thought to block or remove the antineuronal autoantibodies, respectively. A second pillar possibly supporting a pathogenic role of antineuronal antibodies is formed by induction of stereotypic movements in rodents through passive transfer of antibodies by means of striatal microinfusions. Rats microinfused with sera from patients with a tic disorder subsequently show a significant increase in ticlike behaviors (e.g., licks and forepaw shakes) and episodic utterances, which are not observed when sera from healthy controls are microinfused. These findings have not uniformly been replicated, however.

In conclusion, the assessment of serum autoantibodies has appeared to be a fruitful research field in tic disorders. However, this area is very much a work in progress, especially with regard to standardization of methods and elucidating the pathogenic relevance of the antibody–antigen interactions in animal models.

Association with Antistreptococcal Antibody Titers

It is remarkable that studies that did not preselect tic disorders according to PANDAS criteria provide the best available evidence for an association of tic disorders with streptococcal infections, even when the exact nature of this possible association remains unclear. Such studies have repeatedly found markedly increased serum levels of antistreptococcal antibodies in a single-time-point design. Interestingly, it has been reported that levels of streptococcal antibody titers correlate with tic severity and that elevated streptococcal antibody titers are associated with the presence of anti-basal-ganglia antibodies. The cross-sectional nature hampers interpretation of these findings, especially since antibody levels are typically not assessed at the time of the first appearance of the tics, nor at a time of symptom exacerbation, but rather at an arbitrary point in time.

The cross-sectional data of increased antistreptococcal titers fit well with a longitudinal study that

found that the average annual rate of new streptococcal infections was 0.42 infections per patient per year among unselected pediatric patients with Tourette's disorder or OCD, compared with 0.28 infections per person per year for controls, even when no association was found between new streptococcal throat infections and symptom exacerbations. In another longitudinal study, however, positive correlations were detected between streptococcal titers and obsessive–compulsive severity rating changes in a subgroup of patients with large symptom fluctuations over time. These subjects were also more likely to have elevated streptococcal titers in comparison with patients without such dramatic fluctuations. Furthermore, there are data indicating that patients with tic disorder or OCD are more likely than controls to have experienced streptococcal infection in the 3 months prior to disease onset date, as well as multiple streptococcal infections within the preceding 12 months. Finally, in a longitudinal study involving a large number of healthy children, a strong relationship has been demonstrated between positive streptococcal throat swab cultures and both hyperactive behavior and choreiform movements. All in all, these studies indicate an intriguing association between streptococcal infections and tic and OCD symptoms. Large-scale prospective studies are needed to fully understand the relevance of streptococcal infections.

Alterations in Other Immune Parameters

Studies of lymphocyte subsets in tic disorder/OCD patients have provided some interesting preliminary findings. A D8/17-specific mouse monoclonal immunoglobulin M (IgM) antibody has been reported to bind to an increased percentage of B lymphocytes in rheumatic fever patients and patients with tic disorder, OCD, or PANDAS, in comparison with healthy controls. These studies seemed to suggest that increased D8/17 B cell expression could not only serve as a peripheral susceptibility marker for rheumatic fever, as had previously been investigated, but also as a marker for movement disorders and/or OCD associated with preceding streptococcal infections. Antibodies against D8/17 were originally prepared from fusions of spleen cells from mice that had repeatedly been immunized with isolated human B lymphocytes obtained from rheumatic fever or rheumatic heart disease patients. Unfortunately, several problems considerably reduce the enthusiasm for D8/17. More recent studies that used more sophisticated methods (flow cytometry vs. immunofluorescence microscopy; proper isotype control to rule out nonspecific binding) have failed to replicate earlier findings, perhaps due to insufficient stability of the antibody. A major problem is the lack of molecular characterization of the antibody. Therefore, the precise meaning of elevated D8/17 expression remains elusive.

New data suggest that patients with tic disorders may have a decreased capacity to inhibit autoreactive lymphocytes through a deficit in T regulatory cells. A significant decrease in T regulatory cells is observed in patients with moderate to severe tic symptoms compared with healthy age-matched control children. A decrease in T regulatory cell number is also noted during symptom exacerbations. The T regulatory cells play a major role in preventing autoimmunity, and the observation of decreased numbers offers an interesting potential mechanism for the induction of autoimmunity in tic disorders.

Only a limited number of studies have investigated cytokine profiles in patients with tic disorders and/or OCD. Interleukin-12 and tumor necrosis factor-α concentrations are found to be elevated in pediatric patients, compared with healthy controls. Both of these markers appear to be further increased during periods of symptom exacerbation. These findings suggest that symptom exacerbations are associated with an inflammatory process propagated by systemic and local cytokine synthesis that might involve the central nervous system. This is compatible with an autoimmune hypothesis of tic disorders and pediatric-onset OCD. In contrast, in adult patients with OCD, tumor necrosis factor-α has generally been reported to be lowered.

Children fulfilling PANDAS criteria have also been demonstrated to have increased levels of soluble intercellular adhesion molecule-1, but not vascular cell adhesion molecule-1 and E-selectin. This also points to the involvement of systemic inflammation and supports the hypothesis of an ongoing immune-mediated process in PANDAS. Finally, in a peripheral leukocyte-based gene expression study, tic disorders were found to be characterized by several gene expression clusters, including one cluster in which six genes were overexpressed, all of which were associated with immune cell function. This had been assessed by microarrays, which provide the opportunity to analyze thousands of genes at once.

To summarize, alterations in a number of immune parameters, including B and T cell subsets, cytokine profiles, and adhesion molecules, in patients with a tic disorder and/or OCD could be in line with inflammatory processes and/or autoimmunity. Still, as yet, these have no place in the clinical assessment of patients with (suspected) PANDAS.

Treatment

As described in case studies, a number of immunomodulatory interventions have been applied with some

success in children fulfilling PANDAS criteria. These include immunosuppression with corticosteroids, therapeutic plasmapheresis, or intravenous immunoglobulins. In some of these case studies, after successful plasmapheresis, attempts have been made to prevent new GABHS infections with penicillin prophylaxis.

There has been one placebo-controlled study on the efficacy of immunomodulatory therapy. In that study, 30 children meeting PANDAS criteria were randomly assigned to either plasmapheresis, intravenous immunoglobulins, or a placebo condition (saline solution, given in the same manner as intravenous immunoglobulins), and subsequently each patient was given a regimen of penicillin prophylaxis. After 1 month, the intravenous immunoglobulins and plasma-exchange groups showed striking improvements in severity of OCD symptoms, anxiety, and overall functioning. Tic symptoms were significantly improved by plasma exchange only. The children in the placebo condition did not show any amelioration. Interestingly, these improvements were maintained at 1 year after treatment for both plasmapheresis and intravenous immunoglobulins.

Another treatment option could be to treat or prevent streptococcal infections with antibiotics. One-year treatment with antibiotics, either azithromycin or penicillin, appeared to decrease the number of neuropsychiatric symptoms in a group of children with PANDAS when compared to the year preceding antibiotic treatment. As a final possible treatment option, a case report of two brothers has been described, one with OCD and the other with a tic disorder; both improved significantly after undergoing adenotonsillectomy for treatment of their recurrent tonsillitis. Currently, however, immune-based treatments should not be routinely given. Antibiotic treatment may be associated with development of resistance. Also, plasma exchange and intravenous immunoglobulins are invasive treatments that should only be considered in controlled trials. The best clinical approach for patients fulfilling PANDAS criteria is to consider treating troublesome tics with antipsychotic agents such as risperidone, or with behavioral therapy, and to treat OCD symptoms with behavioral therapy.

Conclusion

Currently, only circumstantial evidence points to a possible role for autoimmunity in tic disorders and pediatric OCD. To classify a disease as autoimmune, transmissibility of symptoms to animals through passive transfer of antibodies or T lymphocytes should be demonstrated. Thus, demonstration of symptom induction through anti-basal-ganglia antibodies in animal models remains a high research priority. At present, results have been conflicting in this area. In a fascinating recent study, however, a subset of mice that were immunized and boosted with a streptococcal homogenate in Freund's adjuvant was demonstrated to exhibit motoric and behavioral disturbances in association with the presence of serum antibodies that were immunoreactive to several brain regions, including globus pallidus and thalamus. This was not the case with mice that were boosted with Freund's adjuvant only. These results are consistent with the hypothesis that immune response to streptococci can result in motor and behavior alterations through antistreptococcal antibodies cross-reactive with brain components.

Large-scale longitudinal data are needed to more fully investigate the role of infections with regard to symptom fluctuation. All in all, tic disorders and pediatric OCD are model neuropsychiatric disorders in which to investigate the complex relationship between brain functioning, autoimmunity, and human behavior, in an interplay between genetic and environmental factors. Ultimately, it is hoped that unraveling the genetic background of tic and related disorders will lead to a better understanding of environmental factors and more targeted treatment.

Panic Disorder

L E Heuer, S J Mathew, and D S Charney, Mount Sinai School of Medicine, New York, NY, USA

Published by Elsevier Ltd.

Introduction

Panic disorder (PD) is a relatively common anxiety disorder (1–3% prevalence in epidemiological surveys) marked by recurrent, often unexpected panic attacks, which are surges of rapid-developing anxiety in a crescendo pattern. The nature of attacks in PD are heterogeneous, but are generally marked by palpitations, chest pain or pressure, dyspnea, and cognitive, neurological, or gastrointestinal symptoms. Besides the discrete attacks, marked anticipatory anxiety about having future attacks, behavioral avoidance of situations which might provoke attacks (such as bridges, elevators, enclosed spaces), and psychological concerns about 'going crazy' or 'losing one's mind' are commonly observed. Lifetime prevalence estimates are 22.7% for panic attacks, 3.7% for PD without agoraphobia, and 1.1% for PD with agoraphobia. Herein, we review the clinical features of PD, the neurobiology of PD, and therapies presently available for PD.

Clinical Presentation

According to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV), a patient with PD has recurrent and unexpected panic attacks (Table 1). A minimum of one of the attacks must have been followed by 1 month (or more) of one (or more) of the following symptoms: persistent concern about having additional attacks, worry about the implications of the attack or its consequences, and/or a significant change in behavior related to the attacks. The panic attacks must not be due to effects of a substance of abuse (e.g., stimulant) or general medical condition (e.g., hyperthyroidism), and the panic attacks are not better accounted for by another psychiatric disorder, such as posttraumatic stress disorder, social phobia, and specific phobia.

It has been suggested that the current DSM-IV categorical system fails to capture the full spectrum of subclinical and atypical manifestations associated with PD and implies that if an individual fails to meet the full criteria for a 'disorder' he or she has no disorder. Recent research has supported the view that subthreshold disorders might be as significant as those meeting full DSM criteria and can lead to a decrease in quality of life.

Assessment Instruments

There are several validated instruments for the assessment of panic and related symptoms. The Panic and Agoraphobia Scale (PAS) is a widely used instrument that contains five subscales – panic attacks, avoidance, anticipatory anxiety, disability, and health worries – found to reduce quality of life in PD patients. The application of the PAS in a double-blind-placebo-controlled PD trial demonstrated its sensitivity to detect differences between panic treatments. Another measurement tool, the Panic Disorder Severity Scale (PDSS), is a seven-item instrument assessing each core symptom of DSM-IV symptoms of PD, with or without agoraphobia, as well as work and social impairment. Items include frequency of panic attacks and limited-symptom episodes, distress caused by panic and limited-symptom episodes, anticipatory anxiety, agoraphobic fear/avoidance, and work and social impairment.

In addition to the clinician-administered PDSS, a self-report version of the PDSS was found to have good test–retest reliability, good sensitivity to change in treatment, and a reliable format, thus providing another useful tool for clinical and research settings. Other tools which can be used in busy outpatient primary care offices include the Hospital Anxiety and Depression Scale, the Patient Health Questionnaire, and a simple screening question ("In the last four weeks, have you had an anxiety attack – suddenly feeling fear or panic?"). Finally, the Anxiety Sensitivity Index (ASI) is a 16-item scale developed to measure 'fear of fear,' that is, the degree to which a person believes that physical symptoms of anxiety have negative consequences. Anxiety sensitivity is a construct that has been specifically linked to PD. Persons with high ASI scores tend to attribute physical signs of arousal as representing a serious illness (e.g., palpitations signaling imminent cardiac arrest) rather than a more benign cause (palpitations due to drinking coffee).

Panic-Agoraphobic Spectrum

The Structured Clinical Interview for Panic-Agoraphobic Spectrum (SCI-PAS), a 114-item tool assessing eight primary domains, was developed in accordance with the view that PD patients have heterogeneous domains of symptomatology. The first domain is that of separation sensitivity, which is highly correlated

Table 1 Diagnostic criteria for PD with/without agoraphobia

A. Both 1 and 2:
  1. Recurrent unexpected panic attacks
  2. At least one of the attacks has been followed by 1 month (or more) of one (or more) of the following:
     (a) Persistent concern about having additional attacks, (b) worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, 'going crazy'), (c) a significant change in behavior related to the attacks
B. Presence/absence of agoraphobia
C. The panic attacks are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism)
D. The panic attacks are not better accounted for by another mental disorder, such as social phobia (e.g., occurring on exposure to feared social situations), specific phobia (e.g., on exposure to a specific phobic situation), obsessive–compulsive disorder (e.g., on exposure to dirt in someone with an obsession about contamination), posttraumatic stress disorder (e.g., in response to stimuli associated with a severe stressor), or separation anxiety disorder (e.g., in response to being away from home or close relatives)

Adapted from First MB (2000) *Diagnostic and Statistical Manual – Text Revision (DSM-IV-TR)*. Arlington, VA: American Psychiatric Publishing Group.

with separation anxiety in childhood. Other features include the patients' uneasiness with sleeping alone or away from home, reluctance to leave their home for vacation or work, fearing harm to their family members, and developing highly dependent, unusually intense, close relationships. The second domain is paniclike symptoms. With this domain, patients report panic attacks without fear, only experiencing physical symptoms, such as rapid heart rate, chest tightness, and sweating. In addition, the patient may change their emotional life and behavior in ways that can cause the development of an anxious, dependent, avoidant personality. Stress sensitivity is the third domain, in which a patient will experience an onset of panic symptoms after a period of high tension or after exiting a stressful situation, rather than during the stressor. This may result in the person avoiding stressors, negative news, and resisting change in their daily routine. The fourth domain is medication and substance abuse sensitivity, which may manifest in the patient's resistance to taking psychoactive drugs. In addition, these patients seem to have increased sensitivity to ingested substances (over-the-counter medications, street drugs, caffeine) and increased sensitivity to withdrawal (benzodiazepines, alcohol). The person may develop a persistent state of vigilance or alertness even in the absence of frequent panic attacks, known as anxious expectation, which is the fifth domain. Agoraphobia is the sixth domain and may be marked by a fear of being home alone, in a public square or mall, traveling through a tunnel or over a bridge, or being in crowded places. Additionally, less obvious, 'atypical' symptoms of agoraphobia should be accounted for. These may include perceived obstacles to breathing (ties, turtlenecks), fear of natural phenomena (thunderstorms, high winds, flooding, earthquakes), and fear of humiliation if panic symptoms should arise, all of which can interfere with social or work relationships. Domain seven is illness phobia and hypochondriasis, usually manifesting as a fear of bodily sensations. The last domain, or domain eight, is reassurance orientation. Patients that fit into this domain will experience immediate relief from anxiety when reassured by 'protective' figures.

Course of Illness

PD, much like major depressive disorder, is generally episodic in nature, although approximately 20–25% percent of patients have a more pernicious and unremitting course. In one longitudinal study over a course of 11 years, it was found that many patients recover from panic attacks and disabilities, and some will achieve full remission. Specifically, 66.7% reported no panic attacks during the year before follow-up, 87.5% reported no panic attacks the month before follow-up, 54% reported no or only mild phobic avoidance, and 33% of the patients were completely remitted according to a composite remission criterion. Another study examined the long-term follow-up (2–14 years, median 8 years) of 132 patients with PD with agoraphobia successfully treated by exposure therapy alone. Two hundred patients satisfying the DSM-IV criteria for PD with agoraphobia were originally treated with a standard therapy protocol consisting of 12 sessions of psychotherapy and exposure homework. One hundred and thirty-six patients became panic free following this treatment and 132 of these patients were available for followup. The study found a high probability of remaining in remission 2–14 years following treatment. Specifically, three out of four patients remained well after 7 years. Positive associations with remission included a younger patient and the absence of any personality disturbances or residual agoraphobia. Higher initial levels of depressed mood and use of antidepressant drugs were related to a poor outcome.

Using observational/longitudinal data from the Harvard/Brown Anxiety Disorders Research Program,

recurrence of panic symptoms after remission in women were compared to men. Although the rates of remission at 5 years for patients with PD with or without agoraphobia were equivalent in both men and women (39%), 25% of these women and 15% of these men reexperienced symptoms in the following 6 months. At the 8-year follow-up, cumulative remission rates were equivalent among men and women. However, relapse events for uncomplicated panic were threefold higher in women than in men by 8 years.

Neurochemistry and Neuroimaging of PD

Varied neurotransmitter and neuropeptide systems have been associated with PD, most notably the norepinephrine (NE), serotonin (5HT), and γ-aminobutyric acid (GABA) systems. Pharmacological probes of the α-adrenergic receptor have served a useful role in developing neurobiological models of PD for more than three decades. Most of these studies have used adrenergic antagonist (yohimbine) or agonist (clonidine) medication, and have compared biochemical, physiologic, and behavioral responses between patient groups and healthy volunteers. Administration of yohimbine, an α-2-adrenergic presynaptic antagonist which increases the release of NE, generally results in increased plasma NE metabolites, blood pressure, heart rate, and anxiety responses in PD patients versus healthy volunteers. The increased sensitivity has been theorized to be attributed to the α-2-adrenergic autoreceptor being less sensitive to the inhibitory feedback of NE in the synapse. Several groups have studied platelet membranes as models for α-2-adrenoreceptor activity. In one study, the α 2-adrenoreceptor density in platelets, as reflected by binding of [^{3}H]yohimbine, was not different between PD and healthy subjects. The study did find, however, a decreased platelet α-2-adrenoreceptor affinity in the PD patients, a finding which has been replicated in subsequent trials. These findings may be due to either increased postsynaptic adrenergic receptor density, enhanced coupling to G-protein, or abnormal postreceptor signal transduction mechanisms.

Multiple studies have demonstrated a blunted growth hormone (GH) response in patients with PD to clonidine, an α-2-adrenoreceptor agonist, possibly reflecting the subsensitivity (increased postsynaptic adrenergic receptor density, enhanced coupling to G-protein, or abnormal postreceptor signal transduction mechanisms) of the postsynaptic α-2-adrenergic receptor. Additionally, blunted GH response in patients with PD was also found with GH releasing factor. A recent investigation examined the question of whether an overall hypoactive GH system, rather than a specific α-2-adrenergic abnormality, was responsible for the blunted GH response to clonidine. The results did not support a reduced basal secretory GH activity, thus increasing the likelihood that a reduced sensitivity of α-2-adrenoreceptors is a mechanism for these findings.

Regarding GABA, the major inhibitory amino acid neurotransmitter, PD patients were found to have regional and/or global reductions in GABA. Preclinical pharmacological models of anxiety have observed that deficits in GABA neuronal function have been associated with anxiogenesis, whereas enhancement of GABA function tends to be anxiolytic. In a study using proton magnetic resonance spectroscopy (MRS), patients with PD had a 22% reduction in total occipital cortex GABA concentrations compared with controls. Central benzodiazepine (BZD) receptor binding has also been assessed in PD. Using single-photon computed tomography (SPECT), a reduced uptake of the selective BZD receptor ligand iomazenil was demonstrated in patients with PD relative to the control group. Additionally, using flumazanil and positron emission tomography (PET) scanning, a global reduction in BZD binding sites in PD patients relative to healthy controls was found.

The 5HT-1A receptor has been investigated in PD, building on previous work demonstrating lower 5HT-1A receptor density in patients with major depressive disorder. One PET study evaluated the volume of distribution of a radioligand for this receptor in unmedicated patients with PD and healthy controls. It was found that patients with PD as compared to controls had a significantly lower volume of distribution in the anterior cingulate, posterior cingulate, and raphe portions of the brain.

Few morphometric studies have been conducted in PD. Magnetic resonance imaging (MRI) studies have found morphometric deficits in temporal lobe, with normal hippocampal volume. A recent study using voxel-based morphometry techniques found increased gray matter volume in the midbrain and rostral pons of brain stem, potentially supporting models of PD that hypothesize that the panic attack stems from brain stem loci.

Genetics of PD

PD has a complex genetic contribution, with an estimated heritability of 30–46%. First-degree relatives of patients with PD have an eightfold increased risk of PD, and there is an emerging literature regarding specific genes implicated in PD. The adenosine 2A receptor gene (*ADORA2A*) is one of two genes to be

implicated in multiple studies in PD as susceptibility loci, with the other being catechol-*O*-methlytransferase gene (*COMT*). Regarding adenosine, caffeine is an antagonist to the adenosine 2A receptor, and has long been known to be anxiogenic in PD. A linkage study analyzed five DNA sequence variations in *ADORA2A*, in a large sample of PD pedigrees (70 pedigrees and 83 child–parent trios). Linkage analysis revealed elevated logarithm of odds (lod) scores for the silent substitution (1976C/T) in the second coding exon, which was consistent with an earlier association study showing an association between the 1976T/T genotype and increased vulnerability to PD. Recent studies have found an association between the V158M *COMT* polymorphism and PD, with a single nucleotide polymorphism in the *COMT* gene leading to a three-to fourfold difference in enzymatic activity. Findings have supported evidence for a susceptibility locus for PD either within the *COMT* gene or in a nearby region of chromosome 22.

A genome scan was performed on 587 individuals in 60 pedigrees segregating PD and bladder/kidney problems and found that there were genes on chromosome 13 (and possibly chromosome 22) that support the existence of a genetic syndrome involving PD and several associated conditions. Common medical conditions observed in family members of PD probands include interstitial cystitis, migraine headaches, thyroid conditions, and mitral valve prolapse. This association may be explained using the model of dysregulation of the noradrenergic system found in PD and the fact that the function of the bladder is regulated through innervation from autonomic nuclei. A genome scan in 120 multiplex PD pedigrees of 1591 individuals was performed, with evidence for linkage in one region on chromosome 15q (near $GABA_A$ receptor subunit genes *GABRB3* and *GABRA5*) and 2q. Several strategies are currently being pursued, including fine mapping of promising regions, investigation of endophenotypes (including gene expression patterns and candidate gene studies), and development of methods to investigate gene–gene interactions.

Therapies for PD

Both medications and psychotherapies, such as cognitive behavioral therapy (CBT), have demonstrated efficacy for PD. Selective serotonin reuptake inhibitors (SSRIs) are considered to be the first-line treatment for PD, although serotonin and norepinephrine reuptake inhibitors (SNRIs) such as venlafaxine XR have recently gained US Food and Drug Administration (FDA) approval.

Three classes of medications have received extensive evaluation in PD, namely SSRIs, tricyclic antidepressants, and benzodiazepines. Each have been found equally effective in treating panic and associated anxiety symptoms, as well as demonstrating a clinically significant response in decreasing the frequency of panic attacks in 50–80% of patients. Safety and side effect profile have therefore become a major determinant when deciding upon treatment for an individual patient. Due to their safety and overall tolerability, SSRIs are recommended as first-line therapy in the treatment of PD. Starting these drugs at low doses with a slow titration helps to minimize initial side effects, which can include nausea, anorexia, tremors, anxiety, sexual dysfunction, jitteriness, and insomnia. If a patient does not respond to an initial trial of SSRI therapy, clinical experience suggests that trying an alternative SSRI may provide the desired result. If there is still no adequate response, switching to another class of drugs, such as tricyclic antidepressants, benzodiazepines, or SNRIs, is recommended (venlafaxine XR). With regard to long-term administration of benzodiazepines, there is concern with respect to dependence, medication abuse, and the rapid reemergence of symptoms after discontinuation. Therefore, benzodiazepines are used most appropriately concurrently with SSRIs at the beginning of treatment to hasten the antipanic response, and for as-needed use for breakthrough anxiety.

CBT is a form of psychotherapy in which a patient receives a limited number of sessions (usually 12–16) over a period of approximately 3–4 months. It focuses on recreating the feared symptoms and then modifying the patient's usual response to these symptoms. One large multicenter trial compared medication and CBT and their combination in the treatment of PD with or without agoraphobia. Three hundred and twelve patients meeting DSM-III-R criteria for PD were randomly assigned to receive imipramine, CBT, placebo, CBT plus imipramine, or CBT plus placebo. Although the follow-up period was limited to 6 months after treatment discontinuation, the intent to treat results demonstrated a 41% response rate for CBT plus placebo, 31.9% for CBT alone, 19.7% for imipramine alone, 13% for placebo, and 26.3% for CBT combined with imipramine. There was no significant difference found between CBT alone and imipramine alone, combined treatment was found superior to CBT and CBT plus placebo, and responders to imipramine, with or without CBT, fared significantly worse in the no-treatment follow-up period than did those who received either CBT alone or CBT plus placebo. These results support the durability of CBT over a 6-month follow-up

period, and suggest high rates of relapse following cessation of medication use in PD.

Panic Disorder as an Emotional Disorder

G M Sullivan, Columbia University College of Physicians and Surgeons, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Panic disorder (PD) is a disabling psychiatric disorder characterized by paroxysmal unexpected panic attacks and ongoing anxiety regarding the attacks. A panic attack is a discrete episode of abruptly developing fear, terror, or extreme discomfort accompanied by a varied constellation of intense physical symptoms, distortions of perception, and emotional distress. This may include palpitations or heart racing, sweating, trembling, dyspnea, gastrointestinal distress, flushing, dizziness, paresthesias, derealization, depersonalization, and the fear one is losing control, one is going crazy, or that death is imminent. Respiratory symptoms and hyperventilation are prominent in some patients, as can be a powerful urge to flee from where the attack is occurring. By definition, the panic symptoms crescendo within 10 min. They often abate or resolve in 20–30 min, although they can last significantly longer. Panic attacks occur in other psychiatric conditions such as posttraumatic stress disorder; and approximately 10% of individuals with no psychiatric diagnosis experience at least one panic attack in their lifetime. Requisite for the diagnosis of PD is that at least one of the panic attacks is followed by at least 1 month of persistent concern about future attacks, irrefutable catastrophic worry about what the attacks portend (e.g., cardiac disease or insanity), and/or significant changes in behavior related to the attacks. In approximately 25% of patients with PD, there is also the development of agoraphobia, which is fear or distress about situations in which escape might be difficult or embarrassing or help may be unavailable should a panic attack develop. Typically, agoraphobic fears and the resulting avoidant behaviors center on being outside the home alone; being in crowds, in a line, on a bridge; or traveling within a vehicle.

The age of onset of PD is usually between late adolescence and the mid thirties. Women are over two times more likely to develop PD than men. Lifetime prevalence is 2–5%, and 1 year prevalence is 1–3%. Comorbidity with other anxiety, mood, and substance use disorders is common. Family and twin studies suggest that genetic factors play a role in the pathophysiology of PD, and heritability estimates approach 50%.

The term panic is derived from the name of the Greek god Pan, who was said to induce terror in travelers of the forests of ancient Greece by repeatedly rustling bush along their path while remaining hidden from view. Panic attacks have been described in the medical literature since at least the American Civil War, when Jacob Mendez DaCosta coined the term irritable heart for a constellation of severe cardiac-like symptoms in the absence of cardiac pathology. Later, terms such as neurasthenia and anxiety neurosis were used for PD. With the discovery of the panic-ablating effects of the tricyclic antidepressant imipramine in the 1960s, PD was proposed to be a separate anxiety condition. It was not until 1980 that PD became established as an officially recognized psychiatric diagnosis, ushering in a boom of research aimed at understanding the neurobiology underlying PD. This article summarizes the current understanding of the neurobiology of PD as derived from clinical studies and basic research efforts.

Challenge Studies

Panic attacks are particularly amenable to study in the laboratory setting, in large part because they are discrete, time-limited events and can be artificially induced by the administration of particular chemical agents. The term challenge study refers to the research procedure in which a panic-eliciting agent, or panicogen, is administered to PD patients and comparison subjects so that the behavioral, autonomic, and endocrine responses may be measured. An array of remarkably diverse chemical panicogens, which precipitate panic attacks in most PD patients but only a small subset of controls, has been identified. Intravenous sodium lactate was the first panicogen to be identified, followed by list that includes inhaled CO_2; noradrenergic (NA) agents, including isoproterenol, yohimbine, and epinephrine; serotonergic agents, including fenfluramine and *m*-chlorophenylpiperazine (mCPP); caffeine, an adenosine 2A antagonist; doxapram, a respiratory stimulant; cholecystokinin (CCK)-derived peptides CCK-4 and pentagastrin; and the γ-aminobutyric acid ($GABA_A$) antagonist flumazenil. One of the realizations that came from the variety of challenge studies is the remarkable pharmacodynamic diversity among the panicogens. Yet preclinical work with these panicogens points to cohesive elements, in terms of common activation of central pathways, potentially explaining the panicogenic effects (see the section titled 'Anxiety sensitivity theory of panic disorder').

Heuristic Models for Understanding Panic Disorder Neurobiology

Modern Learning Theory of Panic Disorder

One model of PD is based on modern learning theory and posits the involvement of neural circuits that mediate conditioned fear and avoidance. Panic attacks are considered normal but misfired fight-or-flight responses, activated in the absence of a proximate threat. PD develops as a result of conditioning. In learning theory terminology, when the adverse unconditioned stimulus (US), the panic attack, is paired with previously innocuous exteroceptive (environmental) and/or interoceptive (visceral) conditioned stimuli (CS), an association is learned such that the CS alone can trigger anxiety and panic when reencountered. Conditioning to exteroceptive stimuli therefore can result in agoraphobic behaviors. Conditioning to interoceptive cues can result in seemingly spontaneous or out-of-the-blue panic attacks or heightened anxiety on future encounters with similar visceral stimuli. The elicitation of this conditioned anxiety may potentiate further panic attacks in a vicious cycle, leading to PD.

The neural correlates of conditioned fear are well described. For example, the pathway mediating auditory fear conditioning in the rat involves pathways by which somatosensory information about the US (pain) and auditory information about the CS (tone) converge on the temporal lobe structure known as the amygdala. Relayed by thalamic and cortical processing regions, neural signals representing the US and CS pathways meet on single cells in the lateral nucleus of amygdala (LA). The LA connects directly and indirectly with the central nucleus of amygdala (CE), considered the output station of the amygdala. The outputs from the CE project to diverse brain regions that control components of the fear response. Those to the periaqueductal gray (PAG) mediate freezing and analgesia; those to the lateral hypothalamus (LH), parabrachial nucleus (PBN), and locus coeruleus (LC) mediate autonomic changes (cardiovascular and respiratory); and those to the paraventricular nucleus of hypothalamus (PVN) mediate hypothalamic–pituitary–adrenal (HPA) axis activation. Distinct from its role in explicit (conscious declarative) memory, the hippocampus provides CS information to the amygdala about the context in which the adversity is occurring. Extinction is the process whereby the learned conditioned response (CR) is weakened or dissipated, such as by repeated CS presentations nonreinforced by the US. Extinction appears to involve interactions between the prefrontal cortex (PFC) and subcortical brain areas, including the amygdala. Through extinction, the ability of the CS to control CRs via the LA-to-CE communication becomes regulated by the ventromedial PFC. Activity between these regions may also be modulated by contextual information provided by the hippocampus. The modern learning theory hypothesis of PD is consistent with a notion of a failure to limit the amygdala-mediated fight-or-flight responses by the PFC and/or hippocampus. Figure 1 illustrates how the fear circuit may be central to PD pathophysiology.

False Suffocation Alarm Hypothesis of Panic Disorder

The false suffocation alarm hypothesis focuses on the panic attack as the aberrant response in PD. The hypothesis assumes the existence of an early evolved brain monitoring and alarm system for usable air. When tripped by poor air, emergency response escape behaviors are activated. The panic attack is the alarm response tripped in absence of poor air. The distinction between panic and conditioned fear is emphasized, noting that HPA axis activation is an element of the fear response, whereas in panic attacks it is not requisite. Acute anxiety is viewed as a more recently evolved response involving anticipation of danger and deriving from fear. Potential neural correlates are suggested by Ondine's curse, a disorder involving deficient activation of the brain stem metabolic respiratory system. This condition, which has the opposite defect proposed in PD, is associated with a deficiency in cholinergic neurotransmission in the arcuate nucleus of hypothalamus. In this light, it is of interest that pathologically enhanced muscarinic cholinergic neurotransmission has been proposed as underlying the hypersensitivity to suffocation stimuli and hypercapnia in PD.

Anxiety Sensitivity Theory of Panic Disorder

This model posits that particular individuals have a cognitive predisposition to interpret the arousal symptoms of anxiety as harmful beyond the inherent discomfort or displeasure experienced. Anxiety symptoms are interpreted as threatening to their physical, psychological, and/or social well-being, and the harm they cause may accumulate over time. PD patients score high on measures of anxiety sensitivity, such as the widely employed Anxiety Sensitivity Index (ASI). Notably, an ASI score is a good predictor of panic to a panicogen. In this model, the enhanced response of PD patients to challenge with a panicogen stems from catastrophic misinterpretations about the induced arousal symptoms rather than direct stimulation of a biochemical defect. Yet the anxiety sensitivity model is not inconsistent with a neurobiological explanation involving an enhanced sensitivity to afferent viscerosensory input transmitted via the glossopharyngeal and vagus nerves. These viscerosensory

Figure 1 Hypothetical neurocircuitry of panic disorder. The proposed circuit for panic disorder centers on amygdala-mediated processing of environmental and viscerosensory stimuli (yellow). The stimuli are transmitted to amygdala directly by thalamus and nucleus tractus solitarius (red) and indirectly via cortical processing areas including the sensory, insular, and anterior cingulate cortices (blue). Contextual information is relayed from the cortex via hippocampus. The amygdala also influences attention, perception, and memory during heightened anxiety by connections with cortical areas such as the orbital prefrontal cortex (oPFC) and anterior cingulate cortex (ACC; blue). A panic attack results when the amygdala activates, in parallel, hypothalamic (brown) and brain stem nuclei (purple) that mediate particular components of the fight-or-flight response (dark purple). Panicogens may cause panic attacks through a common mechanism of enhancing activity in viscerosensory pathways mediated through nucleus tractus solitarius. The selective serotonin reuptake inhibitors (SSRIs) may act by enhancing serotonergic neurotransmission to the amygdala, hippocampus, and periaqueductal gray. Cognitive behavioral therapy (CBT) may have its effects by enhancing the inhibitory influence of the medial prefrontal cortex (mPFC) on the amygdala.

pathways synapse in the nucleus tractus solitarius (NTS), and the signals are relayed to the amygdala and hypothalamus, as well as the PBN and LC, potentially lowering the threshold for a fight-or-flight response. In this light, it is notable that an action common to most the panicogens is the activation of the viscerosensory areas of NTS (see Figure 1). Here too, inadequate top-down control of the amygdala, limiting the impact of cortically processed information provided to it through the hippocampus and/or PFC, could further lower the threshold for an inappropriately triggered fight-or-flight response.

Neurotransmitter Systems and Panic Disorder

Neurotransmitter systems are the mediators and modulators of neurotransmission within all neural circuits. Therefore, specific pathology in a neurotransmitter system could lead to dysfunction in circuitry involved in PD. Yet it is also possible that identified dysfunction in a neurotransmitter system is simply a reflection of changes in circuit functioning caused by a pathology of a completely different etiology.

Noradrenergic System

Both rodent models of stress and fear and human challenge studies point to a role for a dysfunction in the NA system in PD. The LC is the primary brain stem nucleus for NA neurons, and these neurons project to key cortical, limbic, and other brain stem regions involved in visceral sensitivity and fearful responding. There are reciprocal connections involving corticotropin-releasing hormone (CRH)-secreting neurons between the LC and amygdala. The presence of threat increases the firing rate of the LC, resulting in cortical norepinephrine (NE) release and neural activity reflected in electroencephalograms. Laboratory manipulations of the early developmental environment in the rodent, such as in handling and maternal deprivation paradigms, lead to long-term alterations in CRH receptor and α_2-adrenergic autoreceptor

densities in the LC. This suggests a significant environmental sculpting of the stress response system.

In PD patients, clonidine, an α_2-agonist that decreases LC firing by feedback inhibition at α_2-auto receptors, decreases vulnerability to panic on challenge with lactate. Yohimbine, an α_2-antagonist, produces greater paniclike anxiety in PD patients accompanied by a decrease in frontal cortical cerebral blood flow (CBF). This contrasts with the response to yohimbine reported in healthy volunteers in which there is CBF increase in the medial PFC.

Recent application of cardiac imaging and microneurography in PD suggests impaired cardiac sympathetic function due to a central mechanism. Anxiety sensitivity is predictive of lower cardiac NE reuptake, implicating NA system dysfunction in vulnerability to panic. In this light, animal studies showing that chronic imipramine treatment decreases α_2-autoreceptor density in the LC and the A2 region of the NTS suggest that this treatment may work through correction of the effects of adverse early environmental factors on the stress response system. It is also important to emphasize the interdependence of the NA and serotonergic systems. As an example of the tight cross-regulation of these systems, stress-induced sympathetic activity and fight-or-flight defensive behaviors are inhibited by serotonin release in the PAG and rostral ventrolateral medulla (RVLM), in part via actions on serotonin 5-HT_{1A} receptors.

Serotonergic System

Evidence for serotonin system dysfunction in PD is also extensive. Perhaps most compelling is the efficacy of the serotonin selective reuptake inhibitors (SSRIs) for symptoms of PD. It is also notable that a wealth of preclinical experiments have demonstrated a modulating role of serotonin neurotransmission on various fearful and avoidant behaviors. Yet in some anxiety paradigms serotonin is anxiogenic and in others it is anxiolytic, often with site-specific and paradigm-specific effects. A provocative hypothesis for PD reconciles the seemingly contradictory animal data by suggesting opposite roles for serotonin in panic versus anxious anticipation. Raphe projections to the PAG and medial hypothalamus normally inhibit fight-or-flight behaviors, so deficient serotonin neurotransmission is permissive to the panic response. In contrast, raphe projections to the amygdala and hippocampus are proposed to enhance anticipatory anxiety and resilience to chronic stress, respectively, but, here too, deficiency in serotonin signaling is proposed to unbridle a normal restraining influence of this upstream fear circuitry on a PAG-mediated panic response (see Figure 1). Recent studies testing an SSRI on conditioned fear memory in the rodent suggest a similar pattern of effect of SSRIs on conditioned fear as they have on PD symptoms. Acute SSRI administration before training increased conditioned fear behavior, whereas several weeks of SSRI reduced the behavior. In PD patients, SSRIs often increase panic and anxiety when first started, the panic-ablating effect only beginning after several weeks.

Challenge of PD patients with serotonergic agents such as mCPP and fenfluramine produces heightened anxiety and can provoke panic, similar to the acute effects of an SSRI. Abnormal serotonin metabolism in PD is suggested by a sevenfold higher level of the main serotonin metabolite in jugular venous samples from nonmedicated, nonpanicking PD patients. Acute depletion of tryptophan, the amino acid precursor of serotonin, results in SSRI-treated PD patients becoming newly vulnerable to flumazenil-induced panic, suggesting enhanced serotonin neurotransmission is necessary for the protective effects of SSRI treatment. Interestingly, female PD patients homozygous for a functional polymorphism in the transcriptional control region of the serotonin reuptake protein (i.e., the serotonin transporter) have a poor response in terms of ablation of panic attacks to treatment with an SSRI.

A particular receptor for serotonin, the 5-HT_{1A} receptor, is located at presynaptic sites on serotonin neurons of the brain stem raphe nuclei, where it acts as an inhibitory feedback autoreceptor; it is located on postsynaptic neurons in brain regions that receive serotonin terminals projecting from raphe. Experiments with transgenic mice involving site-specific rescue of the 5-HT_{1A} receptor have indicated the importance of the postsynaptic receptors in anxiolysis and the necessity of this receptor during early development for normal serotonergic mediation of anxiety. Of note, when context-conditioned 5-HT_{1A} knockout mice are tested in the same context but with novel cues added, they do not have the normal decrement in fear behavior of the wild-type mice. This suggests the 5-HT_{1A} knockout is biased toward threatening cues in ambiguous environments, analogous to the memory bias of PD patients to panic-related cues in an otherwise neutral environment.

Patients with PD and depression have been shown to have attenuated hypothermic and neuroendocrine responses to challenge agents acting on the 5-HT_{1A} receptor, implying a subsensitivity of the receptor. In the gene coding for 5-HT_{1A}, there is a functional promoter polymorphism, -1019C/G, believed to de-repress 5-HT_{1A} autoreceptor expression, thereby enhancing negative feedback and reducing overall serotonergic neurotransmission. PD patients homozygous for the G-allele have been reported to have less activation of the right PFC regions in response to fearful stimuli. This suggests a dysfunction of 5-HT_{1A}

autoreceptor activity in PD may contribute to deficient top-down control. In other words, the response to threat may be conceded to subcortical fear structures that produce a stereotyped fear response rather than a more appropriate response influenced by complex, cortically processed information provided by the PFC. It must be noted that the G-allele has been associated with PD with agoraphobia but not with PD overall. It would be of interest to know whether the G-allele is associated with enhanced fear conditioning, as might be predicted by the learning theory model of PD. It is notable that in clinical depression the G-allele has been associated with higher cortical postsynaptic 5-HT_{1A} binding by positron emission tomography (PET) and poorer response to antidepressants.

Recent work in healthy volunteers using both PET and functional magnetic resonance imaging (fMRI) demonstrates an inverse relationship between raphe 5-HT_{1A} autoreceptor binding and amygdala reactivity to angry and fearful faces. This suggests another direct link between 5-HT_{1A} autoreceptor functioning and subcortical fear system hyperreactivity. PET radioligand studies assessing 5-HT_{1A} binding in PD indicate lower 5-HT_{1A} binding both in the cortex and brain stem raphe. Somatic and hypochondriacal anxiety, which predominate in PD, inversely correlate with cortical postsynaptic 5-HT_{1A} receptor binding, whereas psychic anxiety, more germane to depression and generalized anxiety disorder, positively correlates with it. PET and fMRI studies in this area are only beginning to be reported and promise to clarify the links among the G-allele, 5-HT_{1A} receptor binding, and fear system reactivity.

GABA System

GABA is the predominant inhibitory neurotransmitter throughout the brain. The two main receptor subtypes for GABA are the $GABA_A$ and $GABA_B$ receptors. $GABA_A$ is a multisubunit receptor with a central ligand-gated chloride ion channel. It can be allosterically modulated due to multiple binding sites for benzodiazepines, neurosteroids, barbiturates, and other compounds. The $GABA_A$ receptor complex comprises five protein subunits, and there are a variety of combinations of subunit types, termed α, β, γ, δ, and ρ, that make up the $GABA_A$ receptor. Murine knockouts of individual subunits have provided clues to the various physiological effects, and particular subunits appear more involved in anxiolysis than others. Interestingly, 5-HT_{1A} knockout mice have been shown to have downregulation in $GABA_A$ α-subunits, reduced $GABA_A$ binding, and benzodiazepine-resistant anxiety, indicating the impact of serotonergic system dysfunction on the GABA system. There is evidence for GABA system dysfunction in PD, although it is not clear whether this is indicative of primary pathology, compensatory changes, or, in some cases, the effects of long-term treatment with benzodiazepines. PET and single photon emission computed tomography (SPECT) studies of benzodiazepine binding in PD indicated decreased global binding as well as specifically decreased binding in the hippocampus and frontal cortical regions, although there are conflicting reports. The higher-potency benzodiazepines, such as alprazolam, clonazepam, and lorazepam, have played a large role in the routine pharmacological treatment of PD, although the potential for abuse of this class of medications has led to a more judicious selection of patients appropriate for this treatment approach. The benzodiazepines also have a role in the first several weeks of treatment with SSRIs when the SSRIs are initially ineffective or paradoxically anxiogenic for some PD patients. GABA reuptake inhibitors, inhibitors of GABA metabolism, and partial agonists at the $GABA_A$ receptor are now being explored as potential anxiolytics in PD and other anxiety conditions.

Glutamate System

Glutamate is the major excitatory neurotransmitter throughout the central nervous system, playing a role in functioning of up to 40% of synapses. The two major classes of glutamate receptors are the metabotropic (second-messenger) glutamate receptors and the ionotropic (ion channel) glutamate receptors, including *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA), and kainate receptors. The metabotropic receptors appear to modulate activity of the ionotropic receptors via actions at pre- and postsynaptic sites as well as presence on glial cells and GABAergic neurons. The ionotropic receptors are generally postsynaptic and mediate fast synaptic transmission through sodium- and calcium-permeable ligand-gated ion channels. These receptors are also involved in synaptic plasticity in which activity-induced structural changes in synapses occur through processes dependent on gene transcription and new protein synthesis. Under development as anxiolytics are agents that modulate glutamatergic activity through actions on either metabotropic or ionotropic receptors. There are also several existing anticonvulsant medications that act through glutamatergic mechanisms, and some, such as valproic acid, appear to have some efficacy in the treatment of PD. D-Cycloserine, a partial agonist at NMDA receptors, facilitates extinction of fear memory in the rodent model. Agents such as D-cycloserine have been suggested as useful adjuncts to psychotherapies, such as cognitive-behavioral therapy (CBT), that employ techniques aimed at extinguishing anxious

responses to conditioned interceptive and exteroceptive stimuli. Preliminary trials to date have shown promising results.

Neuropeptide Systems

CRH is a 41-amino-acid peptide that plays a key role in the coordinated behavioral, autonomic, neuroendocrine, and neuroimmune responses to stress. First described for its endocrine role in the HPA axis response, CRH was later found also to act as a neurotransmitter or neuromodulator in widespread brainregions involved in fear and anxiety including the cortical areas, amygdala, bed nucleus of the stria terminalis (BNST), hippocampus, nucleus accumbens, raphe nuclei, and LC. CRH has actions via two receptor subtypes, CRH_1 and CRH_2; and CRH_2 has three functional splice variants, $CRH_{2A–C}$. Blocking activity at CRH_1 produces anxiolytic-like responses, and CRH_1 knockout mice have reduced anxiety-like behaviors. There is also a role for CRH_2 in anxious responding, although it has been shown to be anxiogenic, anxiolytic, and anxio-neutral in different animal models. Therefore, CRH receptors have been prime targets for anxiolytic drug development.

CCK, a peptide found in the gastrointestinal tract and brain, is co-localized with other neurotransmitters, particularly dopamine and GABA. CCK stimulates both cortical and hippocampal neurons via two described receptors, CCK_1 and CCK_2, effects that are blocked by benzodiazepines. In PD, the endogenous CCK level has been reported to be lower in the cerebrospinal fluid (CSF). CCK-tetrapeptide (CCK-4) is cleaved from the N-terminus of CCK. It has selective activity at the CCK_2 receptor and has been shown to bind throughout the fear system regions. CCK-4 is also a potent panicogen. PD patients have reduced CBF in the medial PFC following challenge with the peptide, similar to the effect shown with yohimbine. And, like most panicogens, CCK-4 administered systemically induces cFos-like immunoreactivity in the NTS and several hindbrain regions. Thus, the central CCK receptor system is also a target for therapeutics, and CCK-4 challenge is being used to test potential panic-ablating medications.

Neuropeptide Y (NPY) and galanin are two peptides widely expressed in key stress and fear circuits. Both are co-localized with NE, and galanin is also co-localized with serotonin. Both peptides have anxiolytic-like activity, apparently through modulation of the monoaminergic systems. Similarly, substance P is a peptide found in brain and sensory afferents and is co-localized with glutamate, serotonin, and acetylcholine. Substance P is released under aversive conditions. It binds to several neurokinin (NK) receptors, including NK-1. Central administration of substance P is anxiogenic in animal models. All three of these neuropeptide systems are targets for therapeutic drug development in PD and other anxiety conditions.

Animal Models Relevant to Panic Disorder

Several rodent models have particular relevance to the behavioral and physiological responses of PD. One focuses on the dorsomedial hypothalamus, in which local disruption of GABA activity results in vulnerability to lactate-induced paniclike behavioral and physiological responses. Similarly, the repeated local delivery of exogenous CRH to the basolateral nucleus (BL) results in vulnerability to lactate, suggesting both sites are involved in sensitivity to the panicogen. Even in the absence of pharmacological manipulation of these regions, several panicogens, including lactate, CO_2, and doxapram, have been shown to enhance anxiety-related behaviors in diverse paradigms of fear, conflict, and avoidance. Systemic administration of doxapram, which activates carotid body chemoreceptors, is reported to increase endogenous CRH expression in the CE. CCK-8, a CCK cleavage product that activates gut CCK_1 receptors, illustrates how viscerosensory activation of fear circuitry may occur. The visceral signal induced by CCK-8 is transmitted via the vagus nerve to the caudal NTS, where it is transferred to NA neurons projecting to the hypothalamus, PBN, and amygdala. If such NA neurons co-express CRH, a similar rise in CRH could be expected in the CE. And, like doxapram and epinephrine, CCK-8 enhances the retention of conditioned fear memories. Therefore, sensitivity of the fear circuitry to viscerosensory pathway activation in PD is implied by both preclinical models, human challenge studies, and the anxiety sensitivity theory. Animal models specific to PD are useful for dissecting the neural pathways key to pathological anxiety and panic, and advances in brain imaging are allowing the direct testing of the implications for PD pathophysiology.

Functional Imaging in Panic Disorder

Although there have been several reports of regional brain-volume differences in PD by MRI, no consistent pattern has yet emerged. In contrast, functional imaging in PD has added considerably to our understanding of the pathophysiological mechanisms. For example, magnetic resonance spectroscopy (MRS) studies in PD showed higher brain lactate levels in response to controlled hyperventilation in

PD, suggesting there may be an exaggerated global cerebrovascular response in PD to hyperventilation-induced hypocarbia. A tilt table challenge of PD patients demonstrated an exaggerated decrease in middle cerebral artery flow by transcranial Doppler in both remitted and symptomatic patients, indicating such cerebrovascular dysautonomia may be a trait of PD. PET and SPECT studies of regional CBF and glucose metabolism have been aimed at establishing both baseline and panic state differences in PD from controls. Several studies point to baseline differences in left/right ratios of hippocampal and parahippocampal activity in PD as well as decreased left hippocampal activity. Anxiety and panic states in PD have been associated with a decrease or a smaller increase in global CBF compared with controls. Regional differences from controls have included relative decreases in the PFC regions and increases in the insula and striatum. In particular, the panic state induced by CCK-4 was associated with decreased medial PFC activity. A recent ^{18}F-fluorodeoxyglucose PET study of PD patients with high prescan state anxiety showed elevated activity in the bilateral amygdala, hippocampus, thalamus, brain stem, and cerebellum. Moreover, successful treatment with CBT for PD was associated with reduced activity in the hippocampus, anterior cingulate, cerebellum, and pons and increased activity in the medial PFC (see Figure 1). In summary, functional imaging in PD supports abnormal global cerebrovascular response, deficiency in PFC-mediated breaking on subcortical activity, hyperactivity in the subcortical fear network, and lateralized abnormalities in hippocampal activity.

Comments

Although the pathophysiology of PD has yet to be delineated, the past 25 years of research have focused attention on the most likely brain regions, circuits, and neurotransmitter systems involved. Building on the neurobiological foundations established by preclinical neuroscience research, plausible heuristic models explaining PD symptomatology have been proposed. Converging evidence from challenge studies, genotyping for functional polymorphisms, and radioligand receptor imaging studies implicates substantial roles for noradrenergic and serotonergic system dysfunction in PD. A better appreciation of key neuropeptide systems may soon allow more specific targeting of dysfunctional fear and anxiety circuits, with the promise of more efficacious, more tolerable, and safer therapies. Functional imaging has indicated exaggerated cerebrovascular responses in PD and some data support the notion of deficient top-down control of hyperresponsive subcortical fear circuits by regions of the PFC. The rapid advances in our understanding of PD have been propelled by an extraordinary array of scientific disciplines and research modalities. Such efforts should make PD one of the first psychiatric disorders to yield to an accurate identification of the neuropathology.

Introduction

Of the large number of protozoan and metazoan parasites that may infect humans, many have the potential to affect the nervous system. Protozoan parasites are unicellular and have the ability to replicate and proliferate within the human host. In contrast, metazoan parasites are multicellular and include nematodes (roundworms) and two groups of flatworms, trematodes (flukes) and cestodes (tapeworms). In general, almost all metazoan parasites lack the ability to replicate within the human body and hence augmentation of intensity of infection requires additional exogenous reinfection. Metazoan, but not protozoan, parasites are characteristically associated with an immunological response that includes increased numbers of eosinophilic leukocytes in the blood and tissues.

Some parasites have a characteristic predilection for involvement of the nervous system, whereas other infections are only rarely associated with neurological manifestations. This article does not exhaustively list all parasites reported to have possible neurological effects, but instead discusses those infections that are most likely to present with symptoms related to the nervous system.

Protozoan Parasites

Malaria, widely prevalent in tropical and subtropical areas of the world, is caused by mosquito-transmitted infections with one of four species of *Plasmodium*. Of the four species, the most serious infection is caused by *Plasmodium falciparum*, which accounts for almost all deaths due to malaria. In falciparum malaria, after an initial hepatic phase of development, parasites invade cells and engage in an erythrocytic cycle of development that eventuates in red cell lysis and liberation of parasitic forms that perpetuate the infection. Fever is typical and may, but need not, occur in daily or every-other-day paroxysms with chills. One of the most serious complications of falciparum malaria is the development of cerebral malaria, which may develop rapidly over many hours and is associated with high mortality. Neurological manifestations include disturbances of consciousness (ranging from somnolence to frank coma), acute organic brain syndromes with behavioral or intellectual changes or hallucinations, major motor seizures, meningismus, or rarely focal neurological alterations. There are a number of potential pathogenic mechanisms underlying cerebral symptoms in malaria, and the neurological complications are often part of a multisystem dysfunction. Adherence of falciparum-infected erythrocytes to vascular endothelial cells within the brain leads to obstruction of blood flow within microvasculature and secondary cerebral ischemia. In addition, cytokine release and metabolic derangements such as hypoglycemia and lactic acidosis can also contribute to cerebral dysfunction. Untreated, cerebral malaria is uniformly fatal, so prompt diagnosis and therapy are mandatory. Diagnosis is made by finding malarial parasites in red cells on stained blood smears or via antigen-capture test kits. In most geographic regions, there is increasing resistance of falciparum malarial parasites to chloroquine and sulfadoxine-pyramethamine drugs, so combination therapy with alternative agents such as mefloquine, quinine, or artemisinin derivatives is required. Even with therapy, cerebral malaria is associated with up to 30% mortality, particularly in children, and permanent neurologic sequelae occur in up to 10% of survivors.

Toxoplasmosis, due to the intracellular parasite *Toxoplasma gondii*, is a globally distributed zoonotic infection. Infection, which is acquired either congenitally or by ingestion of oocysts or tissue cysts present in meat, can result in one of four clinical syndromes. Acute toxoplasmosis in normal hosts usually results in asymptomatic lymphadenopathy or lymphadenitis; only very rarely does encephalitis occur. In contrast, acute toxoplasmosis in an immunodeficient host is frequently marked by central nervous system (CNS) involvement, including encephalitis, meningoencephalitis, or mass lesions. The second form of toxoplasmosis arises from reactivation of latent parasites and occurs in immunosuppressed individuals, including those with AIDS. CNS mass lesions and meningoencephalitis are frequent manifestations in immunodeficient hosts. Patients present with headache, altered levels of consciousness, seizures, and/or focal neurological findings. Ocular toxoplasmosis manifests as chorioretinitis and may develop from acute acquired or congenital infection. In the fourth form, congenital toxoplasmosis may be associated with sequelae of varying severity due to CNS involvement. Diagnosis is made by finding appropriate morphological forms of the parasites in tissues or with the assistance of serological tests. Findings on computed tomography (CT) scans or magnetic resonance imaging (MRI) vary considerably with the different forms of infection, but

typically consist of intracerebral calcifications or hypodense lesions involving the thalamus and basal ganglia that show ring enhancement following contrast. Treatment is not usually required for primary infection in immunocompetent hosts, but pregnant women, immunocompromised individuals, and children with congenital infection should be treated. Unless contraindicated, therapy typically consists of a combination of oral pyrimethamine, sulfadiazine, and folinic acid.

Infections with amebic protozoa can involve the nervous system. *Entamoeba histolytica* causes amebiasis, which is principally a colonic infection. Hematogenous spread from the bowel can lead to the development of an amebic abscess, most commonly in the liver, but on occasion involving the brain. In addition, other free-living amebas of *Naegleria*, *Acanthamoeba*, and *Balamuthia* species, which are found in soil and water, can cause neurological infections. *Naegleria*, presumably entering through the cribriform plate, can produce a fulminant primary amebic meningoencephalitis resembling bacterial meningitis. Victims tend to be young and healthy, typically with a recent history of water-sport activities. Infections with *Acanthamoeba* are more indolent and often occur in immunocompromised hosts. Hematogenous spread to the CNS from primary pulmonary or skin lesions are thought to occur, resulting in a subacute granulomatous encephalitis manifest by headache, seizures, altered mental status, and/or focal neurological deficits. Infections due to *Balamuthia mandrillaris* also cause chronic granulomatous meningoencephalitis, occurring in both immunocompetent and immunocompromised individuals. Diagnosis of free-living amebic infections generally relies on identification of the parasites in cerebrospinal fluid (CSF) or brain tissue. All species are difficult to treat and are commonly fatal.

Microsporidia are obligate intracellular parasites. A number of different species can infect humans, but symptomatic infections are seen predominantly in immunosuppressed hosts. Microsporidia belonging to the *Encephalitozoon* species are most common and can result in serious disseminated infections, particularly in patients with human immunodeficiency virus (HIV) infection. Transmission occurs mainly via ingestion of contaminated food or water. Primary infection usually begins in the intestines or lungs, but widespread dissemination resulting in sinusitis, keratoconjunctivitis, and CNS involvement can follow. CNS symptoms vary according to the location of the lesion, but seizures are the most common manifestation. The diagnosis is made by detection of organisms in body fluids or tissue biopsy specimens via microscopy or polymerase chain reaction (PCR). In CNS infections, parasite spores are often present in peripheral blood and occasionally may also be present in CSF. Imaging of the brain usually shows multifocal ring-enhancing lesions. Treatment is with albendazole.

The causative organisms of African trypanosomiasis, or sleeping sickness, have a special predilection for invading the CNS. The disease, caused by hemoflagellates of the genus *Trypanosoma*, is prevalent in equatorial Africa. Two forms infect humans. West African trypanosomiasis is present in tropical forests of western and central Africa and is caused by *Trypanosoma brucei gambiense*, a parasite not found in major animal reservoirs. East African trypanosomiasis is due to *T. brucei rhodesiense*, which exists in wild animal reservoirs and is prevalent in the savanna and woodlands of eastern tropical Africa. Both forms of infection are transmitted by tsetse flies. East African trypanosomiasis is an acute febrile illness, and death may occur from pancarditis prior to CNS involvement. In contrast, West African trypanosomiasis is a chronic illness, and progressive CNS involvement produces meningoencephalitis and meningomyelitis which develop slowly over years. Increasing somnolence and lassitude progress to coma and death from inanition or intercurrent infection. Definitive diagnosis depends on finding the parasite in blood, CSF, lymph node aspirate, or bone marrow specimens. CSF analysis generally shows pleocytosis when the CNS is involved. Treatment relies on the chemotherapeutic agents suramin, pentamidine, arsenical derivatives, or eflornithine, all of which have significant toxicities and at best moderate efficacy, particularly in advanced stages of disease.

There are three stages of disease associated with American trypanosomiasis (Chagas disease) due to *Trypanosoma cruzi* infections: acute, intermediate, and chronic. In the acute stage, symptomatic infection typically manifests with fever, facial edema, lymphadenopathy, myocarditis, and occasionally meningoencephalitis. The encephalitis is due to direct destructive and inflammatory changes by the parasite in the CNS, which can be life-threatening, although spontaneous resolution is usual. The intermediate stage is not associated with clinical symptoms or with significant nervous system involvement. The chronic stage is characterized by immune mediated destruction of many nerve components, especially the autonomic innervation of the heart and gastrointestinal tract. Cardiac involvement causes arrhythmias, congestive heart failure, and thromboembolic events, and parasympathetic denervation of the gastrointestinal tract leads to dilatation of the esophagus or colon. In addition, immunosuppression due to malignancy, HIV, or following transplantation has recently been shown to be associated with reactivation of infection, often

resulting in meningoencephalitis and brain abscesses. Available therapeutic agents include nifurtimox and benznidazole, but neither has significant efficacy once complications from chronic infection have developed.

Metazoan Infections

Nematode Infections

Eosinophilic meningitis may develop when humans are infected with the rat lungworm, *Angiostrongylus cantonensis*. This parasite is present principally in the Far East and the islands of the Pacific basin, including Hawaii, and has been found in Cuba. Third-stage larvae of the parasite are infective. Humans are accidental, dead-end hosts and acquire the infection by ingesting infected land snails or slugs or by consuming inadequately cooked carrier hosts (freshwater shrimp, aquatic and amphibious crabs, and certain marine fish) that have ingested infected mollusks. After the larvae are ingested, they migrate to the brain, spinal cord, and nerve roots, where they induce an eosinophilic inflammatory reaction. Common symptoms include severe headache, nuchal rigidity, vomiting, weakness, and paresthesias. Fever is not prominent. Seizures and extraocular muscle palsies occur uncommonly. CSF pleocytosis develops, with greater than 20% of the cells being eosinophils. The illness is usually self-limited and resolves over several weeks. Anthelminthic agents should not be given as they can result in an enhanced inflammatory reaction to dying parasite larvae within the CNS, with a consequent clinical deterioration.

Infective larvae of species of *Gnathostoma* are found in tissues of freshwater fish, in eels, frogs, and snakes, and in poultry or pigs fed infected fish. Ingestion of these infected foods by humans introduces larvae which can migrate within human tissues, usually within the skin. Infection has been noted principally in the Far East. Less commonly, larvae migrate along a nerve track and enter the CNS, producing radiculomyelitis and an eosinophilic meningoencephalitis. Characteristic symptoms include headache, severe radicular pain, migratory parasthesias, or paralysis. Subarachnoid hemorrhage and coma can also ensue. Examination of the CSF will show an eosinophilic pleocytosis which is often xanthochromic or bloody, and cerebral imaging typically shows areas of hemorrhage.

Strongyloidiasis arises from infection with *Strongyloides stercoralis*, which is unique because it can internally reinfect humans. This internal autoinfection cycle allows the parasite to perpetuate its infection for decades. The autoinfection is modulated by the human immune system; if immunosuppression develops, such as by the administration of corticosteroids, the autoinfection cycle can become unbridled, leading to the hyperinfection syndrome. Large numbers of infective larvae are produced and penetrate the colon to disseminate hematogenously. Any organ, including the brain, may be invaded by larvae. In addition, secondary bacterial infections, including polymicrobial pneumonia or meningitis, are not infrequent complications of disseminated strongyloidiasis. Treatment in these cases will consist of antibiotic therapy plus ivermectin.

Ingestion of larvae of *Trichinella spiralis*, encysted in the flesh, especially pork, of carnivorous mammals, leads to the development of trichinosis. The intestinal phase of trichinosis develops first as adult parasites generate new larvae that enter the bloodstream. Thereafter, the muscle phase of the illness ensues, with the common development of periorbital and facial edema, subconjunctival and retinal hemorrhages, and subungual splinter hemorrhages. About 3 weeks after infection, larvae begin to encyst in striated muscle, and signs and symptoms of myositis, fever, and eosinophilia occur. Although larvae encyst only in striated muscle, inflammatory lesions may develop due to larval migration in the heart, lungs, and CNS. Neurologic involvement can result from vascular obstruction, eosinophil infiltration, or toxic effects of parasite antigens. Clinical manifestations include meningeal irritation resembling meningitis, intracerebral hemorrhages, and occasionally seizures, paresis, delerium, or coma. Diagnosis relies on serology or direct demonstration of organisms in biopsy specimens. Treatment is not always necessary, but in severe cases prednisolone and/or specific anthelminthic therapy with albendazole or mebendazole can be given.

Visceral larva migrans develops when the infectious eggs of dog or cat ascarids, *Toxocara* species, are ingested. Since these eggs are found in soil contaminated with dog or cat feces, the illness is seen in those who ingest soil, particularly children with geophagous pica. Larvae hatch from the eggs and are carried from the intestinal tract in the bloodstream. The larvae then migrate to various organs and induce an eosinophil-rich inflammatory response before they die. Although many with this visceral form of the infection are minimally symptomatic, malaise, weight loss, fever, hepatomegaly, and rashes may occur. With heavy infection neurological involvement may occur. The spectrum of neurological manifestations includes muscular weakness, sensory abnormalities, seizures, behavioral disorders, and coma. Peripheral eosinophilia will often be present. A second form of the illness, the ocular form, is also recognized. This form presents solely with ocular findings due to a retinal granuloma formed around a larva; less commonly,

endophthalmitis or uveitis may occur. Therapy for toxocaral infections is not always necessary and is primarily symptomatic. Another potential cause of the larva migrans syndrome is infection with the raccoon-derived ascarid parasite, *Bayliascaris*. Larvae can enter the brain, causing an often-fatal eosinophilic meningoencephalitis.

Trematode Infections

Schistosomiasis is a major, snail-transmitted infection due principally to one of three species of *Schistosoma*: *Schistosoma japonicum* in the Orient, *Schistosoma mansoni* in Africa and the Americas, and *Schistosoma hematobium* in Africa and Arabia. Adult parasites localize in the venous system draining the colon (for *S. mansoni* and *S. japonicum*) or the urinary tract (*S. hematobium*). Much of the morbidity of schistosomiasis is due to granulomatous responses developing around eggs deposited in the colon or urinary tract or, for the former two species, carried hematogenously into the liver. Neurological complications usually occur in chronically infected individuals but can also occur in the acute stage. These complications arise either as a result of embolization of eggs with deposition in nervous tissue or due to the anomalous migration of adult worms. Cerebral schistosomiasis occurs predominantly with *S. japonicum* and presents as focal or generalized seizures. Spinal schistosomiasis, due principally to *S. mansoni*, results in the development of transverse myelitis. Diagnosis is usually presumptive since confirmatory biopsy tissue is not available, but positive serology and/or visualization of eggs in urine or feces may be helpful. Praziquantel is highly efficacious in the killing of adult worms. Adjunctive corticosteroids are sometimes given to reverse the inflammatory pathology associated with egg deposition.

Paragonimiasis is due to infection with flukes of *Paragonimus westermani* in the Orient and other *Paragonimus* species in Africa and the Americas. Infection is acquired by consumption of freshwater crabs or crayfish. Young flukes migrate principally into the lungs, and pulmonary manifestations are usual. However, flukes may occasionally migrate into the CNS. An acute meningoencephalitis or progressive neurological signs including paraplegia, visual disturbances, seizures, or coma develop secondary to a space-occupying mass lesion in the brain or spinal cord. Neuroimaging findings and serological testing of serum or CSF can aid in the diagnosis. The active stage of infection shows a characteristic 'grapelike' cluster of multiple, ring-enhancing lesions, whereas old, chronic lesions are often calcified and are typically described as showing 'soap-bubble' calcification. Treatment is usually with an extended course of praziquantel.

Fasciola hepatica, the liver fluke, which is widely distributed in Europe, Asia, Africa, and the Americas, may cause human infection if parasitic cysts attached to aquatic plants, especially watercress, are ingested. Although fascioliasis involves primarily the liver, aberrant migration of flukes to the CNS can occur. Imaging, serology, or visualization of eggs on fecal microscopy can help make the diagnosis. Triclabendazole is now the treatment of choice.

Cestode Infections

The fish tapeworm, *Diphyllobothrium latum*, does not leave the intestinal tract. It does, however, compete with the host for dietary vitamin B12, and megaloblastic anemia and neuropathy due to vitamin B12 deficiency can develop in some infected patients.

The pork tapeworm, *Taenia solium*, may cause cysticercosis. Neurocysticercosis is the most common parasitic infection of the brain, affecting over 50 million people worldwide. Pigs serve as the intermediate hosts for this parasite; humans who eat undercooked pork containing cysts develop intestinal tapeworm infection rather than cysticercosis. Instead, cysticercosis is contracted by ingestion of *T. solium* eggs, which usually occurs via contamination of food such as fruits or vegetables. CNS lesions can occur in the brain parenchyma, in the subarachnoid space, in the ventricular system, or in the spinal cord, and multiple cysts are not uncommon. Symptoms will vary depending on the number, size, viability, and location of the lesions. Patients commonly present with seizures; other potential complications include headache, hydrocephalus, or focal neurological signs. CT scans or MRIs often suggest the diagnosis, and serological tests are also available. Optimal treatment varies, ranging from observation, symptomatic therapy only, or chemotherapy with albendazole $\pm$ praziquantel, to surgical intervention, depending on the individual characteristics of the lesion(s).

CNS lesions, similar to those of cysticercosis, also occur with coenurosis, which develops from infection with dog tapeworms of the genus *Multiceps*. Sparganosis is another tapeworm infection due to larvae of the species *Spirometra*. The disease is most common in East Asia. Humans can be accidentally infected by drinking water that is contaminated by larval stages of the parasite, by ingesting infected amphibians or mammals that serve as intermediate hosts, or by applying poultices of raw infected frog flesh to a wound or eye. Subcutaneous tissue, subconjunctival tissue, and other organs can be affected in addition to the CNS. Brain abscesses and spinal cord involvement can occur, causing seizures, paresis, paresthesias, and other symptoms. MRI or CT scanning can help establish the diagnosis, but definitive diagnosis and treatment

usually relies on surgical excision, which is indicated particularly if the worm is still viable.

Echinococcosis in humans results predominantly from infection with either *Echinococcus granulosus* or *Echinococcus multilocularis*. Cystic hydatid disease is more common and is due to *E. granulosus*, whereas *E. multilocularis* causes alveolar echinococcosis. The adult parasites live in the intestines of dogs and wild canids such as foxes and wolves. Infective eggs, passed in the feces, are ingested by intermediate hosts, including sheep, cattle, and humans. The life cycle is maintained when dogs or wolves ingest the carcasses of infected intermediate hosts. Hence, cystic hydatid disease is most prevalent in sheep- and cattle-raising countries. In infected humans, unilocular cysts most commonly develop in the liver, but other organs, including the brain, may be involved either from primary inoculation or via secondary spread of a ruptured cyst. Variable clinical findings develop referable to the location and size of space-occupying cystic lesions. The spinal cord can also be involved, with secondary cord compression. Neurological hydatid disease is associated with concomitant hepatic cysts in up to 80% of cases. The diagnosis may be suspected on CT scan or MRI, and serological tests can help establish the etiology. Definitive therapy of lesions usually involves surgical excision, but treatment with albendazole can also be considered. Further information regarding echinococcal infection can be found at Echinonet Online Version of Echinonews.

Parasomnias

M W Mahowald, M A Cramer Bornemann, and C H Schenck, Hennepin County Medical Center, Minneapolis, MN, USA; and University of Minnesota Medical School, Minneapolis, MN, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

There are many different parasomnias. They may be divided into two broad categories: primary, which represent abnormalities of the sleep states *per se*, and secondary due to activity of other organ systems, which occur primarily or predominately during sleep. The primary parasomnias can be divided with regard to the parent state: nonrapid eye movement (NREM) sleep, rapid eye movement (REM) sleep, or a miscellaneous category not respecting sleep states. The secondary parasomnias can be categorized by the organ system involved. The most common primary parasomnias are the disorders of arousal, REM sleep behavior disorder, and rhythmic movement disorder. Common secondary parasomnias are nocturnal seizures and, less common, sleep-related expiratory groaning.

Primary Sleep Parasomnias

The concept that sleep and wakefulness are not invariably mutually exclusive states, and that the various state-determining variables of wakefulness, NREM sleep, and REM sleep may occur simultaneously or oscillate rapidly, is key to the understanding of the primary sleep parasomnias. The admixture of wakefulness and NREM sleep would explain confusional arousals (sleep drunkenness), automatic behavior, or microsleeps. The tonic and phasic components of REM sleep may become dissociated, intruding or persisting into wakefulness, thus explaining cataplexy, wakeful dreaming, lucid dreaming, and the persistence of motor activity during REM sleep (REM sleep behavior disorder).

Parasomnias are most apt to appear as the brain becomes reorganized across states; therefore, they often occur during the transition periods from one state to another. In view of the large number of neural networks, neurotransmitters, and other state-determining substances which must be recruited synchronously for full state declaration and the frequent transitions among states during the wake–sleep cycle, it is surprising that errors in state declaration do not occur more frequently.

In addition to the phenomenon of state dissociation, in which two states of being overlap or occur simultaneously, there are likely additional underlying physiologic phenomena which contribute to the appearance of complex motor behaviors during sleep. These include activation of locomotor centers during sleep, sleep inertia upon arousal, and sleep state instability.

NREM Parasomnias

Disorders of Arousal

The disorders of arousal are the most impressive and most common of the NREM sleep parasomnias. These share common features: They tend to arise from the deepest stages of NREM sleep (slow-wave sleep (stages 3 and 4 of NREM sleep)), thus usually occurring in the first third of the sleep cycle (and rarely during naps); and they are common in childhood, usually decreasing in frequency with increasing age. Disorders of arousal may be primed by febrile illness, alcohol, prior sleep deprivation, physical activity, emotional stress, or medications. Such factors should be considered as priming events in susceptible individuals, and not causal. Numerous other sleep disorders which result in arousals (obstructive sleep apnea, nocturnal seizures, or periodic limb movements) may also trigger disorders of arousal.

Persistence of these behaviors beyond childhood or their development in adulthood have erroneously been taken as an indication of underlying psychopathology. Numerous studies have dispelled this myth, indicating that significant psychopathology is usually not present in adults with disorders of arousal.

Disorders of arousal occur on a broad spectrum ranging from confusional arousals, through somnambulism (sleepwalking), to sleep terrors. Some take the form of 'specialized' behaviors, such as sleep-related eating and sleep-related sexual activity– without conscious awareness.

Confusional Arousals

These are often seen in children and are characterized by movements in bed, occasionally thrashing about, or inconsolable crying. 'Sleep drunkenness' is probably a variation on this theme. The prevalence of confusional arousals in adults is approximately 4%.

Sleepwalking

Sleepwalking is prevalent in childhood (1–17%), peaking at 11 or 12 years of age, and is far more common in adults (nearly 4%) than generally acknowledged. Sleepwalking may be either calm or agitated, with varying degrees of complexity and duration.

Sleep Terrors

The sleep terror is the most dramatic disorder of arousal. It is frequently initiated by a loud, bloodcurdling scream associated with extreme panic, followed by prominent motor activity such as hitting the wall and running around or out of the bedroom, or even out of the house, resulting in bodily injury or property damage. A universal feature is inconsolability, and attempts at consolation are fruitless and may serve only to prolong or even intensify the confusional state. Complete amnesia for the activity is typical but may be incomplete. Sleep terrors are much more prevalent in adults than generally acknowledged (4% or 5%). Although usually benign, these behaviors may be violent, resulting in considerable injury to the victim or others or damage to the environment, occasionally with forensic implications.

Treatment of disorders of arousal is often not necessary. Reassurance of their typically benign nature, lack of psychological significance, and the tendency to diminish over time is often sufficient. The tricyclic antidepressants and benzodiazepines may be effective, and they should be administered if the behaviors are dangerous to person or property or extremely disruptive to family members. Nonpharmacologic treatment such as hypnosis is recommended for long-term management. Anticipatory awakening has been reported to be effective in treating sleepwalking in children. The avoidance of priming factors such as drugs, alcohol, and sleep deprivation is also important.

REM Sleep Parasomnias

REM Sleep Behavior Disorder

The most common REM sleep parasomnia is the REM sleep behavior disorder (RBD). One of the defining features of REM sleep is active paralysis of all somatic musculature (with the exception of the diaphragm to permit respiration during REM sleep). In experiments reported in 1965, bilateral lesions of pontine regions adjacent to the locus coeruleus in cats caused the absence of the expected atonia associated with REM sleep, allowing the cats to demonstrate prominent motor behaviors during REM sleep (oneiric behaviors). Patients with RBD lack the paralysis of REM sleep, permitting the acting out of dream mentation, often with violent or injurious results. The prevalence of RBD is approximately 0.5%.

The presenting complaint is that of vigorous sleep behaviors usually accompanying vivid striking dreams. These behaviors may result in repeated injury, including ecchymoses, lacerations, and fractures. The potential for injury to self or bed partner raises interesting and difficult forensic medicine issues. Two striking demographic characteristics of RBD are that it predominately affects males (approximately 90%) and usually begins after the age of 50 years. RBD in humans occurs in both an acute and a chronic form.

Until recently, most reported cases of acute transient RBD fell in the toxic/metabolic category, with the best-studied conditions being the withdrawal states – most commonly involving ethanol. A growing cause of acute RBD appears to be iatrogenic, particularly associated with tricyclic antidepressants and serotonin-specific and noradrenergic-specific reuptake inhibitors – both widely prescribed categories of antidepressants.

The chronic form is most often either idiopathic or associated with neurological disorders. Each basic category of neurological disease (vascular, neoplastic, toxic/metabolic, infectious, degenerative, traumatic, congenital, and idiopathic) could be expected to manifest this disorder. Careful longitudinal evaluation has demonstrated that the majority of patients with what initially appears to be 'idiopathic' RBD will eventually develop neurodegenerative disorders, most notably the synucleinopathies (Parkinson's disease, multiple system atrophy, including olivopontocerebellar degeneration and the Shy–Drager syndrome, or dementia with Lewy body disease). RBD may be the first manifestation of these conditions, and it may precede any other manifestation of the underlying neurodegenerative process by more than 10 years. With such a high percentage of patients with RBD eventually developing other manifestations of neurodegenerative diseases, it has been proposed that the term idiopathic RBD be replaced by 'cryptogenic' RBD – the implication being that if followed long enough, the underlying neurologic condition will declare itself.

Systematic longitudinal study of patients with such neurological syndromes indicates that RBD and REM sleep without atonia may be far more prevalent than previously suspected. Although the exact prevalence of RBD in extrapyramidal disease is unknown, subjective reports indicate that 25% of patients with Parkinson's disease have behaviors suggestive of RBD or sleep-related injurious behaviors, and polysomnographic studies found RBD in up to 47% of patients with Parkinson's disease with

sleep complaints. In one large series of patients with multiple system atrophy, 90% were found to have REM sleep without atonia and 69% had clinical RBD.

There is a higher incidence of RBD in patients with narcolepsy. This association could be expected, because both narcolepsy and RBD are characterized by 'state boundary control' abnormalities. Furthermore, tricyclic antidepressants, SSRIs, and monoamine oxidase inhibitors, often prescribed to treat cataplexy associated with narcolepsy, can trigger or exacerbate RBD in this population.

Neuroimaging studies indicate dopaminergic abnormalities in RBD. Single-photon emission computed tomography (SPECT) studies have found reduced striatal dopamine transporters, and decreased striatal dopaminergic innervation has been reported. Decreased blood flow in the upper portion of the frontal lobe and pons has been reported, as has functional impairment of brain stem neurons. Positron emission tomography and SPECT studies have revealed decreased nigrostriatal dopaminergic projections in patients with multiple system atrophy and RBD. Decreased blood flow in the upper portion of the frontal lobe and pons has been found in one magnetic resonance imaging and SPECT study. Whole brain perfusion changes in patients with RBD are similar to those seen in Parkinson's disease. Impaired cortical activation as determined by electroencephalographic spectral analysis in patients with idiopathic RBD supports the relationship between RBD and neurodegenerative disorders.

There are a number of fascinating variations on RBD (beyond the scope of this article), all likely representing abnormalities of state boundary control. These include status dissociatus, the parasomnia overlap syndrome, and agrypnia excitata.

Clonazepam 0.5–1.0 mg at bedtime is effective in approximately 90% of cases, with little evidence of tolerance or abuse. Melatonin, often at doses of 3–12 mg at night, may also be effective. Pramipexole or levodopa may be effective. The other essential therapeutic intervention concerns environmental safety.

Rhythmic Movement Disorder

Rhythmic movement disorder (RMD), formerly termed jactatio capitis nocturna, refers to a group of behaviors characterized by stereotyped movements (rhythmic oscillation of the head or limbs and head banging or body rocking during sleep) seen most frequently in childhood. Its persistence into adulthood is not uncommon. It may be familial, and it is not the manifestation of any underlying psychiatric or psychological condition. RMD may arise from either REM or NREM sleep and may occur in the transition from wake to sleep. Significant injury from repetitive pounding may result. The etiology of RMD is unknown, and no systematic studies of pharmacologic or behavioral treatment have been reported.

Numerous other conditions may perfectly mimic the primary sleep parasomnias. These include obstructive sleep apnea, nocturnal seizures, psychogenic dissociative disorders, or malingering.

Isolated, often bizarre, sleep-related events may be experienced by perfectly normal people, and most do not warrant further extensive or expensive evaluation. The initial approach to the complaint of unusual sleep-related behavior is to determine whether further evaluation is necessary. The patient should be queried regarding the exact nature of the events. Because many of these episodes may be associated with partial or complete amnesia, additional descriptive information from a bed partner or other observer may prove invaluable. Home videotapes of the clinical event may be quite helpful. In general, indications for formal evaluation of parasomnias include behaviors that are potentially violent or injurious, are extremely disruptive to other household members, result in the complaint of excessive daytime sleepiness, or are associated with medical, psychiatric, or neurological symptoms or findings.

Secondary Sleep Parasomnias

Nocturnal Seizures

Sleep and epilepsy are common bedfellows. In most cases, epilepsy is highly state dependent: NREM sleep promotes seizures, whereas REM sleep is a relatively antiepileptic state. This state-dependent vulnerability to seizures reflects the dramatic reorganization of the entire central nervous system as it moves across the three states of being: wakefulness, NREM sleep, and REM sleep. There is extensive overlap and potential for confusion between other parasomnias and nocturnal seizures, particularly nocturnal frontal lobe epilepsy.

Sleep-Related Expiratory Groaning (Catathrenia)

Groaning during sleep has been termed 'catathrenia.' The behaviors occur intermittently during either REM or NREM sleep and are characterized by prolonged, often very loud, socially disruptive groaning sounds during expiration. It is poorly understood and awaits further definition and therapeutic studies. There is no known effective treatment.

Conclusion

Evaluation of problematic behaviors arising from the sleep period is best performed by experienced,

multidisciplinary teams of sleep medicine professionals in centers with extensive polysomnographic monitoring capability.

Parasympathetic Nervous System

J B Furness, University of Melbourne, Parkville, VIC, Australia

© 2009 Elsevier Ltd. All rights reserved.

The parasympathetic nervous system is a division of the autonomic nervous system (ANS). The parasympathetic nervous system is not truly a system; it does not act as a coordinated whole, except to the extent that it is part of the ANS. The reasons for classifying a part of the ANS as the parasympathetic nervous system are buried in the history of the investigation of the anatomy and physiology of the ANS. The major reasons are (1) that the autonomic outflows from the central nervous system are divided anatomically into cranial, thoraco-lumbar, and sacral outflows (between these are sections of the neuraxis without autonomic outflows) and (2) that some pathwys in the cranial and sacral parts provide vasodilator commands, whereas the thoraco-lumbar outflows include vasoconstrictor pathways.

The organs and functions that are controlled through the parasympathetic division of the ANS are summarized in Table 1. An inspection of Table 1 emphasizes that the parasympathetic nervous system is not a system in a functional sense. For example, there is no obvious physiological link between micturition and gastric acid secretion or between lacrimation and penile erection. In another instance, for control of the airway caliber, both a pathway for bronchoconstriction and a pathway for bronchodilation travel in the parasympathetically defined vagus nerve.

Nevertheless, a number of features do link the components of the parasympathetic nervous system. The preganglionic parasympathetic neurons form synapses in the ganglia close to the organs that they influence, in some cases within the walls of the organs. This is generally not the case for the sympathetic pathways, in which most peripheral ganglia are remote from the innervated organs. Exceptions include the spleen and kidney, which are close to the sympathetic ganglia that supply them. There are even reports of sympathetic

Table 1 Parasympathetic pathways and their functions

Function/organ	*Pathway from CNS*[a]	*Ganglia of supply*	*Final transmitters to effector*[b]
Heart (negative chronotropic action)	Vagus	Cardiac	ACh
Heart (negative ionotropic action)	Vagus	Cardiac	ACh
Vasodilation, cranial blood vessels	Facial nerve	Sphenopalatine, otic and cranial microganglia	NO (VIP, ACh)
Vasodilation, genital organs (penile erection, clitoral and labial engorgement), and uterus	Pelvic nerves	Pelvic (hypogastric)	NO (VIP)
Pupillary constriction	Oculomotor nerve	Ciliary	ACh
Accommodation of lens for near vision	Oculomotor nerve	Ciliary	ACh
Lacrimation	Facial nerve	Sphenopalatine	ACh
Parotid gland	Glossopharyngeal nerve	Otic	ACh (VIP)
Submaxillary gland	Facial nerve	Submaxillary	ACh
Gastric glands (acid secretion)	Vagus	Via enteric ganglia	ACh
Gastric relaxation (primarily fundus)	Vagus	Via enteric ganglia	NO (ATP, VIP)
Gastric contraction (primarily antral)	Vagus	Via enteric ganglia	ACh, TK
Exocrine pancreas	Vagus	Via enteric (pancreatic) ganglia	ACh
Pulmonary glands	Vagus	Tracheal ganglia	ACh
Bronchoconstriction	Vagus	Tracheal ganglia	ACh
Bronchodilation	Vagus	Tracheal ganglia	NO (VIP)
Glands of genital organs	Pelvic nerves	Pelvic ganglia	ACh
Gall bladder contraction	Vagus	Intramural ganglia of gall bladder	ACh
Contraction of urinary bladder (micturition reflex)	Pelvic nerves	Pelvic ganglia and intramural ganglia of bladder	ACh, ATP
Initiation of defecation reflex	Pelvic nerves	Via enteric ganglia	ACh, TK

[a]The nerves that carry vagal pathways are cranial nerves III (oculomotor), VII (facial), IX (glossopharyngeal), and X (vagus) and the sacral outflows S2–S4 whose autonomic components continue as the pelvic nerves. There are slight differences in which sacral roots participate, between individuals and between species.
[b]Primary transmitters are indicated, with co-transmitters in brackets.
ACh, acetylcholine; ATP, adenosine triphosphate; CNS, central nervous system; NO, nitric oxide; TK, tachykinin; VIP, vasoactive intestinal peptide family of peptides.

neurons in the capsule of the kidney. Another exception is the pelvic ganglia, which contain the cell bodies both of parasympathetic and of sympathetic postganglionic neurons.

A second feature of the parasympathetic nervous system is that the primary transmitters of the postganglionic neurons are acetylcholine (ACh) and nitric oxide (NO). So far as is known, NO is not a primary transmitter of postganglionic sympathetic neurons. Conversely, noradrenaline is a sympathetic postganglionic transmitter, but it is not used by parasympathetic postganglionic neurons. ACh is a transmitter of a majority of parasympathetic postganglionic neurons, but it is a transmitter only of those sympathetic neurons that innervate the sweat glands. Adenosine triphosphate (ATP) is a transmitter of some postganglionic neurons in each autonomic division.

It is often written that sympathetic pathways become active in emergency functions (flight or fight) and that parasympathetics are active in resting functions, such as digestion. Like other generalizations, this in only partly true. The maintenance of blood pressure at rest is a function of the sympathetic vasoconstrictor neurons. Penile and clitoral engorgement is ordinarily not regarded as a resting function, nor is micturition, although these are all parasympathetic functions. In addition, it is hard to imagine an emergency as profound as drowning, or the threat of drowning, a situation in which there is strong discharge of parasympathetic pathways to the heart.

Parietal Cortex and Spatial Attention

M E Goldberg, Columbia University, New York, NY, USA

© 2009 Published by Elsevier Ltd.

Introduction

The brain has a problem: sights, sounds, smells, and touches bombard our sensory apparatus constantly, and the primate brain cannot possibly deal with all of them simultaneously. Instead, it chooses among the myriad objects in our intense sensory world those most relevant to its behavior for further processing. This act of selection is called attention. In 1890, William James described attention as "the taking possession by the mind in clear and vivid form, of one out of what seem several simultaneously possible objects or trains of thought... It implies withdrawal from some things in order to deal effectively with others." James then described two different kinds of attention:

> It [attention] is either passive, reflex, non-voluntary, effortless or active and voluntary. Voluntary attention is always derived; we never make an effort to attend to an object except for the sake of some remote interest which the effort will serve. In passive immediate sensorial attention the stimulus is a sense-impression, either very intense, voluminous, or sudden...big things, bright things, moving things...blood. (William James (1890), *The Principles of Psychology*)

The attention you are now paying to this article is voluntary. Your momentary distraction by a thunderclap or a flash of lightning would be involuntary. Recently, these two kinds of attention have been described as endogenous, or 'top-down' attention, and exogenous, or 'bottom-up' attention, respectively.

Studies of attention have relied upon a number of different methods to establish the locus of attention. The simplest, but least precise, is *post hoc*: if a person has responded to something, then at some point he/she attended to it. There are three other precisely measurable effects of attention. (1) Attention lowers reaction time: if a cue flashes in the visual field, for the next 300 ms an individual has a faster reaction time to respond to a second stimulus that appears at the position of the cue, and a longer reaction time to respond to a second stimulus that appears away from the cue. (2) Attention improves perception: when for some reason an individual attends to a position in space (e.g., if a cue flashes there), the contrast sensitivity – how different the stimulus must be from the background – improves at the attended location relative to another part of the visual field. (3) Attention limits the effect of distractors: it is easier to pick out a searched-for object among cluttering distractors at the locus of attention.

The posterior parietal lobe, Brodmann's area 7, has long been thought to be important in the neural mechanisms underlying spatial attention. This concept arose from the study of patients with lesions of the parietal lobe, who exhibit two different sorts of deficits. The most severe deficit is a neglect of the contralateral world: patients with right parietal lesions do not recognize that the paralyzed contralateral limb is theirs, nor do they recognize that they are ill. Although they cannot see the left visual field, or the left side of their egocentric space, they are unaware of the deficit. As this extreme deficit recovers they begin to perceive their own contralateral space and limbs, but can have three types of milder deficits. One is a residual neglect: these patients have difficulty constructing the contralateral side of objects. When they are asked to draw a clock they cram the numbers into the right half of the clock (Figure 1). When they are asked to bisect a line they place the midline far to the right of the true midpoint. When they are asked to strike out lines on a page they begin at the far right and often leave out a few lines at the far left. The second deficit is extinction: these patients have an inability to see an object in the affected visual field when a similar object appears in the unaffected visual field, although they can see a single object in the affected field perfectly well. Extinction can be tactile as well – a patient who can appreciate a light tap on his left hand may not perceive the same tap when his right hand is tapped simultaneously. These patients behave as if objects in their unaffected field grab their attention, so they neglect objects in the affected field. The third deficit is in making accurate visually guided movements: patients with parietal lesions often misreach. All of these clinical observations suggest that the parietal lobe is important for three interrelated functions – attention, spatial perception, and the generation of accurate movements to visual stimuli.

Although introspectively we tend to think of perceptual space as being unitary, a homogeneous sphere of which we are at the center, neuropsychological studies have questioned this idea. Thus, certain patients who can bisect a line accurately when they shine a laser pointer at a distant light cannot use a pencil to bisect the same line when it is within arm's reach. Thus, neural mechanisms of spatial attention must distinguish more than the azimuth and elevation of the attended object, but also its distance. One way to explain this multiplicity of attentional spaces is to view them as

Figure 1 A clock drawn by a parietal patient. The examiner draws the circle and asks the patient with a right parietal lesion to write in the numerals of the clock phase in their proper position. The patient places 1 through 6 in their proper position, but fails to place the remaining numbers properly, putting them on the right side of the clock rather than the left. Adapted from Critchley M (1953) *The Parietal Lobes*. London: Edward Arnold.

Figure 2 Location of visually responsive areas in rhesus monkey cortex. In this dorsal view of the right hemisphere, the lunate and intraparietal sulci are opened up to show the locations of several extrastriate areas and visually responsive areas within the intraparietal sulcus. Visual areas V2, V3, and V3A are shown in the lunate sulcus. Other areas: PO, the parieto-occipital area; PIP, the posterior intraparietal area; MIP, the medial intraparietal area; LIP, the lateral intraparietal area; VIP, the ventral intraparietal area; AIP, the anterior intraparietal area. Area 7a lies on the surface of the prelunate gyrus. Adapted from Colby CL, Gattass R, Olson CR, et al. (1988) Topographic organization of cortical afferents to extrastriate visual area PO in the macaque: A dual tracer study. *Journal of Comparative Neurology* 269: 392–413.

related to motor workspaces. Thus, attention for far space ranges through the part of space uniquely explored by eye movements. Attention for near space ranges through the workspace for reaching movements.

A second major function of the posterior parietal lobe is to describe the world for action. When you reach out to grab a thick object such as an apple, you open your hand so that when your fingers reach the apple they are opened wider than the apple, and you easily close your hand around the apple. When you reach out to grasp a pencil, you open your fingers much less widely than you did when you grasped the apple. Patients with parietal lesions cannot do this: they cannot use visual information to set their grasp, even though they can tell you whether the apple or the pencil is wider.

Physiological studies of parietal function have emphasized both of these major functions of the parietal lobe: generating spatial attention and analyzing the visual world for action. Most of our understanding of the neurophysiology of the posterior parietal lobe comes from studies of the parietal lobe of the rhesus monkey. Brodmann described the posterior parietal cortex as a single area, area 7, on the basis of its cellular morphology. Recent studies have shown that area 7 is divided into a number of different regions, with differing anatomical projections and physiology. Many of these subdivisions lie within the intraparietal sulcus (Figure 2). Each of the areas in the intraparietal sulcus has neurons which respond to the appearance of visual stimuli. These neurons do not respond to the appearance of stimuli everywhere in the visual field; instead, they respond only to stimuli which appear in a limited part of the visual field. The part of the visual field which can excite the neuron is called its receptive field, and the receptive fields of parietal neurons usually lie in the visual field opposite the hemisphere in which the neuron lies – the contralateral visual field. The properties of each individual area make them suitable for representing objects which can be the target for a specific set of movements – a 'motor workspace'.

Each area in the intraparietal sulcus sends projections to premotor areas which define the actual movements in that workspace. Thus, the ventral intraparietal (VIP) area has neurons which represent the near space around the mouth, and the tactile areas on the face. The neurons have congruent responses: neurons which represent the upper visual field also represent the upper face (Figure 3). Many VIP neurons respond to visual stimuli close to the face, but not to stimuli with the identical visual angle further away. The VIP area projects to area F4 in premotor cortex, which represents movements of the face and head. The medial intraparietal (MIP) area has neurons responding to tactile stimulation of the arm and discharges when the monkey reaches to targets. The MIP area projects to F2 in premotor cortex, which represents movements of the arm. The anterior intraparietal (AIP) area has neurons which respond to visual stimuli which can be grasped, and which discharge when a monkey makes a grasping movement in the dark. The AIP area projects to area F5 in premotor cortex, which is important in the generation of grasping movements.

The most extensively studied area in the intraparietal sulcus is the lateral intraparietal (LIP) area. This area has reciprocal connections with two areas important in

Figure 3 Correspondence of visual and tactile receptive fields in the ventral intraparietal area of the monkey. The top of each column has a drawing depicting the experiment, and the raster diagram of the activity of a single neuron in the ventral intraparietal area under different circumstances is below, showing the individual neuronal response. Each dot is an action potential; each line is a single trial. Successive lines are synchronized on a single event – on the left when the experimenter began to stroke the animal, and on the right when the visual stimulus appeared. The vertical lines show when the synchronizing event began. Histograms beneath the rasters sum the activity of the rasters. Each tick in the raster is 200 ms. The raster in the left column shows the tactile responses and that in the right column shows the visual responses of a neuron in ventral intraparietal area. The receptive fields correspond if one considers the mouth to be analogous to the fovea. Each depicted neuron was directionally selective: Visual and tactile stimuli moving in the opposite direction had little or no effect on the neuron (not shown here). Reproduced from Duhamel J-R, Colby CL, and Goldberg ME (1998) Ventral intraparietal area of the macaque: Congruent visual and somatic response properties. *Journal of Neurophysiology* 79: 126–136, with permission.

the generation of rapid eye movements (saccades), the frontal eye field (FEF) and the superior colliculus (SC). The projection from the SC to the LIP area is disynaptic via the thalamus; the projections to and from the FEF are monosynaptic. The LIP area also has reciprocal connections with areas important for the analysis of patterns in the visual world: prestriate area V4, and TEO and TE in the inferior temporal cortex. Activity in the LIP area is consistent with providing information both for generation of eye movements and for pinning attention in the visual field.

LIP neurons do not respond to every object in the visual field. Most of the objects in the visual field, especially those that are stable and irrelevant to an individual's behavior, are not represented by activity in the LIP area. Instead, only those objects which can be the object of voluntary or involuntary attention are represented. The same object can evoke little or no response when it appears in the receptive field of neuron, or a very strong response, depending upon the behavioral significance of the object. LIP neurons are closely related to the neural mechanisms for the control of saccadic eye movements. When a monkey plans a memory-guided saccade to the spatial location of a recently vanished stimulus in a LIP neuron's receptive field, the neuron discharges in response to the appearance of the stimulus, during the delay period, and before the saccade itself. This activity is consistent with saccade planning, and also voluntary attention, because attention, as measured by an improvement in perceptual threshold, lies at the goal of the memory-guided saccade. However, LIP neurons also respond to the abrupt onset of a distractor which appears in the receptive field when the animal is planning a saccade elsewhere. Attention lies at the goal of the planned saccade unless a distractor appears elsewhere in the visual field, at which point the mechanisms for involuntary attention overwhelm the voluntary attention induced by the eye movement, and attention shifts away from the goal of the saccade to the location of the distractor. The activity of the LIP area in this case parallels the location of the monkey's attention. The time at which attention returns from the distractor to the saccade goal is predicted by the time at which the activity evoked by the distractor falls below that evoked by the saccade plan (Figure 4). Under the circumstances of this experiment, although LIP reflects a saccade plan, its activity does not necessarily correlate with when, where, or if the monkey will make a saccade – the distractor has no effect on the monkey's eye movements. Instead, its activity correlates with the

Figure 4 Top-down and bottom-up attentional activity in the lateral intraparietal area. (a) Average activity of 23 lateral intraparietal neurons during the delayed saccade task. Blue trace: the saccade target appears briefly in the receptive field (blue bar). The normalized neuronal spike density is calculated with a sigma of 10 ms (ordinate) plotted against time (abscissa). The thickness of the line is the standard error of the mean of the activity, Note the onset transient in response to the target appearance, followed by delay period activity well above the background activity, despite the fact that the target is no longer present. The delay activity continues until the monkey makes the saccade (not shown). Red trace: distractor appears in the receptive field (red bar) while the monkey is planning a saccade away from the receptive field. Note the brisk onset transient and decay of activity beneath the level of the saccade delay period activity. (b) Relationship of the monkey's attention to neuronal activity in the lateral intraparietal area. The top trace shows the monkey's perceptual performance during the task. The normalized contrast threshold for a stimulus flashed for one video frame (abscissa) is plotted against time from the appearance of the distractor (ordinate). A significant decrement in contrast threshold denotes that the monkey's attention lies at the spatial location of the stimulus. Before the distractor appeared, the perceptual threshold was lower at the saccade goal (not shown). At 200 ms after the distractor appeared, the perceptual threshold was significantly lower at the distractor site but not at the saccade goal. The bottom trace shows the neuronal activity during this epoch. Note that when the neuronal activity was greater at the distractor site (red trace) than it was at the saccade goal (blue trace), the distractor site was the locus of attention. When there was no difference between the activity at the distractor site and the saccade goal (the black line shows the Wilcoxon *p* value of the difference between the two points), there was no attentional advantage at either site. When the neuronal advantage became significant again at the saccade goal, the attentional advantage returned to the saccade goal and remained there throughout the delay period.

location of the monkey's attention on a millisecond-by-millisecond basis, including the attention that is pinned to a location in space by the plan to make a saccade there. In contrast, when a monkey is exploring the visual field in a search task, activity in the LIP area predicts the goal and reaction time of the saccade. Thus activity in the LIP area is best understood as representing a map of the salient locations in the visual field in the far space explored by eye movements. The visual system presumably uses this representation to pin attention at the peaks in the salience map; the oculomotor system can drive the eyes to the peak of the salience map when a saccade is appropriate.

Neurons in the LIP area have retinotopic receptive fields. The visual, memory, and saccade-related signals carried by these neurons describe stimuli in terms of the distance and direction of the stimulus or saccade location relative to the center of gaze. This retinotopic organization presents a paradox: how can accurate spatial information be derived from retinotopic input? Every time we move our eyes, each object in our surroundings activates a new set of retinal neurons. Despite these changes, we experience the world as stable and move accurately in it. This perceptual stability has long been understood to reflect the fact that what we see is not a direct impression of the external world but an internal image of it. The brain must construct a representation that can compensate for changes in eye position. Neurons in the LIP area compensate for eye movements: if a stimulus flashes outside the receptive field of a neuron, but an eye movement brings the spatial location of the vanished stimulus into the receptive field, neurons in the LIP area will respond, after the eye movement, to a stimulus which never appeared in their receptive field, but would do so if it were still illuminated after the eye movement (Figure 5). Some neurons respond to stimuli which will be brought into their receptive fields by an impending saccade even before the saccade. Thus, LIP neurons update their representation of the visual world, compensating for eye movements, so that there is a continuously spatially accurate representation of the visual world in the LIP area despite a moving eye. Neurons in the MIP area, which describe the workspace for reaching movements, also describe the world in retinal coordinates and compensate for saccades in a similar way. In keeping with this, patients with right parietal lesions cannot make this compensation: they cannot make a saccade to a stimulus which appears and disappears before an intervening saccade. This suggests that without an intact parietal lobe they cannot compensate for

Figure 5 Remapping of visual activity in the lateral intraparietal area. Diagrams show the arrangement of the fixation point, receptive field, stimulus location, and saccade. (Left) In the fixation task, the neuron responds to the onset of a stimulus in the receptive field. (Middle) The same neuron responds when a saccade moves the receptive field onto the location of a recent stimulus. (Right) Response after a saccade moves the receptive field onto a previously stimulated location. The stimulus is flashed on for only 50 ms and is extinguished before the saccade begins. The neuron is responding to the remapped memory trace of the previous stimulus. Control experiments (not shown) indicate that neither the stimulus alone nor the saccade alone can drive the neuron. Adapted from Duhamel J-R, Colby CL, Goldberg ME, et al. (1992) The updating of the representation of visual space in parietal cortex by intended eye movements. *Science* 255: 90–92.

their own eye movements. Thus, the neural activity in the LIP area reflects the three functions described by lesions in patients: attention, spatial perception, and describing the visual world for movement. Whether the other areas in the intraparietal sulcus perform the same functions for the motor workspaces they describe will be the subject for future research.

Parkinsonian Syndromes

C Schwarz, New York Presbyterian Hospital – Weill Cornell Medical Center, New York, NY, USA
C Henchcliffe, Weill Medical College of Cornell University, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction and Clinical Features

Parkinsonian syndromes occur as part of multiple underlying pathologies that involve the striatum (Table 1). This article focuses on Parkinson's disease (PD), which is the most common cause of parkinsonism, accounting for approximately 80% of cases. PD is the second most common neurodegenerative disease after Alzheimer's disease. Most cases of PD occur between ages 40 and 70 years, with the peak of onset in the sixth decade. In the United States, the prevalence is 1% by age 65 years and 3.5% by age 85 years. PD is suggested to arise due to both environmental and genetic causes. In approximately 90% of cases, no apparent genetic defect can be detected, and it is referred to as idiopathic. The disease is progressive, and treatment is mainly symptomatic. Clinically, PD is characterized by cardinal motor features that are caused by a loss of dopaminergic neurons in the substantia nigra, which project to the striatum. They include tremor at rest with a frequency of 4–7 Hz, lead-pipe rigidity of the extremities on examination, bradykinesia and akinesia (slowness and paucity or absence of movement), and postural instability later in the course of disease. Patients suffer from hypophonia (decreased voice volume), dysphagia, drooling, hypomimia (loss of facial expression or 'masked facies'), micrographia (decreased size of handwriting), flexed posture, shuffling gait, and freezing (motor block, often affecting gait). The onset is gradual and usually asymmetric. Dystonia may be associated with PD early in a minority of patients or, more often, later in the course of the disease. PD patients also suffer from a variety of nonmotor symptoms, including cognitive and behavioral changes, depression and anxiety, olfactory loss, sleep disorders, and autonomic symptoms. These are related to neurodegeneration in brain regions other than the substantia nigra and may precede motor symptoms. The longitudinal course of PD is followed clinically using the Unified Parkinson Disease Rating Scale, which consists of ratings for mentation, behavior and mood, the ability to conduct activities of daily living, and motor performance.

The previously mentioned features of PD are found in varying combinations in other parkinsonian syndromes (Table 1), raising a diagnostic challenge in some individuals. The presence of atypical features, however, may raise suspicion. Progressive supranuclear palsy (PSP) typically manifests with symmetric parkinsonism, impaired oculomotor function (particularly vertical gaze), prominent axial rigidity, and early falls. The cortical involvement of corticobasal-ganglionic degeneration may lead to apraxia, alien limb, cortical sensory impairment, and myoclonus, in the setting of asymmetric parkinsonism. Multiple system atrophy (MSA) may comprise prominent parkinsonism (striatonigral degeneration or MSA-P); cerebellar signs and symptoms (olivopontocerebellar atrophy or MSA-C); or autonomic dysfunction, including orthostatic hypotension and syncope, urinary symptoms, constipation, and sexual dysfunction (Shy–Drager syndrome or MSA-A). These Parkinson's-plus syndromes typically display more rapid progression and little, if any, response to dopamine replacement. The presence of dementia early in disease should raise suspicion of dementia with Lewy bodies (DLB), typically associated with hallucinations and fluctuating clinical symptoms. However, parkinsonism is also a feature of Alzheimer's disease and frontotemporal dementia in some patients, and tau mutations on chromosome 17 lead to autosomal dominant inherited frontotemporal dementia with parkinsonism (FTDP-17).

Neuroimaging

In general, patients with parkinsonian syndromes undergo conventional magnetic resonance imaging (MRI) to rule out any structural abnormalities that may lead to parkinsonism, such as tumor, stroke or infection of the basal ganglia, or hydrocephalus. The neurodegenerative diseases under discussion in this article typically have subtle or no abnormalities revealed by MRI. However, in some with MSA, T2-weighted images demonstrate hyperintense signals along the lateral aspect of the putamina, the 'hot cross bun' sign due to degeneration of neural pathways in the pons, and/or cerebellar atrophy. Positron emission tomography (PET) and single photon emission computerized tomography (SPECT) allow imaging of basal ganglia and nigrostriatal tract integrity using appropriate radioligands. Fluorodopa PET has revealed progressive presynaptic dopaminergic nigrostriatal damage in PD patients: while not a satisfactory measure of progression, it may help to assess nigrostriatal tract integrity in atypical cases. Fluorodeoxyglucose PET shows normal or increased metabolism in the

striatum in PD, whereas in Parkinson's-plus syndromes there may be decreased striatal metabolism. Currently, however, PET and SPECT are little used in clinical management of PD and other parkinsonian syndromes.

Table 1 Differential diagnosis for parkinsonian syndromes

Parkinson's disease (sporadic, familial)
Secondary parkinsonism
Toxic: MPTP, manganese, copper, cyanide
Trauma
Tumor
Vascular
Postencephalitic
Hypoxia
Carbon monoxide
Normal pressure hydrocephalus
Drug-induced: dopamine antagonists and depletors
Hemiatrophy–hemiparkinsonism
Multisystem degeneration (Parkinson's-plus syndromes)
Multiple asystem atrophy (MSA)
MSA-P (striatonigral degeneration)
MSA-A (Shy–Drager)
MSA-C (sporadic olivopontocerebellar atrophy)
Progressive supranuclear palsy
Corticobasal ganglionic degeneration
Progressive pallidal atrophy
Lytico–Bodig (Parkinson–dementia–ALS complex of Guam)
Dementia associated: dementia with Lewy bodies, frontotemporal dementia, Alzheimer's disease
Hereditary neurodegenerative diseases
Lubag
Dopa-responsive dystonia
Olivopontocerebellar and spinocerebellar atrophy
Huntington's disease
Mitochondrial myopathies
Neuroacanthocytosis
Wilson's disease
Neurodegeneration with brain iron accumulation type1

Pathology

The disease is characterized by loss of dopaminergic neurons in the substantia nigra pars compacta (SNpc), which affects nigrostriatal dopaminergic pathways leading to striatal dopamine (DA) deficiency. Depigmentation of the SNpc in autopsy tissue is caused by loss of these neurons, which contain neuromelanin. Findings indicate a more widespread pathology with neurodegeneration also involving the olfactory bulb, the dorsal motor nucleus of the vagus nerve, the nucleus basalis of Meynert, the superior cervical ganglia, the mesenteric plexus, and the locus coeruleus (Table 2). Neurodegeneration in these areas likely precedes neuronal death in the SNpc and accounts for some of the nonmotor symptoms in PD. Clinical symptoms of PD emerge when approximately 80% of striatal dopamine and 50% of nigral dopaminergic neurons are lost. Thus, early diagnosis remains a challenge.

A pathological hallmark of PD is the formation of intraneuronal cytoplasmic inclusion bodies, termed Lewy bodies (Figure 1). The major components of Lewy bodies are α-synuclein and ubiquitin. Lewy bodies occur not only in the SN but also in other areas involved in neurodegeneration mentioned previously. The relationship between Lewy bodies and cell death remains to be determined, and of note, they are not found in PD arising from parkin mutations nor in all cases of PD associated with LRRK2 mutations.

Etiology and Pathogenesis

Multiple lines of evidence point to a combination of environmental factors and genetic mutations or susceptibility factors as the cause of PD, and their relative contributions vary between individuals.

Table 2 Proposed pathologic stages of Parkinson's disease (Braak classification)

Stage	*Location*	*Structures affected*
1	Medulla oblongata	Dorsal nucleus of vagal and glossopharyngeal nerves and/or intermediate reticular zone; olfactory bulb and anterior olfactory nucleus
2	Medulla oblongata and pontine tegmentum	Pathology of stage 1 plus caudal raphe nuclei, gigantocellular reticular nucleus, and coeruleus–subcoeruleus complex
3	Midbrain	Pathology of stages 1 and 2 plus midbrain, especially in the pars compacta of the substantia nigra
4	Basal prosencephalon and mesocortex	Pathology of stages 1–3 plus prosencephalic and cortical involvement confined to the temporal mesocortex (transentorhinal region) and allocortex (CA2 plexus)
5	Neocortex	Pathology of stages 1–4 plus higher order sensory association areas of neocortex and prefrontal neocortex
6	Neocortex	Pathology of stages 1–5 plus sensory association areas of the neocortex and premotor areas; occasionally mild changes in primary sensory areas and the primary motor field

Figure 1 Photomicrograph of a hematoxylin–eosin-stained section taken from the substantia nigra pars compacta at autopsy of a PD patient. A surviving dopaminergic neuron in the center of the field contains a cytoplasmic Lewy body, with a central eosinophilic dense core surrounded by a halo. Also in the cytoplasm are numerous neuromelanin granules (brown pigment). Cortical Lewy bodies are less well-defined in structure. Courtesy of Ehud Lavi, MD, Department of Pathology, Weill Medical College of Cornell University.

Several studies have examined the role of environmental factors in the pathogenesis of PD. These have identified a number of risk factors, including rural living, pesticide exposure, well water consumption, as well as mining and welding. Exposure to manganese, a component of herbicides, pesticides, and welding fumes, produces a parkinsonian syndrome and leads to damage of the globus pallidus with sparing of the substantia nigra. Exposure to the pesticide rotenone has been shown to reproduce neuropathological features of PD with cytoplasmic inclusions that contain ubiquitin and α-synuclein in rats. Ingestion of annonacin in the Caribbean is associated with parkinsonism in humans and induces nigral and striatal neurodegeneration in rats. Exposure of humans to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) results in an acute parkinsonian syndrome. These findings have been used to create animal models of PD by administering a variety of the previously mentioned toxins to different species. In contrast, other environmental factors, such as cigarette smoking, alcohol, and caffeine, are associated with a lower risk for PD, although the reason for this negative association remains to be elucidated.

PD Genetics: Implications for PD Pathogenesis

In the past few years, various gene mutations have been identified in familial PD (Table 3), beginning with the discovery of α-synuclein mutations in the large Contursi kindred in 1997. Even though only approximately 10% of PD cases are clearly hereditary, the study of genetic forms of the disease offers valuable insights into the pathogenesis of PD (Table 3). Aided by the discovery of specific genes mutated in familial PD, genetic animal models in different species have been generated to address the previous questions and to test pharmacological interventions that could be applied to nonfamilial forms of PD as well. The discovery of mutations in several PD genes involved in the function of the ubiquitin–proteasome system provides evidence that dysfunction of this pathway leads to abnormal protein aggregation, Lewy body accumulation, and neuronal death in PD. Study of normal and mutant function of several PD genes also strongly implicates a role for mitochondrial dysfunction and oxidative stress in PD pathogenesis. In addition, oxidative stress or environmental toxins most likely contribute to proteasomal dysfunction.

α-Synuclein (PARK1) was the first gene to be identified in hereditary PD, but mutations in this gene affect only a very small number of families. α-Synuclein is a 140-amino acid presynaptic protein that is involved in vesicle trafficking and neurotransmitter release, and it is a major component of Lewy bodies in PD and DLB. Three missense mutations and several genomic multiplications of the α-synuclein gene have been identified in hereditary PD. However, promoter polymorphisms may also be associated with sporadic PD. Mutant or overexpressed α-synuclein is misfolded and aggregates within the cell, thus impairing degradation by the ubiquitin–proteasome system. Transgenic mouse lines have been generated, including α-synuclein knockouts, and lines overexpressing human α-synuclein under the control of various promoters. The behavioral phenotype, such as decreased locomotor activity and increased righting time on an inverted screen, correlates with the level of overexpression of the protein. However, only a few of the lines have dopaminergic neurodegeneration in the striatum, which limits their usefulness as PD models. In contrast, injection of viral vectors containing human α-synuclein into adult rat SN leads to formation of α-synuclein-positive, Lewy body-like inclusions and dopaminergic neuronal cell death. A *Drosophila* model of PD overexpressing wild-type or mutant α-synuclein has been developed. Dopamine neuron loss in these flies was associated with Lewy body-like inclusions and behavioral changes that were corrected by administration of dopamine agonists and levodopa.

Mutations in the parkin gene (PARK2) cause juvenile autosomal recessive parkinsonism. They are found at high frequency in early onset PD (18% sporadic early

Table 3 Parkinson's disease genetics

Gene	*Inheritance*	*Function*	*Observations*
α-Synuclein (PARK1, -4)	Dominant	?	Aggregation into oligomers or fibrils Substrate for ubiquitin–proteasomal system Knockout mutant: ↑ resistance to MPTP (mice) Mutation: A53T overexpression; abnormal mitochondria (mice)
Parkin (PARK2)	Recessive	Ubiquitin E3 ligase	Ubiquitin–proteasomal system impairment Mitochondrial outer membrane association (partial) Mutation: abnormal mitochondria, ↑ sensitivity to oxidative stress (*Drosophila*)
UCH-L1 (PARK5)	Recessive	Ubiquitin C-terminal esterase L1	Ubiquitin–proteasomal system impairment Requires confirmation as PD gene in further families
PINK1 (PARK6)	Recessive	Mitochondrial serine–threonine kinase	Mitochondrial membrane localization siRNA: ↑ sensitivity to MPP+, rotenone Mutation: abnormal mitochondria, ↑ sensitivity to oxidative stress (*Drosophila*)
DJ-1 (PARK7)	Recessive	Oxidative stress sensor, chaperone	Oxidative stress causes re-localization to mitochondria (matrix/intermembrane space) Protects against oxidative stress siRNA: ↑ sensitivity to oxidative stress (*Drosophila*) Mutation: ↑ sensitivity to rotenone, paraquat, hydrogen peroxide (*Drosophila*); ↑ sensitivity to oxidative stress (mice)
LRRK2 (PARK8)	Dominant	Serine–threonine kinase	GTPase or MAPKKK dysregulation
Lysosomal ATPase (PARK9)	Recessive	?	Responsible for Kufor–Rakeb syndrome of parkinsonism with dementia

onset and 49% familial autosomal recessive early onset). Heterozygous mutations in the parkin gene might constitute a risk factor in sporadic PD, and polymorphisms in the parkin gene appear to confer an increased risk toward the development of idiopathic PD. Parkin is a ubiquitin E3 ligase that is involved in the ubiquitination of proteins prior to degradation by the proteasome. Mutations in parkin therefore interfere with normal clearing of proteins by the cell and lead to accumulation of parkin substrates, such as α-synuclein, Pael-R, synphilin 1, and CDCrel-1. A role for parkin in mitochondrial function has also been suggested. Parkin knockout mice, however, do not display accumulation of parkin substrates and there is no loss of dopaminergic neurons. These mice do show altered dopaminergic neurotransmission as well as behavioral changes but are not regarded as a good model for parkinsonism. Ubiquitin–proteasomal system dysfunction is further implicated by the finding of ubiquitin C-terminal hydrolase L1 (UCH-L1) mutation in a family with autosomal recessive PD, but its role in PD remains to be confirmed with additional families.

PINK1 (PTEN-induced kinase1) is another cause of autosomal recessive PD, although far less commonly than parkin. It localizes to the mitochondria and possibly exerts a protective effect on the cell.

Deletions or point mutations in the DJ-1 gene (PARK7) cause rare autosomal recessive early onset PD. DJ-1 is a multifunctional oncogene product, a regulatory subunit of RNA binding protein, and has been implicated in the cellular response to oxidative stress. DJ-1 knockout mice show an increased vulnerability to oxidative stress and decreased dopamine release from striatal neurons but no loss of dopaminergic neurons. These mice have decreased locomotor activity and increased sensitivity to the neurotoxin MPTP.

Leucine-rich repeat kinase 2 (LRRK2) is increasingly recognized as an important cause of autosomal dominant PD in particular populations. Its function remains to be elucidated, but its structure comprises a Ras-GTPase domain and a MAPKKK domain, thus implicating dysfunction of multiple cell signaling pathways.

Several important questions remain in the pathogenesis of genetic PD, such as the basis for selective neuronal vulnerability and the exact mechanism of cell death. It is unclear why there is a delayed clinical presentation in adulthood in the genetic forms of PD, even though the gene is expressed at or before birth. It is very likely that there are molecular changes in the affected cells before expression of the phenotype, which cannot yet be studied in patients.

Neurotoxin-Based Animal Models of PD

Nongenetic, neurotoxin-based animal models of PD have played a critical role in understanding the pathways that lead to selective degeneration of dopaminergic neurons in sporadic PD. Toxin-induced animal

models are based on the assumption that dopaminergic neurons follow a common pathway of cell death regardless of the initial stimulus. The toxins used are all thought to provoke the formation of reactive oxygen species. Elucidating the cascade that leads to cell death in these models might contribute to a better understanding, identify novel molecular pathways that might be targeted to prevent degeneration, and might lead to the discovery of novel treatment strategies. Moreover, they may prove valuable for preclinical testing of novel treatments that modulate the ubiquitin–proteasome pathway or mitochondrial function.

Exposure of humans and nonhuman primates to MPTP, a by-product of chemical synthesis of a synthetic heroin analog, results in an acute parkinsonian syndrome that recapitulates many clinical features of PD. Its metabolite, 1-methyl-4-pyridinium (MPP+), binds to the dopamine transporter and thus accumulates in dopaminergic neurons. It inhibits NADH dehydrogenase and NADH CoQ reductase of complex I of the mitochondrial electron transport chain (ETC), resulting in cell death of dopaminergic neurons of the SNpc.

Local stereotactic injection of the neurotoxin 6-hydroxydopamine (6-OHDA) into the SN or striatum of animals induces selective degeneration of the nigrostriatal dopamine system, resulting from preferential uptake by dopamine and noradrenergic transporters. Animals with 6-OHDA-induced lesions undergo extensive loss of DA neurons in the basal ganglia, with corresponding neurological impairments including akinesia, dyskinesias in response to dopaminergic treatment, and improved motor function after the administration of dopaminergic agents. However, 6-OHDA injections do not produce Lewy body-like inclusions.

The herbicide, paraquat, and the pesticide, rotenone, are also used to produce toxic animal models of PD. Intravenous infusion of rotenone, which binds to and inhibits complex I of the mitochondrial respiratory chain, produces dopaminergic degeneration in the SN and induces α-synuclein-positive Lewy body-like inclusions in rats. Animals treated with rotenone develop bradykinesia and abnormal posturing. Paraquat shows structural similarity to MPP+. When infused into mice, it leads to dopaminergic degeneration in the SN and formation of α-synuclein-positive inclusions.

Oxidative Stress and Mitochondrial Dysfunction in PD Pathogenesis

There is mounting evidence supporting mitochondrial dysfunction, either primarily or secondarily, in the PD pathogenetic process, and several PD genes are suggested to be involved in mitochondrial function and oxidative stress (Table 3). The mitochondrial ETC is a major source of highly reactive free radicals, particularly when impaired, that may oxidatively damage neighboring molecules. Moreover, impaired mitochondrial function increases susceptibility to oxidative stress.

Complex I is the largest of the ETC complexes, and it is the major site of superoxide production in the ETC. Its activity in PD patients is decreased in the SN and other brain regions, and cell cybrids (fusion of platelets isolated from PD patients with cell lines deficient in mitochondria) can have a complex I deficiency. Moreover, higher levels of acquired mitochondrial DNA deletions have been demonstrated in autopsy brain tissue in PD compared with non-PD controls. Finally, several studies have suggested that specific clusters of mitochondrial DNA haplogroups may decrease the risk of PD. Postmortem analysis of SN tissue has provided direct evidence of oxidative stress in PD, with increased levels of malondialdehyde and cholesterol lipid hydroperoxides and others. Moreover, oxidative damage impairs the ubiquitination and degradation of proteins mediated by the ubiquitin–proteasomal system, suggesting a link between oxidative damage and characteristic abnormal protein aggregates. In addition to mitochondrial ETC dysfunction, impaired antioxidant mechanisms and increased exposure to environmental or endogenous sources of oxidative stress may all contribute to increased oxidative stress in PD. Glutathione, an important antioxidant, is decreased in the SN by approximately 50% in PD patients. Iron can act as a catalyst in the formation of hydroxyl radicals from hydrogen peroxide. Neuromelanin, present in some dopamine neurons, chelates iron but is present at decreased levels in PD substantia nigra. Several studies have demonstrated increased iron levels in the brain of PD patients, as well as decreased amounts of ferritin, which inhibits iron's catalytic properties. Therefore, the potential use of iron chelators, combined with monoamine oxidase (MAO) inhibition, is being pursued.

Current Treatments for PD

Pharmacologic treatment is symptomatic. The mainstay of PD treatment is the DA precursor L-DOPA (L-3,4-dihydroxyphenylalanine). L-DOPA provides adequate control of akinesia and tremor for several years, but over time treatment is complicated by the development of motor fluctuations and dyskinesias, requiring more advanced therapeutic strategies. Many clinicians therefore prefer to use alternative therapies, such as dopamine agonists or MAO-B inhibitors, when possible, early in the disease. These may also be used as adjunctive therapies in later disease, along with

catechol-*O*-methyltransferase inhibitors such as entacapone, which inhibit levodopa metabolism and help decrease motor fluctuations. Other agents in use are amantadine, with multiple mechanisms of action including NMDA receptor blockade, and anticholinergic agents, which are helpful for tremor. Side effect profiles of these, however, are often limiting. Cholinesterase inhibitors seem to have mild benefit for cognitive dysfunction, and various antidepressants are under investigation for PD-associated depression.

Deep brain stimulation (DBS) is a surgical approach to treating advanced PD in which electrodes are implanted into specific brain regions. Continuous high-frequency stimulation is then delivered via an externally programmable pulse generator. Stimulation of either the subthalamic nucleus (STN) or the internal segment of the globus pallidus (GPi) relieves bradykinesia, rigidity and tremor, as well as drug-induced dyskinesias in PD patients. DBS of the GPi and STN can reduce the need for dopaminergic medications and alleviate motor fluctuations. Stimulation of the ventral intermediate nucleus of the thalamus can reduce tremor associated with PD, but since other symptoms usually become more prominent over time, this target is seldom used. Although the exact mechanism of action remains to be determined, it is thought that DBS modulates a motor circuit formed by the basal ganglia, thalamus, and cortex that is dysfunctional in PD. Dopamine depletion in the basal ganglia induces changes in electrical activity in this circuit, resulting in increased output from the GPi and STN. DBS appears to act in restoring electrical imbalance in the affected pathways. Indications for DBS in PD are intractable tremor, drug-related motor fluctuations, and dyskinesias, with a good previous clinical response to medical treatment with L-DOPA being the best prognostic indicator for success of DBS. Unfortunately, 'midline symptoms,' such as postural instability, and nonmotor symptoms, such as cognitive decline, may continue to worsen after DBS.

New Directions in PD Therapy

A great deal of research is dedicated toward identifying neuroprotective agents to prevent or treat PD. Several trials have investigated the neuroprotective properties of selegiline, a selective, irreversible inhibitor of MAO-B, which inhibits dopamine metabolism. Its metabolite, desmethylselegiline, has been shown to protect animals against MPTP toxicity by inducing transcriptional changes leading to upregulation of antiapoptotic and downregulation of proapoptotic genes. In PD patients, selegiline significantly delayed the need for levodopa compared to placebo, but this was most likely due to symptomatic effect, and any potential neuroprotective activity remains highly controversial. The Food and Drug Administration has approved rasagiline (*N*-propargyl-1R-aminoindan), a novel, highly potent irreversible MAO-B inhibitor for the treatment of PD. Studies have shown a neuroprotective effect in cell culture via activation of the antiapoptotic protein Bcl-2 and downregulation of the proapoptotic Bax family of proteins by its propargylamine moiety. A delayed-start design phase III clinical trial demonstrated greater benefit in subjects taking rasagiline early, suggesting a possible neuroprotective effect that remains to be clarified and is currently under investigation.

Based on increasing understanding of underlying pathogenetic mechanisms of PD, avenues to retard disease progression that include modulation of mitochondrial function, oxidative stress, and ubiquitin–proteasomal system function are being evaluated. One such promising compound is coenzyme Q10 (CoQ10), an electron acceptor for mitochondrial complex I, shown to be decreased in mitochondria of PD patients. Treatment of PD patients with CoQ10 leads to an increase of platelet mitochondrial complex I and III activity. In a phase II clinical trial, high-dose CoQ10 was well tolerated and it may slow clinical progression in PD patients. High-dose CoQ10 is under further evaluation in a large phase III clinical trial.

Restorative therapy is a future goal for treatment, potentially allowing arrest or reversal of disease progression. Transplantation of fetal and stem cells has attracted considerable attention since it might lead to a more physiologic replacement of dopamine, potentially avoiding the motor complications associated with long-term medical treatment. Based on evidence from animal models of PD that transplantation of fetal dopaminergic neurons can relieve PD symptoms, PD patients have received bilateral intrastriatal transplants of fetal mesencephalic cells, with demonstrated dopaminergic cell survival. However, development of 'runaway dyskinesias' – that is, dyskinesias persisting after overnight withdrawal of dopaminergic medication – indicates the need for more sophisticated understanding and modulation of transplanted cell function. Embryonic stem cells are pluripotent cells that can be differentiated into dopaminergic neurons. Transplantation of these cells into the striatum of MPTP-lesioned monkeys and rats after 6-OHDA administration leads to behavioral improvement. No clinical trials have been conducted in PD patients.

Neuroregeneration by infusion of growth factors in a site-specific manner would potentially avoid side effects resulting from activation of other neuronal circuits. Neurotrophic factors, which undergo retrograde axonal transport over intact nigrostriatal axons, have been infused into the striatum of PD patients.

A phase I trial continuously infused glial cell line-derived neurotrophic factor (GDNF) into the putamen of PD patients, which resulted in improvement of certain aspects of motor function with reduction of medication-induced dyskinesias. However, a subsequent randomized controlled study found no detectable clinical benefit from infused intraputamenal GDNF.

Finally, considerable interest has focused on the possibility of using viral vectors to deliver genes to the central nervous system. Lentiviral delivery of GDNF by injecting lenti-GDNF into striatum and substantia nigra of the MPTP primate model of PD reversed functional deficits. Clinical trials of gene therapy in PD patients are under way using adeno-associated virus to deliver glutamic acid decarboxylase to the STN and also aromatic L-amino acid decarboxylase and the trophic factor neurturin to the striatum.

Parkinson's Disease: Alpha-Synuclein and Neurodegeneration

M Goedert, Medical Research Council Laboratory of Molecular Biology, Cambridge, UK

Introduction

Parkinson's disease (PD) is the most common movement disorder. It affects on the order of 1–2% of the general population older than 65. Clinical manifestations include bradykinesia, increased muscle tone, resting tremor, and postural imbalance. Neuropathologially, PD is defined by the loss of dopaminergic nerve cells in the substantia nigra and the presence there of abnormal proteinaceous inclusions known as Lewy bodies. Similar inclusions are also seen in nerve cell processes, where they are called Lewy neurites. The clinical symptoms of PD become manifest when, as a result of dopaminergic nerve cell loss in the substantia nigra, striatal dopamine levels are reduced by more than 70%. In addition, nerve cell loss and Lewy body pathology are found in a number of other brain regions, such as the dorsal motor nucleus of the vagus nerve, the nucleus basalis of Meynert, and some autonomic ganglia. Lewy bodies and Lewy neurites also constitute the defining neuropathological characteristics of Lewy body dementias (encompassing dementia with Lewy bodies and Parkinson's disease with dementia), common late-life dementias that exist in a pure form or overlap with the neuropathological characteristics of Alzheimer's disease (AD). Unlike PD, Lewy body dementias are characterized by the presence of a large number of Lewy bodies and Lewy neurites in cortical brain areas. Ultrastructurally, Lewy bodies and Lewy neurites consist of abnormal filamentous material. Even though Friedrich Lewy described the Lewy body as long ago as 1912, its molecular composition remained unknown until 1997.

A new direction to research on the etiology and pathogenesis of PD and Lewy body dementias was imparted by the twin discoveries that a missense mutation in the *α-synuclein* gene is a rare genetic cause of PD and that α-synuclein is the main component of Lewy bodies and Lewy neurites in PD, dementia with Lewy bodies, and several other diseases. Subsequently, the filamentous glial and neuronal inclusions of multiple system atrophy (MSA), also known as Papp–Lantos bodies, were found to be made of α-synuclein, revealing an unexpected molecular link with Lewy body diseases. These findings have placed dysfunction of α-synuclein at the center of PD and several atypical parkinsonian disorders (Table 1).

The Synuclein Family

Synucleins are abundant brain proteins whose physiological functions are only poorly understood. The human synuclein family consists of three members – α-synuclein, β-synuclein, and γ-synuclein – which range from 127 to 140 amino acids in length and are 55–62% identical in sequence, with a similar domain organization. The N-terminal half of each protein is taken up by imperfect 11-amino acid repeats that bear the consensus sequence KTKEGV. Individual repeats are separated by an interrepeat region of five to eight amino acids. The repeats are followed by a hydrophobic intermediate region and a negatively charged C-terminal domain. By immunohistochemistry, α- and β-synuclein are concentrated in nerve terminals, with little staining of somata and dendrites. Ultrastructurally, they are found in proximity to synaptic vesicles. In contrast, γ-synuclein is present throughout nerve cells in many brain regions. In rat, α-synuclein is most abundant throughout telencephalon and diencephalon, with lower levels in more caudal regions. Beta-synuclein is distributed fairly evenly throughout the central nervous system, whereas γ-synuclein is most abundant in midbrain, pons, and spinal cord, with much lower levels in forebrain areas.

Synucleins are natively unfolded proteins with little secondary structure and have been identified only in vertebrates. Mammals and birds have three synuclein genes; a fourth gene (called γ2-synuclein) is present in teleost fish. Experimental studies have shown that α-synuclein can bind to lipid membranes through its N-terminal repeats, indicating that it may be a lipid-binding protein. It adopts structures rich in α-helical character on binding to synthetic lipid membranes containing acidic phospholipids. In presence of the lipid mimetic sodium dodecyl sulphate, this conformation is taken up by amino acids 1–98 and consists of two α-helical regions (residues 1–42 and 45–98) that are interrupted by a break of two amino acids (residues 43 and 44). Residues 99–140 are unstructured. In cell lines and primary neurons treated with high fatty acid concentrations, α-synuclein was found to accumulate on phospholipid monolayers surrounding triglyceride-rich droplets. Beta-synuclein binds in a similar way, but γ-synuclein fails to bind to lipid droplets and remains cytosolic. Accordingly,

Table 1 α-Synucleinopathies

Idiopathic Parkinson's disease
Dementia with Lewy bodies
Pure autonomic failure
Lewy body dysphagia
Inherited Lewy body diseases
Incidental Lewy body disease
Rapid eye movement sleep behavioral disorder
Multiple system atrophy

α-synuclein binds to fatty acids *in vitro*, albeit with a much lower affinity than physiological fatty acid-binding proteins. Both α- and β-synuclein have been shown to inhibit phospholipase D2. This isoform of phospholipase D localizes to the plasma membrane, where it may be involved in signal-induced cytoskeletal regulation and endocytosis. A fraction of α-synuclein in normal brain is phosphorylated at S129. Casein kinase-1 and casein kinase-2 phosphorylate S129 of α-synuclein *in vitro*, as do several G-protein-coupled receptor kinases.

Inactivation of the *α-synuclein* gene by homologous recombination does not lead to a neurological phenotype, with the mice being largely normal. A loss of function of α-synuclein is therefore unlikely to account for its role in neurodegeneration. Analysis of mice lacking β- or γ-synuclein has similarly failed to reveal any gross abnormalities. The same is true of mice double knockout for α- and β-synuclein. The most compelling evidence for a physiological function comes from experiments showing that increased expression of α-synuclein rescues mice lacking cysteine string protein α (CSPα), a presynaptic molecular chaperone that aids in the folding and refolding of synaptic proteins critical for neurotransmitter release and vesicle recycling. CSPα-deficient mice are normal at birth but develop progressive neurodegeneration that causes defects in synaptic transmission after 2–3 weeks of age and is lethal after 1–4 months. Deletion of CSPα inhibits soluble NSF (N-ethylmaleimide-sensitive factor) attachment protein receptor (SNARE) protein assembly, and transgenic α-synuclein ameliorates this inhibition in a phospholipid binding-dependent manner. Alpha-synuclein may therefore play a physiological role in maintaining synaptic integrity.

Parkinson's Disease and Other Lewy Body Diseases

Alpha-Synuclein Mutations Cause Familial PD

In 1990, an autosomal dominantly inherited form of PD was described in an Italian-American kindred (the Contursi kindred). It was the first familial form of disease in which Lewy bodies were shown to be present. In 1997, a missense mutation (A53T) in the *α-synuclein* gene was identified as the cause of disease in the Contursi kindred (Figure 1). Subsequently, a second mutation (A30P) was identified in a German family with PD. More recently, a third mutation (E46K) was described in a Spanish family with PD and Lewy body dementia. All three missense mutations are located in the repeat region of α-synuclein.

Figure 1 α-Synuclein. (a) Schematic representation of the 140-amino-acid protein, with the N-terminal, lipid-binding repeats shown as black bars. (b) Duplications and triplications of the *α-synuclein* gene and missense mutations (black box) in the *α-synuclein* gene cause inherited forms of Parkinson's disease/Lewy body dementia. (c) Three missense mutations in *α-synuclein* are shown (in blue).

In addition to changes in primary structure, overexpression of wild-type α-synuclein has also been identified as a cause of inherited PD and Lewy body dementia. Thus, duplications and triplications of the *α-synuclein* gene are responsible for autosomal dominantly inherited forms of disease with abundant and widespread Lewy body pathology. Triplications lead to early onset, rapidly progressive parkinsonism dementia with autonomic dysfunction. Duplication mutations result in disease that is more closely related to PD, with later onset parkinsonism, slower progression, and without autonomic dysfunction. In addition, polymorphic variations in the 5′ noncoding region of the *α-synuclein* gene have been found to be associated with idiopathic PD in some studies. They probably influence the level of α-synuclein expression. Variation in the expression levels of α-synuclein may be an important risk factor for the development of Lewy body diseases.

Lewy Body Filaments Are Made of α-Synuclein

Shortly after the identification of the genetic defect responsible for PD in the Contursi kindred, Lewy bodies and Lewy neurites in the substantia nigra from patients with sporadic PD were shown to be strongly immunoreactive for α-synuclein (Figure 2). Subsequently, Lewy body filaments were found to be decorated by antibodies directed against α-synuclein. The same was true of the Lewy body pathology of dementia with Lewy bodies.

Filaments associated with PD and dementia with Lewy bodies are unbranched, with a length of 200–600 nm and a width of 5–10 nm. Full-length α-synuclein is present, with its N- and C-termini being exposed on the filament surface (Figure 3). The core of the filament extends over a stretch of about 70 amino acids that overlaps almost entirely with the lipid-binding region of α-synuclein. Of the three human synucleins, only α-synuclein is associated with the filamentous inclusions of Lewy body diseases. Prior to this work, ubiquitin staining was the most sensitive marker of Lewy body pathology. By the use of double-labeling, the number of α-synuclein-positive structures was found to be greater than that stained for ubiquitin, suggesting that ubiquitination of α-synuclein occurs after assembly. Phosphorylation and nitration are two additional posttranslational modifications of filamentous α-synuclein. Phosphorylation at S129 has been documented in Lewy bodies and Lewy neurites, and it has been suggested that it may trigger filament assembly. However, it remains to be determined whether phosphorylation at S129 occurs before or after filament assembly in the human brain. Nitration of filamentous α-synuclein was found using antibodies specific for nitrated tyrosine residues. As for ubiquitin, staining for nitrotyrosine was less extensive than staining for α-synuclein, suggesting that nitration of α-synuclein occurs after its assembly into filaments.

Figure 2 Substantia nigra from patients with Parkinson's disease immunostained for α-synuclein. (a) Two pigmented nerve cells (large arrows), each containing an α-synuclein-positive Lewy body. Lewy neurites (small arrows) are also immunopositive. (b) Pigmented nerve cell with two α-synuclein-positive Lewy bodies. (c) α-Synuclein-positive extracellular Lewy body. Scale bar = 20 μm (a), 8 μm (b), 4 μm (c).

Lewy body pathology is also the defining feature of several other, rarer diseases, such as Lewy body dysphagia and pure autonomic failure. In these diseases, Lewy bodies and neurites are largely limited to the enteric and peripheral nervous systems. In PD, Lewy body pathology is also present in the enteric and autonomic nervous systems.

Incidental Lewy body disease describes the presence of small numbers of Lewy bodies and Lewy neurites at autopsy. It is observed in 5–10% of the general population older than 60 and is believed to represent a preclinical form of Lewy body disease. In cases with incidental Lewy body disease, the first α-synuclein-positive structures in the brain form in the dorsal motor nucleus of the vagus nerve, the intermediate reticular zone, the olfactory bulb, and the anterior olfactory nucleus. Rapid eye movement sleep behavioral disorder and olfactory dysfunction can be the clinical correlates of these abnormalities. The pathology ascends from vulnerable regions in the medulla oblongata to the pontine tegmentum, midbrain, basal forebrain, and cerebral cortex. Alpha-synuclein deposits may form even earlier in the enteric nervous system, the peripheral nervous system, and layer I of the dorsal horn of the spinal cord, suggesting that Lewy body diseases may begin outside the brain. Autonomic dysfunction and pain can be the clinical correlates of these abnormalities. The first deposits develop in the form of Lewy neurites, suggesting that the filamentous assembly of α-synuclein in axons may precede assembly in cell bodies and dendrites. Incidental Lewy body disease may be at one end of the spectrum of Lewy body diseases, with Lewy body dementias at the other end, and with Lewy body dysphagia, pure autonomic failure, and PD in between. These findings underscore the fact that there is more to PD than the mere degeneration of dopaminergic cells in the substantia nigra.

Figure 3 Decoration of filaments from substantia nigra of Parkinson's disease brain with α-synuclein antibodies. (a–c) Antibody recognizing the C-terminus of α-synuclein. (d–f) Antibody recognizing the N-terminal region of α-synuclein. (g–i) Antibody recognizing the N-terminus of α-synuclein. The gold particles indicating positive staining appear as black dots. Scale bar = 100 nm.

Besides amyloid-β and tau deposits, Lewy body pathology is also present in some cases of familial AD, indicating that mutations in the amyloid precursor protein and the presenilin genes can lead to dysfunction of α-synuclein. Similarly, Lewy bodies and Lewy neurites are present in some cases of sporadic AD. Conversely, plaques and tangles are often found in Lewy body dementias. The amygdala is most consistently affected, suggesting that α-synuclein pathology may start there. These findings in AD define a type of α-synucleinopathy that is distinct from the one described above.

MSA

Filamentous α-synuclein deposits characterize this atypical parkinsonian disorder, but Lewy body pathology is not generally observed. Instead, glial cytoplasmic inclusions (Papp–Lantos bodies), which consist of filamentous aggregates, are the defining neuropathological feature of MSA. They are found mostly in the cytoplasm and, to a lesser extent, the nucleus of oligodendrocytes. Inclusions are also observed in the cytoplasm and nucleus of some nerve cells and in neuropil threads. The principal brain regions affected are the substantia nigra, striatum, locus coeruleus, pontine nuclei, inferior olives, cerebellum, and spinal cord. Typically, nerve cell loss and gliosis are observed. The formation of glial cytoplasmic inclusions may be the primary lesion that will eventually compromise nerve cell function and viability.

Glial cytoplasmic inclusions are strongly immunoreactive for α-synuclein, and filaments isolated from the brains of patients with MSA are labeled by α-synuclein antibodies. Assembled α-synuclein is nitrated and phosphorylated at S129, and the number of α-synuclein-positive structures exceeds that stained by antiubiquitin antibodies, confirming that the

accumulation of α-synuclein precedes ubiquitination. Filament morphologies and their staining characteristics were found to be similar but not identical to those of filaments extracted from the brains of patients with PD and dementia with Lewy bodies. This work revealed an unexpected molecular link between MSA and Lewy body diseases. The main difference is that in MSA, most of the α-synuclein pathology is found in glial cells, whereas in Lewy body diseases, most of the pathology is in nerve cells.

Synthetic α-Synuclein Filaments

Recombinant α-synuclein assembles into filaments that share many of the morphological characteristics of the disease filaments. Assembly is a nucleation-dependent process that occurs through the N-terminal repeats of α-synuclein. The C-terminal region, in contrast, is inhibitory. Assembly is accompanied by the transition from random coil to a β-pleated sheet. By electron diffraction and solid-state nuclear magnetic resonance spectroscopy, filaments assembled from recombinant wild-type human α-synuclein show a conformation characteristic of amyloid fibers, with evidence for the existence of filaments with different morphologies. Assembly of monomeric α-synuclein into filaments probably passes through an oligomeric stage that after prolonged incubation results in the formation of elongated protofibrils that disappear on filament formation. Oligomeric α-synuclein may be toxic to nerve cells. Under the conditions of these experiments, β- and γ-synucleins failed to assemble, consistent with their absence from the filamentous lesions of the human diseases. Both β- and γ-synucleins have been shown to inhibit the assembly of α-synuclein *in vitro*. Inhibition of α-synuclein assembly by a number of small organic molecules has also been described.

Mutations E46K and A53T increase the rate of assembly of α-synuclein, indicating that this may be their primary effect. The mechanism of action of the A30P mutation is less clear. One study reported that it causes the accumulation of oligomeric, nonfibrillar α-synuclein, implying that this may be a toxic species. Mutation A30P reduces the binding of α-synuclein to rat brain vesicles, whereas mutation E46K increases lipid binding. Mutation A53T has no significant effect on lipid binding. Many factors have been shown to influence the rate and/or extent of α-synuclein assembly *in vitro*. They include nitration, oxidation, dopamine, cytochrome C, polyamines, some pesticides, several di- and trivalent cations, and sulphated glycosaminoglycans. However, the relevance, if any, of these factors for the transition from soluble to filamentous α-synuclein in nerve cells in the brain remains to be established.

Animal Models of Human α-Synucleinopathies

Rodents and Primates

Mice expressing wild-type and mutant human α-synuclein in nerve cells or glial cells have been shown to develop numerous α-synuclein-immunoreactive cell bodies and processes. However, filament formation and nerve cell loss were a less consistent feature. One study has documented the presence of α-synuclein filaments in brain and spinal cord of mice transgenic for A53T α-synuclein. The formation of inclusions correlated with the appearance of a severe movement disorder, suggesting a possible cause and effect relationship. A minority of inclusions was ubiquitin immunoreactive. Signs of Wallerian degeneration were in evidence in ventral roots, but motor neuron numbers were not reduced. A major difference with PD was the absence of significant pathology in dopaminergic cells of the substantia nigra. However, a more recent study of transgenic mice expressing a C-terminally truncated form of α-synuclein that fibrillizes more readily than the full-length protein *in vitro* has shown some evidence of filament formation and neurodegeneration in substantia nigra. Expression of high levels of human α-synuclein in oligodendroglia recapitulates features of MSA, including the accumulation of filamentous human α-synuclein aggregates in oligodendrocytes linked to their degeneration. In addition, mouse α-synuclein also accumulated in axons in association with neuronal cell loss and motor impairments.

Viral vector-mediated gene transfer differs from standard transgenic approaches by being targeted to a defined region of the central nervous system and by being inducible at any point during the life of the animal. Adeno-associated and lentiviral vectors have been used to express human wild-type and mutant α-synuclein in rodent and primate substantia nigra. Lewy body-like inclusions formed, and a significant proportion of nerve cells degenerated. In the rat, about a quarter of animals were impaired in spontaneous and drug-induced behavior. In the marmoset monkey, expression of human A53T α-synuclein in the substantia nigra resulted in the formation of inclusions and nerve cell death in most (but not all) animals. Fewer inclusions and less nerve cell death were observed on expression of wild-type human α-synuclein.

A neurotoxin model of α-synuclein pathology has been developed in the rat through the chronic administration of the pesticide rotenone, a high-affinity inhibitor of complex I. The rats developed a progressive degeneration of nigrostriatal neurons and Lewy body-like inclusions that were immunoreactive for α-synuclein and ubiquitin. Behaviorally, they showed bradykinesia, postural instability, and resting

tremor. Under these conditions, the inhibition of complex I was only partial, indicating that a bioenergetic defect with adenosine triphosphate (ATP) depletion was probably not involved. Instead, oxidative damage might have played a role since partial inhibition of complex I by rotenone stimulates the production of reactive oxygen species. It would therefore seem that oxidative stress can lead to the assembly of α-synuclein into filaments.

Flies, Worms, and Yeast

One of the first reports to describe the overexpression of human α-synuclein made use of *Drosophila melanogaster*, an organism without synucleins. Expression in nerve cells resulted in the formation of filamentous Lewy body-like inclusions and an age-dependent loss of some dopaminergic nerve cells. The inclusions were α-synuclein- and ubiquitin-positive. The ensuing motor defect was reversed by L-dopa and dopamine agonists. Toxicity of α-synuclein in this system depended on aggregation and required phosphorylation of S129. Chaperones modulated these effects. Thus, co-expression of heat shock proteins reduced the toxicity of α-synuclein, whereas a reduction in endogenous chaperones exacerbated nerve cell loss. Overexpression of wild-type and mutant human α-synuclein in *Caenorhabditis elegans* resulted in dopaminergic nerve cell loss and motor deficits, but in the apparent absence of α-synuclein fibrils.

When expressed in the yeast *Saccharomyces cerevisiae*, human wild-type and A53T α-synucleins were found to localize at the plasma membrane, whereas the A30P mutant had a cytosolic distribution, consistent with lipid binding *in vitro*. Unlike the A30P mutant, wild-type and A53T α-synucleins were toxic to yeast cells. A genome-wide screen to identify genetic enhancers of α-synuclein toxicity identified genes involved in lipid metabolism and vesicle-mediated transport as the predominant functional class. It has been suggested that toxicity of overexpressed α-synuclein in yeast may not require filament formation but may result from the coating of the plasma membrane and internal membranes via amphipathic α-helix formation, resulting in the disruption of normal membrane processes, including vesicle trafficking. Expression of α-synuclein has been shown to block selectively endoplasmic reticulum to Golgi transport, causing endoplasmic reticulum stress. The ensuing toxicity could be suppressed by overexpression of the small GTPase Ypt1/Rab1. It is interesting that overexpression of the latter also rescued nerve cell loss in invertebrate models of α-synuclein-induced neurodegeneration.

Outlook

The work of the past 10 years has shown conclusively that a neurodegenerative pathway leading from soluble to insoluble, filamentous α-synuclein is central to Lewy body diseases and MSA. The development of experimental models of α-synucleinopathies has opened the way to the identification of the detailed mechanisms by which the formation of inclusions can cause disease. These model systems have also made it possible to identify disease modifiers that may lead to the development of mechanism-based therapies for these diseases. At a conceptual level, it will be important to understand whether α-synuclein has a role to play in inherited parkinsonian disorders caused by mutations in other genes. They include autosomal-recessive juvenile forms of parkinsonism caused by mutations in the *Parkin*, *DJ-1*, and *PINK-1* genes and the dominantly inherited diseases caused by mutations in the lysosomal type 5 adenosine triphosphatase gene (*ATP13A2*) and the leucine-rich repeat kinase-2 gene (*LRRK2*). The latter is particularly interesting since activating missense mutations in the kinase domain of LRRK2 are a relatively common cause of Lewy body PD, demonstrating the existence of a pathway leading from activation of LRRK2 to aggregation of α-synuclein. The molecular dissection of this pathway is likely to shed new light on the understanding of Lewy body diseases.

Paroxysmal Paralysis

M Salajegheh and A A Amato, Brigham and Women's Hospital, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Periodic paralyses are a group of muscle disorders characterized by episodic attacks of muscle weakness, secondary to abnormal sarcolemmal excitability, which may progress into paralysis. They are often induced by certain triggers, most often (but not always) are associated with changes in serum potassium level and are occasionally accompanied by myotonia (the inability to relax muscle after contraction). The familial cases are usually inherited in an autosomal dominant pattern, but can also occur sporadically. Classically, based on serum potassium levels or response to potassium administration, they have been classified as hyper-, hypo- or normo-kalemic periodic paralysis. Since their pathogenesis is related to disorders of muscle membrane sodium, calcium, and potassium ion channels (channelopathies), we prefer to classify them based on the various channels involved (Table 1). All forms of familial periodic paralyses share the common final pathway of aberrant depolarization, which results in the inactivation of sodium channels and electrical inexcitability of muscle fibre. Differences in attack frequency, severity, precipitating factors, and electrodiagnostic findings suggest the channel gene that is affected, and the specific alterations in mutant channel function. The episodic nature of these channelopathies suggests that while channel mutations are necessary to cause the disease, they are not sufficient. Understanding potential triggers that could induce the attacks are imperative to the management of the various channelopathies. Secondary cases also exist and are related to alterations in serum potassium levels and thyrotoxicosis, which need to be excluded in patients with periodic paralysis and no family history.

Sodium Channelopathies

Sodium channelopathies include potassium-sensitive (hyperkalemic) periodic paralysis (HyperPP), paramyotonia congenita (PMC), potassium aggravated myotonias (PAMs) (e.g., myotonia fluctuans, myotonia permanens, and acetazolamide responsive myotonia), and familial hypokalemic periodic paralysis type 2 (HypoPP2) which are autosomal dominant myopathies with certain clinical similarities as well as differences. These disorders have been demonstrated to be allelic, and caused by missense mutations in the pore-forming α-subunit of the voltage-gated skeletal-muscle sodium channel NaV1.4 (encoded by the gene *SCN4A*). In general, each missense mutation of *SCN4A* is consistently associated with one of the four allelic sodium channel disorders, suggesting the presence of separate classes of functional defects. However, some variability exists and the distinction is often blurred between PMC and HyperPP, even for affected members of the same family.

The skeletal-muscle voltage-gated sodium channel is a heterodimer consisting of α- and β-subunits that are encoded on chromosomes 17q23-25 and 19q13.1, respectively. Point mutations in the α-subunit gene, *SCN4A*, are responsible for the mentioned disorders. The α-subunit of the sodium channel is composed of four homologous domains (1–4) each containing six hydrophobic segments (S1–S6) that traverse the plasma membrane. Studies have suggested that the S4 segment is critical for inactivation of the open channel, while the S3 segment plays a role in the recovery of inactivated channels. Thus, the S3 and S4 segments interact during the transition to and from inactivation states. Over 30 different point mutations in *SCN4A* have been described and most are located in regions of the α-subunit critical for fast inactivation. Almost all tested missense mutations produce gain-of-function defects, either disrupted inactivation or enhanced activation. The notable exception is the mutations associated with HypoPP2, which are all clustered in the voltage sensor region of the second repeat (D2S4) and diminish activity by enhancing inactivation The β-subunit is noncovalently linked to the α-subunit and functions to increase the amplitude of the current and speed of inactivation.

Normally, upon depolarization to the threshold potential, the voltage-gated sodium channels open (activate) quickly and then close to a fast-inactivated state within milliseconds, from which further openings are rare (Figure 1). This is accompanied by an inward sodium current that peaks within milliseconds, followed by a drop back to zero as the channel inactivates. In order for the sodium channels to recover from the inactivated state, and become available for opening up with subsequent depolarizations, the muscle membrane must become hyperpolarized by the influx of potassium. Thus, fast inactivation of channels limits the duration of the action potential, results in a refractory period that limits the firing rate of muscle fibers, and initiates repolarization of the muscle membrane. In doing so, it regulates the number of sodium channels available for activation. Gain-of-function mutations in PMC

Table 1 Hereditary channelopathies with clinical features of periodic paralysis

Channelopathy type	*Inheritance*	*Gene/ location*	*Onset*	*Triggers*	*Duration*
Sodium channel					
Potassium-sensitive periodic paralysis (HyperPP)	Autosomal dominant	*SCN4A*/ 17q23-25	First decade	Rest following exercise, fasting, potassium, stress, fatigue, cold[b]	Hours
Paramyotonia congenita[a] (PMC)	Autosomal dominant	*SCN4A*/ 17q23-25	First decade	Exercise, cold, potassium	Hours
Hypokalemic periodic paralysis type 2 (HypoPP2)	Autosomal dominant	*SCN4A*/ 17q23-25	First two decades	Rest following exercise, carbohydrates, stress	Hours to days
Calcium channel					
Hypokalemic periodic paralysis type 1 (HypoPP1)	Autosomal dominant	*CACNA1S*/ 1q31-32	First two decades	Rest following exercise, carbohydrates, alcohol, cold, stress and lack of sleep, viral illness, menstruation and specific medications[c]	Hours to days
Potassium channel[d]					
Andersen–Tawil syndrome (ATS)	Autosomal dominant	*KCNJ2*/ 17q23-25	First two decades	Prolonged rest following exercise	Hours to days

[a]As opposed to myotonia, muscle stiffness is induced or worsened by exercise in paramyotonia.
[b]Cooling more commonly provokes weakness in patients with paramyotonia.
[c]β-Agonists, corticosteroids, and insulin.
[d]In some reports, KCNE3 gene (11q13-q14) mutation has been suggested in HypoPP and thyrotoxic periodic paralysis, although not fully verified.

and PAM often slow the rate of inactivation by three- to fivefold, resulting in increased duration of the action potential, and the availability of Na^+ channels (i.e., fraction not inactivated) at the end of each action potential, in turn augmenting the membrane excitability and causing myotonia. In addition to slow inactivation, many PMC mutations also disrupt the final extent of inactivation. The steady inward Na current generated through the small fraction of mutant channels that have failed to inactivate depolarizes the membrane to a new stable resting potential of approximately -50 mV. This in turn results in inactivation of the wild-type and most of the mutant Na channels, resulting in a system that is refractory from generating an action potential, leading to a paralytic attack. In these patients, increased extracellular potassium results in further depolarization of the muscle membrane, thus leading to muscle fiber inexcitability.

Primary Hyperkalemic or Potassium-Sensitive Periodic Paralysis (Adynamia Episodica Hereditaria)

We generally prefer to use the term potassium-sensitive periodic paralysis, since while patients are sensitive to and become weak when given potassium, not all attacks are associated with hyperkalemia.

Clinical features Potassium-sensitive periodic paralysis is transmitted in an autosomal dominant fashion, with a high degree of penetrance in both females and males. In the majority of patients, symptoms manifest within the first decade of life. While attacks of weakness usually develop in the morning, they can occur at any time, and are precipitated by rest following exercise or fasting. The attacks can be mild or severe, with the latter more commonly occurring after strenuous physical activity. These may also be triggered by intake of potassium-rich food, stress, and fatigue. Paresthesia and a sense of heaviness in the legs or small of the back may herald the onset of an attack in some individuals. The weakness then manifests in the thighs and calves and progresses to involve multiple other muscle groups. The weakness can also be focal, and unlike hypokalemic periodic paralysis, it rarely develops into generalized flaccid paralysis. While as with all periodic paralyses the sphincter muscles are well preserved during attacks, the degree of weakness may be severe enough to affect bulbar and respiratory muscles in some patients. During attacks, the reflexes are diminished or absent, while sensation remains normal. Sustained mild exercise after a period of strenuous activity may postpone or prevent weakness from developing in the exercising muscles while resting muscle groups become weak.

Figure 1 Cation channel model showing the four domains (D1–D4) of the cation channel arranged around the ion pore in the membrane. The S4 segments of cation channels contain a repeating motif of positively charged (+) amino acids (arginine or lysine) at every third position separated by two neutral amino acids. In the closed state (a), the pore is closed and the inactivation gate is open. In response to depolarization, the S4 segments move slightly under the influence of electrostatic forces. Depolarization leads to a conformational shift, which results in pore opening (b). Channel closing is thought to result from a 'ball-valve' mechanism where a cytoplasmic loop between domains D3 and D4 falls into the ion pore, thus blocking it (c). In this model, repolarization would then result in the protein assuming its closed conformation (d) and release of the inactivation gate. The channel is now in the closed state (a) and is ready to open in response to the next depolarization. Reproduced from Ptacek L (1998) The familial periodic paralyses and nondystrophic myotonias. *American Journal of Medicine* 105(1): 58–70, with permission from Elsevier.

Following a bout of weakness, it is not uncommon for pain to be experienced in the affected muscles up to several days. The duration of weakness is usually less than 2 h, although mild weakness can persist for a few days. The frequency of attacks is highly variable, and while it may occur several times a day in some patients others experience difficulty once a year. In addition, there is great variation of attack severity and frequency within and between families, and the frequency of paretic attacks often decreases with age. Between the attacks, sensation and deep tendon reflexes are normal and lid lag or eyelid myotonia may be the only clinical signs present. Over time, some patients develop fixed weakness, unrelated to attack frequency, usually involving the more proximal muscles.

Potassium-sensitive periodic paralysis can occur in three forms: (1) without myotonia, (2) with clinical or electrical myotonia, or (3) associated with PMC. The course of the attacks of weakness is the same in all three forms, except that cooling more commonly provokes weakness in patients with PMC. Clinical myotonia is usually mild, and can be elicited in the face/eyelids, tongue, finger extensors, and the thenar eminence with percussion or activity. Patients with PMC exhibit paradoxical myotonia in which muscle stiffness is induced or worsened by exercise or cold temperature.

While provocative testing can be performed when the diagnosis is unclear, the availability of commercial genetic testing usually makes it unnecessary. Provided the patient has no significant underlying cardiac or renal disease, a potassium load can be administered to increase the serum potassium levels, and to see whether an attack of weakness can be provoked. The patient's strength, electrolytes, and cardiac function (electrocardiogram (EKG)) need to be closely monitored during the study.

Laboratory features Although the attacks of weakness are usually associated with serum potassium levels of up to 5 to 6 $mEq\,l^{-1}$, serum levels may also

remain within normal limits. During this time, urinary excretion of potassium increases and serum sodium levels decrease. At the end of an attack, diuresis and transient hypokalemia commonly occur. In between the attacks, serum potassium levels are within normal limits and serum creatine kinase (CK) levels can be normal or mildly elevated. Increased amplitudes of the precordial T waves are occasionally noted on the EKG and are secondary to hyperkalemia (Table 2).

Histopathology Muscle biopsy in patients with potassium-sensitive periodic paralysis is frequently associated with vacuoles in the myofibers, and patients with fixed weakness may have nonspecific myopathic changes (Table 2).

Electrophysiologic findings Both motor and sensory nerve conduction studies are normal between and during attacks, while the compound muscle action potential (CMAP) amplitude is reduced during an attack of weakness. Abnormalities are usually apparent with the short and long exercise tests. The short-exercise test is performed by having the patient isometrically exercise a muscle (e.g., abductor digiti minimi) for 10 s, followed by measurement of CMAP 2 s immediately after exercise and every 10 s thereafter up to 50 s. This test is usually repeated twice more with a rest period of 60 s between trials. The long exercise test is performed by having the patient isometrically exercise a muscle (e.g., abductor digiti minimi) for 5 min (with 3–4 s of rest every 30–45 s), while CMAPs are being recorded every minute during the exercise period, 2 s immediately after cessation of exercise, then every minute for 5 min and finally every 5 min for 40–45 min. In normals, CMAP amplitudes mildly increase during exercise, and slightly decrease immediately after exercise completion along with increased duration, resulting in an increase of the total CMAP area. Recovery of preexercise values occurs after 30–60 s and remains unchanged within the following 40–50 min (Table 2).

After the short exercise test in patients with potassium-sensitive periodic paralysis, most show an increase in CMAP amplitudes that are significantly higher and last longer than that observed in unaffected individuals, and repetition of the short exercise amplifies the increase in CMAP amplitude. With the long exercise test, during the exercise period and immediately afterwards, there is an initial increase in CMAP amplitude. This is followed by a progressive decline in amplitude over the subsequent 40–45 min. A short exercise trial during the paretic phase may induce a marked CMAP increment, partially correcting the loss of excitability.

Needle electromyographic examination findings depend on whether myotonia is present or absent. Electrical myotonia is found in 50–75% of affected individuals, while it is clinically apparent in less than 20%. In patients with myotonia, examination of the muscle between attacks of weakness reveals an increase in insertional activity, in the form of fibrillation potentials and positive sharp waves, along with mild to moderate amounts of spontaneous runs of myotonic potentials. These are reflective of the underlying hyperexcitability or instability of the muscle membrane and are not due to denervation. A reduction in limb temperature may exacerbate the runs of myotonic potentials. Analysis of motor unit action potential (MUAP) parameters may reveal either normal potentials or a slight increase in the percentage of small duration, polyphasic potentials. If an attack of weakness is provoked during the examination, there may be a slight initial increase in spontaneous activity followed by a reduction in all electrical activity, both spontaneous and voluntary; the number of MUAPs detected decreases and the recruitment pattern may be reduced to a few motor units of normal or short duration that are firing rapidly.

In patients with potassium-sensitive periodic paralysis without myotonia, the insertional activity is normal and needle movement or voluntary contraction does not provoke the appearance of fibrillation potentials, positive sharp waves, or myotonic potentials. During an attack of weakness, there is a progressive reduction in the electrical activity, without any transitory increase in membrane excitability. The MUAPs not only decrease in number but also in duration and amplitude. In patients with profound weakness, complete electrical silence may be observed in some muscles with respect to voluntary MUAPs. In some patients, there may be a mild increase in the number of short-duration polyphasic MUAPs suggestive of a mild and persistent myopathy.

Molecular genetics Potassium-sensitive periodic paralysis is caused by mutations in the α-subunit of the voltage-gated sodium channel (*SCN4A*).

Treatment Preventive therapy with a low-potassium, high-carbohydrate diet and avoidance of fasting, strenuous activity, and cold is recommended. The acute attacks of weakness are often mild in severity, short lasting, and do not require treatment. Ingestion of simple carbohydrates (e.g., fruit juices, glucose-containing candies) results in insulin excretion and a decrease in serum potassium levels, which can lead to an improvement in strength. Beta-adrenergic agonists (e.g., metaproterenol, albuterol, and salbutamol)

Table 2 Diagnostic features of some channelopathies presenting with periodic paralysis

Diseases	*Short exercise*	*Long exercise*	*Needle EMG*	*Musce biopsy*	*CK*	*K^+*
Potassium-sensitive periodic paralysis	Absence of PEMPs, CMAP increase postexercise amplified by exercise repetition	CMAP increase immediately postexercise, with gradual and prolonged decrement in rest phase	Myotonia[a] and increased spontaneous activity,[b] normal MUAP or slight increase in small duration, polyphasic potentials in patients with fixed myopathy	Fiber size variation, occasional vacuolated muscle fibers	↑ or normal	↑ or normal during attack
Paramyotonia congenita	Postexercise PEMPs and decrement in CMAP, worsening with exercise repetition[c]	CMAP decrement during and following exercise, occasionally lasting for hours	Myotonia, worsened by cold,[c] increased jitter, and occasional blocking on SFEMG	Fiber size variation, occasional vacuolated muscle fibers, myofibrillar disarray, and tubular aggregates	↑ or normal	↑ or normal during attack
Hypokalemic periodic paralysis type 1	Absence of PEMPs or CMAP changes postexercise	CMAP unchanged immediately postexercise, but delayed decrement in rest phase	Absence of myotonia, normal MUAPs or slight increase in small duration, polyphasic potentials in patients with fixed myopathy	Fiber size variation, vacuolated muscle fibers, sarcoplasmic reticulum dilation, tubular aggregates	↑ or normal	↓ during attack
Andersen–Tawil syndrome		CMAP may show delayed decrement in rest phase	Absence of myotonia	Fiber size variation, tubular aggregates	↑ or normal	↑, normal, or mostly ↓ during attack

[a]Myotonia is seen in a subgroup of patients with potassium-sensitive periodic paralysis.
[b]Fibrillation potentials and positive sharp waves are seen in the subgroup of patients with myotonia, and are reflective of the underlying hyperexcitability or instability of the muscle membrane.
[c]In patients with PMC local cooling results in decrement in CMAPs, dense fibrillation-like potentials on EMG with gradual reduction in MUAP activity.
CK, serum creatine kinase levels; CMAP, compound muscle action potential; EMG, electromyography; K^+, serum potassium levels; SFEMG, single fiber electromyography; PEMP, postexercise myotonic potential.

may be effective in improving strength and can be used safely provided there are no associated cardiac arrhythmias. Only rarely, and with severe attacks, is treatment with intravenous glucose, insulin, or calcium carbonate indicated. Prophylactic treatment with acetazolamide (125–1000 mg daily), chlorothiazide (250–1000 mg daily), and dichlorphenamide (50–150 mg daily) may be beneficial in reducing the frequency of attacks and may also help with myotonia. Mexiletine also diminishes the myotonia.

Normokalemic Periodic Paralysis

Some patients with potassium-sensitive periodic paralysis develop weakness while serum potassium levels remain within normal limits. Most patients in this group develop weakness when given potassium, and have clinical and electrophysiological features which are similar to those with weakness and elevated serum potassium levels. Furthermore, mutations in the muscle sodium channel gene have been demonstrated in families with normokalemic periodic paralysis.

PMC (Eulenburg Disease)

The prefix 'para' derives from the paradoxical reaction these patients show toward exercise, where in contrast to the warm-up phenomenon observed in other myotonic syndromes, repeated exercise worsens their muscle stiffness. Cold temperature can also precipitate myotonia and occasionally weakness in individuals with PMC.

Clinical features PMC is an autosomal dominant disorder with high penetrance and is allelic to potassium-sensitive periodic paralysis, with some kinships having clinical features of both (paralysis periodica paramyotonica). The attacks of myotonia are usually induced by exercise or cold, and some patients develop either focal or a more generalized weakness occasionally progressing to flaccid paralysis. The facial, hand, pharyngeal, and tongue muscles are the most sensitive to these phenomena. Patients usually display evidence of the disease within the first decade of life. Infants may be noted to have the disease during a crying spell, when they are unable to open their eyes secondary to exercise-induced myotonia of the orbicularis oculi muscles. Alternatively, it may be noticed that washing the infant's face with a cold washcloth may result in a cold-induced myotonic spasm of the facial muscles. Patients who live in cold climates may note an increase in exercise-induced muscle contraction leading to weakness during the shoveling of snow, and there may be an occasional patient who complains of hand weakness when shopping in the frozen food section of the supermarket. A cold-induced attack can last for several hours even after return to a warm environment. Weakness can also be induced in some cases by potassium intake. Paramyotonia, particularly of the eyelids, is typically evident in most patients. While percussion myotonia may be demonstrated, it is usually not prominent, and myalgias are not a common complaint. Muscle strength is normal in between attacks of paralysis, in those with pure PMC, as are the deep tendon reflexes and sensory examination. These symptoms are usually nonprogressive and the patients either remain stable or improve slightly with aging.

Laboratory features Serum CK levels may be mildly to moderately elevated in some patients. Serum potassium levels may be elevated during an attack of paralysis (Table 2).

Histopathology Minimal changes are noted on muscle biopsy, although there might be mild fiber size variation with a mixture of normal, atrophic, and hypertrophic fibers. While fiber type differentiation is usually normal, few reports have suggested abnormalities of differentiation. A few patients may display intracytoplasmic vacuoles, particularly those with superimposed periodic paralysis. Electron microscopy may reveal myofibrillar disarray and tubular aggregates (Table 2).

Electrophysiologic findings Routine sensory and motor nerve conduction studies are normal between attacks, while abnormalities are usually apparent during the short-exercise test. There is repetitive activity immediately after exercise, where the first component of the CMAP response, evoked by a single supramaximal stimulus, is followed by several signals of decreasing amplitude that occur every 7–10 ms (post-exercise myotonic potentials or PEMPs). There is also evidence for a decrement in the CMAP in some patients. Repetition of the short exercise, even in those who do not show any CMAP decline after the first trial, displays a marked reduction of CMAP amplitudes after the third trial. In some patients, there is also a gradual decrease in PEMPs.

With a long-exercise test, both during and after exercise, there is often marked reduction of CMAPs from baseline which can remain so for prolonged periods, sometimes exceeding an hour. Furthermore, if the muscle is cooled and the patient asked to exercise the muscle, a pronounced (50% or more)

decrement in the CMAP can be documented in most patients with paramyotonia.

While needle electromyography reveals normal MUAPs, this may be quite difficult to observe secondary to the overt induction of profuse trains of myotonic potentials. The myotonia is usually worse in the distal compared to proximal aspects of the limbs. In patients with PMC and periodic paralysis, local cooling of the muscle results in dense fibrillation-like potentials and the gradual reduction in MUAP activity. As the muscle becomes flaccid, electrical myotonia vanishes and complete electrical silence is observed. In contrast in patients with pure PMC, while cooling results in increased myotonic discharges, the muscle strength, MUAP morphology, and recruitment remain normal and the patients continue to generate maximal interference pattern (Table 2).

Molecular genetics PMC with and without episodes of periodic paralysis are caused by mutations in the α-subunit of the voltage-gated sodium channel (*SCN4A*).

Treatment While tocainide and mexiletine have both shown to prevent the muscle stiffness and weakness associated with cold, mexiletine is the preferred medication due to the side effects associated with tocainide. Mexiletine has been demonstrated to correct the cold-induced decrements of baseline CMAPs following exercise or repetitive stimulation, in correlation with the observed clinical improvement. Hydrochlorothiazide has also been shown to be effective in relieving the myotonia.

Hypokalemic Periodic Paralysis Type 2

While approximately 70% of familial hypokalemic periodic paralysis cases are caused by mutations in the L-type Ca channel gene *CACNA1S* (HypoPP1), mutations in *SCN4A* (HypoPP2) account for approximately 10% of genetically confirmed families. Missense mutations in the highly conserved arginine residues (R699 and R672) of the voltage-sensing segment 4 (S4) of domain 2 (D2) are associated with HypoPP2. These mutations enhance inactivation to produce a net loss-of-function defect, as opposed to the gain-of-function observed in potassium-sensitive periodic paralysis, although the mechanism linking this defect to depolarization and hypokaliemia remains obscure.

Clinical Features Whereas no definite clinical features truly identify HypoPP1 from HypoPP2, a large retrospective series, including patients characterized with molecular lesions for HypoPP1 (42) and HypoPP2 (7), showed that age of onset was earlier (average 10 years) and the duration of episodes longer (average 20 h) in HypoPP1 versus HypoPP2 (16 years and 1 h, respectively), and more than 70% of HypoPP1 patients had fixed proximal weakness compared with none of the HypoPP2 patients.

Histopathology Unlike HypoPP1, in which muscle biopsies demonstrate myofibers that contain vacuoles, the myofibers in patients with hypoPP2 show mostly tubular aggregates.

Electrophysiologic findings With the long exercise test, 10–20 min into the rest phase and after cessation of exercise, there is a decrease of CMAP amplitude which is significantly milder than that observed in HypoPP1 patients. The needle electromyographic examination between attacks of muscle paralysis does not show any detectable myotonia or other abnormalities in the majority of patients.

Treatment It is important to note that patients with hypoPP2 may worsen with acetazolamide treatment, unlike patients with hypoPP1 or the potassium-sensitive periodic paralysis caused by *SCN4A* mutations.

Calcium Channelopathies

Primary hypokalemic periodic paralysis type 1 (HypoPP1) is caused by mutations in the muscle L-type voltage-gated calcium channel gene, specifically in the α1-subunit (*CACNA1S*), which is encoded on chromosome 1q31-32. This calcium channel (CaV1.1) is composed of five subunits (α1, α2, β, δ, and γ). The α1-subunit is composed of four domains, each containing six transmembrane segments (S1–S6), and contains the dihydropyridine (DHP) receptor. This receptor functions not only as a pore, conducting calcium ions into the T-tubule of skeletal muscle, but also as a voltage sensor for excitation–contraction coupling. The other subunits of the calcium channel serve to regulate the function of the α1-subunit. The S4 segment of the α1-subunit is important in conferring voltage-sensing properties to the channel, and is the site for most of the mutations identified in patients with hypokalemic periodic paralysis. The mechanism for the induced attacks of weakness in HypoPP is not understood. As with other forms of periodic paralysis, muscle fibers are depolarized and inexcitable during an attack. *In vitro*, as opposed to the hyperpolarization seen in wild-type fibers in low

K solutions, muscle fibers from patients with HypoPP1 paradoxically depolarize. However, the source of the depolarizing current has remained elusive. The available data suggest a loss-of-function defect with reduced ionic current density. A study on fibers biopsied from a patient with an R528H calcium channel mutation detected a reduction in ATP-sensitive K current, more easily tying it to the depolarization seen with hypokalemia and suggesting a secondary channelopathy resulting from altered calcium homeostasis. It has been also suggested that reduced calcium influx through the T-tubule may be the cause of impaired excitation–contraction coupling.

Primary Hypokalemic Periodic Paralysis Type 1

Clinical features Hypokalemic periodic paralysis type 1 is the most frequent form of periodic paralysis with an estimated prevalence of 1/100 000. It is an autosomal dominant disorder, with reduced penetrance in women (a male to female ratio of 3 or 4 to 1). Symptom onset is usually in the first two decades when patients note the development of episodic weakness. The bouts of weakness can occur at any time of day, although early morning hours appear to have a slightly higher propensity for being associated with weakness. Most patients note that some form of strenuous exercise or exertion followed by rest or sleep usually precipitates an attack. Other aggravating factors include heavy meals rich in carbohydrates and sodium, alcohol consumption, exposure to cold, emotional stress, intercurrent viral illness, lack of sleep, menstruation and specific medications (e.g., beta agonists, corticosteroids, and insulin). The episodes of weakness are often preceded by a vague sensation of heaviness in the lumbosacral region, thighs, and calves which spreads to involve other muscle groups, primarily those in the proximal upper limbs. If the patient notes the above prodrome, mild exercise may stave off the full blown attack of weakness; however, this is not always successful. Severity of an attack can range from mild weakness of an isolated muscle group to severe generalized paralysis. The facial and respiratory muscles as well as the sphincter muscles are typically spared or only minimally involved during particularly severe attacks; however, during peak weakness, reflexes are absent and the muscle is electrically unexcitable. Myotonia or paramyotonia are not seen in hypokalemic periodic paralysis. Death from respiratory muscle involvement and cardiac arrhythmia secondary to hypokalemia have been reported. Profound weakness may last for several hours to more than a day in some instances. Some patients may note a residual weakness for several days following an attack. Characteristically, those muscles affected last are the first to return to normal strength. The frequency of these attacks of weakness is highly variable and can occur from several times per week to a few lifetime episodes. It generally decreases after the age of 30 years and some patients become attack free in their 40s or 50s. Many patients eventually develop fixed permanent weakness after multiple attacks of paralysis, independent of their frequency or severity, with the proximal muscles being the most prone, especially in the legs.

While provocative testing can be performed when the diagnosis is unclear, the availability of commercial genetic testing usually makes it unnecessary. The goal of provocative testing is to reduce serum potassium levels to see whether typical attack of weakness could be induced. This could be accomplished by an oral or intravenous load of glucose, although insulin is also sometimes required to sufficiently lower the potassium level. The patient's strength, cardiac function (EKG), and electrolytes need to be carefully monitored during the study.

Laboratory features Between bouts of weakness, the serum potassium is normal, while attacks of weakness are associated with decreased serum potassium levels, usually below 3.0 mEq l^{-1}. During severe attacks, there is oliguria with urinary retention of sodium, potassium, chloride, and water. Obstipation and diaphoresis may also occur. The EKG may demonstrate bradycardia, flattened T waves, prolonged PR and QT intervals, and notably U waves, secondary to the hypokalemia. Serum CK levels are normal or only mildly elevated between attacks and increased during an attack of weakness (Table 2).

Histopathology The muscle biopsy may demonstrate multiple or single intracellular vacuoles, tubular aggregates, and dilation of the sarcoplasmic reticulum (Table 2). Muscle fiber size variation, split fibers, hypertrophic and atrophic fibers may also be present, and rarely necrotic and degenerating muscle fibers are noted.

Electrophysiologic findings Sensory and motor nerve conduction studies are normal between attacks of weakness. During paralytic attacks, sensory studies remain normal and motor responses continue to demonstrate a normal conduction velocity for as long as a response can be obtained. During the attack, the CMAP amplitudes decline precipitously secondary to muscle membrane inexcitability. Repetitive stimulation during this time can maintain

the CMAP amplitudes to some degree, supporting the clinical impression that mild exercise can stave off an attack.

In between the attacks, contrary to patients with potassium-sensitive periodic paralysis, there are minimal changes in CMAP immediately after the exercise phase of the short- or long-exercise tests, or with repeated trials of short exercise. The long-exercise test shows a delayed decline in CMAP amplitudes 10–20 min after the end of exercise.

The needle electromyographic examination between attacks of muscle paralysis does not show any detectable abnormality in the majority of patients. However, in the patients who develop a myopathy characterized by persistent muscle weakness, MUAPs with decreased amplitudes and durations and an increase in the number of polyphasic potentials is noted. Rarely, sparse fibrillation potentials may be observed, and there are indications of early recruitment pattern during voluntary activity. Early in an attack of weakness, there is a slight increase in spontaneous potentials (fibrillation potentials and positive sharp waves) and insertional activity, which are a reflection of the hyperirritable muscle membranes and not indicative of denervation. As the paralytic attack progresses, there is a decrease in the amplitude and duration of voluntary MUAPs as well as an overall decrease in the number contributing to the interference pattern. When the paralytic attack is maximal there is marked reduction or complete absence of insertional activity, and there are minimal, if any, voluntary MUAPs. A careful search usually demonstrates end plate activity, although this is also reduced in amplitude. Recovery from muscle paralysis essentially displays the above-noted needle electromyographic changes in reverse.

Between attacks, single fiber electromyography shows normal jitter along with a slight increase in fiber density. The latter is likely the result of a mild myopathic process which is also noted on histopathology. During an attack, the reduction in muscle membrane excitability results in a dropout of single muscle fibers and a decrease in fiber density, compared to both normal and interattack values for the patients. This is accompanied by a slight increase in jitter with occasional potential blocking (Table 2).

Molecular genetics Primary hypokalemic periodic paralysis is caused by mutations in the α-subunits of skeletal muscle L-type calcium channel gene (*CACNA1S*) in up to 70% of cases (HypoPP1). In 10% of affected individuals (HypoPP2), the mutations are present in the α-subunits of skeletal muscle sodium channel gene, *SCN4A*, and no mutation has been identified for the remaining 20% of patients. For both, the mutations occur in highly conserved arginine residues in the voltage-sensing segments. A small number of definitely affected kindreds do not have a mutation in either the calcium or sodium genes and are not linked to these loci. The possibility that they are caused by mutations in the potassium channel gene (*KCNE3*) has been suggested, but not verified. HypoPP1 may be allelic with malignant hyperthermia; malignant hyperthermia susceptibility without PP has been described with mutation in *CACN1AS*. Hence, all HypoPP patients undergoing surgery should be monitored for malignant hyperthermia-like reactions (rigidity and marked elevation in CK). However, postoperatively, paralysis in this group of patients is more likely related to the stress of surgery.

Treatment Preventive measures include avoidance of provocative factors (e.g., ingestion of high-carbohydrate meals and strenuous exercise). Acetazolamide (125–1000 mg daily) and potassium salts (0.25–0.5 mEq kg^{-1}) can be prophylactically administered to prevent hypokalemia and attacks of weakness. Dichlorphenamide (50–150 mg daily) appears to be effective in reducing attack frequency and severity. Triamterene (25–100 mg daily), and spironolactone (25–100 mg daily) may also be used to prevent attacks and improve interattack weakness, when acetazolamide and dichlorphenamide are not effective. Patients may take oral potassium (15–30 mEq) at the beginning of an attack to alleviate or shorten the episode. We treat acute attacks with oral potassium salts (0.25 mEq kg^{-1} body wt.) every 30 min until strength improves. If the patient's condition precludes oral potassium, intravenous potassium (KCL bolus 0.05–0.1 mEq kg^{-1} body wt. or 20–40 mEq l^{-1} of KCL in 5% mannitol) may be administered. Cardiac monitoring is essential throughout treatment.

Potassium Channelopathies

Andersen–Tawil Syndrome (Andersen Syndrome, or Klein–Lisak–Andersen Syndrome)

Clinical features Andersen–Tawil syndrome (ATS) is a rare ion channel disorder characterized by the clinical triad of periodic paralysis, ventricular arrhythmias associated with long QT and skeletal developmental anomalies. A diagnosis of ATS can be made when an individual exhibits two of these three cardinal features. Sixty percent of affected individuals manifest the complete triad while ~80% express two of the three cardinal features. Inheritance is autosomal dominant although *de novo* mutations

are frequent, and phenotypic expression is extremely variable. Prevalence is unknown but estimated at 1/10 that of HypoPP, and symptom onset is typically within the first or second decade. ATS must be excluded in all individuals presenting with episodic weakness and/or a long QT syndrome.

Neuromuscular manifestations. The neuromuscular manifestations of ATS consist of intermittent weakness that may arise spontaneously or be triggered by rest following exertion and prolonged rest. The attacks of paralysis usually begin in the first or second decade of life and may be associated with elevated, normal, or most commonly reduced ictal serum K^+ levels. Patients with ATS do not show evidence of myotonia or paramyotonia. The attacks vary in duration (hours to days), severity, and frequency between and within affected individuals, and might range from a single lifetime event to daily bouts of weakness. Permanent proximal weakness often develops over time.

Cardiac manifestations. Ventricular arrhythmias occur as a primary manifestation of ATS, and a number of potentially life-threatening arrhythmias, including bidirectional ventricular tachycardia (VT), polymorphic VT, and torsades de pointes may occur. The cardiac arrhythmias may be asymptomatic or manifest as palpitations, syncope, or even cardiac arrest necessitating defibrillator implantation. No specific triggers have been associated with the ventricular arrhythmias of ATS. One of the most common ECG findings is a long QT interval, which is recognized as an integral feature of ATS and may serve as a trigger for fatal ventricular arrhythmias.

Developmental anomalies. Various developmental abnormalities are associated with ATS, most commonly including clinodactyly, hypertelorism, low set ears, mandibular hypoplasia, syndactyly, and scoliosis. Other features less commonly associated are short stature, a broad nose and forehead, cleft or high-arched palate, short digits, vaginal atresia, brachydactyly, cardiac valve abnormalities, and hypoplastic kidney. A recent study on ten subjects with the *KCNJ2* mutation has suggested a distinct neurocognitive phenotype in this group of patients, characterized by deficits in executive function and abstract reasoning.

While provocative testing with the induction of hypo- or hyperkalemia may be performed when the diagnosis is unclear, there is an increased risk of precipitating arrhythmias. Genetic testing is also available to aid in the diagnosis.

Laboratory features Serum CK is normal or only mildly elevated (less than 5 times normal). Serum potassium levels can be normal, elevated, or decreased during attacks of weakness. EKG manifestations include prolongation of the corrected QT interval (present in 80% of patients), prominent U waves, premature ventricular contractions, ventricular bigeminy, and polymorphic VT. A subset of patients manifests a unique form of VT, bidirectional VT, which ischaracterized by beat-to-beat alternating QRS axis polarity (Table 2).

Histopathology Muscle biopsy frequently reveals tubular aggregates, and patients with fixed weakness may have nonspecific myopathic changes (Table 2).

Electrophysiologic findings Motor and sensory nerve conduction studies are normal, and there are no myotonic discharges. Electromyography is normal between the attacks. The long-exercise protocol may detect a delayed decrement in ATS patients, similar to what is seen in HypoPP1 (Table 2).

Molecular genetics and pathophysiology The molecular basis for the majority (approximately two-thirds) of ATS cases is missense mutations or small deletions in the *KCNJ2* gene (ATS1), which encodes an inwardly rectifying potassium channel (Kir2.1) and is predominantly expressed in the heart, skeletal muscle, and brain. While this mutation is known to cause symptomatic impairment of muscle membrane depolarization and repolarization, its role in the associated skeletal developmental anomalies and possible CNS manifestations is not fully clear. Kir2.1 channels stabilize the resting membrane potential in skeletal and cardiac muscle. The majority of *KCNJ2* mutations result in the failure of appropriate conduction, and many alter the binding of phosphatidylinositol 4,5 bisphosphate, an important regulator of Kir2.1 channel function. It is postulated that reduced Kir2.1 channel function in skeletal muscle may result in sustained membrane depolarization, failure of action potential propagation, and flaccid paralysis. It may also prolong the most terminal phase of repolarization in the heart and lead to delayed after-depolarizations. Targeted disruption of *KCJN2* in homozygous knockout mice results in neonatal lethality owing to aspiration and asphyxia from a severe cleft palate, which suggests a role for Kir2.1 in skeletal development and may be the basis for dysmorphic features in ATS. In approximately 20% of patients with an ATS phenotype, no mutation of *KCJN2* has been identified (ATS2). Possible molecular candidates include genes homologous to Kir2.1, and gene products that modulate Kir2.1 channel expression, trafficking, and function.

Treatment Early recognition of the potential cardiac conduction abnormalities is important, since it might necessitate treatment with antiarrhythmic agents or an implantable cardioverter-defibrillator. The involvement of both cardiac and skeletal muscle in ATS presents a unique treatment challenge, since specific treatments may have paradoxical effects on cardiac and skeletal muscle function. Treatment to date has been largely anecdotal and empirical, and while small doses of acetazolamide may prevent paralytic attacks in some patients, it has not been shown to be beneficial in all cases.

Other Causes of Periodic Paralysis

Secondary Hyperkalemic or Hypokalemic Paralysis

Secondary hyperkalemia and hypokalemia may cause generalized weakness, mimicking the familial forms of periodic paralyses, and must be excluded particularly in patients with no family history (Table 3). In comparison with potassium-sensitive periodic paralysis, the secondary cases do not exhibit clinical or electrical myotonia on examination. Secondary hypokalemia might also precipitate bouts of weakness as well as causing a necrotizing myopathy. In both cases, muscle weakness resolves with correction of the electrolyte imbalance.

Thyrotoxic Periodic Paralysis

Thyrotoxic periodic paralysis resembles hypokalemic periodic paralysis, except that it occurs sporadically and the associated hypokaliemia is often profound. It should be excluded in patients presenting after age 20 years or without a family history, by looking for a suppressed thyroid stimulating hormone (TSH) and elevated free T4 or free T3 levels. It is possible that the patients have an underling channel defect that clinically manifests itself when the patient becomes hyperthyroid. An initial report of an R83H mutation in the *KCNE3* gene causing thyrotoxic PP proved erroneous, since it is present in 1% of healthy controls. While hyperthyroidism is more common in women, the majority of cases of thyrotoxic periodic paralysis are male. The disorder is most prevalent in Asian men, where it may be inherited, although it has been described in all races. The patients can develop progressive muscle weakness secondary to hyperthyroidism, with the attacks of weakness resolving with treatment of the thyrotoxicosis and recurring with exacerbation of the hyperthyroid state. Unlike the familial forms of hypokalemic and hyperkalemic periodic paralysis, acetazolamide does not appear to have any significant benefit; however, β-blockers may be effective in reducing the frequency and severity of the paralytic attacks.

Table 3 Selected causes of hyperkalemic and hypokalemic paralysis

Hyperkalemic paralysis
Addison's disease
Chronic renal failure
Hypoaldosteronism
Iatrogenic (spironolactone, triamterene, and potassium supplementation)
Rhabdomyolysis
Hypokalemic paralysis
Alcoholism
Barium poisoning
Bartter's syndrome
Renal tubular acidosis
Hyperaldosteronism
Hyperthyroidism
Iatrogenic (diuretics, corticosteroids, Amphotericin B toxicity, and licorice)

Paroxysmal Sympathetic Storms

E E Benarroch, Mayo Clinic, Rochester, MN, USA

© 2009 Elsevier Ltd. All rights reserved.

Clinical Manifestations and Pathophysiology

Clinical Manifestations

Massive sympathoexcitation, as occurs in acute neurologic catastrophes, results in activation of both sympathoneural (peripheral sympathetic ganglia) and sympathoadrenal (adrenal medulla) discharge, as reflected by increased muscle and skin sympathetic nerve activities and circulating levels of norepinephrine and epinephrine. Paroxysmal sympathetic hyperactivity produces hypertension, tachycardia, pallor, and excessive sweating (hyperhidrosis), commonly associated with abnormalities in thermoregulation (hypothermia or hyperthermia). Massive sympathoexcitation may result in severe hypertension, malignant tachyarrhythmias, myocardial injury, and pulmonary edema. Sympathetic hyperactivity may occur with disorders affecting the central or peripheral nervous systems (Table 1). In general, sympathetic hyperactivity of central origin tends to begin abruptly after the acute injury, then fluctuates, and persists for several hours or days. Sympathetic hyperactivity due to peripheral disorders is often paroxysmal and recurs over longer periods.

Pathophysiology

The manifestations of paroxysmal sympathetic hyperactivity reflect excessive activation of vascular α-adrenergic receptors, cardiac β-adrenergic receptors, and cholinergic muscarinic receptors in the sweat glands. Sympathetic hyperactivity may occur with disorders affecting the cerebral cortex, diencephalon, brain stem, spinal cord, or peripheral nervous system. The mechanisms triggering sympathetic hyperactivity are incompletely understood, and vary according to the underlying cause (Figure 1).

In focal seizures, sympathetic hyperactivity results from paroxysmal discharges of neurons in the temporal or frontal lobes connected with hypothalamic and brain stem autonomic centers. In stroke, it may reflect loss of descending sympathoinhibitory output to these areas. Immediately after an intracranial catastrophe, such as traumatic or hypoxic brain injury, subarachnoid or intracerebral hemorrhage, or mass lesions affecting the brain stem, there is a massive sympathoneural and sympathoadrenal activation, resulting in increase in sympathetic discharge and catecholamine release. This dramatic response reflects direct excitation or disinhibition, or both, of sympathoexcitatory areas of the hypothalamus or the medulla. These areas include the paraventricular nucleus of the hypothalamus, which is involved in the stress response, and the rostral ventrolateral medulla, which contains sympathoexcitatory neurons that are activated by hypoxia or ischemia. The rostral ventrolateral medulla neurons are thought to be responsible for the hypertension experienced during the classical 'Cushing reflex.' This response is characterized by hypertension, bradycardia, and apnea in response to an increase in intracranial pressure, resulting in decrease in cerebral perfusion pressure. An initial tachycardia associated with hypertension occurs before the onset of bradycardia.

Another mechanism of acute sympathetic hyperactivity is massive activation of segmental spinal sympathoexcitatory reflexes in the setting of interruption of descending modulatory pathways from the hypothalamus and brain stem. This is called autonomic dysreflexia and occurs in patients with spinal cord injury above the T5 level. Episodes of sympathoexcitation may also occur in patients with failure of baroreflex inhibition of sympathetic output, as occurs in patients with Guillain–Barré syndrome or porphyria. In some disorders, the mechanisms of sympathoexcitation may be both central and peripheral. In these conditions, sympathetic hyperactivity is associated with confusional state and with motor abnormalities, such as muscle rigidity, tremor, or myoclonus. Important examples are alcohol withdrawal delirium, neuroleptic malignant syndrome, and serotonin syndrome. Stimulant drugs, such as cocaine or amphetamine, may lead to excessive release or impaired uptake of catecholamines, resulting in similar manifestations. In many conditions, sympathetic hyperactivity is associated with increased muscle tone. This suggests that somatosympathetic reflexes from muscle mechanoreceptors or chemoreceptors during the episodes of increase muscle tone may trigger or contribute to excessive sympathetic activation.

Syndromes of Sympathetic Hyperactivity

Sympathetic hyperactivity is a critical manifestation of specific syndromes that require prompt recognition for appropriate management.

Acute Sympathetic Hyperactivity in Neurologic Catastrophes

Severe brain injury An episodic hypersympathetic state occurs in patients with severe brain injury. This

Table 1 Causes of autonomic hyperactivity

Forebrain disorders
Insular stroke
Temporal or anterior cingulate seizures
Close head injury
Subarachnoid hemorrhage
Mass lesions producing increased intracranial pressure
Episodic hyperhydrosis with or without hypothermia
Familial or sporadic fatal insomnia
Limbic encephalitis
Posterior fossa disorders
Brain stem ischemia
Cerebellar or brain stem neoplasms
Syringobulbia
Tetanus
Leigh syndrome
Spinal cord disorders
Traumatic injury
Devic syndrome
Stiff-man syndrome
Peripheral nerve disorders
Guillain–Barré syndrome
Porphyria
Thallium intoxication
Morvan syndrome
Iatrogenic disorders
Neuroleptic malignant syndrome
Serotonin syndrome
Monoamine oxidase inhibitors
Drug intoxication or withdrawal
Stimulant (cocaine, amphetamines) intoxication
Alcohol withdrawal
Opioid withdrawal

episodic sympathetic hyperactivity has been variably referred to in the literature as diencephalic seizures, paroxysmal sympathetic storm, and paroxysmal autonomic instability with dystonia. It occurs most commonly in the setting of severe head trauma with diffuse axonal injury and in the postresuscitation period after severe anoxic–ischemic brain insults, but may also occur in the setting of intracerebral hemorrhage, hydrocephalus, brain stem ischemia, or mass lesions. The manifestations of this episodic hypersympathetic state include fever (often $>39\,^{\circ}C$), tachycardia, hypertension, diaphoresis, pupil dilatation, tachypnea, and shivering, associated with muscle hypertonia and extensor posturing. The paroxysms usually start 5–7 days after the injury, but they may appear earlier. The episodes follow a regular pattern, occur on average 1–3 times per day, and each lasts between 2 and 10 h. Although in most patients sympathetic outflow diminishes over time and the manifestations of sympathetic hyperactivity tend to disappear within a few days, some patients develop recurrent paroxysms of sympathetic hyperactivity during the acute hospitalization phase and later recovery phase. Over time, the episodes tend to become less frequent but more prolonged and severe, before subsiding several months after the acute event.

The differential diagnosis of this syndrome is based on the recognition of the regular pattern of hypersympathetic spells in a patient with acute intracranial lesions. This syndrome should be distinguished from other disorders that present with autonomic instability, including seizures, impending brain herniation causing the Cushing response, tetanus, malignant hyperthermia, neuroleptic malignant syndrome, and lethal catatonia. In all patients with suspected sympathetic storms, serial blood cultures and cerebrospinal fluid examination should be performed to exclude the possibility of sepsis, meningitis, or encephalitis. All patients should also have a computed tomography or magnetic resonance scan of the brain to exclude the presence of hydrocephalus or brain stem distortion. In patients with traumatic head injury, the possibility of acute spinal injury above the fifth thoracic level producing acute autonomic dysreflexia should also be excluded by imaging study. An electroencephalogram should be obtained to exclude seizures.

Drugs that have been reported helpful to treat these sympathetic paroxysms include morphine, bromocriptine, labetalol, clonidine, clonazepam, or dantrolene. Antiepileptic drugs are typically not helpful, but should be tried if there is a persistent possibility of an epileptic nature of the spells. Autonomic storms have been associated with poor functional outcome after severe traumatic brain injury.

Subarachnoid hemorrhage Subarachnoid hemorrhage is the prototype of an acute neurologic catastrophe associated with massive sympathoexcitation. One mechanism is development of acute hydrocephalus, resulting in mechanical distortion of periventricular hypothalamic areas, particularly the paraventricular nucleus, which is critical for sympathetic activation in response to stress. The acute sympathoadrenal excitation may produce electrocardiographic (ECG) changes of cardiac injury, including depression or elevation of the ST segment, inverted or biphasic T waves, QT prolongation, and Q waves. The ECG changes resembling cardiac ischemia in patients with severe subarachnoid hemorrhage are associated with increased levels of creatine kinase and troponin, and there is echocardiographic evidence of ventricular hypokinesia. In general, the ECG and enzymatic abnormalities reverse within 1–4 days. Some patients may develop pulmonary edema, which may be due to neurogenic or cardiogenic causes. Myocardial injury is not due to cardiac ischemia, as coronary angiogram is normal in these patients. Myocardial damage results from massive release of norepinephrine from nerve terminals adjacent to the myocardium, leading to

Figure 1 Pathophysiological mechanisms of paroxysmal sympathetic hyperactivity and representative examples. Sympathetic hyperactivity results from excessive sympathoexcitatory outflow from limbic circuits (as occurs with temporal lobe seizures) or the hypothalamus (as occurs in severe head injury) or subarachnoid hemorrhage (SAH). These circuits activate the preganglionic sympathetic neurons of the intermediolateral cell column (IML), either directly or via the sympathoexcitatory neurons of the rostral ventrolateral medulla (RVLM). The RVLM may be directly activated by hypoxia or mechanical distortion, as occurs in the setting of increased intracranial pressure (ICP). The sympathoexcitatory output of the RVLM is tonically inhibited by the baroreflex, via the nucleus of the solitary tract (NTS). Therefore, baroreflex failure, as occurs in the Guillain–Barré syndrome (GBS), results in paroxysmal sympathetic discharge. Interruption of descending modulatory inputs from the hypothalamus and medulla unmasks segmental sympathoexcitatory reflexes, resulting in massive sympathetic activation in response to visceral or somatic stimulation, as typically occurs in autonomic dysreflexia following high spinal cord injuries. Sympathoexcitatory effects are mediated by norepinephrine (NE). Therefore, drugs that increase NE availability, such as cocaine, amphetamines, or monoamine oxidase inhibitors, produce excessive sympathetic activity.

subendocardial contraction band necrosis ('stunned heart'). Several tachyarrhythmias may occur in the setting of subarachnoid hemorrhage. Although supraventricular are more common than ventricular arrhythmias, a prolonged QT interval is a predictor of serious arrhythmias (such as torsades de pointes) that may produce sudden death in some cases.

Chronic Recurrent Episodes of Sympathetic Activation

Seizures Seizures of temporal or extratemporal origin, and generalized tonic–clonic seizures, most commonly activate the sympathetic system, producing tachycardia, hypertension, diaphoresis, pupillary dilatation, pallor or facial flushing, and piloerection. These manifestations resemble panic attacks, or pheochromocytoma, and when they are the sole manifestation of partial seizures, the diagnosis is often delayed or missing. Sinus tachycardia can occur in more than 85% of complex partial and generalized tonic–clonic seizures. Patients with refractory epilepsy have one or more abnormalities in repolarization and/or arrhythmias during or immediately after seizures. These include atrial fibrillation, supraventricular tachycardia, premature ventricular complexes, bundle-branch block, and complete atrioventricular block. Cardiovascular and respiratory dysregulation are postulated to be a major factor in sudden unexplained death in epileptic patients. Ictal and postictal apnea and neurogenic pulmonary edema, rather than cardiovascular effects, appear to be the major cause of sudden unexplained death in epilepsy. Pulmonary edema is the result of sympathetically triggered pulmonary vasoconstriction and increased left atrial pressure from systemic hypertension; both lead to increase in intrapulmonary vascular pressure and pulmonary edema. Status epilepticus is a neurological and medical emergency. Sympathetic hyperactivity associated with prolonged seizures may lead to

death due to cardiac arrhythmias and to myocardial injury (contraction band necrosis).

Episodic hyperhidrosis with or without hypothermia This syndrome consists of spontaneous episodes of severe hyperhidrosis, in general associated with hypothermia that may recur several times a day and last several hours. During the episodes, the patients may be confused and poorly responsive. This disorder has been associated with diencephalic lesions (such as tumors leading to obstructive hydrocephalus), agenesis of the corpus callosum (Shapiro syndrome), basal forebrain malformation, hypothalamic strokes, and infections with human immunodeficiency type 1 virus, but commonly occur with no apparent cause. Clonidine, cyproheptadine, anticholinergic drugs (such as oxybutynin or glycopyrrolate), carbamazepine, chlorpromazine, and phenobarbital have been shown to be helpful in reducing hyperhidrosis or hypothermia, or both, in some individual cases.

Sympathetic Hyperactivity, Insomnia, Delirium, and Excessive Motor Activity

In several neurologic disorders, sympathetic hyperactivity is associated with confusional apathetic state, fluctuating delirium, and excessive motor activity. This syndrome is characterized by insomnia with reduced slow-wave sleep and increased incidence of rapid-eye-movement sleep without atonia. Disorders associated with this syndrome include delirium tremens (alcohol withdrawal delirium), fatal insomnia, Morvan syndrome, and limbic encephalitis.

Delirium tremens Delirium tremens is the most severe manifestation of the alcohol withdrawal syndrome and constitutes a medical emergency. It is characterized by acute or subacute confusional state with anxiety, insomnia, and tremor; vivid visual, auditory, or tactile hallucinations; and fluctuating levels of psychomotor activity. These manifestations are accompanied by sympathetic hyperactivity with tachycardia, fever, diaphoresis, flushing, and hypertension. In general, delirium appears after 2–3 days of cessation of drinking and usually lasts 48–72 h, but occasionally lasts much longer. A similar clinical picture may occur after sudden withdrawal of barbiturates or benzodiazepines. The main treatment is benzodiazepines, such as chlordiazepoxide or lorazepam. Clonidine and propranolol can reduce hypertension and tachycardia in selected patients but should only be given together with benzodiazepines.

Fatal insomnia Fatal insomnia is a prion disease that can be sporadic or familial. Patients complain of early insomnia, with inability to fall asleep at night and frequent awakening. Insomnia is associated with perspiration, salivation, tachycardia, increased arterial pressure, and pyrexia. Later in the course of the disease the patients develop increased autonomic hyperactivity and periods of hallucinatory behavior and enacted dreams; this is followed by stupor and eventual coma, preceding death. In addition to insomnia and autonomic hyperactivity, there is increased cortisolemia and suppression of circadian rhythms.

Morvan syndrome Morvan syndrome is a rare disorder characterized by severe insomnia associated with sympathetic hyperactivity manifested with profuse perspiration, tachycardia, hypertension, and increased body temperature. The patients display hallucinatory behavior and motor unit hyperexcitability (neuromyotonia), as well as cramps and myoclonus. Morvan syndrome may be associated with antibodies against voltage-gated K^+ channels, and may be a paraneoplastic manifestation of thymoma or small cell lung carcinoma.

Limbic encephalitis Limbic encephalitis is an inflammatory disorder that affects the medial portion of the temporal lobe (hippocampus and amygdala) and may also involve the insular and orbitofrontal cortex and hypothalamus. It is characterized by subacute onset of memory impairment, changes in personality, temporal lobe seizures, and autonomic instability. The common causes include herpes simplex encephalitis and autoimmune disorders. Autoimmune limbic encephalitis may be a paraneoplastic manifestation of the presence of anti-Hu autoantibodies in patients with small cell lung cancer, anti-Ma2 in patients with testicular germ cell tumors, or voltage-gated K^+ channels in patients with or without associated Morvan syndrome and thymoma. The management of this paraneoplastic syndrome includes identification and treatment of the underlying malignancy, if present, and immunosuppressive therapy with corticosteroids, intravenous immunoglobulin, or plasma exchange.

Autonomic Dysreflexia in Spinal Cord Injury

Acute lesions of the upper spinal cord, resulting from traumatic injuries or severe inflammatory conditions, such as Devic disease, commonly produce autonomic failure, resulting in orthostatic hypotension, urinary retention, and ileus during the state of flaccid paralysis (spinal shock). However, upon recovery from the acute spinal shock state, patients with lesions above the T5 level may experience episodes of severe sympathetic hyperactivity triggered by reflex stimuli below the level of the lesion. This generalized reflex

sympathetic activation, called autonomic dysreflexia, is due to interruption of descending sympathomodulatory inputs from the brain stem, which control segmental sympathetic reflexes and mediate baroreflex inhibition of the sympathetic preganglionic neurons. Autonomic dysreflexia may be triggered by a variety of visceral or somatic stimuli, most commonly bladder distension. The episodes of autonomic dysreflexia may be life threatening. The most serious manifestation is severe hypertension, which may produce hypertensive encephalopathy or intracranial, subarachnoid, or retinal hemorrhages. The episodes are often heralded by headaches and face flushing, and are accompanied by piloerection, extensive diaphoresis above the level of the lesion, and vagally mediated reflex bradycardia. Autonomic dysreflexia may be prevented by appropriate medical care of patients with spinal cord injury, including bowel and bladder programs and skin care. Both the patient and family should be educated about possible causes, prevention, presentation, and first-aid measures. In the acute setting, the patient is placed in an upright position, with removal of the precipitating stimulus. When hypertension persists, α-adrenergic blockers, such as phenoxybenzamine or prazosin, or nifedipine may be used.

Guillain–Barré Syndrome

Autonomic instability is a leading cause of mortality in Guillain–Barré syndrome, and tends to occur in severe cases, associated with respiratory failure. One important mechanism is impaired baroreflex modulation of sympathetic cardiovascular output due to demyelination of vagal afferents in this disorder. Manifestations include paroxysmal or sustained hypertension, orthostatic hypotension, vasodepressor responses, tachyarrhythmias, and vagal-induced bradycardia during intubation or tracheal suction. Severe hypertension may result in subarachnoid hemorrhage or posterior leukoencephalopathy with cortical blindness. In general, spontaneous fluctuations of blood pressure in patients with Guillain–Barré syndrome are best left untreated unless there is compromise of target organs. These patients may suffer severe hypotension or hypertension in response to labetalol or adrenergic agonists, respectively. Treatment of precipitating causes, particularly pain, is critical.

Baroreflex failure may also result from damage of afferent structures, including the arterial baroreceptors, baroreceptor afferents, or nucleus of the solitary tract where these afferents terminate. Common causes include extensive neck surgery and radiation therapy for cancers of the neck, bilateral carotid tumor resections, and repeated trauma to the neck. Baroreflex failure manifests with episodes of paroxysmal hypertension, usually accompanied of tachycardia, headache, sensation of warmth or flushing, diaphoresis, and palpitations. These episodes are commonly triggered by psychological stress, physical exercise, or pain. Patients with baroreflex failure are susceptible to dramatic changes in blood pressure after ingestion of vasoactive drugs, including over-the-counter decongestants. One important differential diagnosis is pheochromocytoma. Clonidine profoundly reduces arterial pressure and plasma norepinephrine levels in patients with baroreflex failure, whereas it has no effect in patients with pheochromocytoma.

Iatrogenic Causes of Sympathetic Hyperactivity

Neuroleptic malignant syndrome Neuroleptic malignant syndrome (NMS) is an idiopathic reaction resulting from impaired central dopaminergic transmission in the hypothalamus and basal ganglia. The two common triggers are drug-induced blockade of D_2 dopaminergic receptors and sudden withdrawal of dopaminergic agonists in patients with Parkinson disease. The drugs that commonly trigger NMS include the first-generation antipsychotic agents (e.g., haloperidol, phenothiazines), and antiemetics (metoclopramide), but NMS has also been described with 'atypical' antipsychotic drugs such as clozapine, olanzapine, risperidone, and quetiapine. NMS may also develop in patients with Parkinson's disease after withdrawal of levodopa, dopaminergic agonists, catechol-*O*-methyltransferase inhibitors, or amantadine. Patients with Lewy body disease are at particular risk to develop NMS after receiving even a low dose of antipsychotic drugs. NMS may also result from overdose of tricyclic antidepressants, citalopram, amphetamines, cocaine, or lithium.

The clinical manifestations of NMS include mental status change ranging from confusional state to coma, severe muscle rigidity with or without tremor, dystonia and mutism, fever (>38 °C), and autonomic hyperactivity, including diaphoresis, tachycardia, and hypertension. Two important laboratory features are leukocytosis and elevated creatine kinase levels, reflecting rhabdomyolysis secondary to muscle rigidity.

Typically, NMS evolves over 24–72 h, but may rarely develop slowly over a few days. In uncomplicated cases, the course lasts 7–10 days. Management of NMS includes immediate withdrawal of the precipitating drug, supportive measures (including intravenous fluids and nutrition, temperature reduction), and pharmacologic treatment with dopaminergic agonists such as bromocriptine, and muscle relaxants such as dantrolene.

The main differential diagnosis includes malignant hyperthermia, acute lethal catatonia, neuroleptic-induced heat stroke, central anticholinergic syndrome, and serotonin syndrome. Malignant hyperthermia typically occurs with the use of potent halogenated inhalation anesthetics (such as halothane or isoflurane) and depolarizing muscle agents such as succinylcholine. Management of this condition consists of immediate withdrawal of the offending agent, supportive measures, and dantrolene sodium. Acute lethal catatonia is typically preceded by a history of behavioral changes (including agitation, automatisms, negativism, and stereotypies) before the onset of motor symptoms, which include not only rigidity but also abnormal postures (catalepsy) and waxy flexibility. Lethal catatonia typically occurs in the setting of schizophrenia but may also follow meningitis, encephalitis, head trauma, and metabolic disturbances such as Wernicke encephalopathy or porphyria. Treatment includes benzodiazepines and electroconvulsive therapy. The central anticholinergic syndrome occurs following administration of drugs that block central and peripheral muscarinic receptors, particularly tricyclic antidepressants such as amitriptyline. However, unlike NMS, fever and tachycardia in anticholinergic syndrome are associated with decreased sweating, dry mouth, mydriasis, and urinary retention.

Serotonin syndrome Serotonin syndrome results from excessive stimulation of central and peripheral serotonin receptors, particularly 5-HT_{2A} receptors. Unlike NMS, serotonin syndrome is a dose-dependent phenomenon and develops rapidly following administration of single doses of, or combinations of, drugs that enhance serotonergic transmission. These include serotonin reuptake inhibitors such as fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram, venlafaxine, trazodone, nefazodone, clomipramine); 5-HT_1 agonists (buspirone, triptan); monoamine oxidase inhibitors; opioids (meperidine, fentanyl, tramadol, dextromethorphan), triptans, valproate, lithium, antiemetic agents (metoclopramide, ondansetron), drugs of abuse such as lysergic acid diethylamide and methylenedioxymethamphetamine ('Ecstasy'), and dietary supplements and herbal products (tryptophan, St. John's wort). The typical manifestations of serotonin syndrome include agitation, hyperreflexia, clonus, fever, mydriasis, tachycardia, diaphoresis, and hyperactive bowel sounds or diarrhea. Severely affected patients may have agitated delirium, muscle rigidity, hyperthermia, and severe hypertension and tachycardia that may abruptly be followed by hypotension and shock in patients. The most distinguishing features of serotonin syndrome are clonus and diarrhea, which help differentiate it from NMS and central anticholinergic syndrome, respectively. Management includes removal of precipitating drugs, supporting measures, control of the hyperthermia and autonomic instability, control of agitation with benzodiazepines, and administration of 5-HT_{2A} antagonists such as cyproheptadine. Propranolol is not indicated because it can produce severe hypotension, and bromocriptine is contraindicated as it can trigger serotonin syndrome.

Pattern Generation

S Grillner, Karolinska Insititutet, Stockholm, Sweden

© 2009 Elsevier Ltd. All rights reserved.

Already in the end of the nineteenth century, the question was asked whether the spinal cord contains networks that coordinate different patterns of motor behavior or, as an alternative, whether they were coordinated through chain reflexes, requiring sensory feedback. The early strategy to address such questions was to compare the motor repertoire before and after a transection of all the afferents to the limb or appendage investigated. The German investigator Munk showed in 1897 that monkeys could use their arm after deafferentation provided that the intact arm was not free to move. Very extensive experiments with deafferentation and other approaches in fish and other vertebrate species have established beyond any doubt that central networks play a very important role in generating and controlling the vertebrate movement repertoire.

Although sensory feedback, in general, is not required for a motor pattern to be produced, it nevertheless plays a prominent role in many types of movements, precision movements as well as larger synergies such as locomotor movements and postural adjustments. For optimal control of most movements, central programming provides the template, but sensory signals are used before the movement starts, to initiate the appropriate motor coordination and to adjust the movement trajectory during the movements when time permits. During slow movements, there may be ample time for sensory control during the actual ongoing movement, but during faster, particularly ballistic movements, there is no time available – and the movement depends entirely on central programming.

The Capacity of the Spinal Cord to Generate Integrated Patterns of Motor Behavior

A very important question to address was to what a degree the spinal cord contained networks that could coordinate behaviorally meaningful motor patterns. One way to address this was by an analyses of what the spinal cord could produce after a complete lesion of the spinal cord, interrupting all nerve fibers from the brain to the spinal cord. In all classes of vertebrates, it is now well established that the spinal cord devoid of any supraspinal control can coordinate locomotor movements, scratching or wiping reflexes, protective reflexes, and also reflexes that control bladder function and other autonomic functions.

Cyclostomes and Fish – Central Programming and Sensory Feedback

Some fish, such as dogfish and eel, show spontaneous well-coordinated swimming activity after a spinal transection with appropriate motor coordination along the body. Species that normally swim continuously apparently have a very high excitatbility in their spinal cord networks at rest. The movement can, however, be inhibited by certain sensory input and accelerated by others. Most fish, however, do not show any coordinated movements immediately after a transection, but sensory input from, for example, the tailfin can generate brief bouts of locomotor activity. Pharmacological activation of the spinal cord with glutamate agonists, serotonin (5-HT) agonists, or noradrenergic agonists can, in general, elicit locomotor activity in the spinal cord.

The spinal cord with afferents is thus able to generate well-coordinated locomotor activity in fish. The next question is whether this motor coordination results from a chain reflex, a view held by many investigators until the 1970s, or depends on a network within the spinal cord itself. Both in the isolated spinal cord, in which the motor coordination can be recorded from the ventral roots along the spinal cord, and in the spinal fish after transection of the sensory dorsal roots, the swimming motor coordination is retained (Figure 1). These experiments clearly demonstrate, beyond any doubt, that there is a spinal neuronal network organization that coordinates the locomotor activity. These networks are often referred to as a central pattern generator networks (CPGs).

The level of activity in the spinal locomotor CPGs is normally controlled from the mesencephalic and diencephalic locomotor command regions in the brain stem. These command regions turn on the locomotor CPGs and determine the level of activity (e.g., fast or slow swimming). The locomotor command regions provide a bilaterally symmetrical activation of the glutamatergic reticulospinal nuclei in the lower brain stem.

The fact that there is a spinal locomotor CPG that can generate the motor pattern without sensory feedback in no way means that the sensory input is without importance. In all species investigated, the activity level of the CPGs can be accelerated by tonic input from the tail region and can be inhibited from other areas such as the skin over the abdomen (for fish resting at the bottom of a lake or the sea). As important is the phasic sensory input onto the CPGs. In lamprey and dogfish, it has been shown that stretch receptors located at the lateral margin spinal cord senses the progression of each locomotor cycle. This

Figure 1 Intersegmental coordination through phase coupling – undulatory locomotion: (a) cyclostomes, fish, and some amphibians and reptiles; (b) in the isolated spinal cord (control). Cyclostomes, fish, and some amphibians and reptiles swim by producing a mechanical wave that is transmitted along the body. As illustrated in (a), during forward locomotion there is a lag between consecutive segments in the spinal cord. This lag is always a certain proportion of the cycle duration and is therefore referred to as a constant phase lag. During backward locomotion, the wave is instead propagated from tail to head. As shown in (b), in the isolated spinal cord a rostrocaudal phase lag can also be produced, and thus the ability to generate a constant phase lag is inherent to the spinal cord. The pattern can be reversed if extra excitation is added to the caudal spinal cord (right). This is explained by the fact that the segments of the caudal part then get a higher excitability and generate a somewhat higher burst rate that is able to entrain the segmental networks in the rostral part of the spinal cord. The rostral segments. then, have a lower inherent burst rate and will therefore be entrained but with a certain lag.

input is fed directly into the CPG network, and if the movement does not proceed according to the plan due to external perturbations, the swim cycle becomes adapted to the external event and is either prolonged or shortened. After discussing the spinal coordination in the other classes of vertebrates next, we then discuss the intrinsic function of the CPGs and the sensory input.

Amphibians and Reptiles

In amphibians and reptiles, the spinal cord can also generate the motor pattern after a spinal transection. The swimming movements in the tadpoles as well as the adult salamander are characterized by an undulatory wave transmitted along the body in a way similar to that of fish. A CPG for swimming has been demonstrated also in this case, as has sensory modulation. During swimming, the limbs are kept close to the body and do not take part in generating the propulsive thrust.

During walking, however, the limbs are responsible for the propulsive thrust, and there is a CPG for each limb that generates a complex output pattern. The wiggling movements of the trunk are part of the walking locomotor synergy in newt and reptiles, and they serve to prolong the step during the swing phase of each limb. To achieve this, the trunk coordination is modified so that it is linked to the step cycle, and instead of the traveling wave used during swimming, the pattern of coordination is that of a standing wave linked to each step cycle.

During development, the tadpoles of frogs, toads, and newts are all very similar and swim through an undulatory wave transmitted along the tail. From a very fast undulatory movement, the frequency decreases as the size of the tadpole increases. Initially there is only one spike in the motor neurons per swim cycle, and later a regular burst occurs and, at the same time, there are changes in the properties of the neurons within the CPG. Later, when the limbs start to develop, their motor activity becomes linked to the tail-muscle activity with synchronous activity in the flexors and extensors, and subsequently a progressive change takes place so that the limb CPG gradually becomes independent. Frogs and toads later lose their tail, whereas the newt maintains it. After losing the tail, frogs acquire a jumping locomotor coordination in which the two hindlimbs are active in-phase – the in-phase relation between the two hindlimbs is, in principle, similar to that occurring in a mammalian gallop. Frogs, however, are also able to generate alternating movements between the two hindlimbs as they move slowly, as do toads.

Birds

As has long been known, spinal birds can generate the walking synergy if the lateral stability is assisted in some way. The synchronous movements of the wings can also be produced by spinal networks – in principle, similar to the in phase coordination occurring during a gallop or a frog jump. Also, the spinal walking and flying networks are normally controlled from the mesencephalic locomotor command region.

The progressive development of the different patterns of motor coordination has been studied in the chick. It is a classic experimental model and very experimentally amenable because the nervous system is accessible in the egg at different developmental stages and can be manipulated in different ways. As in other vertebrates, the isolated spinal cord can be made to generate the different spinal motor patterns.

Mammals (including Humans) – Spinal Generation, Central Pattern Generator Networks, and Sensory Feedback

Although early studies by Philippson 100 years ago demonstrated walking movements in spinal dogs, these results did not impact the neuroscience community for many decades. It was only accepted when it was demonstrated with modern techniques in the 1970s and 1980s that the spinal cord contained the necessary motor programs. This required simultaneous recordings of locomotor movements performed on the treadmill (Figure 2(a)) with different speeds and the timing of the different muscles with electromyography (EMG). These experiments established that the spinal animals are able to generate the same motor pattern as intact walking animals. It is now generally accepted that the motor programs for walking is present in the spinal cord of mammals, including primates.

Locomotor activity can be generated directly after a spinal transection, if the CPG is activated by pharmacological means (e.g., by noradrenergic agonists). However, after a complete transection, the movements of a spinal adult animal take time to reappear (without any further pharmacological manipulation). For the recovery of locomotor function, it has proved to be important to regularly expose the spinal animal to limb movements similar to walking, for instance, on the treadmill. Chronic spinal mammals can, after extensive training, be made to perform well-controlled walking movements on the treadmill, and the range and vigor of the movements can be influenced by sensory stimuli that affect the CPG excitability. Pharmacologically, particularly 5-HT agonists have proven to be effective in facilitating the locomotor movements in most vertebrates. Also in humans with a complete spinal cord lesion, leaving the spinal CPGs intact, treadmill training with appropriate postural support can uncover a spinally generated locomotor pattern.

Figure 2 Locomotor movements in a spinal animal and sensory control mechanisms: (a) spinal cat (lesion at lower thoracic level) walking on a treadmill; (b) representation of the two main sensory mechanisms that help regulate the duration of the step cycle, a position-dependent (extension of the proximal joint (hip)) mechanism and a load-dependent mechanism. As shown in (a), both movements and electromyogrphical activity can be recorded simultaneously and have established a motor pattern virtually identical to that of the intact cat walking at the same speed Panel (a) modified from Pearson KG (2000) Neural adaptation in the generation of rhythmic behavior. *Annual Review of Physiology* 62: 723–753.

That a CPG is responsible for generating a complex output pattern to the limbs and also the muscles of the trunk is now well established. Graham Brown, in the early twentieth century, demonstrated that alternating muscle contractions could be produced in a pair of antagonistic muscles without the contribution of sensory afferents or in the form of a reflex. However, a much more detailed analyses and experimentation was required before these results were accepted in the research community.

From the fact that spinal animals can adapt to the treadmill speed, it follows that sensory input has access to the CPG network. In mammals, this has been studied particularly in the cat. Two major sources for the sensory regulation have been defined (Figure 2(b)). The switch from the support to swing phase is influenced by two main types of sensory signals from the limb: (1) load receptors (as long as there is a significant load on the limb, the transition from the stance to the swing phase is prevented) and (2) hip extension angle (the more the hip extension (posterior position of the leg movement trajectory), the easier it is to trigger the transition to flexion, and, conversely, if the limb is prevented from extending, the transition is also blocked). These two input sources appear functionally very meaningful; they constitute an integral part of the control of each step cycle and play a major role in adapting the movement pattern to external perturbations.

Intrinsic Function of the Central Pattern Generator Network

Lower Vertebrates

The intrinsic function of the segmental CPG of lower vertebrates has been analyzed particularly in the lamprey and in the developing amphibian tadpole; it is now well understood with regard to the main synaptic, cellular, and molecular mechanisms. These networks are arranged on the segmental level with reciprocal

inhibition between the left and right sides. Figure 3(a) depicts the core of the spinal network in the lamprey, consisting of excitatory interneurons (EIN) that excite one another within the pool and at the same time activate commissural inhibitory interneurons that inhibit the contralateral CPG. The network is turned on from the brain stem (command–drive signal). Figure 3 (c) illustrates several cellular and synaptic mechanisms that contribute throughout a cycle. The initial depolarization is thus due to, (1) the excitatory drive from the brain stem, (2) excitation from other EINs, and finally (3) the boosting of the depolarization by voltage-dependent channels such as *N*-methyl-D-aspartate (NMDA) and low-voltage-activated (LVA) Ca^{2+} channels. In turn the Ca^{2+} entry during the depolarization leads to a progressive activation of K_{Ca^+} channels during the depolarization, which leads to a progressive hyperpolarization and a closure of NMDA channels and, finally, a termination of the burst.

The ability to generate burst activity is distributed along the spinal cord, and if isolated, each segment, and even a hemisegment, can generate rhythmic burst activity. In the lamprey, the axons of EINs are asymmetric, with a descending branch extending over five to six segments and a rostral branch extending roughly three segments. There may be around 40 EINs/segment, and they are estimated to interact with only approximately 10% of the EINs within

Figure 3 Neuronal elements: (a) lamprey CPG; (b) mammalian hindlimb CPG; (c) factors that contribute to the initiation of the depolarizing phase, its maintenance, and its termination (lamprey locomotor CPG). Shown in (a) is a representation of the forebrain, brain stem, and spinal components of the lamprey neural circuitry that generates rhythmic locomotor activity. All neuron symbols denote populations rather than single cells. The reticulospinal (RS) glutamatergic neurons excite all classes of spinal interneurons and motor neurons (M). The excitatory interneurons (E) excite all types of spinal neurons, that is, the inhibitory glycinergic interneurons (I) that cross the midline to inhibit all neuron types on the contralateral side and motor neurons. The stretch receptor neurons are of two types: one excitatory (SR-E), which excites ipsilateral neurons, and one inhibitory (SR-I), which crosses the midline to inhibit contralateral neurons. RS neurons receive excitatory synaptic input, the diencephalic and the mesencephalic locomotor regions (DLR and MLR), which in turn receives input from the basal ganglia as well as visual and olfactory input. In addition, metabotropic receptors are also activated during locomotion and are an integral part of the network (5-HT, GABA, and mGluR). As shown in (b), ipsilateral inhibitory premotor interneurons (1a and Renshaw (Rens)) are known to be rhythmically active during locomotion. They receive input also from contralaterally projecting interneurons. Motor neurons receive input directly from both excitatory and inhibitory contralateral interneurons. One ipsilateral glutamatergic locomotor-related interneuron (Hb9) has also been identified. In (c), in addition to conventional synaptic excitation, voltage-dependent NMDA receptors and low-voltage-activated (LVA) Ca^{2+} channels and Na^+ channels may be activated. Ca^{2+} will enter the cell through these channels, cause the activation of K_{Ca^+}, and thereby cause a progressive hyperpolarization leading to the closure of the NMDA channels. In the behaving animal, the initiation of the depolarizing phase is facilitated by the activation of ipsilateral SR-Es, whereas the termination of the depolarized phase is partially a result of activation of contralateral SR-Is. 5-HT, serotonin; CPG, central pattern generator network; E, excitatory; GABA, γ-aminobutyric acid; I, inhibitory interneuron; mGluR, metabotropic glutamate receptor; NMDA, *N*-methyl-D-aspartate.

the field of innervation. In this way, a continuous rostro-caudal network along the spinal cord is formed.

The spinal cord CPG circuits that generate the undulatory wave that results in swimming in fish, lampreys, and amphibians can, in a simplified way, be regarded as a series of segmental oscillator circuits, as already discussed. Normally, the rostral segments are activated first, and the other segments follow from head to tail-fin, with a fixed phase lag of approximately 1% of the cycle duration (lamprey), whether the swimming frequency is low or high (Figure 1). If the opposite situation is induced with a higher relative excitability in the caudal segments (by inhibition of the rostral segments or additional excitation of the most caudal segments) the direction of the wave is reversed and goes from tail to head instead, and backward swimming results, which is required behaviorally if a lamprey gets caught in a corner. In the isolated spinal cord, forward and backward coordination with a constant phase coupling can be generated experimentally in a similar fashion.

How is this type of flexible phase coupling along the spinal cord achieved? We may consider, in a simplified way, a series of unit CPGs coupled in a chain with excitatory connections between the various unit CPGs in both directions. In this case, the unit CPG with the highest inherent frequency becomes the leader, and the other unit CPGs are pulled along – the trailing one is the one with the lowest excitability.

Mammalian Locomotor Central Pattern Generator Networks

The elucidation of the mammalian locomotor CPG has been more demanding than that of the tadpole or the lamprey. In those two cases, a symmetric alternation between the left and right sides generated by pools of excitatory and crossed inhibitory interneurons suffices to generate the segmental motor pattern, whereas mammalian locomotion is dependent on a more complex pattern of muscle activity in each limb, which is coordinated by the limb CPG.

The circuits controlling locomotion resides in the ventral spinal cord because the locomotor pattern can be induced in the isolated rodent spinal cord, even when the dorsal aspect has been removed, and also in each hemicord because the motor pattern of a limb can be produced after the isolation of each side. Moreover, the CPG circuitry of each limb appears to be distributed along the spinal cord, as in the lamprey, although the more rostral segments controlling the proximal hip joint seem to have a more powerful role in entraining the circuits controlling the knee, ankle, and foot joints. In order to elicit alternating flexor and extensor activity, inhibitory mechanisms are, of course, required. After the inhibition has been blocked pharmacologically, burst activity commences, and therefore it appears that, also in this case (in accordance with the findings from lower vertebrates), there is a core excitatory burst-generating circuit that does not require inhibition to generate burst activity.

Considerable progress has come from the development of an *in vitro* preparation of the neonatal rodent brain stem–spinal cord. The details of the CPG are still not clear, but different commissural excitatory and inhibitory premotor interneurons have been identified (Figure 3(b)). Developmental findings in the mouse have led to the genetic delineation of subtypes of precursor interneurons (V0–V3) that give rise to some of the classic types of spinal interneurons. V0 and V3 give rise to neurons that project to the contralateral side, whereas V1 and V2 are ipsilateral. Among the V1 interneurons are the inhibitory 1a and Renshaw premotor interneurons which are active during locomotor activity. The V2 group contains both inhibitory and EINs. These genetic markers have opened up the possibility of expressing different fluorescent probes (e.g., green fluorescent proteins) or other molecules such as receptors in particular subtypes of interneurons. The combination of developmental, molecular, and neurophysiological techniques promises to yield rapid progress in the understanding of the neuronal bases of motor coordination in mammals.

Systems of Central Pattern Generator Networks – Modular Organization

Interaction between the Limb Central Pattern Generator Networks during Various Gaits

Each limb is controlled by a separate spinal CPG that provides a standard pattern of activation of the muscles of that limb (adaptable with regard to support phase duration). Between two limb CPGs acting at the same girdle, there are two preferred modes, alternation and in-phase (approximately). Alternation, as in walking or trotting, is in general produced by reciprocal inhibition between the two CPGs – as a rule due to glycinergic inhibition mediated by commissural interneurons. Mutual excitation between the two CPGs instead results in that their activity becomes synchronous, as during a gallop. The four limbs are, finally, coordinated in different ways during walking, pacing, trotting, and galloping. Each limb CPG is thus part of a system of interacting limb CPGs (Figure 4(a)) that can be coupled in a few stable modes.

Figure 4 Systems of interacting CPGs, inter- and intralimb coordination: (a) command regions in the brain stem; (b) further subdivision in unit CPGs; (c) exploratory simulation of locomotor activity. In (a) the command regions in the brain stem (the mesencephalic locomotor region (MLR) and the diencephalic locomotor region (DLR)) control the level of activity in the CPG networks for each of the four limbs. Each limb CPG is responsible for the complex motor pattern of that limb, whereas the interlimb coordination, as in walking or galloping, results from the interaction between the different limb CPGs. The interaction takes place through inhibitory reciprocal interaction (blue inhibitory) during walking and excitatory mutual excitation during galloping (red). As shown in (b) within each limb CPG there is most likely a further subdivision in unit CPGs controlling the synergists at one joint, such as the hip extensor (HE), knee extensor (KE), ankle extensor (AE), foot extensor (FE), and ankle flexor (AF). Extensor digitorum brevis (EDB) has a particular pattern. The normal pattern of activity results from the interaction between the different unit CPGs at different joints. The advantage is that the unit CPGs could be recombined as in backward or forward walking, in the same way as the different limb CPGs, which can be recombined in the different gaits. Circles indicate inhibition, and forks/triangles indicate excitation. In (c), the network arranged so each unit CPG is designed in a way similar to the lamprey unit CPGs, consisting of 100 excitatory interacting neurons, and the interaction among the nine-unit CPGs arranged as in (b). The output of the activity captures essential features of the locomotor output. CPG, central pattern generator netowork; DLR, diencephalic locomotor region; MLR, mesencephalic locomotor region.

Is there Flexibility within Each Limb Central Pattern Generator Network? – Walking Forward and Backward

The flexibility of the locomotor behavior is considerable, we can thus walk forward, backward, sideways, and even on our knees. Do we need to have a separate limb CPG for each direction of movement? With a hard-wired system for the entire limb, this would actually be the case. Most likely the limb CPG is also composed of a system of limb CPGs. Indirect evidence suggests that each limb CPG can be further subdivided into smaller functional modules, which can be recombined to generate a varied and flexible motor output. Each limb CPG is thought to be composed of a series of unit CPGs, each controlling a group of close synergists such as hip flexors or ankle extensors. Such a system adds flexibility, achieved by changing the mode of interaction between the different unit CPGs, in much the same way as between the limb CPGs in the different gaits.

The conceptual scheme presented in Figure 4(b) proposes that there are unit CPGs for each group of close synergists at a given joint. The model assumes that each unit CPG can burst by itself but that the final pattern is due to three factors: (1) the reciprocal interaction between antagonists (flexors and extensors) at the same joint, (2) mutual excitation between unit CPGs at different joints that are active together, and (3) the possibilities for more complex patterns, with muscles being active in the interval between the main flexors and extensors. To test this conceptual scheme in an exploratory fashion, we made use of the segmental unit CPGs defined in the lamprey system and plugged them in as unit CPGs in the limb system. With no further modification, we simulated the motor pattern of the hindlimb and also the complex pattern of activity of the different muscles of the limb (Figure 4(c)). Although the limb CPG most likely is more complex, it is thought provoking that a distributed circuit of this type can reproduce the motor pattern and add the flexibility of reconfiguring the network to other patterns of coordination. To account for this type of requirement for flexibility, another model has also been considered in which a central rhythmogenic circuit is thought to pace

the rhythm and alternative interneuronal output channels to different motor nuclei provide the necessary flexibility.

Scratching and Wiping Reflexes

The scratch reflex provides another interesting example of a spinal rhythmic precision movement that is present in mammals and other vertebrates with limbs. The objective is to remove an irritant somewhere on the body surface through a limb movement targeting this particular location. It is often elicited by a hindlimb, but it can also be performed with a forelimb. It can reach out to all points on the body surface that are anatomically possible. It is mostly performed as a rhythmic motor act involving rhythmic movements centered around, particularly, the skin area in which the irritant is located.

Well-coordinated scratch reflexes toward a particular skin area (called wiping reflexes in the frog) can be elicited also after a spinal transection. Because the irritant can be located on widely different skin regions, it also means that the motor patterns must be flexible and differ radically between, for instance, an irritant at the head and the lower back. These flexible patterns have been particularly well analyzed in the turtle by Paul Stein. The skin irritant, say, in the cervical area, must provide a signal to the spinal cord which informs about the location of the irritant (proximal or distal location in a given segment). This segmental input must then, in turn, be able to activate the lumbosacral scratch CPG and provide instructions to produce a scratching movement toward the particular target area. A high degree of flexibility is thus required. The turtle scratch reflex is organized with modular units that can be recombined, as already described for the unit CPG organization in the context of the locomotor CPGs. This organization with discrete unit CPGs that can be recombined in different ways also allows for the possibility that they may be integrated into other, widely different patterns of motor behavior.

The spinal cord itself is thus able to provide positional information about the skin irritant on the body surface. If the irritant is located on the distal part of a limb, the orientation of the limb also needs to be considered (pointing forward or backward in relation to the body). The spinal cord at the stimulus segment thus has the astounding ability to direct the movement to the irritant regardless of the skin area stimulated and the orientation of the appendage in relation to the body. This clearly indicates that the spinal cord itself contains information about the spatial coordinates of the body in relation to the trunk and that this information can be used to design the appropriate motor command.

Posture, Static Limb Positions, and Protective Reflexes

Also with posture and static limb position, there is evidence to suggest a subdivision into spinal modules controlling groups of synergists in the lumbosacral spinal cord. Co-activation of different modules produces different positions of the limb.

The flexion and crossed extension reflexes, in Sherringtonian terms, was for a long period considered to be standard example of a behaviorally meaningful integrated spinal reflex. It now turns out that it, instead, represents a family of very precise reflex modules that removes the skin area stimulated by the stimulus. Different combinations of muscles are required depending on the location of the stimulus (e.g., on the lateral or medial part of the foot). A set of different interneuronal modules can account for the family of different site-specific protective reflexes in the limb.

Modular Organization Appears to Be a General Organizational Principle

This type of modular organization appears to apply to a variety of systems, both in vertebrates and invertebrates. It seems likely that these different spinal modules – these integrated circuits – could also be recruited during, for instance, voluntary limb movements or when adapting the human locomotor synergy to other gross movements such as skiing or bicycling.

In Conclusion

The spinal cord contains a number of preformed circuits that can coordinate a variety of movements. The basic design features appear to be evolutionary conserved from cyclostomes to primates, although the fine details may differ. Many aspects of our movement repertoire are, thus, produced through a recruitment of different spinal motor circuits and through the combination of different spinal networks.

Peptidergic Receptors

G Casini and D Cervia, Università della Tuscia, Viterbo, Italy

Peptides and Intercellular Communication

Neuropeptides are peptides involved in nervous system function. They are synthesized in cells in large precursor proteins, and generally several biologically active peptides are contained in the same precursor molecule. In the 1970s the hunt for new peptides was intense, and an ever-growing list could be compiled. Peptidergic signaling molecules are widely distributed throughout the central and peripheral nervous systems and in the peripheral organs. They may act in a neurocrine, paracrine, autocrine, or endocrine manner; the same peptides may participate in intercellular communications through different modalities. For instance, many peptides expressed in the enteric system belong to a class of agents known as brain–gut peptides, functioning both as neuropeptides and gut hormones.

Neuropeptides may be co-stored with other neuropeptides or, alternatively, may coexist with 'classical' neurotransmitters in different cellular compartments. Different combinations of transmitters and peptides are found in ganglionic cells of the autonomic nervous system. For instance, the sympathetic postganglionic input to the heart arises in a large part from the stellate ganglion; these neurons commonly contain neuropeptide Y (NPY) in addition to norepinephrine, similar to almost all sympathetic postganglionic neurons innervating the vasculature of the gut and hindlimbs. Other sympathetic postganglionic neurons in the stellate ganglion project to the sweat glands using acetylcholine as their major transmitter (instead of the expected norepinephrine), and also contain at least two other peptides, that is, calcitonin gene-related peptide (CGRP), and vasoactive intestinal polypeptide (VIP). In addition, many postganglionic parasympathetic neurons contain acetylcholine and VIP. Thus, while autonomic neurons are commonly referred to as cholinergic or adrenergic, they may also contain permutations of other neuropeptide transmitters including angiotensin II (Ang II), enkephalin, neurotensin, substance P (SP), somatostatin, CGRP, etc. Functionally, specific permutations of transmitters may comprise a 'chemical code' for neurons subserving specific actions. Co-stored peptides and classical transmitters are released together at all terminals of a given neuron, and they act together in determining the responses of target cells. It is a general rule that when a peptide and a classical transmitter coexist, the first mediates long-lasting responses and the latter short-term synaptic events in the target cells.

Peptidergic Receptors

Independent of the modality, peptides act through specific receptors which are generally located on the plasma membrane of target cells, although there is growing evidence that certain receptors are also present on the nuclear membrane. Peptidergic receptors belong to the superfamily of heterotrimeric G-protein-coupled receptors (GPCRs), which are characterized by the presence of seven transmembrane domains. The specialized feature of these receptors is to achieve information transfer via the binding of ligands to a recognition domain and allosterically transmit the presence of that ligand to an intracellular domain that leads to G-protein activation. The human genome may code for more than 5000 GPCRs. Less than 10% are known, of which those activated by peptides represent a large proportion. In particular, mammalian peptidergic receptors are grouped into two families of GPCRs: the rhodopsin-like family (the largest family of GPCRs, also called class A), which contains the majority of the known peptidergic receptors, and the secretin-like family (class B). The ligand peptides for the receptors in the secretin-like family are relatively large polypeptides (27–141-amino-acid residues), and seven of them – glucagon, glucagon-like peptides 1 and 2, gastric inhibitory polypeptide, VIP, pituitary adenylate cyclase-activating peptide (PACAP), and growth hormone-releasing hormone – are structurally related.

It has been generally assumed that peptides exert their actions on GPCRs, but there are some exceptions. For instance, FMRFamide (Phe-Met-Arg-Phe-NH_2) and related peptides typically exert their action through GPCRs. However, two ionotropic receptors for these peptides have recently been identified which may have functional roles in the central and the peripheral nervous systems. Another example is one of the neurotensin receptors, which is a single transmembrane domain protein that belongs to a recently identified family of sorting receptors.

Although there is at least one receptor cloned for almost all of the peptides discovered so far, it still remains to be elucidated how many receptors can be

found for each of the peptides. In many cases, it does not seem unreasonable to assume that there are several receptors for one peptide. However, their number may not approach those described for the receptors of some classic transmitters, such as the 15 or so receptors for serotonin. At present, many 'orphan peptides' (for which there are no known receptors) still exist, and many others may be discovered soon. Recently, MrgX2 receptor has been identified as the cortistatin-specific receptor. In contrast, some peptides have been found via one of the many 'orphan receptors,' that is, receptors for which the endogenous ligand is unknown. For instance, orexin-A and -B were initially identified as endogenous ligands for an orphan GPCR. In addition, the endogenous ligand for the growth hormone secretagogue receptor was recently discovered and named ghrelin, while a study focusing on another orphan receptor, the glucocorticoid receptor 3, revealed that a prolactin-releasing peptide in the brain represents an endogenous ligand for this receptor. Also, many naturally occurring peptides exhibit a high degree of promiscuity across GPCRs. The physiological significance of this phenomenon and the degree to which it occurs is not well characterized, but it does not seem an exception in the nervous system. For instance, cortistatin binds to somatostatin receptors with similar high affinity to that of somatostatin itself and it may produce physiological effects similar to those of somatostatin. In addition, the orphan peptide histidine methionine-27 was recently shown to be a potent agonist at the human calcitonin receptors.

Functionally, there is a general agreement that peptidergic receptors are coupled to multiple components of transduction pathways including adenylyl cyclase/cyclic AMP, phospholipase C/diacylglycerol/inositol triphosphate, phospholipase A2/arachidonic acid, guanylyl cyclase, protein kinases and phosphatases, ionic channels and exchanger, reactive oxygen species, metalloproteases, transcription factors, and other intracellular cytoplasmic and nuclear regulators. The diversity of the transduction pathways reflects the pleiotropic actions of peptides. The prevailing mechanisms in any given cell depend on many factors, including receptor distribution and the signaling elements expressed by the cell. Often the situation is further complicated by cross-talk between different pathways. In addition, at the cellular level, many mechanisms are involved in the amplification effects, which occur in the signaling cascade. In particular, posttranslational modification of receptors, different expression of factors interacting with G-proteins, and differences in G-protein repertoire and signaling isoenzymes may affect function in a process which is generally referred to as cross-talk and receptor trafficking. On the other hand, recent results suggest the existence of multiple ligand-specific receptor conformations, which may differentially couple to the intracellular pathways within the signal transduction network. Indeed, peptidergic receptor reserve, coupling efficiency, and probably receptor trafficking may not only depend on transduction mechanisms, but also on the nature of the ligand and the receptor at play. In addition, the type and the magnitude of the response elicited by a ligand is also dictated by the level of receptor available at the plasma membrane.

Endocytosis and recycling of receptors are important for desensitization and resensitization in response to endogenous ligands and drugs. Recent studies of peptidergic receptors have provided exciting insights into specific mechanisms that control endocytosis of receptors from the plasma membrane (internalization) and regulate proteolytic degradation of receptors. For instance, the internalization of the AT_1 receptor (a specific receptor for Ang II) occurs via clathrin-coated pits, but there is evidence that, in contrast to the internalization of other GPCRs, it is independent of dynamin and beta-arrestin. In addition, AT_1 receptor internalization requires two regions in the cytoplasmic tail of the receptor, but it is independent of G-protein activation. The dependence of AT_1 receptor internalization on the presence of a serine–threonine-rich region suggests that phosphorylation of the receptor tail may regulate the internalization process.

GPCRs have been found to be dysfunctional/dysregulated in a growing number of human diseases and the property of 'constitutive activity' which is associated with GPCRs provides a persistent tonic mechanism to fine-tune synaptic transmission during both acute and chronic information transfer. In this respect, GPCRs have been a very successful target for drug discovery and development and almost a third of currently available prescription drugs function as GPCR ligands. In particular, the clinical potential of neuropeptides is well known and, needless to say, the multiplicity of peptidergic receptors offers unique and important openings for the development of specific drugs, which may be useful for treatment of various disorders. In fact, receptor-subtype-selective antagonists and agonists have been developed, and recently an SP-receptor antagonist has been shown to have clinical efficacy in the treatment of major depression and chemotherapy-induced emesis. In addition, the use of somatostatin and its analogs is well established for certain indications, such as acute esophageal variceal bleedings, gastrointestinal disorders, neuroendocrine tumors, and acromegaly as well as the diagnosis and radiotherapy of some tumors. Several other neuropeptide receptor ligands are on clinical trials for various indications.

Peptidergic Receptors in the Autonomic Nervous System and in Peripheral Organs

Multiple peptides and receptor subtypes are expressed in the autonomic nervous system and in peripheral organs, where they are involved in a variety of functions (Table 1). In this section, data from recent scientific reports and review articles have been collected to provide examples of the occurrence and functional actions of peptides and their receptors in the autonomic nervous system and peripheral organs.

Modulation of Parasympathetic Neurons

The submandibular ganglion (SMG) is a parasympathetic ganglion, which receives inputs from preganglionic cholinergic neurons and innervates the submandibular salivary gland to control saliva secretion. Neurotransmitters and neuropeptides acting via GPCRs change the functional activity of neurons in this ganglion by modulating voltage-dependent Ca^{2+} channels.

Opioid peptides Endogenous opioid peptides and their receptors are integral components of neuronal circuits modulating pain transmission. They also produce various effects, such as analgesia, inhibition of diarrhea, respiratory depression, and catalepsy. Opioid peptides act at three distinct types of opioid receptors, namely, μ-, δ-, and κ-opioid receptors. Met-enkephalin causes hyperpolarization, while μ-, δ-, and κ-opioid receptor agonists inhibit currents in voltage-dependent Ca^{2+} channels in a dose-dependent manner. Similar actions of opioid peptides have been reported using different receptor subtype-specific agonists in rat dorsal root ganglion neurons, rat parasympathetic intracardiac neurons, neurons of the rat nodose ganglion, and avian ciliary ganglion.

Tachykinin peptides Three types of tachykinin receptors, neurokinin (NK)-1, NK-2, and NK-3, have been cloned and characterized pharmacologically. They preferentially bind the endogenous tachykinins SP, neurokinin A (NKA), and neurokinin B, respectively. SP is a well-known pain-related peptide synthesized and secreted from primary afferent neurons. SP and NKA are reported as neurotransmitters of the SMG neurons. SP, acting at NK-1 receptors, causes depolarization of SMG neurons by inhibiting M-type K^+ channels. In addition, an NK-1 receptor agonist inhibits voltage-dependent Ca^{2+} channel currents. SP also facilitates ganglionic transmission in sympathetic

Table 1 Examples of the main effects mediated by some of the peptidergic receptors expressed in sympathetic neurons or in sympathoeffector cells

Neuropeptides	*Receptor subtype*	*Site of expression*	*Effect*
Calcitonin gene-related peptide	CGRP1	Postganglionic vasomotor neurons	Vasodilatation
Cholecystokinin	CCK1	Preganglionic neurons of rostral ventrolateral medulla	Inhibition of postganglionic neuron activity
	CCK2	Preganglionic vasomotor neurons	Increase of postganglionic neuron activity
Endocannabinoids	CB1	Preganglionic nerve terminals	Inhibition of transmitter release
Endothelin	ETA	Postganglionic nerve terminals of vasculature/vascular smooth muscles	Increase of vasoconstrictor transmitter release/inhibition of vasodilatator transmitters
	ETB	Postganglionic neurons/postganglionic nerve terminals of vasculature	Increase of oxidative stress/increase of vasoconstrictor transmitter release
Enkephalins	Opioid δ and κ	Postganglionic neurons	Inhibition of transmitter release
Neuropeptide Y	Y1	Vascular smooth muscles	Vasoconstriction
	Y2	Postganglionic nerve terminals of vasculature	Inhibition of vasoconstrictor transmitter release
Somatostatin	sst2 and sst3	Postganglionic nerve terminals	Inhibition of transmitter release
Tachykinins	NK1	Postganglionic neurons of superior cervical ganglion/spinal preganglionic neurons and postganglionic axons of vasculature/vascular smooth muscles	Increase of neuron excitability/ increase of vasoconstrictor transmitter release/vasodilatation
	NK2	Postganglionic neurons in gastrointestinal tract	Smooth muscle relaxation
Vasoactive intestinal polypeptide/pituitary adenylate cyclase activating peptide	PAC1	Postganglionic neurons of superior cervical ganglion	Increase of transmitter release
	VPAC1 and VPAC2	Heart and vascular smooth muscles	Vasodilatation

ganglia, while it inhibits currents in voltage-dependent Ca^{2+} channels in a variety of neuronal cells.

CGRP CGRP is generated through an alternate splicing of the calcitonin gene primary transcript. CGRP receptors are heterodimeric complexes composed of the heptahelical calcitonin receptor-like receptor and the single transmembrane receptor activity-modifying protein 1. They are widely distributed throughout the nervous system and have been studied in several species. Similar to SP, in SMG neurons, CGRP causes depolarization by inhibition of voltage-insensitive K^+ channels. In addition, CGRP facilitates voltage-dependent Ca^{2+} channels.

Ang II Ang II has various physiological effects, including stimulation of increased blood pressure, water and sodium intake, vasopressin secretion, and modulation of baroreflex function. In addition, Ang II acts as a neurotransmitter at two types of receptors (AT_1 and AT_2 receptors). In SMG neurons, Ang II causes depolarization by the combination of an increase in Na^+ conductance and a decrease of K^+ conductance. On the other hand, Ang II inhibits voltage-dependent Ca^{2+} channel currents via AT_1 with transduction mechanisms involving protein kinase C.

VIP and PACAP VIP was first isolated from porcine intestine as a peptide capable of inducing vasodilatation. PACAP was initially isolated from ovine hypothalamus for its ability to stimulate pituitary cell membrane adenylyl cyclase and was further shown to exist in two biologically active forms of 27 and 38 amino acids. At least three receptors for these peptides have been identified in mammals: $VPAC_1$, $VPAC_2$, and PAC_1. $VPAC_1$ and $VPAC_2$ respond to VIP and PACAP with comparable affinity, while PAC_1 binds PACAP with high affinity and VIP with much lower affinity. VIP coexists with acetylcholine in postganglionic SMG neurons, and following stimulation of parasympathetic nerve, it is released from the submandibular gland together with acetylcholine. In SMG neurons, VIP causes depolarization by inhibition of voltage-insensitive K^+ channels. Both VIP and PACAP inhibit voltage-dependent Ca^{2+} channel currents. The inhibition mediated by $VPAC_1$/$VPAC_2$ receptors involves both protein kinase A and protein kinase C, while the PAC_1 receptors inhibit the voltage-dependent Ca^{2+} channel via the $\beta\gamma$ subunits of a Gs-protein. VIP and PACAP may also facilitate voltage-dependent Ca^{2+} channels; however, VIP- and PACAP-induced facilitation is less frequently reported than inhibition.

Functional implications A variety of neuropeptides and their receptors act in SMG neurons. However, such a diversity of signaling substances would presumably not be necessary to only signal neuronal excitation or inhibition. The voltage-dependent Ca^{2+} channels are essential in the regulation of many neuronal processes including membrane excitability, enzyme activity, gene expression, neuronal outgrowth, neuronal regeneration, differentiation, and proliferation. The G-protein-dependent signals elicited by the action of multiple peptidergic receptors and their interactions may provide the necessary versatility to properly accomplish those neuronal functions.

Presynaptic Modulation at Sympathoeffector Junctions

The transmitter release at sympathetic varicosities is modulated by a plethora of different signaling molecules, including classical transmitters, ATP, histamine, prostanoids, and a variety of peptides. Presynaptic receptors located on the sympathetic terminals are activated by transmitters that are released either from the same nerve ending or from a different axon terminal, and the receptors involved are called auto- or heteroreceptors, respectively. The peptidergic receptors involved in this regulation include receptors for NPY as autoreceptors and for Ang II, bradykinin, cannabinoid peptides, endothelin, natriuretic peptide, opioid peptides, somatostatin, and VIP/PACAP as heteroreceptors.

NPY Y_2 receptors NPY shares a family of common receptors with peptide YY and pancreatic polypeptide, which consists of at least five members. These are named Y_1, Y_2, and Y_4 through Y_6 receptors. Selective antagonists have been developed for Y_1 and Y_2 receptors. NPY is co-stored and co-released together with ATP and norepinephrine in most sympathetic axon terminals. In the vasculature, NPY has been found to induce contractions mediated by Y_1 receptors localized on smooth muscle cells. In some cases, postsynaptic effects of NPY may also involve Y_2 receptors. In *in vitro* preparations of noradrenergic postganglionic sympathetic neurons, NPY reduces transmitter release. This inhibitory effect of NPY is typically mimicked by Y_2 receptor agonists. In addition, there is evidence that presynaptic Y_2 receptors are indeed autoreceptors. However, there are reports that a selective Y_2 receptor antagonist has no effect on excitatory junction potentials, indicating a lack of NPY-dependent feedback modulation of sympathoeffector transmission. Thus, it remains to be established under which conditions NPY may mediate an autoinhibition of sympathetic transmitter release.

Ang II AT_1 receptors In a variety of sympathetically innervated tissues obtained from a large number of different species, a facilitation of norepinephrine release by Ang II has been reported. In addition, evidence has been provided that this stimulatory effect is mediated by AT_1 receptors. However, in some instances, presynaptic angiotensin effects have been observed to be antagonized by both AT_1 and AT_2 receptor antagonists, revealing some uncertainty concerning the subtypes of presynaptic angiotensin receptors in sympathetic axonal terminals.

Bradykinin B_2 receptors Actions of bradykinin are mediated by at least two types of receptors, B_1 and B_2, and the existence of a B_3 receptor has also been suggested. B_1 receptors are mainly restricted to the vasculature, whereas B_2 receptors have been detected in most types of tissues including the central and peripheral nervous systems. There are reports that bradykinin may modulate sympathetic transmitter release in a bimodal way, causing inhibition via B_1 and facilitation via B_2 receptors, but in most cases bradykinin enhances stimulation-evoked norepinephrine release via B_2 receptors. However, in a considerable number of investigations, these apparently presynaptic effects of bradykinin have been shown to be indirect and to involve Ang II with AT_1 receptors, CGRP, or SP.

Cannabinoid CB_1 receptors At least two types of cannabinoid receptors, CB_1 and CB_2, have been identified. Aside from their psychoactive and immunomodulatory effects, cannabinoids exert pronounced cardiovascular actions such as vasodilatation, tachycardia, and changes in blood pressure, all mediated most likely by CB_1 receptors. Because central sites of action are not involved in these effects, cannabinoids are believed to elicit vasorelaxation through peripheral mechanisms, which may include inhibition of sympathoeffector transmission. Indeed, there is experimental evidence that cannabinoids may cause sympathoinhibition through presynaptic CB_1 receptors on sympathetic nerve terminals, the activation of which reduces transmitter release.

Endothelin receptors Endothelin-1 was identified originally as an endothelium-derived vasoconstricting peptide, but the family of endothelins (endothelin-1, -2, and -3) has recently been suggested to act as neuropeptides in the central and peripheral nervous systems. The actions of endothelins are mediated by either ET_A or ET_B endothelin receptors. There are data showing presynaptic facilitatory and inhibitory and postsynaptic effects of endothelins. Thus, it appears that endothelins may modulate sympathetic neurotransmission via facilitatory and inhibitory presynaptic receptors, but the receptor subtypes involved remain to be unequivocally identified.

Natriuretic peptide receptors The family of receptors for natriuretic peptides (atrial natriuretic peptide, brain natriuretic peptide, and C-type natriuretic peptide) comprises two members, the ANP_A and the ANP_B receptors. Both are membrane receptors with one transmembrane domain and intracellular guanylyl cyclase activity. The ANP_A receptor is preferentially activated by atrial and brain natriuretic peptides, whereas C-type natriuretic peptide is the endogenous agonist for ANP_B. A role of presynaptic receptors for natriuretic peptides on sympathetic axon terminals remains to be fully elucidated, and the natriuretic peptides may rather be assumed to control the sympathetic nervous system through central sites of action.

Opioid receptors Opioid receptor agonists have long been known to modulate transmitter release in the peripheral nervous system. Evidence has been obtained that each of the three known opioid receptor subtypes may be located on sympathetic axon terminals and, upon activation, reduce transmitter release.

Somatostatin receptors Somatostatin is widely distributed in the nervous system, and five different G-protein-coupled somatostatin receptors (sst_1–sst_5) have been characterized by molecular cloning. Inhibitory effects of somatostatin on transmitter release from sympathetic terminals have been documented. In addition, this action of somatostatin may be mimicked by sst_2 or sst_3 receptor agonists; however, a definite pharmacological characterization of inhibitory presynaptic somatostatin receptors on sympathetic axonal terminals is still missing.

VIP/PACAP receptors Various forms of PACAPs and VIPs are present in and released from sympathetic nerve terminals. Nevertheless, autoregulation of sympathetic transmitter release by VIP or PACAP has not been demonstrated. Therefore, the respective receptors are considered presynaptic heteroreceptors. Presynaptic receptors for VIP and/or PACAP may either facilitate or inhibit sympathetic transmitter release, but the receptor subtypes mediating these opposite effects remain to be identified.

Regulation of Gastrointestinal Motility

The peptide cholecystokinin Cholecystokinin (CCK) is a potent regulator of gastrointestinal motility. It and the related peptide gastrin belong to the class of brain–gut peptides. The actions of CCK include stimulation

of exocrine and endocrine secretion, motility and growth in the gastrointestinal tract, and regulation of satiety, anxiety, pain, and behavior in the central and peripheral nervous systems. Alterations in CCK release and tissue responses to the peptide have been implicated in the pathogenesis of irritable bowel syndrome. There are two principal sources of CCK: endocrine cells in the duodenum and peptidergic nerves, both in the enteric and central nervous systems. In the periphery, CCK-containing neurons are found in the myenteric plexus, submucosal plexus and muscle layers of the small intestine and colon, and in the celiac plexus and the vagus nerve.

CCK receptors The biological actions of CCK are mediated by CCK receptors that are distributed throughout the gut. They include two distinct types that are the products of two distinct genes and are termed CCK_1 and CCK_2 receptors. There is identity between the CCK_2 receptor and the gastrin receptor. The CCK_1 receptor has an approximately 1000-fold greater affinity for CCK than for gastrin, while the CCK_2 receptor has the same high affinity for both CCK and gastrin. The activated G-protein leads to activation of phospholipase C, but high agonist concentrations can also activate adenylyl cyclase via a different G-protein. Although the nucleotide sequences of cloned cDNAs of CCK_1 receptors from different sources are identical, their affinity states may vary. The available evidence suggests that the CCK_1 receptor exists in both high- and low-affinity states and that CCK binding results in the initiation of different intracellular events and consequent biological responses. The CCK analog JMV-180, which is an agonist at the high-affinity CCK_1 receptors and an antagonist toward the low-affinity ones, is a useful tool for functionally distinguishing the two receptor states.

CCK receptors in the gastrointestinal tract In the colon, the main target of CCK is the myenteric plexus, which has predominantly CCK_1 receptors. In addition, CCK_1 receptors are also present, at moderate-to-low density, in the longitudinal muscle, while the circular muscle is negative for both CCK_1 and CCK_2 receptors. Neither CCK_1 nor CCK_2 receptors are in the blood vessels, lymphoid tissue, mucosa, or muscularis mucosa. These data suggest that CCK affects colonic motility by two fundamentally different pathways: acting on neurons in the myenteric plexus and directly on the smooth muscle cells.

A large number of studies implicate vagal afferent mechanisms in the control of several CCK actions such as relaxation of proximal stomach, gallbladder contraction, and pancreatic enzyme secretion.

Figure 1 CCK released by endocrine cells in the duodenum acts on CCK receptors expressed by vagal afferent fibers originating in the duodenal mucosa. The response carried by vagal efferent fibers stimulates pancreatic secretion.

Expression of both CCK_1 and CCK_2 receptors has been demonstrated in vagal afferent fibers and in the nodose ganglion. Several studies indicate that CCK acts via an afferent vagal pathway originating in the duodenal mucosa to stimulate pancreatic secretion in rats as well as in humans (Figure 1). Furthermore, activation of these receptors is thought to initiate a vagovagal reflex inhibition of gastric motor function.

CCK receptor agonists/antagonists in disease treatment Because CCK is involved in sensory and motor responses to distension in the intestinal tract, it may contribute to the symptoms of constipation, bloating, and abdominal pain that are often characteristic of functional gastrointestinal disorders and irritable bowel syndrome. These dysfunctions are associated with motor abnormalities in the small intestine and colon that may depend on exaggerated and prolonged CCK release. CCK_1 receptor antagonists have been evaluated clinically to stimulate transit and treat irritable bowel syndrome. CCK also belongs to the growing list of factors modulating food consumption, and CCK molecules are actually promising targets for anti-obesity drugs. Since the initial discovery of its property as a food-intake inhibitor, CCK was demonstrated to be a short-term, meal-reducing signal in most mammalian species including

humans. The availability of potent and specific CCK agonists and antagonists has allowed the identification of the CCK_1 receptor as the receptor type involved in the satiety actions of CCK. Indeed, specific CCK_1 receptor agonists potently inhibit food intake, whereas agonists of the CCK_2 receptor do not. The CCK_1 receptors mediating CCK action on food intake are localized on the vagus nerve, which relays to the hypothalamus via brain stem areas such as the nucleus tractus solitarius and the area postrema. In the brain, CCK contributes to the sensation of satiety, and it may be involved in the mediation of the control of food intake. In addition to the CCK_1 receptors, the CCK_2 receptor may also be involved in the CCK control of food intake. Indeed, CCK_2 receptors are expressed in the vagus nerve brain stem complex that mediates the satiety effect of peripheral CCK, and the CCK_2 receptor is the predominant form found in the brain. Consistent with a possible involvement of CCK_2 receptors, centrally or peripherally administered CCK_2 receptor antagonists have been reported to increase food intake.

Perception and Eye Movements

The study of eye movements has long enjoyed a special status in biomedical research. First, compared to other sensorimotor systems, quantitative visual stimuli are relatively easy to create and quantitative eye movement measurements are relatively easy to acquire. Second, prior to the development of advanced imaging technologies, eye movements were the most important noninvasive diagnostic tool to localize brain pathology. Third, the eyeball has a constant rotational inertia and does not lift anything; thus, eye movements can be made largely independent of the on-line proprioceptive feedback needed to calibrate the force–displacement relationships of other motor systems. In summary, oculomotor control was perceived to be a straightforward, simple model system for understanding human sensorimotor control.

On the motor side, the 1960s brought about a revolution in oculomotor research, driven largely by the work of David A Robinson and Robert Wurtz. These researchers pioneered the combined use of the rigorous analytical tools of linear systems theory and of the powerful new experimental capability to reliably and precisely monitor eye movements while recording for extended periods of time from single visuomotor neurons of monkeys performing oculomotor tasks. In the subsequent half century, by systematically tracing, recording from, lesioning, stimulating, and ultimately modeling the major oculomotor pathways in cortical and subcortical structures, their two laboratories and those of their scientific progeny and colleagues made amazing progress in extending our understanding of how visual signals are transformed into eye movement motor commands.

On the vision side, the 1960s brought a similar revolution with John Robson, Fergus Campbell, Christina Enroth-Cugell, and others applying linear systems theory to visual perceptual performance. The 1980s brought a second revolution in vision science driven by David Marr and others, who applied a machine vision, computational perspective to human vision. Their synthetic approach of seeking biologically inspired (and constrained) solutions to real-world engineering and robotics problems by emulating the information processing within the human brain served to highlight the full complexity of the visual processing needed for the effective control of motor actions.

During approximately the past two decades, it has become increasingly clear that the initial hope of the 1960s – that quasi-linear feedback models that transform a retinal position signal (and its derivatives) into an eye position signal (and its derivatives) might explain the critical aspects of voluntary oculomotor behavior – was overly optimistic. Indeed, recent results have highlighted that highly complex and nonlinear aspects of visual perception play a critical role in guiding both voluntary smooth pursuit and saccades. Decades of research using small-spot visual stimuli that were nearly infinitely detectable, identifiable, and localizable revealed much about the motor factors and circuits that limit human oculomotor performance; however, much less was learned about the visual mechanisms that both limit and enrich oculomotor performance. A number of laboratories have begun to measure human saccadic and pursuit performance under more realistic visual conditions in order to examine how visual processing shapes oculomotor behavior.

Action and Perception

In 1982, Ungerleider and Mishkin made a major contribution to our understanding of primate visual information processing by identifying two major ascending processing streams through extrastriate cortex: a dorsal stream through parietal cortex with a hierarchical set of areas that focus on static and dynamic spatial characteristics of the stimulus (the 'where' pathway) and a ventral stream through the inferotemporal cortex with a hierarchy of areas that focus on identifying features of the stimulus (the 'what' pathway). Later, based largely on clinical observations, Goodale and Milner pushed this dichotomy a step further by proposing that the dorsal and ventral streams represent separate, largely independent, visual pathways supporting action and perception, respectively. They argued that object shape information from the ventral stream used for perception is not available to motor systems, and that spatial information from the dorsal pathway was not available to support perception. The critical finding from Newsome's laboratory that local microstimulation of the middle temporal (MT) or medial superior temporal (MST) areas generates spatially localized and directionally specific biases in visual motion discrimination performance demonstrates that the dorsal pathway does play a major causal role in perception. However, these

findings do not rule out the possibility that ventral stream information may be inaccessible to motor systems.

A careful reexamination of early reports of dissociations of visual responses for perception and action used to support the Goodale–Milner hypothesis has shown that the purported failure to find a vulnerability to visual illusions for motor actions could be accounted for by subtle differences in the visual demands of the perceptual and motor tasks or by offsetting effects of a misperceived target location and of a distorted motor reference frame that obscure the visual impact of the illusion on motor action. When perception and motor actions are tested either simultaneously or using carefully matched conditions and tasks, both are similarly vulnerable to illusions and other properties of the visual stimulus, undermining the view that visual information for perception is not shared with those systems controlling motor actions.

This article reviews key findings in the recent literature examining the extent to which the visual signals supporting perception are also used to drive voluntary human smooth pursuit and saccadic eye movements.

Smooth Pursuit and Visual Motion Perception

The linear systems view of pursuit has been dominated by retinal image motion models (Figure 1(a)). In this view, pursuit is essentially a simple, quasi-linear,

Figure 1 Pursuit models. (a) Retinal image motion models. In this framework, retinal image motion is analyzed in area MT (and associated extrastriate cortical areas in the superior temporal sulcus) to generate retinal position, velocity, and acceleration error signals. Weighted versions of these signals are summed and then sent to the brain stem–cerebellar structures as a command for pursuit eye acceleration. A positive feedback loop between the brain stem and cerebellum sustains ongoing eye velocity and integrates the eye-acceleration commands to generate changes in eye velocity. (b) Object motion models. In this framework, retinal image motion is first segmented in order to identify local edge motions which are subsequently selectively integrated to yield a measure of object motion. To attempt to resolve the inherent ambiguities in this problem, bottom-up retinal motion data, top-down cognitive assumptions and expectations, and either feed-forward or feedback signals related to ongoing eye motion are combined in a sluggish process that involves at least parietal and frontal cortex. The resulting visual object–motion signal is then sent to brain stem–cerebellar premotor circuits that prefilter the object-motion signal to compensate for the oculomotor plant before sending it on to motor neurons as the command for eye motion. (a) Adapted from Lisberger SG, Morris EJ, and Tychsen L (1987) Visual motion processing and sensory–motor integration for smooth pursuit eye movements. *Annual Review of Neuroscience* 10: 97–129. (b) Adapted from Stone LS, Beutter BR, and Lorenceau J (2000) Visual motion: Integration for perception and pursuit. *Perception* 29: 771–787.

continuous control system that attempts to minimize retinal image velocity through negative feedback. A retinal motion error signal or retinal slip (primarily a retinal velocity signal) is computed in area MT and sent to the brain stem as a command to drive eye acceleration. Meanwhile, ongoing eye velocity is maintained by a positive feedback circuit through the cerebellum which acts as an integrator of the acceleration commands. Although retinal image motion models can do a good job of explaining pursuit responses to a single white spot moving on a dark background (the only situation in which retinal image motion is identical to object motion), they cannot explain human pursuit responses to the wider range of visual conditions (and retinal stimuli) experienced when tracking a realistic object (which generates a set of disparate retinal local-edge motions) across a realistically textured environment.

Early studies revealed problems with the core idea that retinal motion error and eye velocity positive feedback form the command signal ultimately driving pursuit eye movements. The earliest pursuit studies observed zero phase-lag pursuit of sinusoidal motion, demonstrating a predictive component to the pursuit response that cannot be accounted for by eye velocity memory. In 1976, Steinbach showed that humans could pursue the horizontal motion of a rolling wagon wheel when only a few illuminated dots were visible on the rim. The perceived horizontal motion of an invisible rolling wheel is tracked, even though the retinal motions of the visible dots are cycloidal. Any observer who pursues this wagon wheel stimulus becomes immediately aware that pursuit does not simply respond to the motion in the retinal image. An additional red flag was raised in 1988 when Newsome, Wurtz, and Komatsu found signals related to ongoing eye motion in area MST, an area shown by both lesions and microstimulation studies to be causally involved in motion perception as well as generating the motor command for pursuit. Thus, the cortical signal driving smooth pursuit is not simply a retinal error signal but, rather, one more related to object motion in head- or world-centric coordinates. Moreover, that same year, Dursteler and Wurtz found that MST lesions cause direction-specific pursuit deficits, with no effort to make smooth corrections of the large residual retinal motion error during the poor steady-state tracking performance. These findings put into question any model of pursuit that proposes a negative feedback circuit that simply attempts to drive retinal motion to zero.

Numerous studies have shown clear links between pursuit and perceived motion, further distancing pursuit behavior from raw retinal velocity errors. First, perception and pursuit show the same speed and direction discrimination performance and are similarly affected by nonlinear directional anisotropies such as the oblique effect, suggesting that rate-limiting neural speed and direction signals are shared by perception and pursuit. Furthermore, analysis of the trial-by-trial variation in human perceptual and pursuit direction responses shows higher correlation than expected by chance from independent mechanisms (**Figure 2(a)**). Thus, perception and pursuit share a limiting internal direction noise source, thereby undermining the theory that pursuit and perception have separate and independent, but fortuitously equal, underlying direction signals. Second, high-level cognitive expectations affect perception and pursuit equally. For example, in 2001, Krauzlis and Adler showed that when the likely direction of stimulus motion is cued prior to each trial, humans generate similar perceptual and pursuit performance biases toward the likely direction. Third, pursuit and perception appear to be fooled in the same way by visual illusions. For example, in 1996, Ringach, Hawken, and Shapley showed that humans generate a pursuit vergence response to the illusory motion in-depth of the kinetic depth effect. Fourth, the time course of the computation of object motion is similar for perception and pursuit. In particular, a human psychophysical study by Shiffrar and Lorenceau in 1996 and a human pursuit study by Masson and Stone in 2002 showed that the temporal integration of an initial set of local edge motion signals into a bona fide object motion signal is similarly sluggish (on the order of a few hundred milliseconds) for both perception and pursuit. In 2001, Pack and Born found a similarly sluggish temporal evolution of the direction signals encoded in the firing rate of MT neurons and those driving smooth eye movements in monkeys. Fifth, when presented with ambiguous image motion, perception and pursuit choose the same arbitrary interpretation of object motion, influenced by the same static image properties. In particular, when Madelain and Krauzlis asked observers to pursue a motion stimulus whose direction is completely ambiguous such that an observer can select a leftward or rightward percept at will, each perceptual reversal was associated with a pursuit reversal. Furthermore, on average, the perceptual reversal precedes the pursuit reversal by nearly 100 ms, consistent with perception driving pursuit within an object-motion pursuit model (**Figure 3**).

Finally, in 2001, Alais and Lorenceau showed that the spatial configuration or shape of ambiguous line drawings affects their perceived motion. In this regard, humans show similar effects of object shape on pursuit (**Figure 4**). For example, the motion of a diamond occluded by vertical windows appears rigid and is both veridically perceived and accurately
